Few guidelines have been developed for the use of newer antidiabetic drugs in older adults. Insulin analogs appear to have some advantages over conventional insulin. Acarbose, miglitol, and metformin may not be as useful in older adults as in younger ones because of the high prevalence of impaired renal function. These drugs are relatively contraindicated in patients with renal insufficiency because they have a longer half-life and may accumulate. With metformin, dosage should be based on periodic tests of renal function, and the drug should be stopped if renal impairment occurs or if serum lactate increases. In addition, dosage should not be titrated to the maximum amount recommended for younger adults. Use of thiazolidinediones and metformin is often contraindicated in older adults who are more likely to have cardiovascular disorders that increase risks of fluid retention and congestive heart failure. With meglitinides, effects were similar in younger and older adults during clinical trials.

### Use in Patients with Renal Impairment

**Insulin.** Frequent monitoring of blood glucose levels and dosage adjustments may be needed. It is difficult to predict dosage needs because, on the one hand, less insulin is degraded by the kidneys (normally about 25%) and this may lead to higher blood levels of insulin if dosage is not reduced. On the other hand, muscles and possibly other tissues are less sensitive to insulin, and this insulin resistance may result in an increased blood glucose level if dosage is not increased. Overall, vigilance is required to prevent dangerous hypoglycemia, especially in patients whose renal function is unstable or worsening.

**Oral drugs.** **Sulfonylureas** and their metabolites are excreted mainly by the kidneys; renal impairment may lead to accumulation and hypoglycemia. They should be used cautiously, with close monitoring of renal function, in patients with mild to moderate renal impairment, and are contraindicated in severe renal impairment. **Alpha-glucosidase inhibitors** are excreted by the kidneys and accu-

mulate in patients with renal impairment. However, dosage reduction is not helpful because the drugs act locally, within the GI tract. **Metformin** requires assessment of renal function before starting and at least annually during long-term therapy. It should not be given initially if renal impairment is present; it should be stopped if renal impairment occurs during treatment. **Meglitinides** do not require initial dosage adjustments, but increments should be made cautiously in patients with renal impairment or renal failure requiring hemodialysis. Renal function should be assessed before initiation of treatment with sitagliptin, and periodically during therapy. Dosage reductions must be made for patients with moderate to severe renal dysfunction.

### Use in Patients With Hepatic Impairment

**Insulin.** There may be higher blood levels of insulin in patients with hepatic impairment because less insulin may be degraded. Careful monitoring of blood glucose levels and insulin dosage reductions may be needed to prevent hypoglycemia.

**Oral drugs.** **Sulfonylureas** should be used cautiously and liver function should be monitored. They are metabolized in the liver, and hepatic impairment may result in higher serum drug levels and inadequate release of hepatic glucose in response to hypoglycemia. With glipizide, initial dosage should be reduced in patients with liver failure. Glyburide may cause hypoglycemia in patients with liver disease. **Alpha-glucosidase inhibitors** require no precautions with hepatic impairment because acarbose is metabolized in the GI tract and miglitol is not metabolized. **Metformin** is not recommended for use in patients with clinical or laboratory evidence of hepatic impairment because risks of lactic acidosis may be increased. **Meglitinides** should be used cautiously and dosage increments should be made very slowly, because serum drug levels are higher, for a longer period of time, in patients with moderate to severe hepatic impairment. **Thiazolidinediones** have been associated with hepatotoxicity and require monitoring of liver enzymes. The drugs should not be given to patients with active liver disease or a serum ALT more than 2.5 times the upper limit of normal. After **glitazone** therapy is initiated, liver enzymes should be measured every 2 months for 1 year, then periodically.

### Use in Patients With Critical Illness

Critically ill patients, with and without diabetes mellitus, often experience hyperglycemia associated with insulin resistance. Hyperglycemia may complicate the progress of the critically ill patient, resulting in increased complications such as postoperative infections, poor recovery, and increased mortality. Tight glycemic control is a key factor in preventing complications and improving mortality in the intensive care unit patient.

Insulin is more likely to be used in critical illness than any of the oral agents. Reasons include the greater ability to titrate dosage needs in patients who are often debilitated and unstable, with varying degrees of cardiovascular, liver, and kidney impairment. One important consideration with IV insulin

therapy is that 30% or more of a dose may adsorb into containers of IV fluid or infusion sets. In addition, many critically ill patients are unable to take oral drugs.

Some critically ill patients are also at risk for serious hypoglycemia, especially if they are debilitated, sedated, or unable to recognize and communicate symptoms. Vigilant monitoring is essential for any patient who has diabetes and a critical illness.

### Use in Home Care

Most diabetes care is delivered in ambulatory care settings or in the home, and any patient with diabetes may need home care. Hospitalization usually occurs only for complications, and patients are quickly discharged if possible. The home care nurse may need to assist patients of multiple age groups to learn self-care and assist caregivers to support patients' efforts or actively participate in diabetes management. Some aspects of the nursing role include mobilizing and coordinating

health care providers and community resources, teaching and supporting patients and caregivers, monitoring the patient's health status and progress in disease management, assisting the patient to obtain diabetic supplies for monitoring and medication administration, and preventing or solving problems. The person with diabetes has a tremendous amount of information to learn about living with this disease on a day-to-day basis. For most patients, the goal of diabetes education is self-care in terms of diet, exercise, medication administration, and blood glucose monitoring and prevention, recognition, and treatment of complications. For some patients, a parent or caregiver may assume most of the responsibility for diabetes management. Because of the amount and complexity of information, a multidisciplinary health care team that includes a nurse diabetes educator is preferred in home care as in other settings. The role of the home care nurse may include initial teaching or reinforcement and follow-up of teaching done by others.

## Nursing Actions Antidiabetic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

a. With insulin:

- (1) Store the insulin vial in current use and administer insulin at room temperature. Refrigerate extra vials.
- (2) Avoid freezing temperatures (32°F) or high temperatures (95°F or above).
- (3) Discard insulin that has become discolored, turbid, or unusually viscous.
- (4) Use only an orange tipped insulin syringe calibrated to measure U-100 insulin.
- (5) With isophane (NPH, Humulin N, Novolin N) intermediate insulins, be sure they are mixed to a uniform cloudy appearance before drawing up a dose.
- (6) When short-acting and isophane intermediate insulins must be mixed, prepare as follows:
  - (a) Draw into the insulin syringe the amount of air equal to the total amount of both insulins.
  - (b) Draw up the short-acting insulin first. Inject the equivalent portion of air, and aspirate the ordered dose.
  - (c) With the intermediate vial, insert the remaining air (avoid injecting short-acting insulin into the intermediate vial), and aspirate the ordered dose.
  - (d) Expel air bubbles, if present, and verify that the correct dosage is in the syringe.
  - (e) Administer combined insulins consistently within 15 minutes of mixing or after a longer period; that is, do not give one dose within 15 minutes of mixing and another 2 hours or days after mixing.

### RATIONALE/EXPLANATION

Cold insulin is more likely to cause lipodystrophy, local sensitivity reactions, discomfort, and delayed absorption. Insulin preparations are stable for months at room temperature if temperature extremes are avoided.

Extremes of temperature decrease insulin potency and cause clumping of the suspended particles of modified insulins. This clumping phenomenon causes inaccurate dosage even if the volume is accurately measured.

These changes suggest deterioration or contamination of the insulin.

For accurate measurement of the prescribed dose

These insulin preparations are suspensions, and the components separate on standing. Unless the particles are resuspended in the solution and distributed evenly, dosage will be inaccurate.

The insulins must be drawn up in the same sequence every time. Short-acting insulin should *always* be drawn up first, to avoid contamination of the short-acting insulin with the NPH. Because short-acting insulin combines with excess protamine in NPH, the concentration of short-acting insulin is changed when they are mixed. Following the same sequence also leaves the same type of insulin in the needle and syringe (dead space) every time. Although dead space is not usually a significant factor with available insulin syringes, it may be with small doses.

Short-acting insulin combines with excess protamine when mixed with NPH insulin. This reaction occurs within 15 minutes of mixing and alters the amount of short-acting insulin present. After 15 minutes, the mixture is stable for approximately 1 month at room temperature and 3 months when refrigerated. Thus, to administer the same dose consistently, the mixture must be given at approximately the same time interval after mixing.

**NURSING ACTIONS**

- (7) Rotate injection sites systematically, within the same anatomic area (e.g., abdomen) until all sites are used. Avoid random rotation between the abdomen and thigh or arm, for example.
- (8) Inject insulin at a 90-degree angle into a subcutaneous pocket created by raising subcutaneous tissue away from muscle tissue. Avoid intramuscular injection.
- (9) With insulin analogs, give aspart within 5 to 10 minutes of starting a meal; give lispro within 15 minutes before or immediately after a meal; give glulisine 15 minutes before meals or within 20 minutes of beginning the meal; give glargine once daily at bedtime; give levemir with evening meal or at bedtime for once a day dosing schedule.
- b. With oral sulfonylureas: Give glipizide or glyburide 30 minutes before breakfast and the evening meal. Give glimepiride and Glucotrol XL with breakfast.
- c. With acarbose and miglitol: Give at the beginning of each main meal, three times daily.
- d. With metformin: Give with meals. Give Glucophage XR with evening meal
- e. With pioglitazone, rosiglitazone, and sitagliptin: Give once daily, without regard to meals.
- f. With repaglinide and nateglinide: Give 15 to 30 minutes before meals (2, 3, or 4 times daily). If the patient does not eat a meal, omit that dose; if the patient eats an extra meal, give an extra dose.
- g. With pramlintide: Inject Sub-Q into abdomen or thigh before meals. Do not mix in same syringe with insulin. Insulin dosages will be reduced by 50%. Rotate injection sites and do not administer at same site where insulin is administered. Opened vials is can be kept in the refrigerator or at room temperature for up to 28 days.
- h. With exenatide inject Sub-Q into abdomen, thigh or upper arm within 60 minutes of morning or evening meal. Store exenatide in the original package in the refrigerator for up to 30 days.

**2. Observe for therapeutic effects**

- a. Improved blood glucose levels (fasting, preprandial, and postprandial) and glycosylated hemoglobin levels
- b. Absent or decreased ketones in urine (N = none)
- c. Absent or decreased pruritus, polyuria, polydipsia, polyphagia, and fatigue
- d. Decreased complications of diabetes

**RATIONALE/EXPLANATION**

Frequent injection in the same site can cause tissue fibrosis, erratic absorption, and deposits of unabsorbed insulin. Also, if insulin is usually injected into fibrotic tissue where absorption is slow, injection into healthy tissue may result in hypoglycemia because of more rapid absorption. Further, deposits of unabsorbed insulin may initially lead to hyperglycemia. If dosage is increased to control the apparent hyperglycemia, hypoglycemia may occur.

Rates of absorption differ among anatomic sites, and random rotation increases risks of hypoglycemic reactions.

Injection into a subcutaneous pocket is thought to produce less tissue irritation and better absorption than injection into subcutaneous tissue. Intramuscular injection should not be used because of rapid absorption.

Manufacturers' recommendations. Aspart, lispro and glulisine act rapidly; glargine is long acting.

To promote absorption and effective plasma levels. Most of these drugs are given once or twice daily.

These drugs must be in the gastrointestinal (GI) tract when carbohydrate foods are ingested because they act by decreasing absorption of sugar in the foods.

To decrease GI upset

Manufacturers' recommendations

Dosage is individualized according to the levels of fasting blood glucose and glycosylated hemoglobin.

Injection into arm results in variable absorption and is not recommended. Pramlintide and insulin are not compatible to mix in same syringe, and should not be given in same injection site.

Manufacturers recommendations

The general goal is normal or near-normal blood glucose levels. However, specific targeted levels for individuals vary depending on intensity of treatment, risks of hypoglycemia, and other factors. Improved metabolic control can prevent or delay complications.

In diabetes, ketonuria indicates insulin deficiency and impending diabetic ketoacidosis if preventive measures are not taken. Thus, always report the presence of ketones. In addition, when adequate insulin is given, ketonuria decreases. Ketonuria does not often occur with type 2 diabetes.

These signs and symptoms occur in the presence of hyperglycemia. When blood sugar levels are lowered with antidiabetic drugs, they tend to subside.

## Nursing Actions Antidiabetic Drugs (continued)

### NURSING ACTIONS

#### 3. Observe for adverse effects

a. With insulin, sulfonylureas, meglitinides, exenatide and pramlintide:

(1) Hypoglycemia

(a) Sympathetic nervous system (SNS) activation—tachycardia, palpitations, nervousness, weakness, hunger, perspiration

(b) Central nervous system impairment—mental confusion, incoherent speech, blurred or double vision, headache, convulsions, coma

b. With insulin:

(1) Local insulin allergy—erythema, induration, itching at injection sites

(2) Systemic allergic reactions—skin rash, dyspnea, tachycardia, hypotension, angioedema, anaphylaxis

(3) Lipodystrophy—atrophy and “dimpling” at injection site; hypertrophy at injection site

(4) Weight gain

c. With sulfonylureas:

(1) Hypoglycemia and weight gain

(2) Allergic skin reactions—skin rash, urticaria, erythema, pruritus

(3) GI upset—nausea, heartburn

(4) Miscellaneous—fluid retention and hyponatremia; facial flushing if alcohol is ingested; hematologic disorders (hemolytic or aplastic anemia, leukopenia, thrombocytopenia, others)

d. With acarbose and miglitol: GI symptoms—bloating, flatulence, diarrhea, abdominal pain

e. With metformin:

(1) GI effects—anorexia, nausea, vomiting, diarrhea, abdominal discomfort, decreased intestinal absorption of folate and vitamin B<sub>12</sub>

(2) Allergic skin reactions—eczema, pruritus, erythema, urticaria

(3) Lactic acidosis—drowsiness, malaise, respiratory distress, bradycardia and hypotension (if severe), blood lactate levels above 5 mmol/L, blood pH below 7.35

### RATIONALE/EXPLANATION

Hypoglycemia is more likely to occur with insulin than with oral agents and at peak action times of the insulin being used. Insulin plus pramlintide may produce severe hypoglycemia. The SNS is activated as part of the stress response to low blood glucose levels. Epinephrine and other hormones act to raise blood glucose levels. There is an inadequate supply of glucose for normal brain function.

Uncommon with human insulin

Uncommon; if a severe systemic reaction occurs, skin testing and desensitization are usually required.

These changes in subcutaneous fat occur from too-frequent injections into the same site. They are uncommon with human insulin.

This effect may decrease compliance with drug therapy, especially in adolescents and young-adult females.

Hypoglycemia occurs less often with oral agents than with insulin. It is more likely to occur in patients who are elderly, debilitated, or who have impaired renal and hepatic function. Weight gain may decrease drug compliance, especially in adolescents and young adult females.

These reactions may subside with continued use of the drug. If they do not subside, the drug should be discontinued. These are the most commonly reported adverse effects. If severe, reducing drug dosage usually relieves them.

These are less common adverse effects.

These are commonly reported. They are caused by the presence of undigested carbohydrate in the lower GI tract. They can be decreased by low doses initially and gradual increases.

GI symptoms are common adverse effects. They may be minimized by taking the drug with meals and increasing dosage slowly.

A rare but serious adverse effect (approximately 50% fatal). Most likely with renal or hepatic impairment, advanced age, or hypoxia. This is a medical emergency that requires hospitalization for treatment.

Hemodialysis is effective in correcting acidosis and removing metformin.

Lactic acidosis may be prevented by monitoring plasma lactate levels and stopping the drug if they exceed 3 mmol/L. Other reasons to stop the drug include decreased renal or hepatic function, a prolonged fast, or a very-low-calorie diet. The drug should be stopped immediately if a patient has a myocardial infarction or septicemia.

## NURSING ACTIONS

- f. With pioglitazone and rosiglitazone:
- (1) Upper respiratory infections—pharyngitis, sinusitis
  - (2) Liver damage or failure.
- (3) Fluid retention, edema, and congestive heart failure and with rosiglitazone risk of myocardial infarction and death.
  - (4) Weight gain
  - (5) Headache
  - (6) Anemia
- g. With nateglinide and repaglinide:
- (1) Hypoglycemia
  - (2) Rhinitis, respiratory infection, influenza symptoms
- (3) Weight gain
- h. With pramlintide and exenatide:
- (1) Nausea
- i. With Byetta:
- (1) Acute abdominal discomfort

## 4. Observe for drug interactions

- a. Drugs that *increase* effects of insulin:
- (1) Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril)
  - (2) Alcohol
- (3) Anabolic steroids
  - (4) Antidiabetic drugs, oral
- (5) Antimicrobials (sulfonamides, tetracyclines)
  - (6) Beta-adrenergic blocking agents (e.g., propranolol)
- b. Drugs that *decrease* effects of insulin:
- (1) Adrenergics (e.g., albuterol, epinephrine, others)
  - (2) Corticosteroids (e.g., prednisone)
  - (3) Estrogens and oral contraceptives
  - (4) Glucagon
  - (5) Levothyroxine (Synthroid)
  - (6) Phenytoin (Dilantin)
  - (7) Propranolol (Inderal)
  - (8) Thiazide diuretics (e.g., hydrochlorothiazide)
- c. Drugs that *increase* effects of sulfonylureas:
- (1) Acarbose, miglitol, metformin, pioglitazone, rosiglitazone
- (2) Alcohol (acute ingestion)
  - (3) Cimetidine (Tagamet)
- (4) Insulin

## RATIONALE/EXPLANATION

Few cases of liver failure have been reported, but the drugs are related to troglitazone (Rezulin), a drug that was taken off the market because of hepatotoxicity. Monitoring of liver enzymes is recommended during therapy. Several reports indicate increased risks of developing or worsening heart failure and with rosiglitazone an increased risk of myocardial infarction and heart related death.

If occurs, usually of mild to moderate intensity. These were the most commonly reported during clinical drug trials. This effect may decrease compliance with drug therapy, especially in adolescents and young-adult females.

Nausea is common. Nausea decreases with time in most patients. Pramlintide may require reduced dosage to control nausea.

Acute pancreatitis is a rare but serious adverse effect.

Increased hypoglycemia. Ethanol inhibits gluconeogenesis (in people with or without diabetes).

Oral agents are increasingly being used with insulin in the treatment of type 2 diabetes. The risks of hypoglycemia are greater with the combination but depend on the dosage of each drug and other factors that affect blood glucose levels.

Increase hypoglycemia by inhibiting the effects of catecholamines on gluconeogenesis and glycogenolysis (effects that normally raise blood glucose levels in response to hypoglycemia). They also may mask signs and symptoms of hypoglycemia (e.g., tachycardia, tremors) that normally occur with a hypoglycemia-induced activation of the SNS.

These *diabetogenic* drugs may cause or aggravate diabetes because they raise blood sugar levels. Insulin dosage may need to be increased. Except with glucagon, hyperglycemia is an adverse effect of the drugs. Phenytoin and propranolol raise blood sugar by inhibiting insulin secretion; glucagon, a treatment for hypoglycemia, raises blood glucose by converting liver glycogen to glucose.

One of these drugs may be used concomitantly with a sulfonylurea to improve glycemic control in patients with type 2 diabetes. There is an increased risk of hypoglycemia with the combinations.

Additive hypoglycemia  
May inhibit metabolism of sulfonylureas, thereby increasing and prolonging hypoglycemic effects  
Additive hypoglycemia

## Nursing Actions Antidiabetic Drugs (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

d. Drugs that *decrease* effects of sulfonylureas:

- (1) Alcohol
- (2) Beta-blocking agents
- (3) Corticosteroids, diuretics, epinephrine, estrogens, and oral contraceptives
- (4) Glucagon
- (5) Nicotinic acid
- (6) Phenytoin (Dilantin)
- (7) Rifampin

Heavy, chronic intake of alcohol induces metabolizing enzymes in the liver. This accelerates metabolism of sulfonylureas, shortens their half-lives, and may produce hyperglycemia.

Decrease hypoglycemic effects, possibly by decreasing release of insulin in the pancreas

These drugs have hyperglycemic effects.

- (8) Thyroid preparations

Raises blood glucose levels. It is used to treat severe hypoglycemia induced by insulin or oral antidiabetic agents.

Large doses have a hyperglycemic effect.

Inhibits insulin secretion and has hyperglycemic effects

Increases the rate of metabolism of sulfonylureas by inducing liver-metabolizing enzymes

Antagonize the hypoglycemic effects of oral antidiabetic drugs

e. Drugs that *decrease* effects of acarbose and miglitol:

- (1) Digestive enzymes
- (2) Intestinal adsorbents (e.g., charcoal)

Decrease effects and should not be used concomitantly

Decrease effects and should not be used concomitantly

f. Drugs that *increase* effects of metformin:

- (1) Alcohol
- (2) Cimetidine
- (3) Furosemide
- (4) Sulfonylurea hypoglycemic agents

Increases risk of hypoglycemia and lactic acidosis. Patients should avoid acute and chronic ingestion of excessive alcohol.

Increases risk of hypoglycemia. Cimetidine interferes with metabolism and increases blood levels of metformin.

Increases blood levels of metformin

The combination of these drugs is used to improve control of hyperglycemia in type 2 diabetes but it also increases risk of hypoglycemia.

g. Drugs that *increase* effects of pioglitazone:

- (1) Erythromycin, ketoconazole and related drugs

Inhibit cytochrome P450 3A4 enzymes that partially metabolize pioglitazone and may increase adverse effects. This interaction not reported with rosiglitazone, which is metabolized mainly by 2C8 and 2C9 enzymes.

h. Drugs that *increase* effects of nateglinide and repaglinide:

- (1) Nonsteroidal anti-inflammatory drugs and other agents that are highly bound to plasma proteins
- (2) Beta blockers
- (3) Cimetidine, erythromycin, ketoconazole, miconazole
- (4) Sulfonamides

May displace drugs from binding sites, therefore increasing their blood levels

May inhibit hepatic metabolism of repaglinide and nateglinide and increase their blood levels

i. Drugs that *decrease* effects of nateglinide and repaglinide:

- (1) Adrenergics, corticosteroids, estrogens, niacin, oral contraceptives, thiazide diuretics
- (2) Carbamazepine, rifampin

May cause hyperglycemia

Induce drug-metabolizing enzymes in the liver, which leads to faster inactivation

j. Drugs that may *increase* the effects of pramlintide and exenatide

- (1) Anticholinergics
- (2) Alpha-glucosidase inhibitors

May further slow GI motility and intestinal absorption of drugs and/or nutrients.

## Key Concepts

- The American Diabetes Association (ADA) suggests a target A1C of less than 7%.
- The ADA recommends re-evaluation of the management plan for anyone unable to achieve desired goals.
- A1C should be measured every 3 to 6 months.
- Exercise is perhaps the best therapy for the prevention of both type 2 diabetes and the metabolic syndrome. Exercise is an extremely strong hypoglycemic agent.
- Diabetes self-management education involves a continuum of services ranging from the teaching of survival skills to comprehensive self-management education programs to intensive management.
- Educational needs should be assessed at time of diagnosis and whenever there is poor clinical control or a major change in therapy.
- Licensed health care professionals with specific training in diabetes and training in education of people with diabetes should teach self-management education.
- Self-management education needs and plans should be documented in the medical record and acknowledged by all providers.
- Medical nutrition therapy is an integral component of diabetes management and of diabetes self-management education.
- A registered dietitian who is knowledgeable and skilled in implementing diabetes medical nutrition therapy should be the team member with primary responsibility for nutrition care and education.
- Self-monitoring of blood glucose (SMBG) is an important tool for achieving glycemic control.
- The frequency of SMBG should be individualized based on type of diabetes, glucose goals, and other factors.
- Weight loss is recommended to lower elevated blood glucose levels in overweight and obese persons with type 2 diabetes.
- Weight loss and weight maintenance therapy should use the combination of low-calorie diets, increased physical activity, and behavior therapy
- Annual influenza vaccine is recommended for all patients with diabetes.
- Pneumococcal vaccine is recommended for all patients with diabetes.
- Individuals who are at high risk for type 2 diabetes should be screened for disease.
- A fasting plasma glucose test (FPG) is the simplest and least expensive screening test.
- A FPG result of at least 126 milligrams per deciliter on two separate occasions is diagnostic of diabetes; values of 100 to 125 milligrams per deciliter are termed impaired fasting glucose, and values less than 100 milligrams per deciliter are considered normal.
- Individuals with impaired glucose tolerance can significantly reduce the risk of developing type 2 diabetes through intervention with diet and exercise.
- Medication therapy can involve oral hypoglycemic agents; insulin; newer agents such as amylin analogs, incretin mimetics, or dipeptidyl peptidase-4 inhibitors; or a combination of these therapies.
- Medication therapy is a therapeutic tool for use in lowering and maintaining blood glucose levels.
- Candidates for intensive insulin management must be motivated to improve glucose control and able to assume responsibility for their day-to-day care.
- Use of intensive insulin management should be initiated, monitored, and supported by a comprehensive diabetes team.
- Intensive insulin management is essential during pregnancy and recommended for all who wish to reduce their risk of diabetes complications.

## Review and Application Exercises

### Short Answer Exercises

1. What is the function of insulin in normal cellular metabolism?
2. What are the effects of insulin, cortisol, epinephrine, glucagon, and growth hormone on blood glucose levels?
3. What are the major differences between type 1 and type 2 diabetes?
4. What is the rationale for maintaining near-normal blood glucose levels? What is the major risk?
5. At what blood glucose range is brain damage most likely to occur?
6. Compare regular and NPH insulins in terms of onset, peak, and duration of action.
7. Describe major characteristics and uses of insulin analogs.
8. In a diabetic patient with typical signs and symptoms, distinguish between manifestations of hyperglycemia and hypoglycemia.
9. Contrast the five types of oral hypoglycemic agents in terms of mechanisms of action, indications for use, contraindications to use, and adverse effects.

10. For an adult patient newly diagnosed with type 2 diabetes, outline interventions to assist the patient in learning self-care.
  11. Prepare a teaching plan for a patient starting insulin therapy and for a patient starting an oral hypoglycemic drug.
  12. For a diabetic patient who reports using dietary and herbal supplements, analyze specific supplements in relation to their potential impact on blood sugar control.
- NCLEX-Style Questions**
13. Your patient is NPO for surgery at 10:00 A.M. He routinely receives 30 units of Humulin 70/30 every morning at 7:00 A.M. What is the appropriate nursing action in this situation?
    - a. Administer 30 units of Humulin 70/30 Sub-Q.
    - b. Hold the insulin because the patient is NPO.
    - c. Give the patient a light breakfast and administer the insulin as ordered.
    - d. Contact the physician for a pre-surgery insulin order.
  14. The nurse knows that which of the following insulins cannot be administered in a continuous Sub-Q insulin infusion pump?
    - a. regular insulin (Humulin R)
    - b. insulin aspart (NovoLog)
    - c. insulin glulisine (Apidra)
    - d. insulin glargine (Lantus)
  15. When teaching a newly diagnosed diabetic patient how to self-administer short- and intermediate-acting insulin Sub-Q, which of the following instructions is correct?
    - a. The order of drawing up the two insulins into the syringe does not matter.
    - b. Draw the short-acting insulin into the syringe first, followed by the intermediate-acting insulin.
    - c. Draw the intermediate-acting insulin into the syringe first, followed by the short-acting insulin.
    - d. You need to give yourself two injections because mixing these insulins together is unsafe.
  16. An older person with type 2 diabetes who takes metformin presents to the emergency department with symptoms of drowsiness, malaise, respiratory distress, and bradycardia. As the nurse, you suspect
    - a. hypoglycemia
    - b. hyperglycemia
    - c. lactic acidosis
    - d. metabolic alkalosis
  17. The nurse should be especially alert to the adverse effect of hypoglycemia in a type 2 diabetic patient taking which of the following oral hypoglycemics?
    - a. sulfonylureas
    - b. alpha-glucosidase inhibitors
    - c. biguanide
    - d. thiazolidinediones

# Estrogens, Progestins, and Hormonal Contraceptives

## KEY TERMS

- Estrogens
- Menopause
- Progestins
- Teratogenic

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the effects of endogenous estrogens and progestins.
2. Outline the benefits and risks of postmenopausal hormone replacement therapy.
3. Recognize adverse effects associated with estrogens, progestins, and hormonal contraceptives.
4. Apply nursing process with patients taking estrogens, progestins, and hormonal contraceptives.

## Applying Your Knowledge

Vickie Dalquist is a 21-year-old student. She has chosen to use oral contraceptives to prevent unwanted pregnancy. Vickie takes Alesse. You are the nurse at the student health clinic.

## Introduction

*Estrogens* and *progestins* are female sex hormones produced primarily by the ovaries and secondarily by the adrenal cortex in nonpregnant women. Small amounts of estrogens are also synthesized in the liver, kidney, brain, skeletal muscle, testes, and adipose tissue. In normal premenopausal women, estrogen synthesis in adipose tissue may be a significant source of the hormone. Some evidence indicates that a minimum body weight (about 105 lb) and fat content (16%–24%) are required for initiation and maintenance of the menstrual cycle. This view is supported by the observation that women with anorexia nervosa, chronic disease, or malnutrition and those who are long-distance runners usually have amenorrhea. With anorexia nervosa, regaining weight and body mass usually re-establishes normal menstrual patterns.

As with other steroid hormones, estrogens and progestins are synthesized from cholesterol. The ovaries and adrenal glands can manufacture cholesterol or extract it from the blood. Through a series of chemical reactions, cholesterol is converted to progesterone and then to androgens, testosterone, and androstenedione. The ovaries use these male sex hormones to produce estrogens. After formation, the hormones are secreted into the bloodstream in response to stimulation by the anterior pituitary gonadotropic hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). In the bloodstream, the hormones combine with serum proteins and are transported to target tissues where they enter body cells. They cross cell membranes easily because of their steroid structure and lipid solubility. Inside the cells, the hormones bind to estrogen or progestin receptors and regulate intracellular protein synthesis. Estrogen can enhance target-tissue responses to progesterone by increasing progesterone receptors. Progesterone seems to inhibit tissue responses to estrogen by decreasing estrogen receptors.

## Estrogens

Three ovarian estrogens (estradiol, estrone, and estriol) are secreted in significant amounts. Estradiol is the major estrogen because it exerts more estrogenic activity than the other two estrogens combined. The main function of the estrogens is to promote growth in tissues related to reproduction and sexual characteristics in women. More specific effects of estrogens on body tissues are described in Box 27-1.

In nonpregnant women, between puberty and menopause, estrogens are secreted in a monthly cycle called the menstrual cycle. During the first half of the cycle, before ovulation, estrogens are secreted in progressively larger amounts. During the second half of the cycle, estrogens and progesterone are secreted in increasing amounts until 2 to 3 days before the onset of menstruation. At that time, secretion of both hormones decreases abruptly. When the endometrial lining of the uterus loses its hormonal stimulation, it is discharged vaginally as menstrual flow.

During pregnancy, the placenta in conjunction with the fetus produces large amounts of estrogen causing enlargement of the uterus and breasts, growth of glandular tissue in the breasts, and relaxation of ligaments and joints in the pelvis. All these changes are necessary for the growth and birth of the fetus.

Finally, estrogens are deactivated in the liver and readily excreted through the kidneys. Metabolites are also formed in the gastrointestinal tract, brain, skin, and other steroid target tissues. Most of the conjugates are excreted in urine, and some are excreted in bile and recirculated to the liver or excreted in feces.

## Progesterone

In the nonpregnant woman, progesterone is secreted by the corpus luteum during the last half of the menstrual cycle, which occurs after ovulation. This hormone continues the changes in the endometrial lining of the uterus begun by estrogens during

### Box 27-1

### Effects of Endogenous Estrogens

#### Breasts

- Stimulate growth at puberty by causing deposition of fat, formation of connective tissue, and construction of ducts. These ducts become part of the milk-producing apparatus after additional stimulation by progesterone.

#### Sexual Organs

- Enlarge the fallopian tubes, uterus, vagina, and external genitalia at puberty, when estrogen secretion increases greatly
- Cause the endometrial lining of the uterus to proliferate and develop glands that later nourish the implanted ovum when pregnancy occurs
- Increase resistance of the epithelial lining of the vagina to trauma and infection

#### Skeleton

- Stimulate skeletal growth so that, beginning at puberty, height increases rapidly for several years. Estrogen then causes the epiphyses to unite with the shafts of the long bones, and linear growth is halted. This effect of estrogen is stronger than the similar effect of testosterone in the male. Consequently, women stop growing in height several years earlier than men and on the average are shorter than men.
- Conserve calcium and phosphorus for healthy bones and teeth. This action promotes bone formation and decreases bone loss.
- Broaden the pelvis in preparation for childbirth

#### Skin and Subcutaneous Tissue

- Increase vascularity in the skin. This leads to greater skin warmth and likelihood of bleeding in women.

- Cause deposition of fat in subcutaneous tissue, especially in the breasts, thighs, and buttocks, which produces the characteristic female figure

#### Anterior Pituitary Gland

- Decrease pituitary secretion of follicle-stimulating hormone and increase secretion of luteinizing hormone when blood levels are sufficiently high (negative feedback mechanism)

#### Metabolism

- Affect metabolism of both reproductive and nonreproductive tissues. Estrogen receptors are found in female reproductive organs, breast tissue, bone, the brain, liver, heart, and blood vessels. They are also found in various tissues in men.
- Increase protein anabolism, bone growth, and epiphyseal closure in young girls
- Decrease bone resorption
- Increase sodium and water retention, serum triglycerides, and high-density lipoproteins (HDL or “good” cholesterol)
- Decrease low-density lipoproteins (LDL or “bad” cholesterol)
- Increase the amount of cholesterol in bile and thereby increase gallstone formation

#### Blood Coagulation

- Enhance coagulation by increasing blood levels of several clotting factors, including prothrombin and factors VII, IX, and X, and probably increase platelet aggregation

the first half of the menstrual cycle. These changes provide for implantation and nourishment of a fertilized ovum. When fertilization does not take place, the estrogen and progesterone levels decrease and menstruation occurs.

If the ovum is fertilized, progesterone acts to maintain the pregnancy. The corpus luteum produces progesterone during the first few weeks of gestation. Then, the placenta produces the progesterone needed to maintain the endometrial lining of the uterus. In addition to its effects on the uterus, progesterone prepares the breasts for lactation by promoting development of milk-producing cells. Milk is not secreted, however, until the cells are further stimulated by prolactin from the anterior pituitary gland. Progesterone also may help maintain pregnancy by decreasing uterine contractility. This, in turn, decreases the risk of spontaneous abortion.

Progesterone, in general, has opposite effects on lipid metabolism compared with estrogen. That is, progestins decrease high-density lipoprotein cholesterol and increase low-density lipoprotein cholesterol, both of which increase risks of cardiovascular disease. Physiologic progesterone increases insulin levels but does not usually impair glucose tolerance. However, long-term administration of potent synthetic exogenous progestins, such as norgestrel, may decrease glucose tolerance and make diabetes mellitus more difficult to control. Like estrogen, progesterone is metabolized in the liver.

## General Characteristics of Estrogens, Progestins, and Hormonal Contraceptives

### Mechanisms of Action

Estrogens circulate in the bloodstream to target cells, where they enter cells and combine with receptor proteins in cell cytoplasm. The estrogen–receptor complex is then transported to the cell nucleus where it interacts with DNA to produce RNA and new DNA. These substances stimulate cell reproduction and production of various proteins. Progestins also diffuse freely into cells, where they bind to progesterone receptors.

Hormonal contraceptives act by several mechanisms. First, they inhibit hypothalamic secretion of gonadotropin-releasing hormone, which inhibits pituitary secretion of FSH and LH. When these gonadotropic hormones are absent, ovulation and therefore conception cannot occur. Second, the drugs produce cervical mucus that resists penetration of spermatozoa into the upper reproductive tract. Third, the drugs interfere with endometrial maturation and reception of ova that are released and fertilized. These overlapping mechanisms make the drugs highly effective in preventing pregnancy.

### Indications for Use

#### Estrogens

Indications for use of exogenous estrogens include the following:

- As a component in birth control pills and other contraceptive preparations. An estrogen, when combined with a progestin, is used widely in females ages 12 to 45 years to control fertility. If pregnancy does occur, estrogens are contraindicated because their use during pregnancy has been associated with the occurrence of vaginal cancer in female offspring and possible harmful effects on male offspring.
- Menopause. Estrogens are prescribed to relieve symptoms of estrogen deficiency (e.g., atrophic vaginitis and vasomotor instability, which produces “hot flashes” or “hot flushes”) and to prevent or treat osteoporosis. Such use is usually called estrogen replacement therapy (ERT). When estrogen is prescribed for women with an intact uterus, a progestin is also given to prevent unwanted thickening of the lining of the uterus and to decrease the risk of cancer of the uterus, a possible result of using estrogen alone. Both drug therapies are commonly referred to as hormone replacement therapy (HRT) or menopausal hormone therapy (MHT), terms used to describe the administration of one or more female hormones during menopause.
- As replacement therapy in deficiency states. Deficiency states usually result from hypofunction of the pituitary gland or the ovaries and may occur anytime during the life cycle. For example, in the adolescent girl with delayed sexual development, estrogen can be given to produce the changes that normally occur at puberty. In the woman of reproductive age (approximately 12 to 45 years of age), estrogens are occasionally used in menstrual disorders, including amenorrhea and abnormal uterine bleeding due to estrogen deficiency.

Recent large-scale randomized controlled trials indicated that for estrogen-only and combined estrogen–progestin therapy risks are greater than benefits (Box 27-2).

#### Progestins

Progestins are most often used in combination with an estrogen in contraceptive products. They also are used to suppress ovarian function in dysmenorrhea, endometriosis, endometrial cancer, and uterine bleeding. These uses of progestins are extensions of the physiologic actions of progesterone on the neuroendocrine control of ovarian function and on the endometrium. For approximately 20 to 25 years, progestins were used in combination with estrogen for long-term HRT in postmenopausal women with an intact uterus. With HRT, the purpose of a progestin is to prevent endometrial cancer, which can occur with unopposed estrogenic stimulation. Currently, however, the combination is not recommended for long-term use because evidence indicated that the adverse effects outweigh the beneficial effects (see Box 27-2).

#### Hormonal Contraceptives

The primary clinical indication for the use of hormonal contraceptives is to control fertility and prevent pregnancy. Some products are used for contraception after unprotected sexual intercourse. These preparations also are used to treat menstrual disorders (e.g., amenorrhea, dysmenorrhea).

## Box 27-2

## Hormone Replacement Therapy in Postmenopausal Women

From the 1980s until mid-2002, long-term postmenopausal estrogen replacement therapy (ERT) was frequently recommended for women, with the expectation that it would manage menopausal symptoms, exert cardioprotective effects, prevent osteoporosis, and prolong life. Two large-scale randomized controlled trials, the Heart and Estrogen/Progestin Replacement Study (HERS) and the Women's Health Initiative (WHI), disputed this prevailing observational data and expert opinion.

The Heart and Estrogen–Progestin Replacement Studies, HERS and HERS II, involved postmenopausal women with an intact uterus who already had coronary heart disease (CHD). Results indicated that in women who had pre-existing heart disease, hormones provided no benefit in relation to preventing serious cardiovascular events; this increased interest in the NIH-funded WHI trials that were designed to evaluate primary prevention.

The WHI study was conducted in healthy women to determine if an estrogen–progestin combination (in women with an intact uterus) or estrogen alone (in postmenopausal women who have had a hysterectomy) would prevent the development of CHD.

Both arms of the WHI study were stopped in the interest of safety. The consensus was that with estrogen-only therapy in post-hysterectomy women the hormone increased the risk

of stroke and offered no protection against heart disease.

As with healthy women, the conclusion of the WHI was that the hormones should not be started or continued for preventive purposes in women with CHD because risks were greater than benefits.

In the arm of the study looking at postmenopausal women who have had a hysterectomy and thus do not need a progestin, estrogen-only therapy significantly increased the hazard of deep vein thrombosis and had no significant effect on the risk of colorectal or breast cancer. A reduced risk of hip and other fractures was reported. A related study also found that the hormone might also increase the risk of dementia and mild cognitive impairment in older women.

In summary, studies have demonstrated no evidence for HRT in secondary prevention of heart disease and showed increased rates of CHD, thromboembolic stroke, venous thromboembolism, dementia, and breast cancer, which outweigh the benefits of decreased risk of fracture and colon cancer. Thromboembolic disorders are most likely to occur during the first year of use; risks of developing breast cancer increase with the duration of drug use. The FDA recommended that HRT only be used for women with symptoms severe enough to warrant its use, at the lowest dose and for the shortest duration possible, to ease the menopausal transition.

## Contraindications to Use

Because of their widespread effects on body tissues and reported adverse reactions, estrogens, progestins, and hormonal contraceptives are contraindicated in

- Known or suspected pregnancy, because *teratogenic* effects capable of interfering with the normal development of the fetus may result
- Thromboembolic disorders, such as thrombophlebitis, deep vein thrombosis, or pulmonary embolism
- Known or suspected cancers of breast or genital tissues, because the drugs may stimulate tumor growth. An exception is the use of estrogens for treatment of metastatic breast cancer in women at least 5 years postmenopause.
- Undiagnosed vaginal or uterine bleeding
- Fibroid tumors of the uterus
- Active liver disease or impaired liver function
- History of cerebrovascular disease, coronary artery disease, thrombophlebitis, hypertension, or conditions predisposing to these disease processes
- Women older than 35 years of age who smoke cigarettes. These women have a greater risk of thromboembolic disorders if they take hormonal contraceptives, possibly because of increased platelet aggregation with estrogen ingestion and cigarette smoking. In addition, estrogen increases hepatic production of blood clotting factors.
- Family history of breast or reproductive system cancer

## Individual Drugs

When exogenous estrogens and progestins are administered for therapeutic purposes, they produce the same effects as endogenous hormones. Multiple preparations of estrogens and progestins are available for various purposes and routes of administration. Clinical indications, routes of administration, and dosages are discussed in the estrogens and progestins Drugs at a Glance tables.

### Estrogens

Table 27-1 summarizes important drug information about estrogens. The most widely used synthetic steroidal estrogen is **ethinyl estradiol** (Estinyl), which is used in hormonal contraceptives. Ethinyl estradiol is well absorbed with oral administration and reaches peak plasma levels within 2 hours. It is 98% bound to plasma proteins, and its half-life varies from 6 to 20 hours. Ethinyl estradiol undergoes extensive first-pass hepatic metabolism and is further metabolized and conjugated in the liver; the conjugates are then excreted in bile and urine.

Transdermal estradiol patches (e.g., Climara, Estraderm, Vivelle) allow for absorption of estrogen through the skin to the bloodstream. The patches are applied weekly or biweekly depending on the preparation. Serum levels produced through transdermal application more closely mimic premenopausal estrogen levels compared with serum levels with oral estrogens.

Table 27-1

## Drugs at a Glance: Estrogens

## ROUTES AND DOSAGE RANGES FOR VARIOUS INDICATIONS

Generic/ Trade Name	Menopausal Symptoms	Female Hypogonadism	Prevention of Osteoporosis	Other
<b>Conjugated estrogens (synthetic)</b> (Cenestin)	PO 0.625–1.25 mg daily			
<b>Conjugated estrogens</b> (Premarin)	PO 0.3–1.25 mg daily for 21 d followed by 7 d without the drug	PO 2.5–7.5 mg daily in divided doses, cyclically, 20 d on, 10 d off the drug	PO 0.625 mg daily for 21 d, then 7 d without the drug	Dysfunctional uterine bleeding: IM or IV for emergency use, 25 mg, repeated in 6–12 h if necessary Atrophic vaginitis: Topically, 2.4 g of vaginal cream inserted daily
<b>Estradiol</b> (Estrace, Estring)	PO 1–2 mg daily for 3 wk, then 1 wk off or daily Monday through Friday, none on Saturday or Sunday as prescribed		PO 0.5 mg daily for 23 d and no drug for 5 d each month	Atrophic vaginitis: Cream, 2–4 g daily for 2 wk, then 1–2 g daily for 2 wk, then 1 g 1–3 times weekly; vaginal ring (Estring), 1 every 3 mo
<b>Estradiol cypionate</b> (Depo-Estradiol)	IM 1–5 mg every 3–4 wk	IM 1.5–2 mg at monthly intervals		
<b>Estradiol hemihydrate</b> (Vagifem)				Atrophic vaginitis: 1 tablet, inserted into vagina, daily for 2 wk, then twice weekly
<b>Estradiol transdermal system</b> (Estraderm, Climara, Vivelle)	Topically to skin, 1 patch 1 or 2 times per wk			
<b>Estradiol valerate</b> (Delestrogen)	IM 10–20 mg every 4 wk	IM 10–20 mg every 4 wk		
<b>Estrone</b>	IM 0.1–0.5 mg weekly in single or divided doses	IM 0.1–2 mg weekly		Dysfunctional uterine bleeding: IM 2–4 mg daily for several days until bleeding is controlled, followed by progestin for 1 wk
<b>Estropipate</b> (Ogen)	PO 0.625–5 mg daily, cyclically	PO 1.25–7.5 mg daily for 3 wk, followed by an 8- to 10-d rest period. Repeat as needed.	PO 0.625 mg daily for 25 d and no drug for 6 d each month	Ovarian failure: Same dosage as for female hypogonadism Atrophic vaginitis: Topically, 1–2 g vaginal cream daily

Rates of absorption vary, depending on the type of patch applied. The total amount of drug absorbed and the resulting plasma drug concentrations from transdermal estrogen can increase during exposure to heat, so patients should be advised to avoid prolonged sun exposure in the area of the patch.

**Conjugated estrogens** (Premarin) and some synthetic derivatives of natural estrogens (e.g., ethinyl estradiol) are chemically modified to be effective with oral administration. Conjugated estrogens are used to treat moderate to severe vasomotor and atrophic symptoms associated with menopause, to prevent postmenopausal osteoporosis, and as palliative

treatment for metastatic breast carcinoma and advanced androgen-dependent prostatic cancer. Intravenous injection is used, in the absence of organic pathology, for the treatment of abnormal uterine bleeding caused by hormonal imbalance. Conjugated estrogens are well absorbed with oral administration and are released slowly over several hours. Degradation occurs very slowly in the liver, allowing for high intrinsic potency with these preparations.

Along with several cream formulations, a vaginal tablet (Vagifem) and a vaginal ring (Estring) of estrogen are available for topical application in treating atrophic vaginitis.

Nonsteroidal synthetic preparations are chemically altered to slow their metabolism in the liver. They are also less bound to serum proteins than naturally occurring hormones. As with conjugated estrogens, nonsteroidal synthetic preparations are well absorbed with oral administration and are released slowly over several hours. Degradation occurs very slowly in the liver, allowing for high intrinsic potency with these preparations.

The FDA has issued a **BLACK BOX WARNING** that estrogens increase the risk for developing cancer of the uterus. The warning instructs individuals who take estrogens with or without progestins that there is an increased risk of dementia, myocardial infarctions, strokes, breast cancer, and blood clots.

## Progestins

Progestins (Table 27-2) are used as noncontraceptives and as oral contraceptives, both as estrogen–progestin combinations and as progestin-only preparations (“minipills”). The choice of a combination contraceptive product may be determined by the progestin component. Progestins with minimal androgenic activity are **desogestrel** and **norgestimate**, those with intermediate activity include **norethindrone** and **ethynodiol**, and those with high androgenic effects include **norgestrel**. Progestins are rapidly absorbed after oral administration and go through prompt hepatic degradation. The drug can reach maximum concentration in 1 to 2 hours. Drug half-life varies. Dur-

ing the first 6 hours, half-life is about 2 to 3 hours; thereafter, half-life extends to 8 to 9 hours. Metabolites are excreted primarily in the urine. Progestins administered intramuscularly are also rapidly absorbed, with a half-life of just a few minutes. Long-acting forms can maintain effective concentrations for 3 to 6 months; maximum concentrations can be achieved in 24 hours with a half-life of about 10 weeks. Gel preparations have sustained-release properties, and absorption is prolonged with half-lives of 1 to 2 days.

There is no evidence to suggest that use of progestins in the first trimester of pregnancy to prevent habitual abortion is safe. There is evidence that when the drug is given during the first 4 months of pregnancy fetal harm is possible.

Table 27-3 provides information about noncontraceptive estrogen–progestin combinations. Several noncontraceptive combination oral tablets are available for treatment of menopausal symptoms and osteoporosis. Two combination products (Combi-Patch and Ortho Evra) are available in transdermal patches for topical application.

## Hormonal Contraceptives

Most hormonal contraceptives consist of a synthetic estrogen (e.g., ethinyl estradiol) and a synthetic progestin (e.g., norethindrone) (Table 27-4). Three different types of formulation for hormonal contraceptives are commonly prescribed: monophasic contraceptives containing fixed amounts of both

Table 27-2

### Drugs at a Glance: Progestins

#### ROUTES AND DOSAGE RANGES FOR VARIOUS INDICATIONS

Generic/ Trade Name	ROUTES AND DOSAGE RANGES FOR VARIOUS INDICATIONS			
	Menstrual Disorders	Endometriosis	Endometrial Cancer	Other
<b>Medroxyproges-terone acetate</b> (Depo-Provera, Provera)	Dysfunctional uterine bleeding: PO 5–10 mg daily for 5–10 d, beginning on 16th or 21st d of cycle		IM 400–1000 mg weekly until improvement, then 400 mg monthly	
<b>Megestrol acetate</b> (Megace)	Amenorrhea: PO 5–10 mg daily for 5–10 d		PO 40–320 mg daily in 4 divided doses for at least 2 mo	Breast cancer: PO 160 mg daily in 4 divided doses for at least 2 mo
<b>Norethindrone acetate</b> (Aygestin)	Amenorrhea, dysfunctional uterine bleeding: PO 2.5–10 mg daily, starting on 5th d of menstrual cycle and ending on 25th d	PO 5 mg daily for 2 wk, increased by 2.5 mg daily every 2 wk to dose of 15 mg. Then give 10–15 mg daily for maintenance.		
<b>Progesterone</b>	Amenorrhea, dysfunctional uterine bleeding: IM 5–10 mg for 6–8 consecutive d			

Table 27-3

**Drugs at a Glance: Noncontraceptive Estrogen-Progestin Combination**

TRADE NAME	ESTROGEN	PROGESTIN	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
Activella	Estradiol 1 mg	Norethindrone 0.5 mg	Menopausal symptoms; prevention of osteoporosis	PO 1 tablet daily
Combi-Patch	Estradiol 0.05 mg	Norethindrone 0.14 or 0.25 mg	Estrogen deficiency states due to menopause, hypogonadism, castration, or primary ovarian failure	1 transdermal patch twice weekly
Femhrt	Ethinyl estradiol 5 mcg	Norethindrone 1 mg	Menopausal symptoms; prevention of osteoporosis	PO 1 tablet daily
Premphase	Conjugated estrogens 0.625 mg*	Medroxyprogesterone 5 mg	Menopausal symptoms; prevention of osteoporosis	PO 1 tablet of estrogen-only once daily on d 1–14, then 1 combination tablet once daily on d 15–28
Prempro	Conjugated estrogens 0.3, 0.45, 0.625 mg	Medroxyprogesterone 1.5, 2.5, or 5 mg	Menopausal symptoms; prevention of osteoporosis	PO 1 tablet once daily in dial packs 28s

\*Also available with estrogen only.

estrogen and progestin components, and biphasics and triphasics containing either fixed amounts of estrogen and varied amounts of progestin or varied amounts of both estrogen and progestin. Biphasic and triphasic preparations mimic normal variations of hormone secretion, decrease the total dosage of hormones, and may decrease adverse effects. These contraceptives are dispensed in containers with color-coded tablets that must be taken in the correct sequence. Dispensers with 28 tablets contain 7 inactive or placebo tablets of a third color. A few contraceptives are progestin-only products. These are not widely used because they are less effective in preventing pregnancy and are more likely to cause vaginal bleeding, which makes them less acceptable to many women. Several combination products and alternative dosage forms are available to help individualize treatment and promote compliance. Table 27-4 outlines the trade names of hormonal contraceptives

**Herbal and Dietary Supplement**

**Black cohosh** is an herb used to self-treat symptoms of menopause, and reportedly is effective in relieving vasomotor instability. Most published information supports the benefit of the herb for the relief of menopause-related symptoms; however, clinical trials in this area have demonstrated methodologic limitations, and more definitive information regarding safety and efficacy are needed. The product apparently exerts a nonhormonal effect and does not affect the endometrium or estrogen-dependent cancers; however, its effects on bone and osteoporosis are unknown. Trade names include Remifemin, Estroven, Femtrol, and GNC Menopause Formula.

Adverse effects may include nausea, vomiting, dizziness, hypotension, and visual disturbances. Blood pressure should be monitored closely in hypertensive patients, because the herb may increase the hypotensive effects of antihypertensive drugs. Black cohosh is contraindicated in pregnancy and not recommended for use longer than 6 months for menopausal symptoms.

Overall, this herb may be considered in patients who refuse estrogen therapy recommended by a prescriber or have conditions in which estrogen is contraindicated. If Remifemin is taken, the recommended dosage is one tablet (standardized to contain 20 mg of herbal drug) twice daily. Other dosage forms are available, and dosage depends on the method of preparation.

**Applying Your Knowledge 27-1**

Vickie comes to the clinic for a routine visit. You review her medication history. Vickie asks about the different-colored pills in her contraceptive container. What is the best response?

**Emergency Contraceptive**

Plan B

**Applying Your Knowledge 27-2**

Vickie comes back to the clinic and tells you that she has not had a menstrual period this past month. Further assessment reveals that Vickie may not have taken all of her pills in sequence and that she has been sexually active. She is about 3 weeks overdue for her period. What action would you take?

**Applying Your Knowledge 27-3**

Vickie is not pregnant and she decides to remain on oral contraceptives. She explains to you that she sometimes does not take her pill because they make her sick to her stomach. How do you respond?

**Nursing Process****Assessment**

Before drug therapy is started, patients need a thorough history and physical examination, including measurements of blood pressure, serum cholesterol, and triglycerides. These parameters must be monitored periodically as long as the drugs are taken.

- Assess for conditions in which estrogens and progestins are used (e.g., menstrual disorders, menopausal symptoms).
- Assess for conditions that increase risks of adverse effects or are contraindications for hormonal therapy (e.g., thromboembolic disorders, pregnancy).
- Record blood pressure with each outpatient contact or regularly with hospitalized patients. Increases are likely in premenopausal women, especially with oral contraceptives, but are unlikely in women who are postmenopausal who are receiving physiologic replacement doses.
- Check laboratory reports of cholesterol and triglyceride levels when available.
- Assess diet and presence of cigarette smoking. A high-fat diet increases the risks of gallbladder disease and perhaps other problems; cigarette smoking increases risks of thromboembolic disorders in women older than 35 years of age who take oral contraceptives.
- Assess the patient's willingness to comply with instructions about drug therapy and follow-up procedures.
- Assess for signs and symptoms of thromboembolic disorders regularly. These are most likely to occur in women older than 35 years of age who take oral contraceptives, women who are postmenopausal who receive combined estrogen–progestin HRT, and women or men who take large doses for cancer.

## Nursing Diagnoses

- Disturbed Body Image in women, related to effects of hormone deficiency states
- Disturbed Body Image in men, related to feminizing effects and impotence from female hormones
- Excess Fluid Volume related to sodium and water retention
- Deficient Knowledge: Effects of hormonal therapy
- Risk for Injury related to increased risks of hypertension and gallbladder disease

## Planning/Goals

### The patient will

- Be assisted to cope with self-concept and body image changes
- Take the drugs accurately, for the length of time prescribed
- Experience relief of symptoms for which the drugs are given
- Avoid preventable adverse drug effects
- Keep appointments for monitoring of drug effects

## Interventions

- Assist patients of childbearing age to choose an appropriate contraceptive method. If the choice is an estrogen–progestin combination, help the patient take it accurately.
- Help postmenopausal women plan for adequate calcium and vitamin D in the diet and adequate weight-bearing exercise to maintain bone strength and prevent osteoporosis.
- Assist patients in obtaining follow-up health care when indicated.
- Provide patient teaching for drug therapy (see accompanying displays).

## Evaluation

- Interview and observe for compliance with instructions for taking the drugs.
- Interview and observe for therapeutic and adverse drug effects.

## Principles of Therapy

### Need for Continuous Supervision

Because estrogens, progestins, and hormonal contraceptives are often taken for years and may cause adverse reactions, patients taking these drugs need continued supervision by a health care provider. Before the drugs are prescribed, a complete medical history, a physical examination including breast and pelvic examinations and a Papanicolaou (Pap) test, uri-

nalyses, and weight and blood pressure measurements are recommended. These examinations should be repeated at least annually as long as the patient is taking the drugs.

### Drug Selection

Choice of preparation depends on the reason for use, desired route of administration, and duration of action. Conjugated estrogen (e.g., Premarin) is a commonly used oral estrogen, and medroxyprogesterone (e.g., Provera) is a commonly used oral progestin. Transdermal estradiol (e.g., Climara, Estraderm, Vivelle) allows for absorption of estrogen through the skin to the bloodstream. Two advantages have been recognized with this form of administration. Because the liver is bypassed, the total dose of estrogen is reduced. Additionally, the serum levels produced through transdermal application more closely mimic premenopausal estrogen levels compared with serum levels with oral estrogens.

The choice of a combination contraceptive product may be determined by the progestin component. Some progestins are more likely to cause weight gain, acne, and changes in blood lipids that increase risks of myocardial infarction or stroke. These adverse effects are attributed mainly to the androgenic activity of the progestin, and some progestins have more androgenic effects than others. Duration of action may also be a factor. Some crystalline suspensions of estrogens and oil solutions of both estrogens and progesterone prolong drug action by slowing absorption. Long-acting progestin contraceptive preparations such as the intramuscular depot medroxyprogesterone (Depo-Provera) last 3 months per injection, intrauterine progesterone lasts 1 year, and levonorgestrel subcutaneous implants (Norplant) last 5 years.

### Drug Dosage

Although dosage needs vary with patients and the conditions for which the drugs are prescribed, a general rule is to use the smallest effective dose for the shortest effective time. Estrogens are often given cyclically. In one regimen, the drug is taken for 3 weeks and then omitted for 1 week; in another, it is omitted the first 5 days of each month. These regimens more closely resemble normal secretion of estrogen and avoid prolonged stimulation of body tissues. A progestin may be added for 10 days each month.

### Drug Administration

Naturally occurring, nonconjugated estrogens (estradiol, estrone) and natural progesterone are given intramuscularly because they are rapidly metabolized if administered orally. Nonsteroidal synthetic preparations are usually administered orally or topically.

### Drug Interactions

These drugs may interact with several drugs or drug groups to increase or decrease their effects. Most interactions have been reported with oral contraceptives.

Estrogens may decrease the effectiveness of sulfonylurea antidiabetic drugs (probably by increasing their metabolism);

## Patient Teaching Guidelines

## Hormone Replacement Therapy

### General Considerations

- Hormone replacement therapy (HRT) relieves symptoms of menopause and helps to prevent or treat osteoporosis.
- Women receiving HRT should be under medical supervision and should have a physical examination at least annually to check blood pressure and breasts, pelvis, and other areas for possible adverse reactions when these drugs are taken for long periods.
- Women who have not had a hysterectomy should take both estrogen and progestin; the progestin component (e.g., Provera) prevents endometrial cancer, an adverse effect of estrogen-only therapy. Post-hysterectomy, women should take estrogen-only medications. However, the Women's Health Initiative study concluded that risks of adverse effects with estrogen-only therapy and estrogen-progestin combinations are greater than previously believed (see Box 27-2). Women who are considering HRT (e.g., for severe symptoms of menopause) should discuss their individual risks and potential benefits with their health care providers.
- Combined estrogen-progestin therapy may increase blood sugar levels in women with diabetes. This effect is attrib-

uted to progestin and is unlikely to occur with estrogen-only therapy.

- Women with diabetes should report increased blood glucose levels.

### Self-Administration

- Take estrogens and progestins with food or at bedtime to decrease nausea, a common adverse reaction.
- Apply transdermal estrogen patches (Climara, Estraderm, Vivelle) to clean, dry skin, preferably the abdomen. Press the patch tightly for 10 seconds to get a good seal and rotate sites so that at least a week passes between applications to a site; avoid prolonged sun exposure to the area of the patch.
- Apply transdermal estrogen gel (EstroGel) to clean, dry skin, avoiding the breast; avoid fire, flame, or smoking until gel has dried because it is flammable.
- Weigh weekly and report sudden weight gain. Fluid retention and edema may occur and produce weight gain.
- Report any unusual vaginal bleeding.

## Patient Teaching Guidelines

## Oral Contraceptives

### General Considerations

- Seek information about the use of oral contraceptives.
- Oral contraceptives are very effective at preventing pregnancy, but they *do not* prevent transmission of sexually transmitted diseases (e.g., acquired immunodeficiency syndrome, chlamydia, gonorrhea).
- See a health care provider every 6 to 12 months for blood-pressure measurement, breast and pelvic examinations, and other care as indicated. This is very important to monitor for adverse drug effects such as high blood pressure, gallbladder disease, and blood-clotting disorders.
- Do not smoke cigarettes. Cigarette smoking increases risks of blood clots in the legs, lungs, heart, or brain. The blood clots may cause heart attack, stroke, or other serious diseases.
- Several medications may reduce the effectiveness of oral contraceptives (i.e., increase the likelihood of pregnancy). These include several antibiotics (e.g., ampicillin, clarithromycin and similar drugs, rifampin, penicillin V, sulfonamides [e.g., Bactrim], tetracyclines, and antiseizure medications (e.g., carbamazepine, oxcarbazepine, phenytoin, topiramate). Inform all health care providers who prescribe medications for you that you are taking a birth control pill.
- Be prepared to use an additional or alternative method of birth control if a dose is missed, if you are unable to take the oral contraceptive because of illness, or if you have an infection for which an antibiotic is prescribed. For exam-

ple, add a different method of birth control while taking an antibiotic and for the remainder of that cycle.

### Self-Administration

- Read, keep, and follow instructions in the package inserts that are dispensed with the drugs. These inserts provide information about safe and effective use of the drugs.
- Take oral contraceptives with meals or food or at bedtime to decrease nausea. (If using Ortho Evra, a contraceptive skin patch that lasts a week, follow package instructions for correct application.)
- Take at about the same time every day to maintain effective blood levels and establish a routine so that missed doses are less likely. Missing one dose may allow pregnancy to occur. If you forget to take one pill, take it as soon as you remember. If you do not remember until the next scheduled pill, you can take two pills at once. If you miss two pills in a row, you may take two pills for the next 2 days. If you miss more than two pills, notify your health care provider.
- Use sunscreen and protective clothing when outdoors. The drugs may cause photosensitivity, with increased likelihood of sunburn after short periods of exposure.
- Weigh weekly and report sudden weight gain. The drugs may cause fluid retention; decreasing salt intake may be helpful.
- Report any unusual vaginal bleeding; calf tenderness, redness, or swelling; chest pain; weakness or numbness in an arm or leg; or sudden difficulty with seeing or talking.

warfarin, an oral anticoagulant (by increasing hepatic production of several clotting factors); and phenytoin, an anticonvulsant (possibly by increasing fluid retention). Estrogens may increase the adverse effects and risks of toxicity with corticosteroids, ropinirole, and tacrine by inhibiting their metabolism. Ropinirole and tacrine should not be used concurrently with an estrogen.

Oral contraceptives decrease effects of some benzodiazepines (e.g., lorazepam, oxazepam, temazepam), insulin, sulfonylurea antidiabetic drugs, and warfarin. If one of these drugs is taken concurrently with an oral contraceptive, increased dosage may be needed for therapeutic effects. Contraceptives increase effects of several drugs by inhibiting their metabolism. These include alcohol, some benzodiazepines (e.g., alprazolam, triazolam), tricyclic antidepressants, beta blockers (e.g., metoprolol), caffeine, corticosteroids, and theophylline (a xanthine bronchodilator). If one of these drugs is taken concurrently with an oral contraceptive, the drug may accumulate to toxic levels. Dosage may need to be reduced.

## Use for Specific Indications

### Contraception

The most effective and widely used contraceptives are estrogen–progestin combinations (see Table 27-4). Estrogen–progestin contraceptive preparations are nearly 100% effective in preventing pregnancy when taken correctly.

Numerous preparations are available, with different components and different doses of components, so that a preparation can be chosen to meet individual needs. Most oral contraceptives contain an estrogen and a progestin. The estrogen dose is usually 30 to 35 micrograms. Smaller amounts (e.g., 20 mcg) may be adequate for small or underweight women; larger amounts (e.g., 50 mcg) may be needed for large or overweight women. Effects of estrogen components are similar when prescribed in equipotent doses, but progestins differ in progestogenic, estrogenic, antiestrogenic, and androgenic activity. Consequently, adverse effects may differ to some extent, and a patient may be able to tolerate one contraceptive better than another.

Current products contain small amounts of estrogen and cause fewer adverse effects than previous products. Despite the decreased estrogen dosage, oral contraceptives may still be safest when administered to nonsmoking women younger than 35 years of age who do not have a history of thromboembolic problems, diabetes mellitus, hypertension, or migraine. When estrogen is contraindicated, a progestin-only contraceptive may be used.

It is necessary to assess each patient's need and desire for contraception, as well as her willingness to comply with the prescribed regimen. Assessment includes determining a patient's knowledge about birth control, both pharmacologic and nonpharmacologic, and identifying patients in whom hormonal contraceptives are contraindicated or who are at increased risk for adverse drug effects. Compliance involves the willingness to take the drugs as prescribed and to have breast

and pelvic examinations and blood pressure measurements every 6 to 12 months.

### Emergency (Postcoital) Contraception

Plan B (levonorgestrel) is the only emergency contraceptive on the market used to avoid pregnancy after unprotected sexual intercourse. It should be used only as a backup method and is not used for routine birth control. The drug is marketed by prescription and over-the-counter (OTC), with the OTC only being sold to women 18 years and older.

Emergency contraception is most effective if started within 24 hours and no later than 72 hours after exposure. The drug is believed to act mainly by inhibiting ovulation; the drug may also have an effect on fertilization and implantation. Plan B does not appear to have an effect on pregnancy after implantation. Side effects include nausea, abdominal pain, fatigue, headache, menstrual changes, dizziness, breast tenderness, vomiting, and diarrhea. Menstrual bleeding flow and timing may be altered after taking Plan B, and a woman whose menstrual period is delayed for greater than a week from the expected time should get a pregnancy test and follow-up with a health care professional.

### Menopause

*Menopause* usually occurs in women ages 48 to 55 years. A woman who has not menstruated for a full year is considered menopausal, although symptoms of estrogen deficiency and irregular periods start approximately 4 years before final cessation. Physiologic menopause results from the gradual cessation of ovarian function and the resultant decrease in estrogen levels. Surgical menopause results from excision of both ovaries and the sudden loss of ovarian estrogen. Although estrogens from the adrenal cortex and other sites are still produced, the amount is insufficient to prevent estrogen deficiency.

ERT prevents vasomotor instability (“hot flashes” or “hot flushes”) and other menopausal symptoms. A commonly prescribed regimen is a conjugated estrogen (Premarin) 0.625 to 1.25 milligrams daily for 25 days of each month, with a progestin, such as Provera, 10 milligrams daily for 10 days of each month, on days 15 to 25 of the cycle. The main function of the progestin is to decrease the risk of endometrial cancer; thus, women who have had a hysterectomy do not need it. Another regimen uses estradiol as a transdermal patch (e.g., Climara, Estraderm, Vivelle), which releases the drug slowly, provides more consistent blood levels than oral formulations, and is applied weekly or biweekly, depending on the formulation. A newer synthetic conjugated estrogen (Cenestin) is also approved for short-term treatment of hot flashes and sweating; it is not approved for long-term use in preventing osteoporosis in postmenopausal women. In addition, selective serotonin reuptake inhibitors (see Chap. 10) have shown great potential in reducing vasomotor symptoms. In randomized clinical trials, venlafaxine (Effexor), paroxetine (Paxil), and fluoxetine (Prozac) have been shown to reduce hot flashes significantly.

### Osteoporosis: Prevention and Treatment

Estrogen or estrogen–progestin therapy is effective and has been widely used to prevent or treat osteoporosis and prevent fractures in postmenopausal women (see Chap. 25). Estrogenic effects in preventing bone loss include decreased bone resorption (breakdown), increased intestinal absorption of calcium, and increased calcitriol concentration. Calcitriol is the active form of vitamin D, which is required for absorption of calcium.

Estrogen and progestin may be used less often for osteoporosis in future for two main reasons. First, recent evidence (see Box 27-2) indicates that the risks of estrogen–progestin and estrogen-only hormonal therapy outweigh the benefits. Second, there are other effective measures for prevention and treatment of osteoporosis, including calcium and vitamin D supplements, bisphosphonate drugs (e.g., alendronate, risedronate), and weight-bearing exercise. ERT is still considered for fracture prevention among women who are at high risk of fracture and who are unable to take other preventive medications.

### Use in Special Populations

#### Use in Children

There is little information about the effects of estrogens in children, and the drugs are not indicated for use. Because estrogens cause epiphyseal closure, they should be used with caution before completion of bone growth and attainment of adult height. When hormonal contraceptives are given to adolescent girls, as in other populations, the smallest effective doses should be used.

#### Use in Older Adults

The short-term use (1–2 years) of estrogens or estrogens and progestins in postmenopausal women may be indicated for management of menopausal symptoms. Long-term use of estrogen-only therapy and estrogen–progestin combinations is no

longer recommended for most women, because of potentially serious adverse effects.

#### Use in Patients With Hepatic Impairment

Estrogens are contraindicated in impaired liver function, liver disease, or liver cancer. Impaired liver function may lead to impaired estrogen metabolism, with resultant accumulation and adverse effects. In addition, women who have had jaundice during pregnancy have an increased risk of recurrence if they take estrogen-containing contraceptives. Any patient in whom jaundice develops when taking estrogen should stop taking the drug. Because jaundice may indicate liver damage, the cause should be investigated. Progestins are contraindicated in patients with impaired liver function or liver disease.

#### Use in Home Care

Estrogens, progestins, and hormonal contraceptives are usually self-administered. Home care nurses may encounter patients or family members taking one of the drugs when visiting the home for another purpose. It may be necessary to teach or assist patients to take the drugs as prescribed. In addition, patients may need encouragement to keep appointments for follow-up supervision and blood pressure monitoring. When visiting families that include adolescent girls or young women, home care nurses may need to teach about birth control measures or about preventing osteoporosis by improving diet and exercise patterns. In families that include postmenopausal women, home care nurses may need to teach about nonhormonal strategies for preventing or treating osteoporosis and cardiovascular disease.

### Applying Your Knowledge 27-4

#### How Can You Avoid This Medication Error?

Vickie returns to the clinic for a urinary tract infection. The physician prescribes an antibiotic. You send Vickie to the school pharmacy and then home.

.....

## Nursing Actions Estrogens, Progestins, and Hormonal Contraceptives

### NURSING ACTIONS

#### 1. Administer accurately

- Give oral estrogens, progestins, and contraceptive preparations after meals or at bedtime.
- With aqueous suspensions to be given intramuscularly, roll the vial between the hands several times.
- Give oil preparations deeply into a large muscle mass, preferably gluteal muscles.
- With estradiol skin patches, apply to clean, dry skin of the abdomen, buttocks, upper inner thigh, or upper arm. Avoid breasts, waistline areas, and areas exposed to sunlight. Press with palm of hand for about 10 seconds. Rotate sites.
- With Combi-Patch, apply to clean, dry skin of the lower abdomen; rotate sites.

### RATIONALE/EXPLANATION

- To decrease nausea, a common adverse reaction
- To be sure that drug particles are evenly distributed through the liquid vehicle
- To facilitate effective absorption and adherence to the skin and avoid skin irritation
- Manufacturer's recommendation. Rotating sites decreases skin irritation.

**NURSING ACTIONS**

f. With Ortho Evra patch, apply to abdomen, buttocks, upper torso (except breasts), or upper outer arm.

**2. Observe for therapeutic effects**

a. With estrogens:

- (1) When given for menopausal symptoms, observe for decrease in hot flashes and vaginal problems.
- (2) When given for amenorrhea, observe for menstruation.
- (3) When given for female hypogonadism, observe for menstruation, breast enlargement, axillary and pubic hair, and other secondary sexual characteristics.
- (4) When given to prevent or treat osteoporosis, observe for improved bone density tests and absence of fractures.

b. With progestins:

- (1) When given for menstrual disorders, such as abnormal uterine bleeding, amenorrhea, dysmenorrhea, premenstrual discomfort, and endometriosis, observe for relief of symptoms.

**3. Observe for adverse effects**

a. With estrogens:

- (1) Menstrual disorders—breakthrough bleeding, dysmenorrhea, amenorrhea
- (2) Gastrointestinal system—nausea, vomiting, abdominal cramps, bloating
- (3) Gallbladder disease
- (4) Cardiovascular system—thromboembolic conditions such as thrombophlebitis, pulmonary embolism, cerebral thrombosis, and coronary thrombosis; edema and weight gain
- (5) Central nervous system—headache, migraine headache, dizziness, mental depression
- (6) Cancer—endometrial and possibly breast cancer

b. With progestins:

- (1) Menstrual disorders—breakthrough bleeding
- (2) Cardiovascular system—decreased high-density lipoprotein and increased low-density lipoprotein cholesterol
- (3) Gastrointestinal system—nausea, increased or decreased weight

**RATIONALE/EXPLANATION**

Manufacturer's recommendation

Therapeutic effects vary, depending on the reason for use.

Estrogen drugs may alter hormonal balance.

Nausea commonly occurs but usually subsides within 1 to 2 weeks of continued therapy. When high doses of estrogens are used as postcoital contraceptives, nausea and vomiting may be severe enough to require administration of antiemetic drugs.

Postmenopausal women taking an estrogen are 2 to 4 times more likely than non-users to require surgery for gallbladder disease.

Estrogens promote blood clotting by stimulating hepatic production of four clotting factors (II, VII, IX, X). Thromboembolic disorders are most likely to occur in women older than 35 years of age who take oral contraceptives and smoke cigarettes; postmenopausal women taking long-term estrogen and progestin therapy; and men or women who receive large doses of estrogens for cancer treatment. Edema and weight gain are caused by fluid retention.

Estrogens may cause or aggravate migraine headache in some women; the mechanism is unknown.

When estrogens are used alone in postmenopausal women, they cause endometrial hyperplasia and may cause endometrial cancer. Women with an intact uterus should also be given a progestin, which opposes the effects of estrogen on the endometrium.

Opinions differ regarding estrogens as a cause of breast cancer. Most studies indicate little risk; a few indicate some risk, especially with high doses for prolonged periods (i.e., 10 y or longer). However, estrogens do stimulate growth in breast cancers that have estrogen receptors.

Irregular vaginal bleeding is a common adverse effect that decreases during the first year of use. This is a major reason that some women do not want to take progestin-only contraceptives.

These adverse effects on plasma lipids potentially increase the risks of cardiovascular disease.

Nausea may be decreased by taking with food.

## Nursing Actions Estrogens, Progestins, and Hormonal Contraceptives (cont'd)

### NURSING ACTIONS

- (4) Central nervous system—drowsiness, insomnia, mental depression
- (5) Miscellaneous effects—edema, weight gain
- c. Combined estrogen and progestin oral contraceptives:
  - (1) Gastrointestinal effects—nausea, others
  - (2) Cardiovascular effects—thromboembolism, myocardial infarction, stroke, hypertension
  - (3) Gallbladder disease—cholelithiasis and cholecystitis
  - (4) Miscellaneous—edema, weight gain, headache

#### 4. Observe for drug interactions

- a. Drugs that *decrease* effects of estrogens, progestins, and oral contraceptives:
  - (1) Anticonvulsants—carbamazepine, oxcarbazepine, phenytoin, topiramate
  - (2) Antimicrobials
    - (a) Antibacterials—ampicillin, macrolides (erythromycin, clarithromycin, dirithromycin), metronidazole, penicillin V, rifampin, sulfonamides, tetracyclines, trimethoprim
    - (b) Antifungals—fluconazole, itraconazole, ketoconazole
    - (c) Antivirals—efavirenz, ritonavir, lopinavir/ritonavir combination

### RATIONALE/EXPLANATION

Nausea may be minimized by taking the drugs with food or at bedtime.

These effects occurred with earlier oral contraceptives, which contained larger amounts of estrogen than those currently used, and are much less common in most people who take low-dose preparations. However, for women older than 35 years of age who smoke, there is an increased risk of myocardial infarction and other cardiovascular disorders, even with low-dose pills.

Women who use oral contraceptives or estrogen-progestin hormone replacement therapy are several times more likely to develop gallbladder disease than non-users. This is attributed to increased concentration of cholesterol in bile acids, which leads to decreased solubility and increased precipitation of stones.

Decrease effects by inducing enzymes that accelerate metabolism of estrogens and progestins

Most interactions with antimicrobials have been reported with oral contraceptives. Rifampin induces drug-metabolizing enzymes that accelerate drug inactivation. Other antimicrobials act mainly by disrupting the normal bacterial flora of the gastrointestinal tract and decreasing enterohepatic recirculation of estrogens. This action may decrease effectiveness of contraceptives or cause breakthrough bleeding. To prevent pregnancy from occurring during antimicrobial therapy, a larger dose of oral contraceptive or an additional or alternative form of birth control is probably advisable.

## Key Concepts

- When exogenous estrogens and progestins are administered for therapeutic purposes, they produce the same effects as endogenous hormones.
- Oral contraceptives are very effective at preventing pregnancy, but they do not prevent transmission of sexually transmitted diseases.
- Cigarette smoking in individuals who use oral contraceptives increases risks of blood clots in the legs, lungs, heart, or brain.
- Because estrogens cause epiphyseal closure, they should be used with caution in children before completion of bone growth and attainment of adult height.
- When estrogens are used alone in postmenopausal women, they cause endometrial hyperplasia and may cause endometrial cancer. Women with an intact uterus should also be given a progestin, which opposes the effects of estrogen on the endometrium.
- Most interactions with antimicrobials have been reported with oral contraceptives. To prevent pregnancy from occurring during antimicrobial therapy, a larger dose of oral contraceptive or an additional or alternative form of birth control is probably advisable.
- Research has demonstrated no evidence for HRT in secondary prevention of heart disease and shown increased

rates of CHD, thromboembolic stroke, venous thromboembolism, dementia, and breast cancer, which outweigh the benefits of decreased risk of fracture and colon cancer.

- The FDA has issued a **BLACK BOX WARNING** that estrogens increase the risk for developing cancer of the

uterus. The warning instructs individuals who take estrogens with or without progestins that there is an increased risk of dementia, myocardial infarctions, strokes, breast cancer, and blood clots.

## Review and Application Exercises

### Short Answer Exercises

1. What are the reproductive and nonreproductive functions of estrogens?
2. What are the functions of progestins?
3. What is considered the major mechanism of action of hormonal contraceptives?
4. What are the adverse effects of hormonal contraceptives, and how can they be prevented or minimized?
5. Outline the points you would make for and against HRT for a postmenopausal woman.
6. Prepare a teaching plan for a perimenopausal or postmenopausal woman about nonpharmacologic measures to manage menopausal symptoms and prevent osteoporosis.

### NCLEX-Style Questions

7. Estrogen replacement therapy is prescribed to relieve severe menopausal symptoms of hot flashes or flushes, which are the result of
  - a. insufficient gonadotropin secretion
  - b. vasomotor instability
  - c. high levels of estrogen
  - d. decreased progesterone

8. Progesterone is a progestin concerned almost entirely with reproduction. In the nonpregnant women, progesterone is secreted by which of the following?
  - a. corpus luteum
  - b. hypothalamus
  - c. anterior pituitary
  - d. adrenal cortex
9. Black cohosh is an herbal preparation that has been used to self-treat symptoms of menopause. Due to the risk of adverse effects, patients should be monitored closely for which of the following conditions?
  - a. dysrhythmias
  - b. hypertension
  - c. hypotension
  - d. bradycardia
10. Patient teaching for a woman who will be using the transdermal estradiol patch Estraderm should include information about applying the patch to
  - a. the skin daily
  - b. clean and dry skin
  - c. the same area for consistency
  - d. the skin every 2 weeks

# Androgens and Anabolic Steroids

## KEY TERMS

- Anabolic steroids
- Androgens
- Ergogenic
- Testosterone

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Examine the effects of endogenous androgens.
2. Discuss uses and effects of exogenous androgens and anabolic steroids.
3. Identify potential consequences of abusing androgens and anabolic steroids.
4. Counsel patients about the physiologic effects of the dietary supplements androstenedione and dehydroepiandrosterone (DHEA).

## Applying Your Knowledge

Barbara Watson is a 35-year-old woman. She has endometriosis. Ms. Watson is receiving danazol (Danocrine) 800 mg daily in two divided doses.

## Introduction

*Androgens* are male sex hormones secreted by the testes in men, the ovaries in women, and the adrenal cortex of both sexes. Like the female sex hormones, the naturally occurring male sex hormones are steroids synthesized from cholesterol. The sex organs and adrenal glands can produce cholesterol or remove it from the blood. Cholesterol then undergoes a series of conversions to progesterone, androgenic prehormones, and testosterone. The androgens produced by the ovaries have little androgenic activity and are used mainly as precursor substances for the production of naturally occurring estrogens. The adrenal glands produce several androgens, including androstenedione and dehydroepiandrosterone (DHEA). Androstenedione and DHEA are weak androgens with little masculinizing effect that are mainly converted to estrogens.

## Testosterone

*Testosterone* is normally the only important male sex hormone. It is secreted by the Leydig's cells in the testes in response to stimulation by luteinizing hormone from the anterior pituitary gland. The main functions of testosterone are related to the development of male sexual characteristics, reproduction, and metabolism (Box 28-1).

About 97% of the testosterone secreted by the testes binds to plasma albumin or to sex hormone-binding globulin and circulates in the blood for 30 minutes to several hours. The bound testosterone is either transferred to the tissues or broken down into inactive products that are excreted. Much of the testosterone that transfers to tissues undergoes intracellular conversion to dihydrotestosterone which combines with receptor proteins in the cytoplasm; a series of actions stimulate production of proteins. Almost all testosterone effects result from the increased formation of proteins throughout the body, especially in the cells of target organs and tissues responsible for development of male sexual characteristics.

## Box 28-1

## Effects of Testosterone on Body Tissues

**Fetal Development**

Large amounts of chorionic gonadotropin are produced by the placenta during pregnancy. Chorionic gonadotropin is similar to luteinizing hormone (LH) from the anterior pituitary gland. It promotes development of the interstitial or Leydig's cells in fetal testes, which then secrete testosterone. Testosterone production begins in the second month of fetal life. When present, testosterone promotes development of male sexual characteristics (e.g., penis, scrotum, prostate gland, seminal vesicles, and seminiferous tubules), and suppresses development of female sexual characteristics. In the absence of testosterone, the fetus develops female sexual characteristics.

Testosterone also provides the stimulus for the descent of the testes into the scrotum. This normally occurs after the seventh month of pregnancy, when the fetal testes are secreting relatively large amounts of testosterone. If the testes do not descend before birth, administration of testosterone or gonadotropic hormone, which stimulates testosterone secretion, produces descent in most cases.

**Adult Development**

Little testosterone is secreted in boys until 11 to 13 years of age. At the onset of puberty, testosterone secretion increases rapidly and remains at a relatively high level until about 50 years of age, after which it gradually declines.

- The testosterone secreted at puberty acts as a growth hormone to produce enlargement of the penis, testes, and scrotum until approximately 20 years of age. The prostate gland, seminal vesicles, seminiferous tubules, and vas deferens also increase in size and functional ability. Under the combined influence of testosterone and follicle-stimulating hormone (FSH) from the anterior pituitary gland, sperm

production is initiated and maintained throughout the man's reproductive life.

- **Skin.** Testosterone increases skin thickness and activity of the sebaceous glands. Acne in the male adolescent is attributed to the increased production of testosterone.
- **Voice.** The larynx enlarges and deepens the voice of the adult man.
- **Hair.** Testosterone produces the distribution of hair growth on the face, limbs, and trunk typical of the adult man. In men with a genetic trait toward baldness, large amounts of testosterone cause alopecia (baldness) of the scalp.
- **Skeletal muscles.** Testosterone is largely responsible for the larger, more powerful muscles of men. This characteristic is caused by the effects of testosterone on protein metabolism. Testosterone helps the body retain nitrogen, form new amino acids, and build new muscle protein. At the same time, it slows the loss of nitrogen and amino acids formed by the constant breakdown of body tissues. Overall, testosterone increases protein anabolism (buildup) and decreases protein catabolism (breakdown).
- **Bone.** Testosterone makes bones thicker and longer. After puberty, more protein and calcium are deposited and retained in bone matrix. This causes a rapid rate of bone growth. The height of a male adolescent increases rapidly for a time, then stops as epiphyseal closure occurs. This happens when the cartilage at the end of the long bones in the arms and legs becomes bone. Further lengthening of the bones is then prevented.

**Anterior Pituitary Function**

High blood levels of testosterone decrease secretion of FSH and LH from the anterior pituitary gland. This, in turn, decreases testosterone production.

The portion of testosterone that does not become attached to tissues is converted into androsterone and DHEA by the liver. These are conjugated with glucuronic or sulfuric acid and excreted in the bile or urine.

**Anabolic Steroids**

*Anabolic steroids* are synthetic drugs with increased anabolic activity and decreased androgenic activity compared with testosterone. They were developed during attempts to modify testosterone so that its tissue-building and growth-stimulating effects could be retained while its masculinizing effects could be eliminated or reduced.

**Abuse of Androgen and Anabolic Steroid Drugs**

Drugs used to enhance athletic performance are termed *ergogenic* (causing an increase in muscular work capacity). Androgens and anabolic steroids are widely abused in attempts to enhance muscle development, muscle strength, and athletic

performance. Because of their abuse potential, the drugs are Schedule III controlled substances. Although nonprescription sales of the drugs are illegal, they apparently are easily obtained.

Athletes are considered a high-risk group because some start taking the drugs as early as middle school and continue for years. The use of performance-enhancing drugs in nonathletes is also on the rise to improve performance outside of sports. The number of teens taking anabolic steroids is thought to be small in comparison with the number using marijuana, amphetamines, and other illegal drugs. However, the number is increasing, and long-term effects may be as serious as the effects that occur with use of other illegal drugs. Although steroids have a reputation for being dangerous to adult athletes, such as body builders and football players, they are considered even more dangerous for teens because teens are still growing. Anabolic steroids can stop bone growth and damage the heart, kidneys, and liver of adolescents. In addition to those who take steroids to enhance athletic performance, some males take the drugs to produce a more muscular appearance and impress

females. Steroid abusers usually take massive doses and often take several drugs or combine injectable and oral drugs for maximum effects. The large doses produce potentially serious adverse effects in several body tissues:

- **Cardiovascular disorders** include hypertension, decreased high-density blood lipoproteins (HDL), and increased low-density lipoproteins (LDL), all of which promote heart attacks and strokes.
- **Liver disorders** include benign and malignant neoplasms, cholestatic hepatitis and jaundice, and peliosis hepatis, a disorder in which blood-filled cysts develop in the liver and may lead to hemorrhage or liver failure.
- **Central nervous system disorders** include aggression, hostility, combativeness, and dependence characterized by preoccupation with drug use, inability to stop taking the drugs, and withdrawal symptoms similar to those that occur with alcohol, cocaine, and narcotics. In some cases, psychosis may develop.
- **Reproductive system disorders** include decreased testicular function (e.g., decreased secretion of endogenous testosterone, decreased formation of sperm), testicular atrophy, and impotence in men. They include amenorrhea in women.
- **Metabolic disorders** include atherosclerosis-promoting changes in cholesterol metabolism and retention of fluids, with edema and other imbalances. Fluid and electrolyte retention contribute to the increased weight associated with drug use.
- **Dermatologic disorders** include moderate to severe acne in both sexes, depending on drug dosage.

Many of these adverse effects persist several months after the drugs are stopped and may be irreversible. Names of anabolic steroids include oxandrolone (Oxandrin), oxymetholone (Anadrol-50), and stanozolol (Winstrol).

## General Characteristics of Androgens and Anabolic Steroids Used As Drugs

- When male sex hormones or androgens are given from exogenous sources for therapeutic purposes, they produce the same effects as the naturally occurring hormones. These effects include inhibition of endogenous sex hormones and sperm formation through negative feedback of pituitary luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
- Male sex hormones given to women antagonize or reduce the effects of female sex hormones. Thus, administration of androgenic or anabolic steroids to women suppresses menstruation and causes atrophy of the endometrial lining of the uterus.
- Several dosage forms of androgens are available; they differ mainly in route of administration and pharmacokinetics.

- Naturally occurring androgens are given by injection because they are metabolized rapidly by the liver if given orally. Some esters of testosterone have been modified to slow the rate of metabolism and thus prolong action. For example, intramuscular (IM) testosterone cypionate and testosterone enanthate have slow onsets of action and last 2 to 4 weeks.
- Oral testosterone is extensively metabolized in its first pass through the liver, so that nearly half of a dose is lost before it reaches the systemic circulation. As a result, doses as high as 400 milligrams per day may be needed to produce adequate blood levels for full replacement therapy. Methyltestosterone is a synthetic formulation that is less extensively metabolized by the liver and more suitable for oral administration.
- Several transdermal formulations of testosterone are available. They have a rapid onset of action and last approximately 24 hours. A topical gel (a 10-g dose delivers 100 mg) produces normal serum testosterone levels within 4 hours after application, and absorption of testosterone into the blood continues for 24 hours. Steady-state serum concentrations occur by the second or third day of use. When the gel is discontinued, serum testosterone levels remain in the normal range for 24 to 48 hours but decrease to pretreatment levels within about 5 days.
- Androderm is applied to nonscrotal skin, and testosterone is continuously absorbed for 24 hours, with normal blood levels achieved during the first day of drug use. Applying the patch at night produces serum testosterone levels similar to those in healthy young men (i.e., higher concentrations in the morning and lower ones in the evening).
- Like endogenous testosterone, drug molecules are highly bound (98%) to plasma proteins and serum half-life varies (e.g., 8 days for IM testosterone cypionate, 9 hours for oral fluoxymesterone). The drugs are inactivated primarily in the liver. About 90% of a dose is excreted in urine as conjugates of testosterone and its metabolites. About 6% of a dose is excreted in feces.
- Danazol is a synthetic drug with weak androgenic activity. It is given orally, has a half-life of 4 to 5 hours, and is metabolized in the liver. Route of excretion is unknown.
- All synthetic anabolic steroids are weak androgens. Consequently, giving these drugs for anabolic effects also produces masculinizing effects. This characteristic limits the clinical usefulness of these drugs in women and children. Profound changes in growth and sexual development may occur if these drugs are given to young children.

## Mechanism of Action

Like other steroid drugs, androgenic and anabolic drugs penetrate the cell membrane and bind to receptor proteins in the cell cytoplasm. The steroid-receptor complex is then transported to the nucleus, where it activates RNA and DNA production and stimulates cellular synthesis of protein.

## Indications for Use

With male sex hormones, the most clear-cut indication for use is to treat androgen deficiency states (e.g., hypogonadism, cryptorchidism, impotence, oligospermia) in boys and men. Hypogonadism may result from hypothalamic–pituitary or testicular dysfunction. In prepubertal boys, administration of the drugs stimulates the development of masculine characteristics. In postpubertal men who become androgen deficient, the hormones re-establish and maintain masculine characteristics and functions.

In women, danazol (Danocrine) may be used to prevent or treat endometriosis or fibrocystic breast disease. Anabolic steroids are more often abused for body-building purposes than used for therapeutic effects.

Although some drug literature still lists metastatic breast cancer and some types of anemia as indications for use, androgens have largely been replaced by newer drugs for these purposes. In breast cancer, for example, androgens are second-line hormonal agents, after anti-estrogens (e.g., tamoxifen). In anemia associated with renal failure, synthetic erythropoietin is more effective and likely to be used.

## Contraindications to Use

Androgens and anabolic steroids are contraindicated during pregnancy (because of possible masculinizing effects on a female fetus), in patients with pre-existing liver disease, and

in men with prostate-gland disorders. Men with an enlarged prostate may have additional enlargement, and men with prostatic cancer may experience tumor growth. Although not contraindicated in children, these drugs must be used very cautiously and with x-ray studies performed approximately every 6 months to evaluate bone growth.

## Individual Drugs

Clinical indications, routes, and dosage ranges are listed in Table 28-1.

## Herbal and Dietary Supplements

Androstenedione and DHEA, androgens produced by the adrenal cortex, are also available as over-the-counter (OTC) dietary supplements. They are marketed as safe, natural, alternative androgens for building muscles. These products, which have weak androgenic activity, act mainly as precursors for the production of sex hormones. Androstenedione, for example, may be converted to testosterone by way of an enzyme found in most body tissues. However, it may also be converted to estrogens, and the testosterone that is produced may be further converted to estrogen (estradiol). In one study, young men with

Table 28-1

Drugs at a Glance: Androgens

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Hypogonadism	Other
<b>Testosterone cypionate</b> (Depo-Testosterone)	IM 50–200 mg every 2–4 wk	
<b>Testosterone enanthate</b> (Delatestryl)	IM 50–200 mg every 2–4 wk	
<b>Testosterone gel</b> (Androgel 1%)	5 g (50 mg of drug) once daily to skin of shoulders and upper arms or abdomen	
<b>Testosterone pellets</b>	Sub-Q 150–450 mg every 3–6 mo	<i>Delayed puberty:</i> Sub-Q lower dosage range, for a limited duration (e.g., every 3 mo for 2–3 doses)
<b>Testosterone transdermal systems</b> (Androderm)	Apply 2 Androderm systems (dose of 5 mg) nightly to back, abdomen, upper arm, or thigh	
<b>Testolactone</b> (Teslac)		<i>Breast cancer:</i> PO 250 mg 4 times daily
<b>Fluoxymesterone</b> (Halotestin)	PO 5–20 mg daily	
<b>Methyltestosterone</b> (Android, Testred)		<i>Cryptorchidism:</i> PO 30 mg daily; buccal tablets, 15 mg daily
<b>Danazol</b>		<i>Endometriosis:</i> PO 800 mg daily in 2 divided doses for 3–9 mo <i>Fibrocystic breast disease:</i> PO 100–400 mg daily in 2 divided doses for 3–6 mo

normal serum testosterone levels were given an androstenedione supplement for 8 weeks. The researchers found little effect on serum testosterone levels or muscle development with resistance training. They also found increased serum levels of estrone and estradiol, which indicate that a significant proportion of the androstenedione was converted to estrogens. Thus, taking a supplement for masculinizing effects may produce feminizing effects instead.

DHEA is available alone as oral capsules or tablets and in a topical cream with vitamins and herbs. Most DHEA products of plant origin are produced in Europe and China. They are marketed with numerous claims for health benefits, including inhibition of aging, atherosclerosis, cancer, diabetes mellitus, and osteoporosis. Most claims stem from laboratory and animal studies. A few small human studies have been done, most of which used a dose of 50 milligrams daily. Overall, there is no conclusive evidence that DHEA supplementation will prevent or treat such conditions. In addition, long-term effects in humans are unknown.

DHEA is contraindicated in men with prostate cancer or benign prostatic hypertrophy (BPH) and in women with estrogen-responsive breast or uterine cancer, because DHEA may stimulate growth of these tissues. Patients older than 40 years of age should be aggressively screened for hormonally sensitive cancers before taking DHEA.

Adverse effects of DHEA include aggressiveness, hirsutism, insomnia, and irritability. Whether large doses of the OTC products can produce some of the serious adverse effects associated with standard anabolic steroids is unknown.

### Applying Your Knowledge 28-1

You are counseling Ms. Watson about her self-administration of danazol. What teaching points do you cover?

## Nursing Process

### Assessment

Before drug therapy is started, patients need a thorough history and physical examination. Periodic monitoring of the patient's condition is needed throughout drug therapy.

- Assess for conditions in which androgens are used (e.g., deficiency states).
- Assess for conditions that increase risks of adverse effects or are contraindications (e.g., pregnancy, liver disease, prostatic hypertrophy).
- Check laboratory reports of liver function tests (the drugs may cause cholestatic jaundice and liver damage), serum electrolyte levels (the drugs may cause sodium and water retention), and serum lipid levels (the drugs may increase levels and aggravate atherosclerosis).

- Assess weight and blood pressure regularly. These may be elevated by retention of sodium and water with resultant edema, especially in patients with congestive heart failure.
- For children, check x-ray examination reports of bone growth status initially and approximately every 6 months while the drugs are being taken.
- Assess the patient's attitude toward taking male sex hormones.
- Assess the patient's willingness to comply with instructions for taking the drugs and follow-up procedures.

## Nursing Diagnoses

- Disturbed Body Image related to masculinizing effects and menstrual irregularities
- Deficient Knowledge: Physiologic and psychological consequences of overuse and abuse of the drugs to enhance athletic performance
- Noncompliance: Overuse of drugs or dietary supplements
- Risk for Injury: Liver disease and other serious adverse drug effects

## Planning/Goals

### The patient will

- Use the drugs for medical purposes only
- Receive or take the drugs as prescribed
- Avoid abuse of drugs or dietary supplements for body building
- Be counseled regarding effects of overuse and abuse if identified as being at risk (e.g., athletes, especially weight lifters and football players)
- Avoid preventable adverse drug effects
- Comply with monitoring and follow-up procedures

## Interventions

- Assist patients to use the drug correctly (see accompanying patient teaching display).
- Assist patient to reduce sodium intake if edema develops.
- Record weight and blood pressure at regular intervals.
- Participate in school or community programs to inform children, parents, coaches, athletic trainers, and others of the risks of inappropriate use of androgens, anabolic steroids, and related dietary supplements.

## Evaluation

- Interview and observe for compliance with instructions for taking prescribed drugs.
- Interview and observe for therapeutic and adverse drug effects.
- Question athletes about illegal use of the drugs.
- Observe athletes for increased weight and behavioral changes that may indicate drug abuse.

## Patient Teaching Guidelines

### Androgens

#### General Considerations

- Take the drugs only if prescribed and as prescribed. Use by athletes for body building is inappropriate and, if not prescribed by a licensed prescriber, is illegal.
- Continue medical supervision as long as the drugs are being taken.
- Weigh once or twice weekly and record the amount. An increase may indicate fluid retention and edema.
- Practice frequent and thorough skin cleansing to decrease acne, which is most likely to occur in women and children.

#### Self-Administration

- Take oral preparations before or with meals, in divided doses.
- For buccal preparations:
  - Take in divided doses.

- Place the tablet between the cheek and gum and allow to dissolve (do not swallow).
- Avoid eating, drinking, or smoking while the tablet is in place.
- With transdermal systems:
  - Apply 2 Androderm systems nightly to clean, dry skin on back, abdomen, upper arm, or thigh. Do not apply to scrotum. Rotate sites, with 7 days between applications to a site. Press firmly into place for adherence.
  - Apply the prescribed amount of gel to clean, dry, intact skin of the shoulders and upper arms or the abdomen (do **not** apply to the genital area), once daily, preferably in the morning. Wash hands after application and allow sites to dry before dressing. After application, wait at least 1 hour and preferably 4 to 6 hours before showering or swimming.

## Principles of Therapy

### Duration of Therapy

Drug therapy with androgens may be short or long term, depending on the condition in question, the patient's response to treatment, and the incidence of adverse reactions. If feasible, intermittent rather than continuous therapy is recommended.

### Effects of Androgens and Anabolic Steroids on Other Drugs

Androgens may increase effects of cyclosporine and warfarin, apparently by slowing their metabolism and increasing their concentrations in the blood. These combinations should be avoided if possible. However, if required, serum creatinine and cyclosporine levels should be monitored with cyclosporine and prothrombin time or international normalized ratio (INR) with warfarin.

Androgens also increase effects of sulfonylurea antidiabetic drugs. Concurrent use should be avoided if possible. If required, smaller doses of sulfonylureas may be needed, blood glucose levels should be monitored closely, and patients should be assessed for signs of hypoglycemia. Danazol inhibits metabolism of carbamazepine and increases risks of toxicity. Concurrent use should be avoided.

### Applying Your Knowledge 28-2

You are assessing Ms. Watson for adverse effects of her danazol. What signs and symptoms do you assess?

### Use in Special Populations

#### Use in Children

The main indication for use of androgens is for boys with established deficiency states. Because the drugs cause epiphyseal

closure, hands and wrists should undergo x-ray examination every 6 months to detect bone maturation and prevent loss of adult height. Stimulation of skeletal growth continues for approximately 6 months after drug therapy is stopped. If premature puberty occurs (precocious sexual development, enlarged penis), the drug should be stopped. The drugs may cause or aggravate acne. Scrupulous skin care and other anti-acne treatment may be needed, especially in adolescent boys.

#### Use in Older Adults

The main indication for use of androgens is a deficiency state in men. In male adults, levels of total testosterone decrease by nearly 1% per year; bioavailable levels decrease by 2% per year, resulting in a reported prevalence of hypogonadism of 20% in men aged 60 to 69.

Older adults often have hypertension and other cardiovascular disorders that may be aggravated by the sodium and water retention associated with androgens and anabolic steroids. In men, the drugs may increase prostate size and interfere with urination, increase risk of prostatic cancer, and cause excessive sexual stimulation and priapism.

#### Use in Patients With Hepatic Impairment

Androgens and anabolic steroids are contraindicated in patients with pre-existing liver disease. Prolonged use of high doses may cause potentially life-threatening conditions such as peliosis hepatis, hepatic neoplasms, and hepatocellular carcinoma. In addition, androgen therapy should be discontinued if cholestatic hepatitis with jaundice occurs or if liver function tests become abnormal. Drug-induced jaundice is reversible when the medication is stopped.

### Applying Your Knowledge 28-3

Ms. Watson's brother is visiting from out of town. Warren Watson is a 27-year-old body builder. He has an 11-year history of abusing a variety of anabolic steroids. Ms. Watson is

worried about him and convinces him to come to the clinic for a checkup.

At the clinic, Mr. Watson states that he takes no medication. You measure his blood pressure to be 180/94 mm Hg. Mr. Watson says he has “white-coat syndrome”

and that his blood pressure is never elevated except at the office. When approached about his high blood pressure, he refuses to be treated. What is your nursing responsibility?

.....

## Nursing Actions Androgens and Anabolic Steroids

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 1. Administer accurately

- a. Give intramuscular preparations of testosterone, other androgens, and anabolic steroids deeply, preferably in the gluteal muscle.
- b. Give oral preparations before or with meals, in divided doses.
- c. For buccal preparations:
  - (1) Give in divided doses.
  - (2) Place the tablet between the cheek and gum.
  - (3) Instruct the patient not to swallow the tablet and not to drink, chew, or smoke until the tablet is completely absorbed.
- d. With transdermal systems:
  - (1) Apply 2 Androderm systems nightly to clean, dry skin on back, abdomen, upper arm, or thigh. Do not apply to scrotum. Rotate sites, with 7 days between applications to a site. Press firmly into place for adherence.
  - (2) Apply AndroGel 1% to shoulders and upper arms or abdomen, once daily, preferably in the morning.

To decrease gastrointestinal disturbances

Buccal preparations must be absorbed through the mucous membranes.

Correct site selection and application are necessary for therapeutic effects. Scrotal skin is more permeable to testosterone than other skin areas.

Manufacturer's recommendation. Patients may prefer self-application. Skin should be clean, dry, and intact; hands should be washed after application; and showering and swimming should be avoided for at least 1 hour and preferably 4 to 6 hours after application.  
Manufacturer's recommendation

- e. Inject testosterone pellets (Testopel) subcutaneously.

#### 2. Observe for therapeutic effects

- a. When the drug is given for hypogonadism, observe for masculinizing effects, such as growth of sexual organs, deepening of voice, growth of body hair, and acne.
- b. When the drug is given for anabolic effects, observe for increased appetite, euphoria, or statements of feeling better.

#### 3. Observe for adverse reactions

- a. Virilism or masculinizing effects:
  - (1) In adult men with adequate secretion of testosterone—priapism, increased sexual desire, reduced sperm count, and prostate enlargement
  - (2) In prepubertal boys—premature development of sex organs and secondary sexual characteristics, such as enlargement of the penis, priapism, pubic hair
  - (3) In women—masculinizing effects include hirsutism, deepening of the voice, menstrual irregularities
- b. Jaundice—dark urine, yellow skin and sclera, itching
- c. Edema
- d. Hypercalcemia
- e. Difficulty voiding due to prostate enlargement
- f. Inadequate growth in height of children

More likely in patients who are elderly or who have heart or kidney disease  
More likely in women with advanced breast cancer  
More likely in middle-aged or elderly men

#### 4. Observe for drug interactions

- a. Drugs that decrease effects of androgens:
  - (1) Barbiturates
  - (2) Calcitonin

Increase enzyme induction and rate of metabolism  
Decreases calcium retention and thus antagonizes calcium-retaining effects of androgens

## Key Concepts

- The androgens produced by the ovaries have little androgenic activity and are used mainly as precursor substances for the production of naturally occurring estrogens.
- The main functions of testosterone are related to the development of male sexual characteristics, reproduction, and metabolism.
- Androgens and anabolic steroids are used to enhance athletic performance and are termed ergogenic (causing an increase in muscular work capacity); they are widely abused in attempts to enhance muscle development, muscle strength, and athletic performance.
- Because of their abuse potential, androgens and anabolic steroids are classified as Schedule III controlled substances.
- Androstenedione and DHEA, androgens produced by the adrenal cortex, are also available as over-the-counter (OTC) dietary supplements.
- Adverse effects of DHEA include aggressiveness, hirsutism, insomnia, and irritability.
- Because androgens cause premature epiphyseal closure, boys with established deficiency states receiving androgens should undergo x-ray examination every 6 months to detect bone maturation and prevent loss of adult height.

## Review and Application Exercises

### Short Answer Exercises

1. How does testosterone promote development of male sexual characteristics?
2. What is the major clinical indication for therapeutic use of testosterone and related androgens?
3. What is the difference between androgenic activity and anabolic activity?
4. What are the adverse effects of using large doses of anabolic steroids in body-building efforts?
5. If your 14-year-old brother said some friends were telling him to take drugs to increase muscle development and athletic ability, how would you reply? Justify your answer.

### NYCLEX-Style Questions

6. The nurse knows that the most clear-cut therapeutic indication for use of male sex hormones is
  - a. to treat androgen deficiency states in boys and men
  - b. for body-building purposes
  - c. to treat metastatic breast cancer
  - d. to treat anemia associated with renal failure
7. Four patients in an endocrine clinic are ordered to begin androgen therapy. The nurse reviews each patient's current medications and identifies which patient is able to begin androgen therapy without the risk of a known drug interaction?
  - a. patient 1, taking cyclosporine
  - b. patient 2, taking warfarin
  - c. patient 3, taking sulfonylureas
  - d. patient 4, taking heparin
8. What percentage of testosterone secreted by the testes binds to plasma albumin or to sex hormone-binding globulin and circulates in the blood?
  - a. 26%
  - b. 49%
  - c. 78%
  - d. 97%
9. A 19-year-old female athlete presents for her first prenatal visit and tells the nurse she has been on androgen therapy to improve her distance running. She asks the nurse if she can continue taking the androgens to maintain her "competitive edge." The nurse should instruct the patient that
  - a. She can continue taking androgens, because the drugs pose no risk to the fetus.
  - b. She can continue taking androgens, but a higher dose will be required due to increased drug metabolism during pregnancy.
  - c. She can continue taking androgens until the third trimester, when they must be discontinued because androgens cause an increased risk of premature rupture of membranes.
  - d. She must stop taking androgens immediately, because they pose a risk to the fetus; she should discuss this with her health care provider at today's visit.
10. Which of the following statements by a male patient taking transdermal androgens indicates that further teaching is necessary?
  - a. "I need to weigh myself once or twice weekly and record the amount."
  - b. "I should wash my face and body thoroughly to decrease the risk of acne."
  - c. "The patch systems should be applied nightly to skin on my back, abdomen, upper arm, or thigh."
  - d. "I should apply the patch systems in the morning to the same site each and every day."

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify populations who have an increased risk of infection.
2. Discuss common pathogens and methods of infection control.
3. Outline common and potentially serious adverse effects of antimicrobial drugs.
4. Identify patients at increased risk for adverse drug reactions.
5. Discuss ways to increase benefits and decrease hazards of antimicrobial drug therapy.
6. Discuss ways to minimize emergence of drug-resistant microorganisms.
7. State appropriate nursing implications for a patient receiving an antimicrobial drug.
8. Discuss important elements of using antimicrobial drugs in children, older adults, patients with renal or hepatic impairment, and patients with critical illness.

## Applying Your Knowledge

Rosalie Kurth is a 72-year-old grandmother and retired factory worker. Her work in a dusty environment has led her to have chronic bronchitis. She has been treated multiple times over the years with antibiotic drugs for recurrent infections. Ms. Kurth cares for her two grandchildren, ages 3 and 5, while their mother works. Ms. Kurth's exposure to the multiple infective organisms of childhood has resulted in more frequent infections and the need for antibiotics.

## Introduction

Antimicrobial drugs are used to prevent or treat infections caused by pathogenic (disease-producing) microorganisms. The human body and the environment contain many microorganisms, most of which do not cause disease and live in a state of balance with the human host. When the balance is upset and infection occurs, characteristics of the infecting microorganism(s) and the adequacy of host defense mechanisms are major factors in the severity of the infection and the person's ability to recover. Conditions that impair defense mechanisms increase the incidence and severity of infections and impede recovery. In addition, use of antimicrobial drugs may lead to serious infections caused by drug-resistant microorganisms. To help prevent infectious diseases and participate effectively in antimicrobial drug therapy, the nurse must be knowledgeable about microorganisms, host responses to microorganisms, and antimicrobial drugs.

## Microorganisms and Infections

In an infection, microorganisms initially attach to host cell receptors (i.e., proteins, carbohydrates, lipids). For example, some bacteria have hairlike structures that attach them to skin and mucous membranes. Most microorganisms preferentially attach themselves to particular body tissues. The microorganisms may then invade tissues, multiply, and produce infection. A major characteristic of microorganisms is their ability to survive in various environments. Bacteria, for example, may form mutant strains, alter their structures and functions, or become embedded in a layer of mucus. These adaptations help protect them from normal body defense mechanisms and antimicrobial drugs. Drug-resistant bacterial strains can be produced in the presence of antimicrobial drugs. Classifications, normal microbial flora, and common pathogenic microorganisms are described in the following sections.

### Classifications

*Bacteria* are subclassified according to whether they are aerobic (require oxygen) or anaerobic (cannot live in the presence of oxygen), their reaction to Gram's stain (gram positive or gram negative), and their shape (e.g., cocci, bacilli).

*Viruses* are intracellular parasites that survive only in living tissues. They are officially classified according to their structure but are more commonly described according to origin and the disorders or symptoms they produce. Human pathogens include adenoviruses, herpesviruses, and retroviruses (see Chap. 35).

*Fungi* are plant-like organisms that live as parasites on living tissue or as saprophytes on decaying organic matter. Approximately 50 species are pathogenic in humans (see Chap. 36).

### Normal Microbial Flora

The human body normally has areas that are sterile and areas that are colonized with microorganisms. Sterile areas are body fluids and cavities, the lower respiratory tract (trachea, bronchi, lungs), much of the gastrointestinal (GI) and genitourinary tracts, and the musculoskeletal system. Colonized areas include the skin, upper respiratory tract, and colon.

Normal skin flora includes staphylococci, streptococci, diphtheroids, and transient environmental organisms. The upper respiratory tract contains staphylococci, streptococci, pneumococci, diphtheroids, and *Haemophilus influenzae*. The external genitalia contain skin organisms; the vagina contains lactobacilli, *Candida*, and *Bacteroides*. The colon contains *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Proteus*, *Pseudomonas*, *Bacteroides*, clostridia, lactobacilli, streptococci, and staphylococci. Microorganisms that are part of the normal flora and nonpathogenic in one area of the body may be pathogenic in other parts of the body; for example, *E. coli* often cause urinary tract infections.

Normal flora protects the human host by occupying space and consuming nutrients. This interferes with the ability of potential pathogens to establish residence and proliferate. If the normal flora is suppressed by antimicrobial drug therapy, potential pathogens may thrive. For example, the yeast *Candida albicans* is a normal resident of the vagina and the intestinal tract. An antibacterial drug may destroy the normal bacterial flora without affecting the fungal organism. As a result, *C. albicans* can proliferate and cause infection. Much of the normal flora can cause disease under certain conditions, especially in elderly, debilitated, or immunosuppressed people. Normal bowel flora also synthesizes vitamin K and vitamin B complex.

### Infectious Diseases

*Colonization* involves the presence of normal microbial flora or transient environmental organisms that do not harm the host. Infectious disease involves the presence of a pathogen plus clinical signs and symptoms indicative of an infection. These microorganisms are usually spread by direct contact with an infected person or contaminated hands, food, water, or objects. Box 29-1 describes common bacterial pathogens of humans. Accurate assessment and documentation of symptoms can aid diagnosis of infectious diseases.

### Opportunistic Pathogens

*Opportunistic* microorganisms are usually normal endogenous or environmental flora and nonpathogenic. However, they become pathogens in hosts whose defense mechanisms are

#### Box 29-1

#### Common Bacterial Pathogens

##### Gram-Positive Bacteria

##### Staphylococci

*Staphylococcus aureus* organisms are part of the normal microbial flora of the skin and upper respiratory tract and also are common pathogens. Some people carry (are colonized with) the organism in the anterior nares. The organisms are spread mainly by direct contact with people who are infected or who are carriers. The hands of health care workers are considered a major source of indirect spread and nosocomial infections. The organisms also survive on inanimate surfaces for long periods of time.

*S. aureus* organisms cause boils, carbuncles, burn and surgical-wound infections, and internal abscesses. Burns or surgical wounds often become infected from patients' own nasal carriage or from health care personnel. The organisms cannot penetrate intact skin or mucous membranes. However, they can penetrate damaged tissues and produce endotoxins that destroy erythrocytes, leukocytes, platelets, fibroblasts, and other human cells. Also, many strains produce enterotoxins that cause food poisoning when ingested. The enterotoxins survive heating at temperatures high enough to kill the organisms, so reheating foods does not prevent food poisoning.

(continued on page 470)

## Box 29-1

## Common Bacterial Pathogens (continued)

High-risk groups for staphylococcal infections include newborns, the elderly, and those who are malnourished, have diabetes, or are obese. In children, staphylococcal infections of the respiratory tract are most common in those younger than 2 years of age. In adults, staphylococcal pneumonia often occurs in people with chronic lung disease or as a secondary bacterial infection after influenza. The influenza virus destroys the ciliated epithelium of the respiratory tract and thereby aids bacterial invasion.

Staphylococcus species, non-*aureus* (SSNA) describes a group of organisms that are also part of the normal microbial flora of the skin and mucosal surfaces and are increasingly common pathogens. The most common member of this group involved in infections is *Staphylococcus epidermidis*. However, not all laboratories routinely further identify the specific organism when SSNA is identified, and microbiology laboratory reports may just report SSNA. For this discussion, we will use the term SSNA unless a specific reference needs to be made to *S. epidermidis*.

Infections due to SSNA are associated with the use of treatment devices such as intravascular catheters, prosthetic heart valves, cardiac pacemakers, orthopedic prostheses, cerebrospinal fluid shunts, and peritoneal catheters. SSNA infections include endocarditis, bacteremia, and other serious infections and are especially hazardous to neutropenic and immunocompromised patients. Treatment usually requires removal of any infected medical device as well as appropriate antibiotic therapy.

### Streptococci

Certain streptococci are part of the normal microbial flora of the throat and nasopharynx in many healthy people. Infections are usually spread by inhalation of droplets from the upper respiratory tract of carriers or people with infections. However, these organisms do not cause disease unless the mucosal barrier is damaged by trauma, previous infection, or surgical manipulation. Such damage allows the organisms to enter the bloodstream and gain access to other parts of the body. For example, the organisms may cause endocarditis if they reach damaged heart valves.

*Streptococcus pneumoniae* organisms, often called *pneumococci*, are common bacterial pathogens. They cause pneumonia, sinusitis, otitis media, and meningitis. Pneumococcal pneumonia usually develops when the mechanisms that normally expel organisms inhaled into the lower airway (i.e., the mucociliary blanket and cough reflex) are impaired by viral infection, smoking, immobility, or other insults. When *S. pneumoniae* reach the alveoli, they proliferate, cause acute inflammation, and spread rapidly to involve one or more lobes. Alveoli fill with proteinaceous fluid, neutrophils, and bacteria. When the pneumonia resolves, there is usually no residual damage to the pulmonary parenchyma. Older adults have high rates of illness and death from pneumococcal pneumonia, which can often be prevented by pneumococcal vaccine. Pneumococcal vaccine (see Chap. 39) contains 23 strains of the pneumococci that cause most of the serious infections.

Pneumococcal sinusitis and otitis media usually follow a viral illness, such as the common cold. The viral infection injures the protective ciliated epithelium and fills the air spaces with nutrient-rich tissue fluid, in which the pneumococci thrive. *S. pneumoniae* is a common pathogen in bacterial sinusitis. In young children, upper respiratory tract infections may be complicated by acute sinusitis. With otitis media, most children have repeated episodes by 6 years of age and the pneumococcus causes approximately half of these cases. Recurrent otitis media during early childhood may result in reduced hearing acuity. Otitis media rarely occurs in adults.

Pneumococcal meningitis may develop from sinus or middle ear infections or an injury that allows organisms from the nasopharynx to enter the meninges. *S. pneumoniae* infection is a common cause of bacterial meningitis in adults. Other potential secondary complications include septicemia, endocarditis, pericarditis, and empyema.

Susceptible pneumococcal infections may be treated with penicillin G. For people who are allergic to penicillin, a cephalosporin or a macrolide may be effective. *S. pneumoniae* organisms are developing resistance such that empiric treatment must be based on the likelihood of multidrug-resistant *S. pneumoniae* (MDRSP). Rates of MDRSP vary by locale; if high, the organisms will be resistant to penicillin and also cross-resistant to other alternatives such as second- and third-generation cephalosporins and possibly macrolides. Alternatives include fluoroquinolones, vancomycin, telithromycin, or high doses of amoxicillin/clavulanate. Empiric treatment of meningitis where *S. pneumoniae* is known or suspected should include a third-generation cephalosporin (ceftriaxone or cefotaxime) plus vancomycin. Empiric treatment for pneumonia should include a fluoroquinolone or a macrolide in those areas with high penicillin and cephalosporin resistance rates.

*Streptococcus pyogenes* (beta-hemolytic streptococcus) organisms are often part of the normal flora of the skin and oropharynx. The organisms spread from person to person by direct contact with oral or respiratory secretions. They cause severe pharyngitis (“strep throat”), scarlet fever, rheumatic fever, and endocarditis. With streptococcal pharyngitis, people remain infected with the organism for weeks after symptoms resolve and thus serve as a reservoir for infection.

### Enterococci

Enterococci are normal flora in the human intestine but are also found in soil, food, water, and animals. Although the genus *Enterococcus* contains approximately 12 species, the main pathogens are *Enterococcus faecalis* and *Enterococcus faecium*. Most enterococcal infections occur in hospitalized patients, especially those in critical care units. Risk factors for nosocomial infections include serious underlying disease, prior surgery, renal impairment, and the presence of urinary or vascular catheters. These organisms, especially *E. faecalis*, are usually secondary invaders in urinary tract or wound infections. Enterococci may also cause endocarditis. This serious infection occurs most often in people with underlying heart disease, such as an injured valve. When the organisms reach a heart

valve, they multiply and release emboli of foreign particles into the bloodstream. Symptoms of endocarditis include fever, heart murmurs, enlarged spleen, and anemia. This infection is diagnosed by isolating enterococci from blood cultures. If not treated promptly and appropriately, often with ampicillin and gentamicin, enterococcal endocarditis may be fatal. Antimicrobial resistance is increasing among the enterococci, as it is among other gram-positive bacteria.

### Gram-Negative Bacteria

#### *Bacteroides*

*Bacteroides* are anaerobic bacteria normally found in the digestive, respiratory, and genital tracts. They are the most common bacteria in the colon, where they greatly outnumber *Escherichia coli*. *Bacteroides fragilis*, the major human pathogen, causes intra-abdominal and pelvic abscesses (e.g., after surgery or trauma that allows fecal contamination of these tissues), brain abscesses (e.g., from bacteremia or spread from a middle-ear or sinus infection), and bacteremia, which may spread the organisms throughout the body.

#### *Escherichia coli*

*E. coli* inhabit the intestinal tract of humans. They are normally nonpathogenic in the intestinal tract but are common pathogens in other parts of the body. They may be beneficial by synthesizing vitamins and by competitively discouraging growth of potential pathogens.

*E. coli* cause most urinary tract infections. They also cause pneumonia and sepsis in immunocompromised hosts and meningitis and sepsis in newborns. *E. coli* pneumonia often occurs in debilitated patients after colonization of the oropharynx with organisms from their endogenous microbial flora. In healthy people, the normal gram-positive organisms of oral cavities attach to material that coats the surface of oral mucosa and prevents transient *E. coli* from establishing residence. Debilitated or severely ill people produce an enzyme that destroys the material that allows gram-positive flora to adhere to oral mucosa. This allows *E. coli* (and other gram-negative enteric bacteria) to compete successfully with the normal gram-positive flora and colonize the oropharynx. Then, droplets of the oral flora are aspirated into the respiratory tract, where impaired protective mechanisms allow survival of the aspirated organisms.

*E. coli* also cause enteric gram-negative sepsis, which is acquired from the normal enteric bacterial flora. When *E. coli* and other enteric organisms reach the bloodstream of healthy people, host defenses eliminate the organisms. When the organisms reach the bloodstream of people with severe illnesses and conditions such as neutropenia, the host is unable to mount adequate defenses and sepsis occurs. In newborns, *E. coli* are the most common gram-negative organisms causing nosocomial septic shock and meningitis.

In addition, *E. coli* often cause diarrhea and dysentery. One strain, called O157:H7, causes hemorrhagic colitis, a disease characterized by severe abdominal cramps, copious bloody diarrhea, and hemolytic-uremic syndrome (hemolytic anemia,

thrombocytopenia, and acute renal failure). Hemolytic-uremic syndrome occurs most often in children. The main reservoir of this strain is the intestinal tract of animals, especially cattle, and several epidemics have been associated with ingestion of undercooked ground beef. Other sources include contaminated water and milk and person-to-person spread. Because it cannot survive in nature, the presence of *E. coli* in milk or water indicates fecal contamination.

Treatment of *E. coli* infections is complicated by increasing resistance to cephalosporins, commonly used agents. Resistance is mediated by production of extended-spectrum beta-lactamases, which inactivates the antibiotic. Effective treatments may include aminoglycosides, fluoroquinolones, or trimethoprim-sulfamethoxazole.

#### *Klebsiella*

*Klebsiella* organisms, which are normal bowel flora, may infect the respiratory tract, urinary tract, bloodstream, burn wounds, and meninges, most often as opportunistic infections in debilitated persons. *Klebsiella pneumoniae* are a common cause of pneumonia, especially in people with pulmonary disease, bacteremia, and sepsis.

#### *Proteus*

*Proteus* organisms are normally found in the intestinal tract and in decaying matter. They most often cause urinary tract and wound infections but may infect any tissue, especially in debilitated people. Infection usually occurs with antibiotic therapy, which decreases drug-sensitive bacteria and allows drug-resistant bacteria to proliferate.

#### *Pseudomonas*

*Pseudomonas* organisms are found in water, soil, skin, and intestines. They are found in the stools of some healthy people and possibly 50% of inpatients. *Pseudomonas aeruginosa*, the species most often associated with human disease, can cause infections of the respiratory tract, urinary tract, wounds, burns, meninges, eyes, and ears. Because of its resistance to many antibiotics, it can cause severe infections in people receiving antibiotic therapy for burns, wounds, and cystic fibrosis. *P. aeruginosa* colonizes the respiratory tract of most patients with cystic fibrosis and infects approximately 25% of burn patients. Infection is more likely to occur in hosts who are very young or very old or who have an impaired immune system. Sources of infection include catheterization of the urinary tract, trauma or procedures involving the brain or spinal cord, and contamination of respiratory ventilators.

#### *Serratia*

*Serratia marcescens* organisms are found in infected people, water, milk, feces, and soil. They cause serious nosocomial infections of the urinary tract, respiratory tract, skin, burn wounds, and bloodstream. They also may cause hospital epidemics and produce drug-resistant strains. High-risk patients include newborns, the debilitated, and the immunosuppressed.

## Box 29-1

## Common Bacterial Pathogens (continued)

**Salmonella**

Approximately 1400 *Salmonella* species have been identified; several are pathogenic to humans. The organisms cause gastroenteritis, typhoid fever, septicemia, and a severe, sometimes fatal type of food poisoning. The primary reservoir is the intestinal tract of many animals. Humans become infected through ingestion of contaminated water or food. Water becomes polluted by introduction of feces from any animal excreting salmonellae. Infection via food usually results from ingestion of contaminated meat or by hands transferring organisms from an infected source. In the United States, undercooked poultry and eggs are common sources.

*Salmonella* enterocolitis is a common cause of foodborne outbreaks of gastroenteritis. Diarrhea usually begins several hours after ingesting contaminated food and may continue for several days, along with nausea, vomiting, headache, and abdominal pain.

**Shigella**

*Shigella* species cause gastrointestinal problems ranging from mild diarrhea to severe bacillary dysentery. Humans, who seem to be the only natural hosts, become infected after ingestion of contaminated food or water. Effects of shigellosis are attributed to loss of fluids, electrolytes, and nutrients and to the ulceration that occurs in the colon wall.

impaired. Opportunistic infections are likely to occur in people with severe burns, cancer, human immunodeficiency virus (HIV) infection, indwelling intravenous (IV) or urinary catheters, and antibiotic or corticosteroid drug therapy. Opportunistic bacterial infections, often caused by drug-resistant microorganisms, are usually serious and may be life threatening. Fungi of the *Candida* genus, especially *C. albicans*, may cause life-threatening bloodstream or deep-tissue infections, such as abdominal abscesses. Viral infections may cause fatal pneumonia in people with renal or cardiac disorders, in those with HIV infection, and in those who have received bone marrow transplants.

**Laboratory Identification of Pathogens**

Laboratory tests of infected fluids or tissues can identify probable pathogens. Bacteria can be identified based on Gram's stain and culture. Gram's stain identifies microscopic appearance, including shape and color of the organisms. Culture involves growing a microorganism in the laboratory. Growth on selective culture media characterizes color, shape, and texture of the growing colonies. Identification of other microorganisms (e.g., intracellular pathogens such as chlamydiae and viruses) may require different techniques. *Serology* identifies infectious agents indirectly by measuring the antibody level (titer) in the serum of a diseased host. A tentative diagnosis can be made if the antibody level against a specific pathogen rises during the acute phase of the disease and falls during convalescence. *Detection of antigens* uses features of culture and serology but reduces the time required for diagnosis. Another technique to identify an organism involves polymerase chain reaction (PCR), which can detect whether DNA for a specific organism is present in a sample.

**Community-Acquired Versus Nosocomial Infections**

Infections are often categorized as community acquired or nosocomial. Because the microbial environments differ, the two types of infections often have different causes and require different antimicrobial treatment. As a general rule, *community-*

*acquired* infections are less severe and easier to treat, although *antibiotic-resistant* strains are increasing (e.g., methicillin-resistant *Staphylococcus aureus* [MRSA]). *Nosocomial* infections may be more severe and difficult to manage because they often result from drug-resistant microorganisms and occur in people whose immunity is impaired. Drug-resistant strains of staphylococci, *Pseudomonas*, and *Proteus* are common causes of nosocomial infections.

**Antibiotic-Resistant Microorganisms**

The increasing prevalence of bacteria resistant to the effects of antibiotic drugs is a major public health concern (Box 29-2). *Antibiotic resistance* occurs in most human pathogens. Both gram-positive and gram-negative bacteria are producing more antibiotic-resistant strains. Examples of gram-positive organisms with increasing antibiotic resistance include staphylococci, streptococci, and enterococci. Gram-negative bacteria associated with high rates of antibiotic resistance include *Pseudomonas aeruginosa* and *Serratia*, *Enterobacter*, and *Acinetobacter* species. These organisms are inherently resistant to penetration of antibiotics and acquire resistance by multiple mechanisms. Infections caused by drug-resistant organisms often require more toxic and expensive drugs, lead to prolonged illness or hospitalization, and increase mortality rates.

Resistant microorganisms grow and multiply when susceptible organisms, including normal flora, are suppressed by antimicrobial drugs or when normal body defenses are impaired by immunosuppressive disorders or drugs. They may emerge during or after antimicrobial drug therapy.

Broad-spectrum antibiotics affect the bacteria for which they are prescribed, transient organisms, other pathogens, and normal flora. When the normal flora is suppressed, space and nutrients become available to support the growth of organisms resistant to the effects of that antibiotic. The resistant organisms soon become the predominant strain. After they are established, resistant bacteria can cause superinfection in the original host, spread to other hosts, and even spread their resistance properties for that antibiotic to other

## Box 29-2

## Antibiotic-Resistant Staphylococci, Streptococci, and Enterococci

**Methicillin-Resistant and Vancomycin-Intermediate/Resistant *Staphylococcus* Species**

Penicillin-resistant staphylococci developed in the early days of penicillin use because the organisms produced beta-lactamase enzymes (penicillinases) that destroyed penicillin. Methicillin was one of five drugs developed to resist the action of beta-lactamase enzymes and thus be effective in treating staphylococcal infections. Eventually, strains of *Staphylococcus aureus* became resistant to these drugs as well. The mechanism of resistance in methicillin-resistant *S. aureus* (MRSA) is alteration of penicillin-binding proteins (PBPs). PBPs, the target sites of penicillins and other beta-lactam antibiotics, are proteins required for maintaining integrity of bacterial cell walls. Susceptible *S. aureus* have five PBPs called 1, 2, 3, 3a or 3', and 4. Beta-lactam antibiotics bind to these enzymes and produce defective bacterial cell walls, which kill the organisms. MRSA have an additional PBP called 2a or 2'. Methicillin cannot bind effectively to the PBPs and inhibit bacterial cell-wall synthesis except with very high drug concentrations. Consequently, minimum inhibitory concentrations (MICs) of methicillin increased to high levels that were difficult to achieve.

The term MRSA is commonly used but misleading because the organisms are widely resistant to penicillins (including all of the antistaphylococcal penicillins, not just methicillin) and cephalosporins. Many strains of MRSA are also resistant to erythromycin, clindamycin, tetracycline, and the aminoglycosides. MRSA frequently colonize nasal passages of health care workers and are increasing as a cause of nosocomial infections, especially in critical care units. In addition, the incidence of methicillin-resistant *Staphylococcus epidermidis* (MRSE, often reported as *methicillin-resistant SSNA*) isolates is increasing.

A major reason for concern about infections caused by MRSA and MRSE is that vancomycin is the drug of choice for treatment. However, vancomycin has been used extensively to treat or prevent infections caused by *S. aureus*, *S. epidermidis*, and enterococci, and vancomycin resistance is increasing in those species. In 1997, the first case of vancomycin-intermediate *S. aureus* (VISA) in the United States was detected. By 2002, the first cases of vancomycin-resistant *S. aureus* (VRSA) had been reported. Options to treat these infections are limited (linezolid, quinupristin-dalfopristin, daptomycin), and measures to reduce the incidence and prevent spread of the organisms are of paramount importance.

**Penicillin-Resistant *Streptococcus pneumoniae* (Pneumococci)**

Penicillin has long been the drug of choice for treating pneumococcal infections (e.g., community-acquired pneumonia; bacteremia; meningitis; and otitis media in children). However, penicillin-resistant strains and multidrug-resistant strains are being identified with increasing frequency. Risk factors for the development of resistant strains include frequent antibiotic use and prophylactic antibiotics. After they have developed,

resistant strains spread to other people, especially in children's daycare centers and in hospital settings. Children in daycare centers are often colonized or infected with antibiotic-resistant *S. pneumoniae*. This is attributed to a high incidence of otitis media, which is often treated with a penicillin or cephalosporin. Resistant strains in adults and older clients are often associated with previous use of a penicillin or cephalosporin and hospitalization.

*S. pneumoniae* are thought to develop resistance to penicillin by decreasing the ability of their PBPs to bind with penicillin (and other beta-lactam antibiotics). Organisms displaying high-level penicillin resistance may be cross-resistant to second- and third-generation cephalosporins, amoxicillin/clavulanate, and the macrolides. In pneumococcal infections resistant to penicillins and cephalosporins, vancomycin, fluoroquinolones, macrolides, and telithromycin are drugs of choice. To decrease spread of resistant *S. pneumoniae*, the Centers for Disease Control and Prevention (CDC) have proposed:

- Improved surveillance to delineate prevalence by geographic area and assist clinicians in choosing appropriate antimicrobial therapy.
- Rational use of antimicrobials to reduce exposures to drug-resistant pneumococci. For example, prophylactic antibiotic therapy for otitis media may increase colonization and infection of young children with resistant organisms.
- Pneumococcal vaccination for people older than 2 years of age with increased risk of pneumococcal infection, and for all people older than 65 years of age.

**Vancomycin-Resistant Enterococci (VRE)**

Enterococci have intrinsic and acquired resistance to many antibacterial drugs. For example, penicillins and cephalosporins inhibit rather than kill the organisms at achievable concentrations, and aminoglycosides are ineffective if used alone. As a result, standard treatment of an enterococcal infection outside of the urinary tract has involved a combination of ampicillin and gentamicin. This combination is often successful because the ampicillin damages the bacterial cell wall and allows the aminoglycoside to penetrate the bacterial cell. For ampicillin-allergic clients, vancomycin is given with an aminoglycoside.

This treatment is becoming less effective because some strains of enterococci have developed resistance to ampicillin, gentamicin, and vancomycin. The incidence of multidrug-resistant enterococci and VRE has increased in recent years. Three major types (VanA, VanB, and VanC) of VRE have been described, with different patterns of antimicrobial susceptibility. Some strains remain susceptible to ampicillin, whereas others are only susceptible to linezolid, quinupristin-dalfopristin, chloramphenicol, or newer fluoroquinolones.

A major contributing factor to VRE is increased use of vancomycin to prevent or treat other infections such as staphylococcal (MRSA and MRSE) infections. Therefore, to decrease the spread of VRE, the CDC recommends limiting the use of vancomycin. Specific recommendations include avoiding or

## Box 29-2

## Antibiotic-Resistant Staphylococci, Streptococci, and Enterococci (continued)

minimizing use in routine surgical prophylaxis; empiric therapy for febrile clients with neutropenia (unless the prevalence of MRSA or MRSE is high); systemic or local prophylaxis for intravascular catheter infection or colonization; selective decontamination of the gastrointestinal tract; eradication of MRSA colonization; primary treatment of antibiotic-associated colitis; and routine prophylaxis for very low birth weight infants or patients on continuous ambulatory peritoneal

dialysis. Thorough hand hygiene and environmental cleaning are also important, because VRE can survive for long periods on hands, gloves, stethoscopes, and environmental surfaces. Personnel should remove or change gloves after contact with patients known to be colonized or infected with VRE. Stethoscopes should be used only with infected patients or cleaned thoroughly between patients if used for both VRE-infected and uninfected patients.

species of bacteria. In addition to resistance to the effects of one antibiotic, cross-resistance to similar antibiotics also occurs because most antibiotics are variations of a few basic types. Interruption or inadequate antimicrobial treatment of infections may also contribute to the emergence of antibiotic-resistant organisms. Patients often stop taking a prescribed antibiotic when symptoms subside or they feel better. In such circumstances, only the most susceptible bacteria are affected and resistant organisms can become established residents.

Infections often associated with high rates of resistance include lower respiratory tract infections and those infections associated with cystic fibrosis or osteomyelitis. These infections are often difficult to treat because they tend to recur, involve multiple or resistant organisms, and involve anatomic locations that antibiotics do not penetrate well. Patients who are malnourished, severely ill, immunosuppressed, or receiving mechanical ventilation are at high risk for infections, including those caused by antibiotic-resistant organisms.

Resistant organisms are especially likely to emerge in critical care units and large teaching hospitals, where seriously ill patients often require extensive antibiotic therapy. The constant presence of antibiotics provides an environment conducive to selection and replication of resistant organisms. Patients in critical care units are more at risk for infection with antibiotic-resistant organisms because of person-to-person transmission by health care workers or equipment.

Resistant organisms and the antibiotics to which they develop resistance vary in geographic areas, communities, and hospitals according to the use of particular antibiotics. Nationally, resistant bacterial strains of major concern include penicillin-resistant *Streptococcus pneumoniae*, methicillin-resistant *S. aureus* and *Staphylococcus epidermidis*, vancomycin-resistant enterococcus (VRE), extended-spectrum beta-lactamase (ESBL)-producing gram-negative bacilli, and multidrug-resistant tuberculosis (MDR-TB). All of these organisms are resistant to multiple antibiotics. The first four are described in Box 29-2; MDR-TB is discussed in Chapter 34. Viruses and fungi also develop resistance to antimicrobial drugs, as discussed in Chapters 35 and 36, respectively.

### Mechanisms of Resistance

Bacteria have developed numerous ways to acquire resistance to antimicrobial drugs, including

- Production of enzymes that inactivate the drugs. For example, beta-lactamase enzymes change the chemical structure of penicillins and cephalosporins by opening the beta-lactam ring and preventing the antibiotic from binding with its target site (called *penicillin-binding proteins*) in the bacterial cell wall.
- Modification of target sites for the antibiotic. This is a mechanism of resistance used by bacteria against fluoroquinolones.
- Production of an alternative enzyme to bypass antibiotic activity (e.g., methicillin-resistant staphylococci)
- Changing their cell wall structure to reduce permeability. An example is alteration in porin channels among *P. aeruginosa* to produce imipenem resistance.
- Acquiring or increasing the ability to pump drug molecules out of the cell (efflux). Examples include some gram-positive cocci resistant to tetracyclines.
- Modification of a binding target for the antibiotic (e.g., macrolides)

Bacteria have efficient mechanisms for exchange of genetic material (DNA or plasmids) that allow them to spread antibiotic resistance from one bacterial strain to another, including different species or types of bacteria. Thus, when a new antibiotic is used, resistance may rapidly appear and be disseminated to multiple bacteria.

### Host Defense Mechanisms

Although the numbers and virulence of microorganisms help determine whether a person acquires an infection, another major factor is the host's ability to defend itself against the would-be invaders.

Major defense mechanisms of the human body are intact skin and mucous membranes, various anti-infective secretions, mechanical movements, phagocytic cells, and the immune and inflammatory processes. The skin prevents penetration of foreign particles, and its secretions and normal bacterial flora inhibit growth of pathogenic microorganisms. Secretions of the GI, respiratory, and genitourinary tracts (e.g., gastric acid, mucus) kill, trap, or inhibit growth of microorganisms. Coughing, swallowing, and peristalsis help remove foreign particles and pathogens trapped in mucus, as does the movement of cilia. Phagocytic cells in various organs and tissues engulf and

digest pathogens and cellular debris. The immune system produces lymphocytes and antibodies (see Chap. 38). The inflammatory process is the body's response to injury by microorganisms, foreign particles, chemical agents, or physical irritation of tissues. Inflammation localizes, destroys, dilutes, or removes the injurious agents so tissue healing can occur.

Many factors impair host defense mechanisms and predispose to infection by disease-producing microorganisms. These factors include the following:

- Breaks in the skin and mucous membranes related to trauma, inflammation, open lesions, or insertion of prosthetic devices, tubes, and catheters for diagnostic or therapeutic purposes
- Impaired blood supply
- Neutropenia and other blood disorders
- Malnutrition
- Poor personal hygiene
- Suppression of normal bacterial flora by antimicrobial drugs
- Suppression of the immune system and the inflammatory response by immunosuppressive drugs, cytotoxic antineoplastic drugs, and adrenal corticosteroids
- Diabetes mellitus and other chronic diseases
- Advanced age

## Characteristics of Antimicrobial Drugs

### Terms and Concepts

Several terms are used to describe these drugs. *Anti-infective* and *antimicrobial* include antibacterial, antiviral, and antifungal drugs; *antibacterial* and *antibiotic* refer to drugs used in bacterial infections and are often used interchangeably. Most of the drugs in this section are antibacterials. Antiviral and antifungal drugs are discussed in Chapters 35 and 36, respectively.

Additional terms for antibacterial drugs include *broad spectrum*, for those effective against several groups of microorganisms, and *narrow spectrum*, for those effective against a few groups. The action of an antibacterial drug is usually described as *bactericidal* (kills the microorganism) or *bacteriostatic* (inhibits growth of the microorganism). Whether a drug is bactericidal or bacteriostatic often depends on its concentration at the infection site and the susceptibility of the microorganism to the drug. Successful treatment with bacteriostatic antibiotics depends on the ability of the host's immune system to eliminate the inhibited bacteria and an adequate duration of drug therapy. Stopping an antibiotic prematurely can result in rapid resumption of bacterial growth. Bactericidal drugs are preferred in serious infections, especially in people with impaired immune function.

### Mechanisms of Action

Most antimicrobial drugs act on a specific target in the infecting organism (Fig. 29-1). Almost any structure unique to infecting organism, such as proteins or nucleic acids, can be a

target for antibiotics. Specific mechanisms of action of antimicrobial drugs include the following:

- Inhibition of bacterial cell wall synthesis or activation of enzymes that disrupt bacterial cell walls (e.g., penicillins, cephalosporins, vancomycin)
- Inhibition of protein synthesis by bacteria or production of abnormal bacterial proteins (e.g., aminoglycosides, clindamycin, macrolides, ketolides, tetracyclines). These drugs bind irreversibly to bacterial ribosomes, intracellular structures that synthesize proteins. When antimicrobial drugs are bound to the ribosomes, bacteria cannot synthesize the proteins necessary for cell walls and other structures.
- Disruption of microbial cell membranes (e.g., antifungals)
- Inhibition of organism reproduction by interfering with nucleic acid synthesis (e.g., fluoroquinolones, rifampin, anti-acquired immunodeficiency syndrome antivirals)
- Inhibition of cell metabolism and growth (e.g., sulfonamides, trimethoprim)

### Indications for Use

Antimicrobial drugs are used to treat and prevent infections. Because laboratory tests (except Gram's stain and a rapid test for group A streptococci) to identify causative organisms usually take 24 hours or longer, empiric therapy against the most likely pathogens is often begun. After organisms are identified, more specific therapy is instituted. Prophylactic therapy is recommended to prevent the following:

- Group A streptococcal infections and possibly rheumatic fever, rheumatic heart disease, and glomerulonephritis. Penicillin is commonly used.

**Figure 29-1** ■ Actions of antibacterial drugs on bacterial cells.

- Bacterial endocarditis in patients with cardiac valvular disease who are having dental, surgical, or other invasive procedures. Amoxicillin or ampicillin, with an aminoglycoside, is usually recommended for at-risk persons undergoing certain types of procedures.
- Tuberculosis in patients with latent tuberculosis infection (see Chap. 34)
- Perioperative infections in high-risk patients (e.g., those whose resistance to infection is lowered because of age, poor nutrition, disease, or drugs) and for high-risk surgical procedures (e.g., cardiac or GI surgery, certain orthopedic procedures, organ transplants)
- Sexually transmitted diseases (e.g., gonorrhea, syphilis, chlamydial infections) after exposure has occurred
- Recurrent urinary tract infections in premenopausal, sexually active women. A single dose of a fluoroquinolone or trimethoprim-sulfamethoxazole for two doses, taken after sexual intercourse, is often effective.

## Nursing Process

### Assessment

Assess for current or potential infection.

- General signs and symptoms of infection are the same as those of inflammation, although the terms are not synonymous. *Inflammation* is the normal response to any injury; *infection* requires the presence of a microorganism. The two often occur together. Inflammation may weaken tissue, allowing microorganisms to invade and cause infection. Infection (tissue injury by microorganisms) arouses inflammation. Local signs include redness, heat, edema, and pain; systemic signs include fever and leukocytosis. Specific manifestations depend on the site of infection. Common sites are the respiratory tract, surgical or other wounds, and the genitourinary tract.
- Assess each patient for the presence of factors that increase risks of infection (see “Host Defense Mechanisms,” earlier).
- Assess culture reports for causative organisms.
- Assess susceptibility reports for appropriate antibacterial drug therapy.
- Assess patients for drug allergies. If present, ask about specific signs and symptoms.
- Assess baseline data about renal and hepatic function and other factors that aid monitoring for therapeutic and adverse drug effects.
- Assess for characteristics that increase risks of adverse drug effects.

### Nursing Diagnoses

- Fatigue related to infection
- Activity Intolerance related to fatigue

- Diarrhea related to antimicrobial therapy
- Imbalanced Nutrition: Less Than Body Requirements related to anorexia, nausea, and vomiting associated with antimicrobial therapy
- Risk for Injury related to infection or adverse drug effects
- Risk for Infection related to emergence of drug-resistant microorganisms
- Deficient Knowledge: Methods of preventing infections

## Planning/Goals

### The patient will

- Receive antimicrobial drugs accurately when given by health care providers or caregivers
- Take drugs as prescribed and for the length of time prescribed when self-administered as an outpatient
- Experience decreased fever, white blood cell (WBC) count, and other signs and symptoms of infection
- Be monitored regularly for therapeutic and adverse drug effects
- Receive prompt recognition and treatment of potentially serious adverse effects
- Verbalize and practice measures to prevent future infections
- Be safeguarded against nosocomial infections by health care providers

## Interventions

- Use measures to prevent and minimize the spread of infection.
- Wash hands thoroughly and often. This is probably the most effective method of preventing infections.
- Support natural defense mechanisms by promoting general health measures (e.g., nutrition, adequate fluid intake, rest, exercise).
- Keep the patient’s skin clean and dry, especially the hands, underarms, groin, and perineum, because these areas harbor large numbers of microorganisms. Also, take care to prevent trauma to the skin and mucous membranes. Damaged tissues are susceptible to infection.
- Treat all body fluids (e.g., blood, aspirates from abdomen or chest) and body substances (e.g., sputum, feces, urine, wound drainage) as infectious. Major elements of standard precautions to prevent transmission of hepatitis B, HIV, and other pathogens include wearing gloves when likely to be exposed to any of these materials and thorough hand hygiene when the gloves are removed. Wear protective eyewear when a risk of spatter is present. Rigorous and consistent use of the recommended precautions helps to protect health care providers and patients.
- Implement isolation procedures appropriately.

- To prevent spread of respiratory infections, have patients wash hands after coughing, sneezing, or contact with infected people; cover mouth and nose with tissues when sneezing or coughing and dispose of tissues by placing them in a paper bag and burning it; expectorate sputum (swallowing may cause reinfection); and avoid crowds when possible, especially during influenza season (approximately November through February). Recommend an annual influenza vaccine to high-risk populations (e.g., people with chronic diseases such as diabetes and heart, lung, or renal problems; older adults; health care personnel who are likely to be exposed). Pneumococcal vaccine (see Chap. 39) is recommended for the same populations.
- Assist or instruct patients at risk about pulmonary hygiene measures to prevent accumulation or promote removal of respiratory secretions. These measures include ambulating; turning; coughing and deep-breathing exercises; and incentive spirometry. Retained secretions are good culture media for bacterial growth.
- Use sterile technique when changing any dressing. If a wound is not infected, sterile technique helps prevent infection. If the wound is already infected, sterile technique avoids introducing new bacteria. For all but the smallest of dressings without drainage, remove the dressing with clean gloves, discard it in a moisture-proof bag, and wash hands before putting on sterile gloves to apply the new dressing.
- To minimize spread of infections, adhere to current established guidelines for isolation precautions to prevent transmission of infectious agents in health care settings published by the Centers for Disease Control and Prevention.
- For patients with infections, monitor temperature for increased or decreased fever, and monitor WBC count for decrease.
- For patients receiving antimicrobial therapy, maintain a total fluid intake of approximately 3000 mL/24 hours, if not contraindicated by the patient's condition. An adequate intake and avoidance of fluid volume deficit may help decrease drug toxicity, especially with aminoglycoside antibiotics. On the other hand, a patient receiving IV antibiotics, with 50 to 100 mL of fluid per dose, may be at risk for fluid volume overload.
- Assist patients with hand hygiene; maintaining nutrition and fluid balance; getting adequate rest; and handling secretions correctly. These measures help the body to fight the infection, prevent further infection, and enhance the effectiveness of anti-infective drugs.
- Assist patients in using antimicrobial drugs safely and effectively. Provide appropriate patient teaching (see accompanying display).

## Evaluation

- Interview and observe for compliance with instructions for using antimicrobial drugs.
- Observe for adverse drug effects.
- Interview and observe for practices to prevent infection.

## Applying Your Knowledge 29-1

Ms. Kurth tells you that she frequently takes her antibiotic for just long enough to feel better and then saves the rest of her medication for another illness. What teaching guidelines should you provide to her regarding safe and accurate self-administration of antibiotics?

.....

## Principles of Therapy

### Goal of Therapy for Infections

The goal of treatment is to eradicate the causative microorganism and return the host to full physiologic functioning. This differs from the goal of most drug therapy, which is to relieve signs and symptoms rather than cure the underlying disorder.

## Applying Your Knowledge 29-2

Ms. Kurth is hospitalized for acute infection and is receiving IV antibiotic medication. What are the nurse's responsibilities for accurate antibiotic administration?

.....

### Rational Use of Antimicrobial Drugs

Antimicrobials are among the most frequently used drugs worldwide. Their success in saving lives and decreasing severity and duration of infectious diseases has encouraged their extensive use. Authorities believe that much antibiotic use involves overuse, misuse, or abuse of the drugs. That is, an antibiotic is not indicated at all or the wrong drug, dose, route, or duration is prescribed. Inappropriate use of antibiotics increases adverse drug effects, infections with drug-resistant microorganisms, and health care costs. In addition, it decreases the number of effective drugs for serious or antibiotic-resistant infections.

Guidelines to promote more appropriate use of antimicrobial drugs include the following:

- Avoid the use of broad-spectrum antibacterial drugs to treat trivial or viral infections; use narrow-spectrum agents if they are likely to be effective. Give antibacterial drugs only when a significant bacterial infection is diagnosed or strongly suspected or when there is an established indication

for prophylaxis. Antibacterial drugs are ineffective in viral infections and should not be used to treat them.

- Collect specimens (e.g., sputum, urine) for culture and Gram's stain before giving the first dose of an antibiotic. For best results, specimens must be collected accurately and taken directly to the laboratory. If analysis is delayed, contaminants may overgrow pathogenic microorganisms.
- Minimize antimicrobial drug therapy for fever unless other clinical manifestations or laboratory data indicate infection.
- Use antimicrobial drugs in combination with other interventions to decrease microbial proliferation, such as universal precautions, medical isolation techniques, frequent and thorough hand hygiene, and preoperative skin and bowel cleansing.
- Follow recommendations of the Centers for Disease Control and Prevention for prevention and treatment of infections, especially those caused by drug-resistant organisms (e.g., gonorrhea, penicillin-resistant streptococcal infections, MRSA, VRE, MDR-TB).
- Consult infectious disease physicians, infection control nurses, and infectious disease pharmacists about local patterns of drug-resistant organisms and treatment of complicated infections.

## Patient Teaching Guidelines

### General Considerations

- Wash hands often and thoroughly, especially before preparing food or eating and after exposure to any body secretions (e.g., urine, feces, sputum, nasal secretions). This is probably the most effective way to prevent infection and to avoid spreading an infection to others.
- A balanced diet and adequate fluid intake, rest, and exercise also help the body to fight infection, prevent further infection, and increase the effectiveness of antimicrobial drugs.
- Take all prescribed doses of an antimicrobial; do not stop when symptoms are relieved. If medication is stopped too soon, symptoms of the current infection may recur and new infections that are caused by antibiotic-resistant organisms and that are harder to treat may develop.
- If problems occur with taking an antimicrobial drug, report them to a health care provider rather than stopping the drug.
- Do not take antimicrobials left over from a previous illness or prescribed for someone else. Even if infection is present, the likelihood of having the appropriate drug on hand, and in adequate amounts, is extremely small. Thus, taking drugs not prescribed for the particular illness tends to maximize risks and minimize benefits. Also, if the infection is viral, antibacterial drugs are ineffective and should not be used.
- Report any other drugs being taken to the prescribing physician. Drug interactions may occur, and changes in drug therapy may be indicated.

## Drug Selection

After an infection requiring treatment is diagnosed, numerous factors influence the choice of an antimicrobial drug or combination of drugs.

### Empiric Therapy

Because most laboratory tests used to definitively identify causative organisms and to determine susceptibility to antibiotics require 48 to 72 hours, the physician usually prescribes for immediate administration a drug that is likely to be effective. This empiric therapy is based on an informed estimate of the most likely pathogen(s) given the patient's signs and symptoms and apparent site of infection. A single broad-spectrum antibiotic or a combination of drugs is often chosen.

### Culture and Susceptibility Studies

Culture identifies the causative organism, and *susceptibility* tests determine which drugs are likely to be effective against the organism. One can then "match the drug to the bug." Culture and susceptibility studies are important in both suspected gram-positive and gram-negative infections because of the high incidence of drug-resistant microorganisms.

When a specific organism is identified by laboratory culture, tests can be performed to measure the organism's susceptibility to particular antibiotics. Laboratory reports indicate

## Antimicrobial Drugs

- Report any drug allergies to all health care providers and wear a medical identification emblem that lists allergens.
- Some antibiotics (e.g., ampicillin, nitrofurantoin, penicillin V, sulfonamides, tetracyclines) decrease the effectiveness of estrogens and oral contraceptives. Women taking these drugs should use another method of contraception. Inadequate blood levels of estrogen may be indicated by breakthrough bleeding.

### Self-Administration

- Unless instructed otherwise, take antimicrobial drugs at evenly spaced intervals around the clock. This helps maintain beneficial blood levels of most drugs.
- Some oral antimicrobials should be taken on an empty stomach, approximately 1 hour before or 2 hours after meals. Food may decrease absorption and effectiveness. If the medication causes intolerable nausea or vomiting, a few bites of food may be taken.
- Store most liquid preparations in the refrigerator, check expiration dates, and discard them when indicated. These preparations are stable and effective for a limited time.
- Take the medications with a full glass of water. This helps tablets and capsules to dissolve better in the stomach and decreases stomach irritation.
- Report nausea, vomiting, diarrhea, skin rash, recurrence of symptoms for which the antimicrobial drug was prescribed, or signs of new infection (e.g., fever, cough, sore mouth, drainage). These problems may indicate adverse effects of the drug, lack of therapeutic response to the drug, or another infection. Any of these requires evaluation and may indicate changes in drug therapy.

whether the organism is susceptible (S) or resistant (R) to the tested drugs. One indication of susceptibility is the minimum inhibitory concentration (MIC). The MIC is the lowest concentration of an antibiotic that prevents visible growth of microorganisms. Some laboratories report MIC instead of, or in addition to, S or R.

Susceptible organisms have low or moderate MICs that can be attained by giving usual doses of an antimicrobial agent. For the drug to be effective, its serum and tissue concentrations should usually exceed the MIC of an organism for a period of time. By how much and for how long drug concentrations need to exceed the MIC depend on the drug class and the bacterial species. With beta-lactam agents (e.g., penicillins, cephalosporins), the drug concentration usually needs to be maintained above the MIC of the infecting organism for a majority of the dosing interval. With the aminoglycosides (e.g., gentamicin, others), the drug concentration does not need to be maintained above the MIC of the organism for the entire dosing interval, because aminoglycosides have a *postantibiotic effect*. Postantibiotic effect is a persistent effect of an antimicrobial on bacterial growth after brief exposure of the organisms to a drug. Some studies demonstrate that large doses of aminoglycosides, given once daily, are as effective as more frequent dosing and may cause less nephrotoxicity.

Resistant organisms have high MICs and may require higher concentrations of drug than can be achieved in the body. In some cases the minimum bactericidal concentration (MBC) is reported, indicating no growth of the organism in the presence of a particular antibiotic. The MBC is especially desirable for infected hosts with impaired immune functions.

Patients' responses to antimicrobial therapy cannot always be correlated with the MIC of an infecting pathogen. Thus, reports of drug susceptibility testing must be applied in the context of the site of infection, the characteristics of the drug, and the clinical status of the patient.

### Antibiotic Resistance Patterns

Because these patterns of resistance change in the community and agencies, continuing efforts must be made. *P. aeruginosa* is resistant to many antibiotics, and those strains resistant to gentamicin may be susceptible to amikacin, ceftazidime, imipenem, or aztreonam. Some gram-negative organisms have become increasingly resistant to aminoglycosides, third-generation cephalosporins, and aztreonam, but they may be susceptible to carbapenems or ceftepime.

### Organism Most Likely to Infect a Particular Site

For example, urinary tract infections are often caused by *E. coli*. Thus, a drug effective against this organism is indicated.

### Ability to Penetrate Infected Tissues

Several antimicrobials are effective in urinary tract infections because they are excreted in the urine. However, the choice of an effective antimicrobial drug may be limited in infections of the brain, eyes, gallbladder, or prostate gland because many drugs are unable to reach therapeutic concentrations in these tissues.

### Toxicity and Risk-to-Benefit Ratio

In general, the least toxic drug should always be used. However, for serious infections, more toxic drugs may be necessary.

### Cost

If an older, less expensive drug meets the criteria for rational drug selection and is likely to be effective in a given infection, it should be used instead of a more expensive agent. For hospitals and nursing homes, personnel costs relating to preparation and administration should be considered as well as purchasing costs.

### Combination Therapy

Antimicrobial drugs are often used in combination. Indications for combination therapy may include the following:

- Infections caused by multiple microorganisms (e.g., abdominal and pelvic infections)
- Nosocomial infections, which may be caused by many different organisms
- Serious infections in which a combination is synergistic (e.g., an aminoglycoside and an antipseudomonal penicillin for pseudomonal infections)
- Likely emergence of drug-resistant organisms if a single drug is used (e.g., in tuberculosis). Although drug combinations are widely used to prevent resistance, the only clearly effective use of combination therapy is for treatment of tuberculosis.
- Fever or other signs of infection in patients whose immune system is suppressed. Combinations of antibacterial plus antiviral and/or antifungal drugs may be needed.

### Drug Dosage and Administration

Dosage (amount and frequency of administration) should be individualized according to characteristics of the causative organism, the chosen drug, and the patient's size and condition (e.g., type and severity of infection, ability to use and excrete the chosen drug). For example, dosage may need to be increased for more resistant organisms such as *P. aeruginosa* and for infections in which antibiotics have difficulty penetrating to the site of infection (e.g., meningitis). Dosage often must be reduced if the patient has renal impairment or other disorders that delay drug elimination.

Most antimicrobial drugs are given orally or IV for systemic infections. The route of administration depends on the patient's condition (e.g., location and severity of the infection, ability to take oral drugs) and the available drug dosage forms. In serious infections, the IV route is preferred for most drugs.

### Duration of Therapy

Duration of therapy varies from a single dose to years, depending on the reason for use. For most acute infections, the average duration is approximately 7 to 10 days or until the recipient has been afebrile and asymptomatic for 48 to 72 hours.

## Use in Special Populations

### Perioperative Use

When used to prevent infections associated with surgery, a single dose of an antimicrobial medication is usually given within 1 hour of the first incision. This provides effective tissue concentrations during the procedure. If intraoperative contamination occurs, the patient should be treated for an infection. The choice of drug depends on the pathogens most likely to colonize the operative area. For most surgeries involving an incision through the skin, a first-generation cephalosporin such as cefazolin (Kefzol) with activity against *S. aureus* or *Streptococcus* species is commonly used. Repeated doses may be given during surgery for procedures of long duration, procedures involving insertion of prosthetic materials, and contaminated or infected operative sites. Postoperative antimicrobials are indicated with intraoperative contamination, traumatic wounds, or ruptured viscera.

### Use in Children

Antimicrobial drugs are commonly used in hospitals and ambulatory settings for respiratory infections, otitis media, and other infections. General principles of pediatric (see Chap. 4) and antimicrobial drug therapy apply. Other guidelines include the following:

- Penicillins and cephalosporins are considered safe for most age groups. However, they are eliminated more slowly in neonates because of immature renal function and must be used cautiously and dosed appropriately for age. As with other classes of drugs, many penicillins and cephalosporins do not have Food and Drug Administration (FDA) approval for use in children (usually younger than 12 years of age). However, pediatric specialty references reflect the growing body of experience in using these drugs in younger children.
- Erythromycin, azithromycin (Zithromax), and clarithromycin (Biaxin) are considered safe.
- Aminoglycosides (e.g., gentamicin) may cause nephrotoxicity and ototoxicity in any patient population. Neonates are at high risk because of immature renal function.
- Tetracyclines are contraindicated in children younger than 8 years of age because of drug effects on teeth and bone (see Chap. 32).
- Clindamycin (Cleocin) warrants monitoring liver and kidney function when it is given to neonates and infants.
- Fluoroquinolones (e.g., ciprofloxacin [Cipro]) are contraindicated for use in children (<18 years of age) because weight-bearing joints have been impaired in young animals given the drugs. However, if fluoroquinolones are the only therapeutic option for a resistant pathogen, the prescriber may decide to use a fluoroquinolone in children.
- Trimethoprim-sulfamethoxazole (Bactrim) is used in children, although children younger than 2 months of age have not been evaluated.
- Linezolid (Zyvox) is considered safe for use in children.

### Use in Older Adults

Antimicrobial drugs are commonly used in all health care settings for infections in older adults as in younger adults. General principles of geriatric (see Chap. 4) and antimicrobial drug therapy apply. Other guidelines include the following:

- Penicillins are usually safe. However, hyperkalemia may occur with large IV doses of penicillin G potassium (1.7 mEq potassium per 1 million units), and hyponatremia may occur with ticarcillin (Ticar), which contains 5.6 milliequivalents of sodium per gram. Hyperkalemia and hyponatremia are more likely to occur with impaired renal function.
- Cephalosporins (e.g., cefazolin) are considered safe but may cause or aggravate renal impairment, especially when other nephrotoxic drugs are used concurrently. Dosage of most cephalosporins should be reduced in the presence of renal impairment (see Chap. 30).
- Macrolides and ketolides (e.g., erythromycin, telithromycin) are usually safe. Dosage of clarithromycin should be reduced with severe renal impairment.
- Aminoglycosides (e.g., gentamicin) are contraindicated in the presence of impaired renal function if less toxic drugs are effective against causative microorganisms. Older adults are at increased risk of nephrotoxicity and ototoxicity from these drugs. Interventions to decrease adverse drug effects are described in Chapter 31.
- Tetracyclines (except doxycycline) and nitrofurantoin (Macrochantin) are contraindicated in the presence of impaired renal function if less toxic drugs are effective against causative organisms.
- Clindamycin may cause diarrhea and should be used with caution in the presence of GI disease, especially colitis.
- Trimethoprim-sulfamethoxazole (Bactrim, Septra) may be associated with an increased risk of severe adverse effects in older adults, especially those with impaired liver or kidney function. Severe skin reactions and bone marrow depression are the most frequently reported severe reactions.
- Daptomycin (Cubicin), quinupristin-dalfopristin (Synercid), tigecycline (Tygacil), and linezolid (Zyvox) are newer agents that may be used in older adults. Daptomycin dosage should be lowered in the presence of impaired renal function.

### Use in Patients With Renal Impairment

Antimicrobial drug therapy requires close monitoring in patients with renal impairment. Many drugs are excreted primarily by the kidneys; some are nephrotoxic and may further damage the kidneys. In the presence of renal impairment, drugs may accumulate and produce toxic effects. Thus, dosage reductions are necessary for some drugs. Methods of calculating dosage are usually based on rates of creatinine clearance (CrCl). For some antibiotics, such as the aminoglycosides and vancomycin, serum drug concentrations should also be used to individualize dosage.

The following formula may be used to estimate CrCl:

*Male:* Weight in kilograms (IBW)  $\times$  (140–age), divided by  
72  $\times$  serum creatinine (in milligrams per 100 mL)

*Female:* 0.85  $\times$  above value

Dosage may be reduced by giving smaller individual doses, by increasing the time interval between doses, or both. Anti-infective drugs can be categorized as follows in relation to renal impairment:

- Drugs that should be avoided in severe renal impairment (i.e., CrCl < 15–30 mL/minute) unless the infecting organism is sensitive only to a particular drug. These drugs include the tetracyclines (except doxycycline) and flucytosine.
- Drugs that may exacerbate renal impairment and should not be used if safer alternatives are available. If used, dosage must be carefully adjusted, renal function must be closely monitored, and the patient must be closely observed for adverse effects. These drugs include aminoglycosides, amphotericin B, and the fluoroquinolones. Monitoring serum drug concentrations is recommended when using aminoglycoside antibiotics.
- Drugs that require dosage reduction in severe renal impairment. These include penicillin G, ampicillin, most cephalosporins, fluoroquinolones, and trimethoprim-sulfamethoxazole.
- Drugs that require little or no dosage adjustment. These include chloramphenicol, clindamycin, doxycycline, erythromycin, isoniazid, nafcillin, and rifampin.

An additional factor is important in patients with acute or chronic renal failure who are receiving hemodialysis or peritoneal dialysis: Some drugs are removed by dialysis, and an extra dose may be needed during or after dialysis. Patients with acute renal failure receiving continuous renal replacement therapy (CRRT) may also require adjustments in drug doses. Generally, CRRT is more effective at removing drugs than hemodialysis and peritoneal dialysis. Reference texts or scientific articles should be consulted to determine appropriate doses of antibiotics in these patients.

### Use in Patients With Hepatic Impairment

Antimicrobial therapy in patients with liver impairment is not well defined. Some drugs are metabolized by the liver (e.g., cefoperazone, chloramphenicol, clindamycin, erythromycin), and dosage must be reduced in patients with severe liver impairment. Some are associated with elevations of liver enzymes and/or hepatotoxicity (e.g., certain fluoroquinolones, tetracyclines, isoniazid, rifampin). Laboratory monitoring may be helpful in high-risk populations.

Penicillins and other beta-lactam drugs rarely cause jaundice, hepatitis, or liver failure. However, acute liver injuries have been reported with the combination of amoxicillin-clavulanate (Augmentin), and some cases of cholestatic jaundice have been reported with ticarcillin-clavulanate

(Timentin). Hepatotoxicity is attributed to the clavulanate component. These drugs are contraindicated in patients who have had cholestatic jaundice or hepatic dysfunction associated with their use and must be used with caution in patients with hepatic impairment.

Some fluoroquinolones have been associated with liver enzyme abnormalities and hepatotoxicity (e.g., hepatitis, liver impairment or failure). The drugs should be used cautiously in patients with or at risk for development of impaired liver function. The drug should be stopped if jaundice or any other symptoms of liver dysfunction develop.

### Use in Patients With Critical Illness

Antimicrobials are frequently given in critical care units. Many patients have multiple organ impairments or chronic diseases with a superimposed acute illness or injury (e.g., surgery, trauma, burns). Thus, antimicrobial therapy is often more aggressive, complex, and expensive in critically ill patients than in other patients. In addition, measurement of plasma drug levels and dosage adjustment are often necessary to accommodate the changing physiology of a critically ill patient. Drug levels are usually measured after four or five doses are given so that steady-state concentrations have been reached.

Patients in critical care units are at high risk for acquiring nosocomial pneumonia because of the severity of their illness, duration of hospitalization, and antimicrobial drug therapy. The strongest predisposing factor is mechanical ventilation, which bypasses airway defenses against movement of microorganisms from the upper to the lower respiratory tract. Organisms often associated with nosocomial pneumonia are *S. aureus* and gram-negative bacilli. Bacterial pneumonia is usually treated with a broad-spectrum antibiotic until culture and susceptibility reports become available.

Selection of antibacterial drugs may be difficult because of frequent changes in antibiotic resistance patterns. Antibiotic rotation (i.e., switching preferred antibiotic or antibiotic classes used to treat infections, on a scheduled basis) has been successful in reducing rates of ventilator-associated pneumonia and mortality.

### Use in Home Care

Infections are among the most common illnesses in all age groups, and they are often treated by antibiotic therapy at home, with medications administered by the patient or a family-member caregiver. If a home care nurse is involved, responsibilities may include teaching family members how to administer antibiotics (e.g., teaching a parent how to store and measure a liquid antibiotic), how to care for the person with an infection, and how to protect other people in the environment from the infection. General infection-control practices include frequent and thorough hand hygiene, use of gloves when indicated, and appropriate handling and disposal of body substances (e.g., blood, urine, feces, sputum, vomitus, wound drainage).

Increasingly, IV antibiotics are being given in the home. Any patient who needs more than a few days of IV antibiotic therapy may be a candidate for home care. Some infections that require relatively long-term IV antibiotic therapy include

endocarditis, osteomyelitis, and some surgical-wound infections. Numerous people and agencies may be involved in providing this service. First, the patient and family need to be able and willing to manage some aspects of therapy and to provide space for necessary supplies. Second, arrangements must be made for procuring equipment, supplies, and medication. In some areas, nurses employed by equipment companies help families prepare and use IV infusion pumps. Medication is usually obtained from a local pharmacy in a unit-dose package ready for administration.

The role of the home care nurse includes teaching the patient and caregiver how to store and administer the medication, monitor the IV site, monitor the infection, manage problems, and report patient responses. Specific responsibilities may vary according to drug administration (intermittently or by continuous infusion), whether the patient has a peripheral or central IV line, and other factors. The family should be provided with detailed instructions and emergency telephone numbers of the home care nurse, the pharmacy, and the supply company.

## Nursing Actions Antimicrobial Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- Schedule at evenly spaced intervals around the clock.
- Some oral antimicrobials should be given on an empty stomach, approximately 1 hour before or 2 hours after meals. Check specific recommendations.
- For oral and parenteral solutions from powder forms, follow label instructions for mixing and storing. Check expiration dates.
- Give parenteral antimicrobial solutions alone; do not mix with any other drug in a syringe or intravenous (IV) solution.
- Give intramuscular (IM) antimicrobials deeply into large muscle masses (preferably gluteal muscles), and rotate injection sites.
- For IV administration, use dilute solutions, giving direct injections slowly and intermittent infusions over 30–60 minutes. After infusions, flush the IV tubing with at least 10 milliliters of IV solution. For children, check instructions for individual drugs to avoid excessive concentrations and excessive fluids.

#### 2. Observe for therapeutic effects

- With local infections, observe for decreased redness, edema, heat, and pain.
- With systemic infections, observe for decreased fever and white blood cell count, increased appetite, and reports of feeling better.
- With wound infections, observe for decreased signs of local inflammation and decreased drainage. Drainage also may change from purulent to serous.
- With respiratory infections, observe for decreased dyspnea, coughing, and secretions. Secretions may change from thick and colored to thin and white.
- With urinary tract infections, observe for decreased urgency, frequency, and dysuria. If urinalysis is done, check the laboratory report for decreased bacteria and white blood cells.
- Absence of signs and symptoms of infection when given prophylactically

### RATIONALE/EXPLANATION

To maintain therapeutic blood levels  
To decrease binding to foods and inactivation by gastric acid

Several antimicrobial drugs are marketed in powder forms because they are unstable in solution. When mixed, measured amounts of diluent must be added for drug dissolution and the appropriate concentration. Parenteral solutions are usually prepared in the pharmacy. Many solutions require refrigeration to prolong stability. None of the solutions should be used after the expiration date because drug decomposition is likely. To avoid chemical and physical incompatibilities that may cause drug precipitation or inactivation

To decrease tissue irritation

Most antimicrobials that are given IV can be given by intermittent infusion. Although instructions vary with specific drugs, most reconstituted drugs can be further diluted with 50–100 milliliters of IV fluid (D<sub>5</sub>W, NS, D<sub>5</sub>-1/4%, or D<sub>5</sub>-1/2% NaCl). Dilution and slow administration minimize vascular irritation and phlebitis. Flushing ensures that the entire dose is given and prevents contact between drugs in the tubing.

Signs and symptoms of inflammation and infection usually subside within approximately 48 hours after antimicrobial therapy is begun.

Although systemic manifestations of infection are similar regardless of the cause, local manifestations vary with the type or location of the infection.

## NURSING ACTIONS

## RATIONALE/EXPLANATION

## 3. Observe for adverse effects

## a. Hypersensitivity

- (1) Anaphylaxis—hypotension, respiratory distress, urticaria, angioedema, vomiting, diarrhea
- (2) Serum sickness—chills, fever, vasculitis, generalized lymphadenopathy, joint edema and inflammation, bronchospasm, urticaria
- (3) Acute interstitial nephritis (AIN), hematuria, oliguria, proteinuria, pyuria

## b. Superinfection

- (1) Recurrence of systemic signs and symptoms (e.g., fever, malaise)
- (2) New localized signs and symptoms—redness, heat, edema, pain, drainage, cough
- (3) Stomatitis or “thrush”—sore mouth; white patches on oral mucosa; black, furry tongue
- (4) Pseudomembranous colitis—severe diarrhea characterized by blood, pus, and mucus in stools
- (5) Monilial vaginitis—rash in perineal area, itching, vaginal discharge

## c. Phlebitis at IV sites; pain at IM sites

## d. Nausea and vomiting

## e. Diarrhea

## f. Nephrotoxicity

- (1) See AIN, earlier
- (2) Acute tubular necrosis (ATN)—increased blood urea nitrogen and serum creatinine, decreased creatinine clearance, fluid and electrolyte imbalances

## g. Neurotoxicity—confusion, hallucinations, neuromuscular irritability, convulsive seizures

## h. Bleeding—hypoprothrombinemia, platelet dysfunction

## 4. Observe for drug interactions

Reactions are more likely to occur in those with previous hypersensitivity reactions and those with a history of allergy, asthma, or hay fever.

Hypersensitivity may occur with most antimicrobial drugs but is more common with penicillins. Anaphylaxis may occur with oral administration but is more likely with parenteral administration and may occur within 5–30 minutes of injection. Hypotension results from vasodilation and circulatory collapse. Respiratory distress results from bronchospasm or laryngeal edema.

This is a delayed allergic reaction, occurring 1 week or more after the drug is started. Signs and symptoms are caused by inflammation.

AIN is considered a hypersensitivity reaction that may occur with many antimicrobials, including penicillins, cephalosporins, aminoglycosides, sulfonamides, tetracyclines, and others. It is usually reversible if the causative agent is promptly stopped.

Superinfection is a new or secondary infection that occurs during antimicrobial therapy for a primary infection. Superinfections are common and potentially serious because responsible microorganisms are often drug-resistant staphylococci, gram-negative organisms (e.g., *Pseudomonas aeruginosa*), or fungi (e.g., *Candida*).

From overgrowth of fungi

May occur with most antibiotics. Antibiotics suppress normal bacterial flora and allow the overgrowth of *Clostridium difficile*. The organism produces a toxin that kills mucosal cells and produces superficial ulcerations that are visible with sigmoidoscopy. Discontinuing antibiotics and giving metronidazole or oral vancomycin are curative measures. However, relapses may occur.

From overgrowth of yeast organisms

Many antimicrobial parenteral solutions are irritating to body tissues.

These often occur with oral antimicrobials, probably from irritation of gastric mucosa.

Commonly occurs; is caused by irritation of gastrointestinal mucosa and changes in intestinal bacterial flora; and may range from mild to severe. Pseudomembranous colitis is one type of severe diarrhea.

More likely to occur in patients who are elderly or who have impaired renal function.

Aminoglycosides are the antimicrobial agents most often associated with ATN.

More likely with large IV doses of penicillins or cephalosporins, especially in patients with impaired renal function.

Most often associated with penicillins and cephalosporins.

See following chapters. The most significant interactions are those that alter effectiveness or increase drug toxicity.

## Key Concepts

- Bacteria may form mutant strains, alter their structures and functions, or become embedded in a layer of mucus, allowing them to survive in various environments.
- Drug-resistant bacterial strains can be produced in the presence of antimicrobial drugs.
- Anti-infective and antimicrobial agents include antibacterial, antiviral, and antifungal drugs; antibacterial and antibiotic refer to drugs used in bacterial infections.
- The amount and frequency of anti-infective and antimicrobial agents should be individualized according to characteristics of the causative organism, the chosen drug, and the patient's size and condition (e.g., type and severity of infection, ability to use and excrete the chosen drug).
- For most surgeries involving an incision through the skin, a first-generation cephalosporin such as cefazolin (Kefzol) with activity against *S. aureus* or *Streptococcus* species is commonly used.
- Antimicrobial drug therapy requires close monitoring in patients with renal impairment as many drugs are excreted primarily by the kidneys and some are nephrotoxic and may further damage the kidneys.
- Schedule antibiotics at evenly spaced intervals around the clock, to maintain therapeutic blood levels.
- Check specific recommendations with regard to the administration of the antibiotic with food and other medication to decrease binding to food and drugs and prevent inactivation.
- Inappropriate use of antibiotics increases adverse drug effects, infections with drug-resistant microorganisms, and health care costs and reduces the number of available effective drugs for serious or antibiotic-resistant infections.
- Patient education related to antibiotic therapy should stress the importance of completing a full course of antibiotics as prescribed.

## Review and Application Exercises

### Short Answer Exercises

1. How does the body defend itself against infection?
2. When assessing a patient, what signs and symptoms may indicate an infectious process?
3. Do all infections require antimicrobial drug therapy? Why or why not?
4. With antimicrobial drug therapy, what is meant by the terms bacteriostatic, bactericidal, antimicrobial spectrum of activity, and minimum inhibitory concentration?
5. Why is it important to identify the organism causing an infection?
6. Why are infections of the brain, eye, and prostate gland more difficult to treat than infections of the GI, respiratory, and urinary tracts?
7. What factors promote the development of drug-resistant microorganisms, and how can they be prevented or minimized?
8. What are common adverse effects associated with antimicrobial drug therapy?
9. When teaching a patient about a prescribed antibiotic, a common instruction is to take all the medicine and not to stop prematurely. Why is this information important?
10. When a dose of an antibiotic is prescribed to prevent postoperative infection, should it be given before, during, or after surgery? Why?
11. What special precautions are needed for patients with renal or hepatic impairment or critical illness?

### NCLEX-Style Questions

12. When teaching a mother about the antibiotic liquid preparation for her child's acute bronchitis, the nurse should do which of the following?
  - a. Instruct the mother to administer the antibiotic until the child is afebrile.
  - b. Tell the mother to expect the child's respiratory secretions to become thicker and darker as the infection responds to treatment.
  - c. Instruct the mother to keep any remaining antibiotic liquid preparation for the next episode of bronchitis.
  - d. Remind the mother that frequent hand hygiene after handling respiratory secretions is one way to reduce spread of infections.
13. The nurse should give which of the following instructions to patients taking oral antibiotics?
  - a. Take oral antibiotics with a full glass of water.
  - b. Always take an oral antibiotic after a full meal.
  - c. If stomach upset occurs, take the oral antibiotic with a full, fatty meal.
  - d. Do not refrigerate oral liquid antibiotic preparations.
14. Critically ill patients are at increased risk of infections due to resistant organisms for all the following reasons except
  - a. They may have multiple medical conditions.
  - b. Health care workers may spread resistant organisms on their hands in the closed environment.
  - c. They have increased host defenses.
  - d. Equipment used in critical care units may be a fomite for spread between people.

15. A patient is hospitalized with a large sacral wound and a urinary tract infection. The nurse should watch for which of the following signs that the patient is not responding appropriately to antibiotic treatment?
- decreased drainage from the wound
  - increased bacteria and WBC counts on urinalysis
  - decreased pain at the wound site
  - increased activity tolerance
16. To decrease the spread of vancomycin-resistant enterococcus (VRE), the nurse caring for a patient with VRE should do all of the following except
- Use gloves when providing care involving direct patient contact.
  - Thoroughly wash hands after contact with the patient.
  - Clean equipment thoroughly after use by the patient.
  - Ensure that the physician has prescribed vancomycin.

# Beta-Lactam Antibacterials: Penicillins, Cephalosporins, and Other Drugs

## KEY TERMS

- Cross-allergenicity
- Drug resistance
- Hypersensitivity

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe general characteristics of beta-lactam antibiotics.
2. Discuss penicillins in relation to effectiveness, safety, spectrum of antibacterial activity, mechanism of action, indications for use, administration, observation of patient response, and teaching of patients.
3. Differentiate among extended-spectrum penicillins.
4. Question patients about allergies before the initial dose of a penicillin.
5. Describe characteristics of beta-lactamase inhibitor drugs.
6. State the rationale for combining a penicillin and a beta-lactamase inhibitor drug.
7. Discuss similarities and differences between cephalosporins and penicillins.
8. Differentiate cephalosporins in relation to antibacterial spectrum, indications for use, and adverse effects.
9. Describe major characteristics of carbapenem and monobactam drugs.
10. Apply principles of using beta-lactam antibacterials in selected patient situations.

## Applying Your Knowledge

Verra Jang is a 32-year-old professional musician. She is being evaluated for chronic and frequent upper respiratory infections. She is scheduled for a bronchoscopy. The physician orders cefazolin 1 g IV immediately before the procedure.

.....

## Introduction

Beta-lactam antibacterials derive their name from the beta-lactam ring that is part of their chemical structure. An intact beta-lactam ring is essential for antibacterial activity. Several gram-positive and gram-negative bacteria produce beta-lactamase enzymes that disrupt the beta-lactam ring and inactivate the drugs. This is a major mechanism by which microorganisms acquire resistance to

beta-lactam antibiotics. Penicillinase and cephalosporinase are beta-lactamase enzymes that act on penicillins and cephalosporins, respectively.

Despite the common element of a beta-lactam ring, characteristics of beta-lactam antibiotics differ widely because of variations in their chemical structures. The drugs may differ in antibacterial spectrum of activity, routes of administration, susceptibility to beta-lactamase enzymes, and adverse effects. Beta-lactam antibiotics include penicillins, cephalosporins, carbapenems, and monobactams, which are described in the following sections. Routes and usual dosage ranges are listed in the Drugs at a Glance tables.

Beta-lactam antibacterial drugs inhibit synthesis of bacterial cell walls by binding to proteins (penicillin-binding proteins) in bacterial cell membranes. This binding produces a defective cell wall that allows intracellular contents to leak out, destroying the microorganism. Beta-lactam antibiotics are most effective when bacterial cells are dividing.

## Penicillins

The penicillins are effective, safe, and widely used antibacterial agents. The first antibiotic developed was penicillin, which was discovered from the *Penicillium* mold and serves as the prototype. When **P penicillin** was introduced, it was effective against many organisms, had to be given parenterally because it was destroyed by gastric acid, and injections were painful. With extensive use, strains of drug-resistant staphylococci appeared. Semisynthetic derivatives, formed by adding side chains to the penicillin nucleus, were developed to increase gastric acid stability, beta-lactamase stability, and antimicrobial spectrum of activity, especially against gram-negative microorganisms.

After absorption, penicillins are widely distributed and achieve therapeutic concentrations in most body fluids. Thera-

peutic levels are not usually obtained in intraocular and cerebrospinal fluids (CSF) unless inflammation is present because normal cell membranes act as barriers to drug penetration. Penicillins are rapidly excreted by the kidneys and produce high drug concentrations in the urine (an exception is nafcillin, which is excreted by the liver).

### Indications for Use

Clinical indications for use of penicillins include bacterial infections caused by susceptible microorganisms. As a class, penicillins usually are more effective in infections caused by gram-positive bacteria than those caused by gram-negative bacteria. However, their clinical uses vary significantly according to the subgroup or individual drug and microbial patterns of resistance. The drugs are often useful in skin/soft tissue, respiratory, gastrointestinal, and genitourinary infections. However, the incidence of resistance among streptococci, staphylococci, and other microorganisms continues to grow.

### Contraindications to Use

Contraindications include hypersensitivity or allergic reactions to any penicillin preparation. An allergic reaction to one penicillin means the patient is allergic to all members of the penicillin class. The potential for *cross-allergenicity* (allergy to a drug of another class with similar chemical structure) with cephalosporins and carbapenems exists, although recent data suggest that the incidence is less than 1%, lower than previously thought. Administration of cephalosporins or carbapenems should be avoided in individuals with life-threatening allergic reactions to penicillin (anaphylaxis, laryngeal swelling, angioedema, or hives).

### Subgroups and Individual Penicillins

Table 30-1 provides pertinent information about individual penicillins.

Table 30-1

Drugs at a Glance: Penicillins

Generic/Trade Name	ROUTES AND USUAL DOSAGE RANGES	
	Adults	Children
<b>Penicillins G and V</b>		
Penicillin G potassium and sodium (Pfizerpen)	IM 300,000–8 million units daily IV 6–20 million units daily by continuous or intermittent infusion every 2–4h. Up to 60 million units daily have been given in certain serious infections.	IM, IV 25,000–400,000 units/kg/d in divided doses q4–6h (maximum dose 24 million units/d)
Penicillin G benzathine (Bicillin LA)	IM 1.2–2.4 million units in a single dose Prophylaxis of recurrent rheumatic fever, IM 1.2 million units q 3–4 wk Treatment of syphilis, IM 2.4 million units (1.2 million units in each buttock) in a single dose.	IM 25,000–50,000 units/kg (maximum 2.4 million units) Prophylaxis of recurrent rheumatic fever, 25,000–50,000 units/kg times one dose q 3–4 wk (maximum 1.2 million units)

(continued on page 488)

Table 30-1

## Drugs at a Glance: Penicillins (continued)

Generic/Trade Name	ROUTES AND USUAL DOSAGE RANGES	
	Adults	Children
Penicillin G procaine (Wycillin)	IM 600,000–4.8 million units daily in 1 or 2 doses	IM 25,000–50,000 units/kg/d in divided doses q12–24 h
Penicillin V (Veetids)	PO 125–500 mg q6–8h	12 y and older: same as adults under 12 y: PO 25–50 mg/kg/d every 6–8 h.
<b>Penicillinase-Resistant (Antistaphylococcal) Penicillins</b>		
Dicloxacillin	PO 125–1000 mg every 6 h	Not recommended in newborns 40 kg or less: 12.5–100 mg/kg/d divided every 6 h 40 kg or more: 125–500 mg every 6 h
Nafcillin	IM 500 mg every 4–6 h IV 500 mg–2 g every 4–6 h; maximum daily dose 18 g for serious infections.	IM 25 mg/kg every 12 h IV 50–200 mg/kg/d in divided doses every 4–6 h
Oxacillin	IM, IV, 250–2000 mg every 4–6 h	40 kg or less: IM, IV 100–200 mg/kg/d in divided doses every 6 h more than 40 kg: same as adults
<b>Aminopenicillins</b>		
Ampicillin (Principen)	PO, IM, IV 250–500 mg every 6 h. In severe infections, doses up to 2 g every 4 h may be given IV.	Infants/children: PO 50–100 mg/kg/d in divided doses every 6 h (maximum dose 2.4 g/d) IM, IV: 100–400 mg/kg/d in divided doses every 6 h (maximum dose 12 g/d)
Amoxicillin (Amoxil, Trimox)	PO 250–500 mg every 8 h or 500–875 mg every 12 h	3 months or more: PO 20–30 mg/kg/d in divided doses every 12 h more than 3 months: 20–50 mg/kg/d in divided doses every 8–12 h
<b>Extended Spectrum (Antipseudomonal) Penicillins</b>		
Carbenicillin indanyl sodium (Geocillin)	PO 1–2 tabs 4 times daily	PO 30–50 mg/kg/d in divided doses q6h
Ticarcillin (Ticar)	IM, IV 1–4 g q4–6h. IM injections should not exceed 2 g/injection.	Infants/children: IM 50–100 mg/kg/d in divided doses q6–8h. IV 50–300 mg/kg/d in divided doses q4–8h (maximum dose 24 g/d).
Piperacillin (Pipracil)	IM, IV 200–300 mg/kg/d in divided doses q4–6h. Usual adult dosage, 3–4 g q4–6h; maximum daily dose 24 g.	less than 12 y: Dosage not established
<b>Penicillin–Beta-Lactamase Inhibitor Combinations</b>		
Ampicillin-sulbactam (Unasyn)	IM, IV 1.5–3 g q6h	1 y or older: IV 100–400 mg/kg/d in divided doses q6h (maximum 8 g ampicillin/day; 12 g Unasyn) Doses up to 300 mg/kg/day may be given for severe infections in infants older than 1 month of age
Amoxicillin-clavulanate (Augmentin)	PO 250–500 mg q8h; or 875 mg q12h	40 kg or more: same as adults less than 40 kg: 20–90 mg/kg/d in divided doses q8–12h
Piperacillin-tazobactam (Zosyn)	IV 2.25–4.5 g q6–8h	IV 100 mg/kg/d q8h
Ticarcillin-clavulanate (Timentin)	IV 3.1 g q4–6h	Weight less than 60 kg: IV 200–300 mg/kg/d in divided doses q4–6h (maximum dose 18–24 g/d)

## Penicillins G and V

**Penicillin G** (Pfizerpen, Bicillin, Wycillin) remains effective for a limited number of uses. Many strains of staphylococci and gonococci have acquired resistance to penicillin G, preventing its use for treatment of infections caused by these organisms. Some strains of streptococci have acquired resistance to penicillin G, although the drug is still effective in many streptococcal infections. It remains the drug of choice for the treatment of streptococcal pharyngitis, for prevention of recurrent attacks in patients who have had previous acute rheumatic fever due to group A streptococcus, and for treatment of neurosyphilis.

Penicillin G is not effective orally because it is inactivated by gastric acid. Several preparations of penicillin G are available for intravenous (IV) and intramuscular (IM) administration; however, it is important to note that the IV and IM forms of penicillin G can not be used interchangeably. Only aqueous preparations can be given IV. Preparations containing benzathine or procaine can be given only IM. A **BLACK BOX WARNING** alerts health care providers that inadvertent IV administration of penicillin G benzathine may result in cardiopulmonary arrest and death. Long-acting repository forms have additives that decrease their solubility in tissue fluids and delay their absorption.

**Penicillin V** (Veetids) is derived from penicillin G and has the same antibacterial spectrum. It is not destroyed by gastric acid and is given only by the oral route. It is well absorbed and produces therapeutic blood levels.

## Penicillinase-Resistant (Antistaphylococcal) Penicillins

This group includes three drugs (**dicloxacillin**, **nafcillin**, and **oxacillin**) that are the drugs of choice for methicillin-susceptible *Staphylococcus aureus*. These drugs are formulated to resist the penicillinases that inactivate other penicillins. An older member of this group, methicillin, is no longer marketed for clinical use. However, susceptibility of bacteria to the antistaphylococcal penicillins is determined by exposing the bacteria to methicillin (methicillin susceptible or resistant) or oxacillin (oxacillin susceptible or resistant) in bacteriology laboratories. Although called “methicillin resistant,” these staphylococcal microorganisms are also resistant to other antistaphylococcal penicillins.

## Aminopenicillins

**Ampicillin** (Principen) is broad-spectrum, semisynthetic penicillin that is bactericidal for several types of gram-positive and gram-negative bacteria. It has been effective against enterococci, *Proteus mirabilis*, *Salmonella*, *Shigella*, and *Escherichia coli*, but resistant forms of these organisms are increasing. It is ineffective against penicillinase-producing staphylococci and gonococci.

Ampicillin is excreted mainly by the kidneys; thus, it is useful in some urinary tract infections (UTI). Because some is excreted in bile, it is useful in biliary tract infections not caused by biliary obstruction. It is used in the treatment of bronchitis, sinusitis, and otitis media.

**P Amoxicillin** (Amoxil, Trimox) is similar to ampicillin except it is only available orally. It is better absorbed and produces therapeutic blood levels more rapidly than oral ampicillin. It also causes less gastrointestinal distress.

The aminopenicillins are drugs of choice for prevention of bacterial endocarditis due to procedures that produce transient bacteremia.

## Extended-Spectrum (Antipseudomonal) Penicillins

The drugs in this group (**carbenicillin** [Geocillin], **ticarcillin**, and **piperacillin**) have a broad spectrum of antimicrobial activity, especially against gram-negative organisms such as *Pseudomonas* and *Proteus* species and *E. coli*. For pseudomonal infections, one of these drugs is usually given concomitantly with an aminoglycoside or a fluoroquinolone (see Chap. 31). Carbenicillin is available as an oral formulation for UTI or prostatitis caused by susceptible pathogens. The other drugs are usually given by intermittent IV infusion, although most can be given IM.

## Penicillin–Beta-Lactamase Inhibitor Combinations

Beta-lactamase inhibitors are drugs with a beta-lactam structure but little antibacterial activity. They bind with and inactivate the beta-lactamase enzymes produced by many bacteria (e.g., *E. coli*; *Klebsiella*, *Enterobacter*, and *Bacteroides* species; *S. aureus*). When combined with a penicillin, the beta-lactamase inhibitor protects the penicillin from destruction by the enzymes and extends the penicillin’s spectrum of antimicrobial activity. Thus, the combination drug may be effective in infections caused by bacteria that are resistant to a beta-lactam antibiotic alone. Clavulanate, sulbactam, and tazobactam are the beta-lactamase inhibitors available in combinations with penicillins.

**Unasyn** is a combination of ampicillin and sulbactam available in vials with 1 gram of ampicillin and 0.5 grams of sulbactam, or 2 grams of ampicillin and 1 gram of sulbactam. **Augmentin** contains amoxicillin and clavulanate. It is available in 250-, 500-, and 875-milligram tablets, each of which contains 125 milligrams of clavulanate. Thus, two 250-milligram tablets are not equivalent to one 500-milligram tablet. It is also available as 1000-milligram extended-release tablets containing 62.5 milligrams of clavulanate. In addition, a chewable formulation is available as 400 milligrams of amoxicillin and 57 milligrams of clavulanate. Timentin is a combination of ticarcillin and clavulanate in an IV formulation containing 3 grams of ticarcillin and 100 milligrams of clavulanate. Zosyn is a combination of piperacillin and tazobactam in an IV formulation. Three dosage strengths are available, with 2 grams piperacillin and 0.25 grams tazobactam, 3 grams piperacillin and 0.375 grams tazobactam, or 4 grams piperacillin and 0.5 grams tazobactam.

## Cephalosporins

Cephalosporins are a widely used group of drugs derived from a fungus. Although technically cefoxitin and cefotetan

(cephamycins derived from a different fungus) are not cephalosporins, they are categorized with the cephalosporins because of their similarities to the group. Cephalosporins are broad-spectrum agents with activity against both gram-positive and gram-negative bacteria. Compared with penicillins, they are in general less active against gram-positive organisms but more active against gram-negative ones.

After they are absorbed, cephalosporins are widely distributed into most body fluids and tissues, with maximum concentrations in the liver and kidneys. Many cephalosporins do not reach therapeutic levels in CSF; exceptions are cefuroxime, a second-generation drug, and the third-generation agents. These drugs reach therapeutic levels when meninges are inflamed. Most cephalosporins are excreted through the kidneys. An exception includes ceftriaxone, which undergoes dual elimination via the biliary tract and kidneys. Cefotaxime is primarily metabolized in the liver to an active metabolite, desacetylcefotaxime, which is eliminated by the kidneys.

## Indications for Use

Clinical indications for the use of cephalosporins include surgical prophylaxis and treatment of infections of the respiratory tract, skin and soft tissues, bones and joints, urinary tract, brain and spinal cord, and bloodstream (septicemia). In most infections with streptococci and staphylococci, penicillins are more effective and less expensive. In infections caused by MRSA, cephalosporins are not clinically effective even if *in vitro* testing indicates susceptibility. Infections caused by *Neisseria gonorrhoeae*, at one time susceptible to penicillin, are now treated with a third-generation cephalosporin such as ceftriaxone. Cefepime is indicated for use in sepsis; in severe infections of the lower respiratory and urinary tracts, skin and soft tissue, and female reproductive tract; and in febrile neutropenic patients. It may be used as monotherapy for all infections caused by susceptible organisms except *Pseudomonas aeruginosa*; a combination of drugs should be used for serious pseudomonal infections.

## Contraindications to Use

A contraindication to the use of a cephalosporin is a previous severe anaphylactic reaction to a penicillin. Because cephalosporins are chemically similar to penicillins, there is a risk of cross-sensitivity. However, incidence of cross-sensitivity is low, especially in patients who have had delayed reactions (e.g., skin rash) to penicillins. Another contraindication is cephalosporin allergy. Immediate allergic reactions with anaphylaxis, bronchospasm, and urticaria occur less often than delayed reactions with skin rash, drug fever, and eosinophilia.

## Classification

Tables 30-2 and 30-3 provide important information about oral and parenteral cephalosporins.

### First-Generation Cephalosporins

The first cephalosporin, cephalothin, is no longer available for clinical use. However, it is used for determining susceptibility to first-generation cephalosporins, which have essentially the

same spectrum of antimicrobial activity. These drugs are effective against streptococci; staphylococci (except MRSA); *Neisseria*, *Salmonella*, *Shigella*, *Escherichia*, *Klebsiella*, and *Bacillus* species; *Corynebacterium diphtheriae*; *P. mirabilis*; and *Bacteroides* species (except *Bacteroides fragilis*). They are not effective against *Enterobacter*, *Pseudomonas*, and *Serratia* species. Cefazolin is the drug of choice for surgical prophylaxis in most surgical procedures.

### Second-Generation Cephalosporins

Second-generation cephalosporins are more active against some gram-negative organisms and against anaerobic organisms than the first-generation drugs. Thus, they may be effective in infections resistant to other antibiotics, including infections caused by *Haemophilus influenzae*, *Klebsiella* species, *E. coli*, and some strains of *Proteus*. Because each of these drugs has a different antimicrobial spectrum, susceptibility tests must be performed for each drug rather than for the entire group, as may be done with first-generation drugs. Cefoxitin (Mefoxin), for example, is active against *B. fragilis*, an anaerobic organism resistant to most drugs.

### Third-Generation Cephalosporins

Third-generation cephalosporins further extend the spectrum of activity against gram-negative organisms. In addition to activity against the usual enteric pathogens (e.g., *E. coli*, *Proteus* and *Klebsiella* species), they are also active against several strains resistant to other antibiotics and to first- and second-generation cephalosporins. Thus, they may be useful in infections caused by unusual strains of enteric organisms such as *Citrobacter*, *Serratia*, and *Providencia* species. Another difference is that third-generation cephalosporins penetrate inflamed meninges to reach therapeutic concentrations in CSF. Thus, they may be useful in meningeal infections caused by common pathogens, including *H. influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*. Although some of the drugs are active against *Pseudomonas* organisms, drug-resistant strains may emerge when a cephalosporin is used alone for treatment of pseudomonal infection.

Overall, cephalosporins gain gram-negative activity and lose gram-positive activity as they move from the first to the third generation. The second- and third-generation drugs are more active against gram-negative organisms because they are more resistant to the beta-lactamase enzymes (cephalosporinases) produced by some bacteria to inactivate cephalosporins.

### Fourth-Generation Cephalosporins

Fourth-generation cephalosporins have a greater spectrum of antimicrobial activity and greater stability against breakdown by beta-lactamase enzymes compared with third-generation drugs. Cefepime is the first fourth-generation cephalosporin to be developed. It is active against both gram-positive and gram-negative organisms. With gram-positive organisms, it is active against streptococci and staphylococci (except for methicillin-resistant staphylococci). With gram-negative organisms, its activity against *P. aeruginosa* is similar to that of ceftazidime and its activity against Enterobacteriaceae is greater than that

Table 30-2

## Drugs at a Glance: Oral Cephalosporins

Generic/ Trade Name	Characteristics/Indications	ROUTES AND USUAL DOSAGE RANGES	
		Adults	Children
<b>First Generation</b>			
<b>Cefadroxil</b> (Duricef)	A derivative of cephalexin that has a longer half-life and can be given less often	PO 1–2 g twice daily	30 mg/kg/d in divided doses q12h
<b>Cephalexin</b> (Keflex)	First oral cephalosporin; still used extensively	PO 250–500 mg q6h, increased to 4 g q6h if necessary in severe infections	PO 25–50 mg/kg/d in divided doses q6h
<b>Second Generation</b>			
<b>Cefaclor</b> (Ceclor)	More active against <i>Hemophilus influenzae</i> and <i>Escherichia coli</i> than first-generation drugs	PO 250–500 mg q8h	PO 20–40 mg/kg/d in divided doses q8–12 h
<b>Cefprozil</b> (Cefzil)	Similar to cefaclor	PO 250–500 mg q12–24h	PO 7.5–15 mg/kg in divided doses q12 h
<b>Cefuroxime</b> (Ceftin)	1. Can also be given parenterally 2. The tablet may be crushed and added to a food (e.g., apple-sauce), but the crushed tablet leaves a strong, bitter, persistent aftertaste.	PO 250–500 mg q12h; IV, IM 750 mg–1.5 g every 6–8 h	<i>under 13 y</i> : PO 20–30 mg/kg/d in two divided doses. IM, IV 75–150 mg/kg/d in divided doses q8h (maximum dose 6 g/d) <i>13 y or older</i> : same as adults
<b>Third Generation</b>			
<b>Cefdinir</b> (Omnicef)	Indicated for bronchitis, pharyngitis, and otitis media caused by streptococci or <i>H. influenzae</i>	PO 300 mg q12h or 600 mg q24h for 10 d	<i>13 y or older</i> , PO same as adults <i>6 mo–12 y</i> , PO 7 mg/kg q12h or 14 mg/kg q24h for 10 d
<b>Cefditoren pivoxil</b> (Spectracef)	Indicated for pharyngitis, bacterial exacerbations of chronic bronchitis, and skin/skin structure infections	Bronchitis or pharyngitis, PO 400 mg twice daily (q12h) for 10 d Skin infections, PO 200 mg twice daily for 10 d	<i>12 y or older</i> , same as adults
<b>Cefixime</b> (Suprax)	First oral third-generation drug	PO 200 mg q12h or 400 mg q24h	Children ≥ 6mo: 8–20 mg/kg/d in divided doses every 12–24 h. (maximum dose 400 mg/d) PO give adult dose to children 50 kg of weight or 12 y or older
<b>Cefpodoxime</b> (Vantin)	Similar to cefixime except has some activity against staphylococci (except methicillin-resistant <i>Staphylococcus aureus</i> )	PO 200–400 mg q12h	PO 5 mg/kg q12h Give 10 mg/kg (400 mg or adult dose) to children 13 y or older with skin and soft-tissue infections
<b>Ceftibuten</b> (Dax)	1. Indicated for bronchitis, otitis media, pharyngitis, or tonsillitis caused by streptococci or <i>H. influenzae</i> 2. Can be given once daily 3. Available in a capsule for oral use and an oral pediatric suspension that comes in two concentrations (90 mg/5 mL)	PO 400 mg daily for 10 d	9 mg/kg/d for 10 d (maximum dose 400 mg d.)

Table 30-3

## Drugs at a Glance: Parenteral Cephalosporins

Generic/ Trade Name	Characteristics/ Indications	ROUTES AND USUAL DOSAGE RANGES	
		Adults	Children
<b>First Generation</b>			
<b>Cefazolin</b> (Kefzol, Ancef)	Active against streptococci, staphylococci, <i>Neisseria</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Escherichia</i> , <i>Klebsiella</i> , <i>Listeria</i> , <i>Bacillus</i> , <i>Hemophilus influenzae</i> , <i>Corynebacterium diphtheriae</i> , <i>Proteus mirabilis</i> , and <i>Bacteroides</i> (except <i>B. fragilis</i> )	IM, IV 250 mg–2 g q6–12h (maximum dose 12 g/d)	IM, IV 25–100 mg/kg/d in divided doses q6–8h (maximum dose 6 g/d)
<b>Second Generation</b>			
<b>Cefotetan</b> (Cefotan)	<ol style="list-style-type: none"> <li>1. Effective against most organisms except <i>Pseudomonas</i></li> <li>2. Highly resistant to beta-lactamase enzymes</li> </ol>	IV, IM 1–6 g/day in divided doses q12h Surgical prophylaxis, IV 1–2 g 30–60 min before surgery	Dosage not established
<b>Cefoxitin</b> (Mefoxin)	<ol style="list-style-type: none"> <li>1. The first cephamycin (derived from a different fungus than cephalosporins)</li> <li>2. A major clinical use may stem from increased activity against <i>B. fragilis</i>, an organism resistant to most other antimicrobial drugs.</li> </ol>	IV 1–2 g q6–8h Surgical prophylaxis, IV 1 or 2 g 30–60 min before surgery	IV 80–160 mg/kg/d in divided doses q4–6h. Do not exceed 12 g/d.
<b>Cefuroxime</b> (Kefurox, Zinacef)	<ol style="list-style-type: none"> <li>1. Similar to other second generation cephalosporins</li> <li>2. Penetrates cerebrospinal fluid in presence of inflamed meninges</li> </ol>	IV, IM, 750 mg–1.5 g q6–8h Surgical prophylaxis, IV 1.5 g 30–60 min before initial skin incision	Neonates: IM, IV 50–100 mg/kg/d in divided doses q 12h <13 y: PO 20–30 mg/kg/d in divided doses q12h. IM, IV 75–150 mg/kg/d in divided doses q8h (maximum dose 6 g/d).
<b>Cefotaxime</b> (Claforan)	<ol style="list-style-type: none"> <li>1. Antibacterial activity against most gram-positive and gram-negative bacteria, including several strains resistant to other antibiotics</li> <li>2. Recommended for serious infections caused by susceptible microorganisms</li> </ol>	IV, IM 1–2 g q4–12h; maximum dose, 12 g/24 h	Weight >50 kg: same as adults Weight <50 kg to 12y and age > 1 mo: IV, IM 50–200 mg/kg/d, in divided doses q6–8h
<b>Ceftazidime</b> (Fortaz)	<ol style="list-style-type: none"> <li>1. Active against gram-positive and gram-negative organisms</li> <li>2. Especially effective against gram-negative organisms, including <i>Pseudomonas aeruginosa</i> and other bacterial strains resistant to aminoglycosides</li> <li>3. Dosage must be reduced with renal impairment.</li> </ol>	IV 1–2 g q6–12h IM 0.5–1 g q12h	IM, IV 50 mg/kg q8–12h, not to exceed recommended adult dose

of third-generation cephalosporins. Moreover, cefepime retains activity against strains of Enterobacteriaceae and *P. aeruginosa* that have acquired resistance to third-generation agents.

### Applying Your Knowledge 30-1

Why is cefazolin the drug of choice for Ms. Jang's bronchoscopy?

## Carbapenems

Carbapenems are broad-spectrum, bactericidal beta-lactam antimicrobials. Like other beta-lactam drugs, they inhibit synthesis of bacterial cell walls by binding with penicillin-binding proteins. The group consists of three drugs (Table 30-4).

**Imipenem-cilastatin** (Primaxin) is given parenterally and distributed in most body fluids. When given alone, the antibiotic imipenem is rapidly broken down by an enzyme (dehydropeptidase) in renal tubules and therefore reaches only low concentrations in the urine. Imipenem is formulated with cilastatin, which inhibits the destruction of imipenem by the enzyme. The addition of cilastatin increases the urinary concentration of imipenem, and reduces the potential renal toxicity of the antibacterial agent. Recommended doses indicate the amount of imipenem; the solution contains an equivalent amount of cilastatin.

The drug is effective in infections caused by a wide range of bacteria, including penicillinase-producing staphylococci, *E. coli*, *Proteus* species, *Enterobacter–Klebsiella–Serratia* species, *P. aeruginosa*, and *Enterococcus faecalis*. Its main use is treatment of infections caused by organisms resistant to other drugs. Adverse effects are similar to those of other beta-lactam antibiotics, including the risk of cross-sensitivity in patients with penicillin hypersensitivity. Central nervous system toxicity, including seizures, has been reported. Seizures are more likely in patients with a seizure disorder or when recommended doses are exceeded; however, they have occurred in other patients as well. To prepare the solution for IM injection, lidocaine, a local anesthetic, is added to decrease pain. This solution is contraindicated in people allergic to this type of local anesthetic or who have severe shock or heart block.

**Meropenem** (Merrem) has a broad spectrum of antibacterial activity and may be used as a single drug for empiric therapy before causative microorganisms are identified. It is effective against penicillin-susceptible staphylococci and *S. pneumoniae*, most gram-negative aerobes (e.g., *E. coli*, *H. influenzae*, *Klebsiella pneumoniae*, *P. aeruginosa*), and some anaerobes, including *B. fragilis*. It is indicated for use in intra-abdominal infections and bacterial meningitis caused by susceptible organisms. Adverse effects are similar to those of imipenem.

**Ertapenem** (Invanz) also has a broad spectrum of antibacterial activity, although it is more limited than imipenem and meropenem. It is approved for complicated intra-abdominal, skin and skin structure, acute pelvic, and urinary tract infections. It can be used to treat community-acquired pneu-

Table 30-4

## Drugs at a Glance: Carbapenems and Monobactams

Generic/Trade Name	ROUTES AND USUAL DOSAGE RANGES	
	Adults	Children
<b>Carbapenems</b>		
Ertapenem (Invanz)	IV 1 g once daily over 15–30 min	3 mo–12 y: IV, IM 15 mg/kg twice daily (maximum dose 1g/d)
Imipenem-cilastatin (Primaxin)	IV 250–1000 mg q6–8h (maximum dose 4g/d) IM 500–750 mg q12h	>3 mo: Non-CNS infections IV 15–25 mg/kg q6h
Meropenem (Merrem)	IV 1.5–6 g/d in divided doses q8h	≥3 mo: 60 mg/kg in divided doses q8h (maximum dose 6 g/d)
<b>Monobactam</b> aztreonam (Azactam)	For UTI: IM, IV 0.5–1.0 g q8–12h For moderate systemic infection: IM, IV 1 g q8–12h or IV 2 g q8–12h For meningitis: IV 2 g q6–8h	IM, IV 30 mg/kg q6–8h

UTI, urinary tract infection.

monia caused by penicillin-susceptible *S. pneumoniae*. Unlike imipenem and meropenem, ertapenem does not have in vitro activity against *P. aeruginosa* and *Acinetobacter baumannii*.

Ertapenem shares the adverse effect profile of the other carbapenems. Lidocaine is also used in preparation of the solution for IM injection to decrease pain with administration, and the same cautions should be used as with imipenem.

## Monobactam

**Aztreonam** (Azactam) (see Table 30-4) is active against gram-negative bacteria, including Enterobacteriaceae and *P. aeruginosa*, and many strains that are resistant to multiple antibiotics. Activity against gram-negative bacteria is similar to that of the aminoglycosides, but the drug does not cause kidney damage or hearing loss. Aztreonam is stable in the presence of beta-lactamase enzymes. Because gram-positive and anaerobic bacteria are resistant to aztreonam, the drug's ability to preserve normal gram-positive and anaerobic flora may be an advantage over other antimicrobial agents.

Indications for use include infections of the urinary tract, skin and skin structures, and lower respiratory tract, as well as intra-abdominal and gynecologic infections and septicemia. Adverse effects are similar to those for penicillin, including possible hypersensitivity reactions.

## Nursing Process

General aspects of the nursing process in antimicrobial drug therapy, as described in Chapter 29, apply to the patient receiving penicillins, cephalosporins, aztreonam, and car-

bapenems. In this chapter, only those aspects related specifically to these drugs are included.

## Assessment

With penicillins, ask patients if they have ever taken a penicillin and, if so, whether they ever had a skin rash, hives, swelling, or difficulty breathing associated with the drug. With cephalosporins, ask patients if they have ever taken one of the drugs, as far as they know, and whether they ever had a severe reaction to penicillin. Naming a few cephalosporins (e.g., Ceclor, Keflex, Rocephin, Suprax) may help the patient identify previous usage.

## Nursing Diagnoses

- Risk for Injury: Hypersensitivity reactions with penicillins or cephalosporins
- Risk for Injury: Renal impairment with cephalosporins
- Deficient Knowledge: Correct home care administration and usage of oral beta-lactams

## Planning/Goals

### The patient will

- Take oral beta-lactam antibacterials as directed
- Receive parenteral beta-lactam drugs by appropriate techniques to minimize tissue irritation
- Receive prompt and appropriate treatment if hypersensitivity reactions occur

## Interventions

- After giving a penicillin parenterally in an outpatient setting, keep the patient in the area for at least 30 minutes.

Anaphylactic reactions are more likely to occur with parenteral than oral use and within a few minutes after injection.

- In any patient care setting, keep emergency equipment and supplies readily available.
- Monitor patient response to beta-lactam drugs.
- Monitor dosages of beta-lactam drugs for patients with impaired renal function.
- Provide patient teaching regarding drug therapy (see accompanying displays).

### Evaluation

- Observe for improvement in signs of infection.
- Interview and observe for adverse drug effects.

## Principles of Therapy

### Goal of Therapy

The goal of antimicrobial therapy is to prevent or treat infections caused by pathogenic microorganisms.

### Drug Selection

Choice of a beta-lactam antibacterial depends on the organism causing the infection, severity of the infection, and other factors.

### Penicillins

Penicillin G or amoxicillin is the drug of choice in many infections. An antipseudomonal penicillin is indicated in *Pseudo-*

*monas* infections. An antistaphylococcal penicillin is indicated in staphylococcal infections; antistaphylococcal drugs of choice are nafcillin for IV use and dicloxacillin for oral use.

### Cephalosporins

First-generation drugs are often used for surgical prophylaxis, especially with prosthetic implants, because gram-positive organisms such as staphylococci cause most infections of surgical sites. They may also be used alone for treatment of infections caused by susceptible organisms in body sites where drug penetration and host defenses are adequate. Cefazolin (Kefzol) is a frequently used parenteral agent. It reaches a higher serum concentration, is more protein bound, and has a slower rate of elimination than other first-generation drugs. These factors prolong serum half-life, so cefazolin can be given less frequently. Cefazolin may also be administered IM.

Second-generation cephalosporins are also often used for surgical prophylaxis, especially for gynecologic and colorectal surgery. They are also used for treatment of intra-abdominal infections such as pelvic inflammatory disease, diverticulitis, penetrating wounds of the abdomen, and other infections caused by organisms inhabiting pelvic and colorectal areas.

Third-generation cephalosporins are recommended for serious infections caused by susceptible organisms that are resistant to first- and second-generation cephalosporins. They are often used in the treatment of infections caused by *E. coli*; *Proteus*, *Klebsiella*, and *Serratia* species; and other Enterobacteriaceae, especially when the infections occur in body sites not readily reached by other drugs (e.g., CSF, bone) and in patients with immunosuppression. Although effective against many *Pseudomonas* strains, these drugs should not be used alone in treating pseudomonal infections because *drug resistance* (inability to be eradicated by antibiotics) develops.

## Patient Teaching Guidelines

### Oral Penicillins

#### General Considerations

- Do not take any penicillin if you have ever had an allergic reaction to penicillin in which you had difficulty breathing, swelling, or skin rash. However, some people call a minor stomach upset an allergic reaction which is incorrect, and are not given penicillin when that is the best antibiotic in a given situation.
- Complete the full course of drug treatment for greater effectiveness and prevention of secondary infection with drug-resistant bacteria.
- Follow instructions carefully about the dose and how often it is taken. Drug effectiveness depends on maintaining adequate blood levels.
- Penicillins often need more frequent administration than some other antibiotics, because they are rapidly excreted by the kidneys.

#### Self- or Caregiver Administration

- Take most penicillins on an empty stomach, 1 hour before or 2 hours after a meal. Penicillin V, amoxicillin, and Augmentin can be taken with food.

- Take each dose with a full glass of water; do not take with orange juice or with other acidic fluids (they may destroy the drug).
- Take at even intervals, preferably around the clock.
- Shake liquid penicillins well, to mix thoroughly and measure the dose accurately.
- Discard liquid penicillin after 1 week if stored at room temperature or after 2 weeks if refrigerated. Liquid forms deteriorate and should not be taken after their expiration dates.
- Report skin rash, hives, itching, severe diarrhea, shortness of breath, fever, sore throat, black tongue, or any unusual bleeding. These symptoms may indicate an allergy to penicillin.
- Augmentin: Take with meals to increase absorption and decrease gastrointestinal upset.

## Patient Teaching Guidelines

## Oral Cephalosporins

### General Considerations

- Inform your physician if you have ever had a severe allergic reaction to penicillin in which you had difficulty breathing, swelling, or skin rash. A small number of people are allergic to both penicillins and cephalosporins because the drugs are somewhat similar in their chemical structures.
- Also inform your physician if you have had a previous allergic reaction to a cephalosporin (e.g., Ceclor, Keflex). If not sure whether a new prescription is a cephalosporin, ask the pharmacist before having the prescription filled.
- Complete the full course of drug treatment for greater effectiveness and prevention of secondary infection with drug-resistant bacteria.
- Follow instructions about dosing frequency; effectiveness depends on maintaining adequate blood levels.

### Self- or Caregiver Administration

- Take most oral drugs with food or milk to prevent stomach upset.

- Take cefpodoxime (Vantin) and cefuroxime (Ceftin) with food to increase absorption.
- Do not take cefaclor, cefdinir (Omnicef), or cefpodoxime (Vantin) with antacids containing aluminum or magnesium (e.g., Maalox, Mylanta) or with Pepcid, Tagamet, or Zantac. These drugs decrease absorption of these antibiotics and make them less effective. If necessary to take one of the drugs, take it 2 hours before or 2 hours after a dose of these antibiotics.
- Shake liquid preparations well to mix thoroughly and measure the dose accurately.
- Report the occurrence of diarrhea, especially if it is severe or contains blood, pus, or mucus. Cephalosporins can cause antibiotic-associated colitis and the drug may need to be stopped.
- Inform the prescribing physician if you are breast-feeding. These drugs enter breast milk.

Fourth-generation drugs are most useful in serious gram-negative infections, especially infections caused by organisms resistant to third-generation drugs. Cefepime has the same indications for use as ceftazidime, a third-generation drug.

## Drug Dosage and Administration

Choice of route and dosage depends mainly on the severity of the infection being treated. For serious infections, beta-lactam antibacterials are usually given IV in large doses. With penicillins, most must be given every 4 to 6 hours to maintain therapeutic blood levels, because the kidneys rapidly excrete them. The oral route is often used for less serious infections and for long-term prophylaxis of rheumatic fever. The IM route is rarely used in hospitalized patients but may be used in ambulatory settings. With cephalosporins, a few are sufficiently absorbed for oral administration; these are most often used in mild infections and UTI. Although some cephalosporins can be given IM, the injections may cause pain and irritation. Cefazolin is preferred for IM administration because it is less irritating to tissues.

## Hypersensitivity to Penicillins

Before giving the initial dose of any penicillin preparation, ask the patient if he or she has ever taken penicillin and, if so, whether an allergic reaction occurred. Penicillin is the most common cause of drug-induced anaphylaxis, a life-threatening *hypersensitivity* (allergic) reaction, and a person known to be hypersensitive should be given another type of antibiotic.

In the rare instance in which penicillin is considered essential, a skin test may be helpful in assessing hypersensitivity. The reagents used in the skin test procedure are derivatives of the basic benzylpenicillin molecule. They are introduced into the epidermis by a skin prick or into the dermis by an intradermal injection. An immediate wheal-and-flare reaction

confirms immediate hypersensitivity to penicillin. Allergic reactions, including fatal anaphylactic shock, have occurred with skin tests and after negative skin tests. If the scratch test is positive, desensitization may be accomplished by giving gradually increasing doses of penicillin.

Because anaphylactic shock may occur with administration of the penicillins, especially by parenteral routes, emergency drugs and equipment must be readily available. Treatment may require parenteral epinephrine, oxygen, and insertion of an endotracheal or tracheostomy tube if laryngeal edema occurs.

## Applying Your Knowledge 30-2

The physician finds signs of infection during Ms. Jang's bronchoscopy and orders the patient to take amoxicillin 500 mg every 8 hours for 10 days, pending the results of the culture and susceptibility studies. Ms. Jang has the prescription filled and starts taking the medication. What should members of the health care team assess before Ms. Jang takes this medication?

.....

## Use of Penicillins in Specific Situations

### Treatment of Streptococcal Infections

Clinicians should perform culture and susceptibility studies and be aware of local patterns of streptococcal susceptibility or resistance before prescribing penicillins for streptococcal infections. When used, penicillins should be given for the full prescribed course of treatment to prevent complications such as rheumatic fever, endocarditis, and glomerulonephritis.

### Use in Combination With Probenecid

Probenecid (Benemid) can be given concurrently with penicillins to increase serum drug levels. Probenecid acts by blocking renal excretion of the penicillins. This action may be useful when high serum levels are needed with oral penicillins or when a single large dose is given IM for prevention or treatment of syphilis.

### Use in Combination With Aminoglycosides

Aminoglycosides are often given concomitantly with penicillins for serious infections, such as those caused by *P. aeruginosa*. The drugs should not be admixed in a syringe or in an IV solution, because the penicillin inactivates the aminoglycoside.

### Applying Your Knowledge 30-3

Ms. Jang has never before had a reaction to a medication and calls the office to report a skin rash and difficulty breathing. What action should you take?

## Use in Special Populations

### Perioperative Use of Cephalosporins

Some cephalosporins are used in surgical prophylaxis. The particular drug depends largely on the type of organism likely to be encountered in the operative area. First-generation drugs, mainly cefazolin, are used for procedures associated with gram-positive postoperative infections, such as prosthetic implant surgery. Second-generation cephalosporins (mainly cefotetan and cefoxitin) are often used for abdominal procedures, especially gynecologic and colorectal surgery, in which enteric gram-negative postoperative infections may occur. Third-generation drugs should not be used for surgical prophylaxis because they are less active against staphylococci than cefazolin, the gram-negative organisms they are most useful against are rarely encountered in elective surgery, widespread usage for prophylaxis promotes emergence of drug-resistant organisms, and they are very expensive.

When used perioperatively, cephalosporins should be given within 2 hours before the first skin incision is made so the drug has time to reach therapeutic serum and tissue concentrations. A single dose is usually sufficient, although repeat doses are necessary in patients undergoing a surgical procedure exceeding 4 hours or procedures involving major blood loss. Postoperative doses are rarely necessary but, if used, should generally not exceed 24 hours.

### Use in Children

Penicillins and cephalosporins are widely used to treat infections in children and are generally safe. They should be used cautiously in neonates because immature kidney function slows their elimination. Dosages should be based on age, weight, severity of the infection being treated, and renal function. Specialized pediatric dosing references can provide guidance to dosing of most beta-lactams based on the child's age and weight.

### Use in Older Adults

Beta-lactam antibacterials are relatively safe, although decreased renal function, other disease processes, and concurrent drug therapies increase the risks of adverse effects in older adults. With penicillins, hyperkalemia may occur with large IV doses of penicillin G potassium and hypernatremia may occur with ticarcillin. Hypernatremia is less likely with other antipseudomonal penicillins such as piperacillin. Cephalosporins may aggravate renal impairment, especially when other nephrotoxic drugs are used concurrently. Dosage of most cephalosporins must be reduced in the presence of renal impairment, depending on creatinine clearance (CrCl).

With aztreonam, imipenem-cilastatin, meropenem, and ertapenem, dose and frequency of administration are determined by renal status as indicated by CrCl.

### Use in Patients With Renal Impairment

Beta-lactam antimicrobials are excreted mainly by the kidneys and may accumulate in the presence of renal impairment. Dosage of many beta-lactams must be decreased according to CrCl. In addition, some of the drugs are nephrotoxic. References should be consulted to determine dosages recommended for various levels of CrCl. Additional considerations are included in the following sections.

#### Penicillins

- Dosage of penicillin G, carbenicillin, piperacillin, piperacillin-tazobactam, and ticarcillin should be reduced.
- Patients on hemodialysis usually require an additional dose after treatment because hemodialysis removes substantial amounts and produces subtherapeutic serum drug levels.
- Carbenicillin, which is used to treat UTI, does not reach therapeutic levels in urine in patients with severe renal impairment (CrCl < 10 mL/minute).
- Nephropathy, such as interstitial nephritis, although infrequent, has occurred with all penicillins. It is most often associated with high doses of parenteral penicillins and is attributed to hypersensitivity reactions. Manifestations include fever, skin rash, eosinophilia, and possibly increased levels of blood urea nitrogen and serum creatinine.
- Electrolyte imbalances, mainly hypernatremia and hyperkalemia, may occur. Hypernatremia is most likely to occur when ticarcillin (5.6 mEq sodium/g) is given to patients with renal impairment or congestive heart failure. Hypokalemic metabolic acidosis may also occur with ticarcillin because potassium loss is enhanced by high sodium intake. Hyperkalemia may occur with large IV doses of penicillin G potassium (1.7 mEq/1 million units).

#### Cephalosporins

- Reduce dosage because usual doses may produce high and prolonged serum drug levels. In renal failure (CrCl < 20 to 30 mL/minute), dosage of all cephalosporins should be reduced.

- Cefotaxime is converted to active metabolites that are normally eliminated by the kidneys. These metabolites accumulate and may cause toxicity in patients with renal impairment.

### Carbapenems

- Dosage of imipenem should be reduced in most patients with renal impairment and the drug is contraindicated in patients with severe renal impairment (CrCl of 5 mL/minute or less) unless hemodialysis is started within 48 hours. For patients already on hemodialysis, the drug may cause seizures and should be used very cautiously, if at all.
- Dosage of meropenem should be reduced with renal impairment (CrCl < 50 mL/minute).
- Dosage of ertapenem should be reduced to 500 milligram daily with renal impairment (CrCl < 30 mL/minute). For patients on hemodialysis, administer the daily dose after dialysis.

### Monobactam

- After an initial loading dose, the dosage of aztreonam should be reduced by 50% or more in patients with CrCl of 30 milliliters per minute or less. Give at the usual intervals of 6, 8, or 12 hours.
- For serious or life-threatening infections in patients on hemodialysis, give 12.5% of the initial dose after each hemodialysis session, in addition to maintenance doses.

### Use in Patients With Hepatic Impairment

- A few beta-lactam antibiotics may cause or aggravate hepatic impairment.
- Amoxicillin-clavulanate (Augmentin) should be used with caution in patients with hepatic impairment. It is contraindicated in patients who have had cholestatic jaundice and hepatic dysfunction with previous use of the drug. Cholestatic liver impairment usually subsides when the drug is stopped. Hepatotoxicity is attributed to the clavulanate component and has also occurred with ticarcillin-clavulanate (Timentin).
- Aztreonam, imipenem, meropenem, and ertapenem may cause abnormalities in liver function test results (i.e., elevated alanine and aspartate aminotransferases [ALT and AST] and alkaline phosphatase), but hepatitis and jaundice rarely occur.

### Use in Patients With Critical Illness

Beta-lactam antimicrobials are commonly used in critical care units to treat pneumonia, bloodstream, wound, and other infections. The beta-lactam drugs are frequently given concomitantly with other antimicrobial drugs because critically ill patients often have multiorganism or nosocomial infections. Renal, hepatic, and other organ functions should be monitored in critically ill patients and drug dosages should be reduced when indicated.

With penicillins, the extended-spectrum drugs (e.g., piperacillin) and penicillin–beta-lactamase inhibitor combinations (e.g., Unasyn) are most likely to be used. With cephalosporins, third- and fourth-generation drugs are commonly used and are usually given by intermittent IV infusions every 8 or 12 hours. Continuous infusions of beta-lactam antibiotics also may be used. Blood levels of cephalosporins and penicillins need to be maintained above the minimum inhibitory concentration (MIC) of the microorganisms causing the infection being treated. Thus, continuous infusions may be of benefit with serious infections, especially those caused by relatively resistant organisms such as *Pseudomonas* or *Acinetobacter*.

### Use in Home Care

Many beta-lactam antibiotics are given in the home setting. With oral agents, the role of the home care nurse is mainly to teach accurate administration and observation for therapeutic and adverse effects. With liquid suspensions for children, shaking to re-suspend medication and measuring with a measuring spoon or calibrated device are required for safe dosing. Household spoons should not be used because they vary widely in capacity. General guidelines for IV therapy are discussed in Chapter 29; specific guidelines depend on the drug being given.

## Applying Your Knowledge 30-4

### How Can You Avoid This Medication Error?

Ms. Jang recovers from her allergic reaction to the penicillin. Her medical records now indicate that she is allergic to PCN. Her culture reports from the bronchoscopic examination have become available; her infection is caused by an organism sensitive to Zosyn. The on-call physician orders a dose of IV Zosyn. The nurse prepares the dose to be administered and starts the infusion. Ms. Jang experiences anaphylaxis and has to be resuscitated.

## Nursing Actions

## Beta-Lactam Antibacterials

### NURSING ACTIONS

#### 1. Administer accurately

##### a. With penicillins:

- (1) Give most oral penicillins on an empty stomach, approximately 1 hour before or 2 hours after a meal. Penicillin V, amoxicillin, and amoxicillin/clavulanate may be given with food.

### RATIONALE/EXPLANATION

To decrease binding to foods and inactivation by gastric acid. The latter three drugs are not significantly affected by food.

**NURSING ACTIONS****RATIONALE/EXPLANATION**

<p>(2) Give oral drugs with a full glass of water, preferably.</p> <p>(3) Give intramuscular (IM) penicillins deeply into a large muscle mass.</p> <p>(4) For intravenous (IV) administration, usually dilute reconstituted penicillins in 50–100 milliliters of 5% dextrose or 0.9% sodium chloride injection and infuse over 30–60 minutes.</p> <p>(5) Give reconstituted ampicillin IV or IM within 1 hour.</p>	<p>To promote absorption and decrease inactivation, which may occur in an acidic environment</p> <p>To decrease tissue irritation</p> <p>To minimize vascular irritation and phlebitis</p> <p>The drug is stable in solution for a limited time, after which effectiveness is lost.</p>
<p>b. With cephalosporins:</p> <p>(1) Give most oral drugs with food or milk. Cefpodoxime and cefuroxime should be taken with food. Chilling cefpodoxime improves flavor.</p> <p>(2) Give IM drugs deeply into a large muscle mass.</p> <p>(3) For IV administration, usually dilute reconstituted drugs in 50–100 milliliters of 5% dextrose or 0.9% sodium chloride injection and infuse over 30 minutes.</p>	<p>To decrease nausea and vomiting. Food delays absorption but does not affect the amount of drug absorbed. An exception is the pediatric suspension of cefibuten, which must be given at least 1 hour before or 2 hours after a meal. Food increases the absorption of cefpodoxime and cefuroxime.</p> <p>The drugs are irritating to tissues and cause pain, induration, and possibly sterile abscess. The IM route is rarely used. These drugs are irritating to veins and cause thrombophlebitis. This can be minimized by using small IV catheters, large veins, adequate dilution, and slow infusion rates, and by changing venipuncture sites. Thrombophlebitis is more likely to occur with doses of more than 6 g/day for longer than 3 days.</p>
<p>c. With carbapenems:</p> <p>(1) For IV imipenem, mix reconstituted solution in 100 milliliters of 0.9% NaCl or 5% dextrose injection. Give 250- to 500-mg doses over 20–30 minutes; give 750-mg to 1-g doses over 40–60 minutes.</p> <p>(2) For IM imipenem and ertapenem, mix with 1% lidocaine without epinephrine and inject deeply into a large muscle mass with a 21-gauge, 2-inch needle.</p> <p>(3) For IV meropenem, give as an injection over 3–5 minutes or as an infusion over 15–30 minutes.</p> <p>(4) For IV ertapenem, mix in 50 milliliters of 0.9% sodium chloride and infuse over 30 minutes.</p>	<p>Manufacturer's recommendations</p> <p>To decrease pain of injection</p> <p>Manufacturer's recommendations</p>
<p>d. With aztreonam:</p> <p>(1) For IM administration, add 3 milliliters diluent per gram of drug, and inject into a large muscle mass.</p> <p>(2) For IV injection, add 6–10 milliliters sterile water, and inject into vein or IV tubing over 3–6 minutes.</p> <p>(3) For IV infusion, mix in at least 50 milliliters of 0.9% NaCl or 5% dextrose injection per gram of drug and give over 20–60 minutes.</p>	<p>See Chapter 29.</p>
<p><b>2. Observe for therapeutic effects</b></p> <p>a. Decreased signs of local and systemic infection</p> <p>b. Decreased signs and symptoms of the infection for which the drug is given</p> <p>c. Absence of signs and symptoms of infection when given prophylactically</p>	
<p><b>3. Observe for adverse effects</b></p> <p>a. Hypersensitivity—anaphylaxis, serum sickness, skin rash, urticaria</p> <p>b. Phlebitis at IV sites and pain at IM sites</p> <p>c. Superinfection</p> <p>d. Nausea and vomiting</p>	<p>See Nursing Actions in Chapter 29 for signs and symptoms. Reactions are more likely to occur in those with previous hypersensitivity reactions and those with a history of allergy, asthma, or hay fever. Anaphylaxis is more likely with parenteral administration and may occur within 5–30 minutes of injection.</p> <p>Parenteral solutions are irritating to body tissue.</p> <p>See Chapter 29 for signs and symptoms.</p> <p>May occur with all beta-lactam drugs, especially with high oral doses</p>

## Nursing Actions Beta-Lactam Antibacterials (continued)

### NURSING ACTIONS

- e. Diarrhea, colitis, pseudomembranous colitis
- f. Nephrotoxicity
  - (1) Acute interstitial nephritis (AIN)—hematuria, oliguria, proteinuria, pyuria
  - (2) Increased blood urea nitrogen and serum creatinine; casts in urine
- g. Neurotoxicity—confusion, hallucinations, neuromuscular irritability, convulsive seizures
- h. Coagulation disorders and bleeding from hypoprothrombinemia or platelet dysfunction

### 4. Observe for drug interactions

- a. Drugs that *increase* effects of penicillins:
  - (1) Gentamicin and other aminoglycosides
  - (2) Probenecid (Benemid)
- b. Drugs that *decrease* effects of penicillins:
  - (1) Acidifying agents (ascorbic acid, cranberry juice, orange juice)
  - (2) Erythromycin
  - (3) Tetracycline
  - (4) Aminoglycosides, if admixed
- c. Drugs that *increase* effects of cephalosporins:
  - (1) Loop diuretics (furosemide, ethacrynic acid)
  - (2) Probenecid
- d. Drugs that *decrease* effects of cephalosporins:
  - (1) Antacids containing aluminum or magnesium (e.g., Mylanta) and histamine H<sub>2</sub> antagonists (e.g., cimetidine, ranitidine)
- e. Drugs that *increase* effects of carbapenems:
  - (1) Probenecid
  - (2) Cyclosporine
- f. Drugs that *alter* effects of aztreonam

### RATIONALE/EXPLANATION

- Diarrhea commonly occurs with beta-lactam drugs and may range from mild to severe. The most severe form is pseudomembranous colitis, which is more often associated with ampicillin and the cephalosporins than other beta-lactams.
- AIN may occur with any of the beta-lactams, especially with high parenteral doses of penicillins. More likely with cephalosporins, especially in patients who are older or who have impaired renal function, unless dosage is reduced. More likely with large IV doses of penicillins, cephalosporins, or carbapenems, especially in patients with impaired renal function. Ticarcillin may cause decreased platelet aggregation. Cefoperazone and cefotetan may cause hypoprothrombinemia (by killing intestinal bacteria that normally produce vitamin K or a chemical structure that prevents activation of prothrombin) or platelet dysfunction. Bleeding can be treated by giving vitamin K. Vitamin K does not restore normal platelet function or normal bacterial flora in the intestines.
- Synergistic activity against *Pseudomonas* organisms when given concomitantly with extended-spectrum (antipseudomonal) penicillins. Synergistic activity against enterococci that cause subacute bacterial endocarditis, brain abscess, meningitis, or urinary tract infection. Synergistic activity against *Staphylococcus aureus* when used with nafcillin. Decreases renal excretion of penicillins, thus elevating and prolonging penicillin blood levels.
- Most oral penicillins are destroyed by acids, including gastric acid. Amoxicillin and penicillin V are acid stable. Erythromycin inhibits the bactericidal activity of penicillins against most organisms but potentiates activity against resistant strains of *S. aureus*. These bacteriostatic antibiotics slow multiplication of bacteria and thereby inhibit the penicillins, which act against rapidly multiplying bacteria. The penicillin will inactivate the aminoglycoside.
- Increased renal toxicity. Increases blood levels by decreasing renal excretion of the cephalosporins. This may be a desirable interaction to increase blood levels and therapeutic effectiveness or allow smaller doses.
- These drugs decrease absorption of cefaclor, cefdinir, and cefpodoxime. Give the drugs at least 2 hours apart.
- Probenecid minimally increases serum drug levels of carbapenems, but it is not recommended for concomitant use with any of the drugs. May increase central nervous system adverse effects of imipenem.
- Few documented, clinically significant interactions reported, but potential interactions are those that occur with other beta-lactam antibiotics.

## Key Concepts

- Beta-lactam antibiotics include penicillins, cephalosporins, carbapenems, and monobactams.
- Choice of a beta-lactam antibacterial depends on the organism causing the infection, severity of the infection, and other factors.
- As a class, penicillins usually are more effective in infections caused by gram-positive bacteria than those caused by gram-negative bacteria.
- In the rare instance in which penicillin is considered essential, a skin test may be helpful in assessing hypersensitivity.
- Metabolic and electrolyte imbalances may occur in patients receiving penicillins who have renal impairment or congestive heart failure: hypernatremia and hypokalemic metabolic acidosis is most likely to occur when ticarcillin and hyperkalemia with large IV doses of penicillin G potassium.
- Probenecid (Benemid) blocks renal excretion of the penicillins and can be given concurrently with penicillins to increase serum drug levels.

## Review and Application Exercises

### Short Answer Exercises

1. How do beta-lactam drugs act against bacteria?
2. What adverse effects are associated with beta-lactam drugs, and how may they be prevented or minimized?
3. What are beta-lactamase enzymes, and what do they do to beta-lactam antibacterial drugs?
4. How are penicillins and other beta-lactam drugs excreted?
5. What are the main differences between penicillin G or V and antistaphylococcal and antipseudomonal penicillins?
6. What is the reason for combining clavulanate, sulbactam, or tazobactam with a penicillin?
7. When giving injections of penicillin in an outpatient setting, it is recommended to keep patients in the area and observe them for at least 30 minutes. Why?
8. When probenecid is given concurrently with a penicillin, what is its purpose?
9. What are the signs and symptoms of anaphylaxis?
10. For patients with renal impairment, which drugs in this chapter require reduced dosage?
11. Which drugs in this chapter may cause pseudomembranous (antibiotic-associated) colitis?
12. What are the signs, symptoms, and treatment of pseudomembranous colitis?

### NCLEX-Style Questions

13. A nurse is preparing to administer the first dose of piperacillin-tazobactam (Zosyn) to a patient in an infusion clinic. The nurse should take which of the following precautions?
  - a. Ask the patient about past allergic reactions to penicillins.
  - b. Ask the patient about past allergic reactions to aminoglycosides.
  - c. Mix the piperacillin-tazobactam with lidocaine to reduce pain of infusion.
  - d. Instruct the patient to eat a snack to decrease stomach upset from piperacillin-tazobactam.
14. A woman is to receive Augmentin 500 mg PO q8h for bronchitis. The nurse retrieves two 250-mg tablets from the medication cart. This is incorrect for which of the following reasons?
  - a. The amount of sulbactam in Augmentin 250 mg is 62.5 mg per tablet, twice the intended amount.
  - b. This will provide twice the intended dose of clavulanate.
  - c. The 250-mg tablets have less absorption than the 500-mg tablets.
  - d. Augmentin can only be given IV, so giving tablets means that the wrong drug is being administered.

15. A nurse working in the neurointensive care unit is caring for a head-injury victim who has been experiencing seizures and now has *P. aeruginosa* pneumonia. The physician has prescribed imipenem 1 g IV q6h plus gentamicin for the pneumonia. Before administering the antibiotics, the nurse should do which of the following?
- Not admix the imipenem and gentamicin in the same IV bag to prevent inactivation of the gentamicin.
  - Remind the physician of the patient's seizures and inquire whether a different antibiotic might be safer.
  - Suggest to the physician that imipenem is used to treat gram-positive infections and will not be effective in this patient.
  - Set the infusion pump to deliver the imipenem over 15 minutes.
16. In acute renal failure, doses of all of the following antibiotics must be reduced except
- nafcillin
  - cefazolin
  - meropenem
  - aztreonam
17. Which of the following classes of cephalosporins has the best activity against gram-positive organisms?
- first-generation cephalosporins
  - second-generation cephalosporins
  - third-generation cephalosporins
  - fourth-generation cephalosporins

# Aminoglycosides and Fluoroquinolones

## KEY TERMS

- Concentration-dependent bactericidal effects
- Initial loading dose
- Maintenance doses
- Nephrotoxicity
- Ototoxicity
- Peak serum drug levels
- Postantibiotic effects
- Single daily dosing
- Trough serum drug levels

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify characteristics of aminoglycosides and fluoroquinolones in relation to effectiveness, safety, spectrum of antimicrobial activity, indications for use, administration, and observation of patient responses.
2. Recognize factors influencing selection and dosage of aminoglycosides and fluoroquinolones.
3. State the rationale for the increasing use of single daily doses of aminoglycosides.
4. Discuss the importance of measuring serum drug levels during aminoglycoside therapy.
5. Describe measures to decrease nephrotoxicity and ototoxicity with aminoglycosides.
6. Describe characteristics, uses, adverse effects, and nursing process implications of fluoroquinolones.
7. Discuss principles of using aminoglycosides and fluoroquinolones in renal impairment and critical illness.

## Applying Your Knowledge

Roger Dallas is an 84-year-old man who has been prescribed ciprofloxacin (Cipro) 500 mg PO every 12 hours to treat an infected leg wound. He has experienced arterial insufficiency to his lower extremities for many years, secondary to atherosclerosis. The medical plan is to clear the infection so that Mr. Dallas can have surgery to restore circulation to his lower extremities.

## Introduction

The aminoglycosides have been widely used to treat serious gram-negative infections for many years. The quinolones are also older drugs originally used only for treatment of urinary tract infections (see Chap. 32). The fluoroquinolones are synthesized by adding a fluorine molecule to the quinolone structure. This addition increases drug activity against gram-negative microorganisms, broadens the antimicrobial spectrum to include several other microorganisms, and allows use of the drugs in treating systemic infections. General characteristics, mechanisms of action, indications for and contraindications to use, nursing process implications, and principles of therapy for these drugs are described in this chapter. Individual drugs, with routes of administration and dosage ranges, are listed in the Drugs at a Glance tables.

## Aminoglycosides

Aminoglycosides (Table 31-1) are bactericidal agents with similar pharmacologic, antimicrobial, and toxicologic characteristics. They are used to treat infections caused by gram-negative

microorganisms such as *Pseudomonas* and *Proteus* species, *Escherichia coli*, and *Klebsiella*, *Enterobacter*, and *Serratia* species.

These drugs are poorly absorbed from the gastrointestinal (GI) tract. Thus, when given orally, they exert local effects in the GI tract. They are well absorbed from intramuscular

Table 31-1

### Drugs at a Glance: Aminoglycosides

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Amikacin</b> (Amikin)	Retains a broader spectrum of antibacterial activity than other aminoglycosides because it resists degradation by most enzymes that inactivate gentamicin and tobramycin Major clinical use is in infections caused by organisms resistant to other aminoglycosides (e.g., <i>Pseudomonas</i> , <i>Proteus</i> , <i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Serratia</i> ), whether community or hospital acquired.	IM, IV 15–20 mg/kg q24h. Renal dosing: 5–7.5 mg/kg/d q8–24h	Older children: Same as adults Neonates: IM, IV 10 mg/kg initially, then 7.5 mg/kg q12h
<b>Gentamicin</b> (Garamycin)	Effective against several gram-negative organisms, although some strains have become resistant Acts synergistically with antipseudomonal penicillins against <i>Pseudomonas aeruginosa</i> and with ampicillin or vancomycin against enterococci	Conventional dosing IM, IV 1–2.5 mg/kg q8–24h depending on renal function. ODA dosing: 4–7 mg/kg/dose once daily	<5y: IM, IV 2.5 mg/kg q8h ≥5y: IM, IV 2–2.5 mg/kg q8h
<b>Kanamycin</b> (Kantrex)	Occasionally used to decrease bowel organisms before surgery, treat hepatic coma, or treat multidrug-resistant tuberculosis	IV, IM 15 mg/kg/d, in divided doses q8–12h	IV, IM same as adults
<b>Neomycin</b>	Given orally or topically to prepare GI tract for surgery Although poorly absorbed from GI tract, toxic levels may accumulate in presence of renal failure. Used topically, often in combination with other drugs, to treat infections of the eye, ear, and skin (burns, wounds, ulcers, dermatoses) When used for wound or bladder irrigations, systemic absorption may occur if the area is large or if drug concentration exceeds 0.1%.	PO, suppression of intestinal bacteria (with erythromycin 1 g) 1 g at 19, 18, and 9 h before surgery (3 doses); hepatic coma, 4–12 g daily in divided doses q4–6h for 5–6 d	
<b>Streptomycin</b>	May be used in a 4- to 6-drug regimen for treatment of multidrug-resistant tuberculosis	IM 15–30 mg/kg/d or 1–2g/d.	IM 20–40 mg/kg/d in 2 divided doses, q12h (maximum dose, 1 g/d)
<b>Tobramycin</b>	Similar to gentamicin in antibacterial spectrum, but may be more active against <i>Pseudomonas</i> organisms Often used with other antibiotics for septicemia and infections of burn wounds, other soft tissues, bone, the urinary tract, and the central nervous system	Conventional dosing: IM, IV 1–2.5 mg/kg q8–24h depending on renal function. ODA dosing: 4–7 mg/kg/dose once daily.	under 5y: IM, IV 2.5 mg/kg/dose q8h 5y or older: 2–2.5 mg/kg/dose q8h

GI, gastrointestinal; ODA, once daily aminoglycoside.

injection sites and reach peak effects in 30 to 90 minutes if circulatory status is good. After intravenous (IV) administration, peak effects occur within 30 to 60 minutes. Plasma half-life is 2 to 4 hours with normal renal function.

After parenteral administration, aminoglycosides are widely distributed in extracellular fluid and reach therapeutic levels in blood, urine, bone, inflamed joints, and pleural and ascitic fluids. They accumulate in high concentrations in the proximal renal tubules of the kidney, leading to acute tubular necrosis. This damage to the kidney is termed *nephrotoxicity*. They also accumulate in high concentrations in the inner ear, damaging sensory cells in the cochlea (disrupting hearing) and the vestibular apparatus (disturbing balance). This damage to the inner ear is termed *ototoxicity*. They are poorly distributed to the central nervous system, intraocular fluids, and respiratory tract secretions.

Injected drugs are not metabolized; they are excreted unchanged in the urine, primarily by glomerular filtration. Oral drugs are excreted in feces.

### Mechanism of Action

Aminoglycosides penetrate the cell walls of susceptible bacteria and bind irreversibly to 30S ribosomes, intracellular structures that synthesize proteins. As a result, the bacteria cannot synthesize the proteins necessary for their function and replication.

### Indications for Use

The major clinical use of parenteral aminoglycosides is to treat serious systemic infections caused by susceptible aerobic gram-negative organisms. Many hospital-acquired infections are caused by gram-positive cocci and gram-negative organisms. These infections have become more common with control of other types of infections, widespread use of antimicrobial drugs, and diseases (e.g., acquired immunodeficiency syndrome [AIDS]) or treatments (e.g., radical surgery, therapy with anti-neoplastic or immunosuppressive drugs) that lower host resistance. Although they can occur anywhere, infections due to gram-negative organisms commonly involve the respiratory and genitourinary tracts, skin, wounds, bowel, and bloodstream. Any infection with gram-negative organisms may be serious and potentially life threatening. Management is difficult because the organisms are in general less susceptible to antibacterial drugs, and drug-resistant strains develop rapidly. In pseudomonal infections, an aminoglycoside is often given concurrently with an antipseudomonal penicillin (e.g., piperacillin) for synergistic therapeutic effects. The penicillin-induced breakdown of the bacterial cell wall makes it easier for the aminoglycoside to reach its site of action inside the bacterial cell. Decreased mortality has been demonstrated from combination antibiotic therapy in treatment of infections due to *Pseudomonas aeruginosa* and other multidrug-resistant gram-negative bacilli. However, routine use of combination antibiotic therapy containing an aminoglycoside has not been associated with decreased mortality in other gram-negative infections.

A second clinical use is for treatment of tuberculosis. Streptomycin may be used as part of a four- to six-drug regimen for treatment of multidrug-resistant tuberculosis (MDR-TR). However, it is considered a second-line agent because of increasing resistance and should only be used after susceptibility results confirm its usefulness. For patients who develop drug-induced hepatitis in response to first-line drugs, streptomycin or another second-line drug may be substituted until the hepatitis resolves or the causative antitubercular agent is identified.

A third clinical use is for synergistic action when combined with ampicillin, penicillin G, or vancomycin in the treatment of enterococcal and *Staphylococcus epidermidis* infections. Regimens for these infections, particularly meningitis or endocarditis, should include gentamicin in divided doses rather than once-daily dosing. Some strains are resistant to gentamicin, however, and microbiology results should be reviewed for each patient.

A final clinical use is oral administration to suppress intestinal bacteria. Neomycin and kanamycin may be given before bowel surgery and to treat hepatic coma. In hepatic coma, intestinal bacteria produce ammonia, which enters the bloodstream and causes encephalopathy. Drug therapy to suppress intestinal bacteria decreases ammonia production.

A few aminoglycosides are administered topically to the eye or to the skin. These are discussed in Chapters 63 and 64, respectively.

### Contraindications to Use

Hypersensitivity to the aminoglycosides is a contraindication. Aminoglycosides are generally reserved for infections that have not responded to less toxic drugs. A **BLACK BOX WARNING** alerts health care professionals that these drugs are nephrotoxic and ototoxic and must be used very cautiously in the presence of renal impairment. Dosages are adjusted according to serum drug levels and creatinine clearance. The drugs must also be used cautiously in patients with myasthenia gravis and other neuromuscular disorders because muscle weakness may be increased.

## Fluoroquinolones

Fluoroquinolones are synthetic bactericidal drugs with activity against gram-negative and gram-positive organisms. They may allow oral, ambulatory treatment of infections that previously required parenteral therapy and hospitalization. Most fluoroquinolones are given orally, after which they are well absorbed, achieve therapeutic concentrations in most body fluids, and are metabolized to some extent in the liver. The kidneys are the main route of elimination, with approximately 30% to 60% of an oral dose excreted unchanged in the urine. Dosage should be reduced in renal impairment.

### Mechanism of Action

The drugs act by interfering with topoisomerase II (DNA gyrase) and topoisomerase IV, enzymes that are required for

Table 31-2

## Drugs at a Glance: Fluoroquinolones

GENERIC/TRADE NAME	CHARACTERISTICS	ROUTES AND DOSAGE RANGES
<b>Ciprofloxacin</b> (Cipro)	<ol style="list-style-type: none"> <li>1. Effective in respiratory, urinary tract, gastrointestinal tract, and skin and soft-tissue infections as well as sexually transmitted diseases caused by chlamydiae and <i>Neisseria gonorrhoeae</i> organisms</li> <li>2. Used as one of 4 to 6 drugs in treatment of multidrug-resistant tuberculosis</li> <li>3. Used to treat anthrax infections</li> </ol>	PO 250–750 mg q12h UTI/pyelonephritis; extended-release tablets 500 mg–1 g q24h IV 200–400 mg q12h
<b>Gatifloxacin</b> (Tequin)	Indicated for pneumonia, bronchitis, sinusitis, skin and soft tissue infections, urinary infections, pyelonephritis, and gonorrhea	PO, IV infusion 400 mg once daily. Give IV dose over 60 min; avoid rapid administration.
<b>Gemifloxacin</b> (Factive)	Indicated for acute bacterial exacerbation of chronic bronchitis and community-acquired pneumonia (mild to moderate severity)	PO 320 mg once daily for 5–7 d
<b>Levofloxacin</b> (Levaquin)	A broad-spectrum agent effective for treatment of bronchitis, cystitis, pneumonia, sinusitis, skin and skin-structure infections, and pyelonephritis	PO, IV 250–750 mg once daily. Infuse 250–500 mg IV dose slowly over 60 min. Infuse 750 mg IV dose over 90 min.
<b>Moxifloxacin</b> (Avelox)	Indicated for community-acquired pneumonia, sinusitis, bronchitis, skin and soft-tissue infections	PO, IV 400 mg once daily. Infuse IV dose slowly over 60 min.
<b>Norfloxacin</b> (Noroxin)	Used only for UTI	PO 400 mg twice daily
<b>Ofloxacin</b> (Floxin)	See ciprofloxacin, above	PO 200–400 mg q12h for 3–10 d Gonorrhea, PO 400 mg as a single dose

UTI, urinary tract infection.

synthesis of bacterial DNA and therefore are required for bacterial growth and replication.

### Indications for Use

Fluoroquinolones are indicated for various infections caused by aerobic gram-negative and other microorganisms. Thus, they may be used to treat infections of the respiratory, genitourinary, and GI tracts as well as infections of bones, joints, skin, and soft tissues. Currently, the Centers for Disease Control and Prevention no longer recommends the use of fluoroquinolones for gonococcal disease, unless no other option exists and susceptibility can be confirmed. Because recommendations for treatment of gonorrhea change as resistance becomes more prevalent, consult [www.cdc.gov/std](http://www.cdc.gov/std) for the most current recommendations.

Fluoroquinolones, specifically ciprofloxacin, are currently recommended as the first-line treatment for suspected *Bacillus anthracis* infections (anthrax) until culture and susceptibility results are available. Additional uses include treatment of MDR-TR (see Chap. 34), *Mycobacterium avium* complex

(MAC) infections in patients with acquired immune deficiency syndrome (AIDS; see Chap. 34), and fever in neutropenic cancer patients. Indications vary with individual drugs and are listed in Table 31-2.

### Contraindications to Use

Fluoroquinolones are contraindicated in patients who have experienced a hypersensitivity reaction and in children younger than 18 years of age, if other alternatives are available. Limited data are available on the safety of fluoroquinolones in pregnant or lactating women; the drugs should not be used unless the benefits outweigh the potential risks.

### Applying Your Knowledge 31-1

Mr. Dallas tells you that he is experiencing a moderate amount of indigestion and asks what he should use to treat it. What is the best response, taking into consideration Mr. Dallas's use of Cipro?

.....

## Nursing Process

General aspects of the nursing process as described in Chapter 29 apply to the patient receiving aminoglycosides and fluoroquinolones. In this chapter, only those aspects related specifically to these drugs are included.

### Assessment

With aminoglycosides, assess for the presence of factors that predispose to nephrotoxicity or ototoxicity.

- Check laboratory reports of renal function (e.g., serum creatinine, creatinine clearance, blood urea nitrogen [BUN]) for abnormal values.
- Assess for impairment of balance or hearing, including audiometry reports if available.
- Analyze current medications for drugs that interact with aminoglycosides to increase risks of nephrotoxicity or ototoxicity.
- With fluoroquinolones, assess for the presence of factors that increase risks of adverse drug effects (e.g., impaired renal function, inadequate fluid intake, concomitant use of multivitamins or antiacids, frequent or prolonged exposure to sunlight in usual activities of daily living).
- Assess laboratory tests (e.g., complete blood counts, tests of renal and hepatic function) for abnormal values.

### Planning/Goals

#### The patient will

- Receive aminoglycoside dosages that are individualized by age, weight, renal function, and serum drug levels
- Have serum aminoglycoside levels monitored when indicated
- Have renal function tests performed regularly during aminoglycoside and fluoroquinolone therapy
- Be well hydrated during aminoglycoside and fluoroquinolone therapy
- Be observed regularly for adverse drug effects

### Interventions

- With aminoglycosides, weigh patients accurately (dosage is based on ideal body weight) and monitor laboratory reports of BUN, serum creatinine levels, serum drug levels, and urinalysis for abnormal values.
- Force fluids to at least 2000 to 3000 mL daily if not contraindicated. Keeping the patient well hydrated reduces risks of nephrotoxicity with aminoglycosides and crystaluria with fluoroquinolones.
- Avoid concurrent use of other nephrotoxic drugs when possible.
- Provide appropriate teaching (see accompanying Patient Teaching Guidelines).

## Evaluation

- Interview and observe for improvement in the infection being treated.
- Interview and observe for adverse drug effects.

## Principles of Therapy

### Drug Selection

The choice of aminoglycoside depends on local susceptibility patterns and specific organisms causing an infection. Gentamicin is often given for systemic infections if resistant microorganisms have not developed in the clinical setting. If gentamicin-resistant organisms have developed, amikacin or tobramycin may be given because they are usually less susceptible to drug-destroying enzymes. In terms of toxicity, the aminoglycosides cause similar effects.

The choice of fluoroquinolone is also determined by local susceptibility patterns and specific organisms because individual drugs differ somewhat in their antimicrobial spectra. The drugs cause similar adverse effects.

### Drug Dosage: Aminoglycosides

Dosage of aminoglycosides must be carefully monitored based on serum concentrations. Two major dosing schedules are used: one involving multiple daily doses (conventional dosing) and one involving a single daily dose (once-daily aminoglycosides [ODA]). Single-dose regimen has gained favor over the traditional multiple-dose regimen, which takes advantage of the pharmacodynamic properties of aminoglycosides. These two regimens are described in the following sections. Multiple-dose regimens of aminoglycosides must be carefully monitored with evaluation of *peak serum drug levels* and *trough serum drug levels*. Once-daily regimens are monitored with random level (12-hour) serum evaluation.

#### Multiple Daily Dosing

An *initial loading dose*, based on patient weight and the desired peak serum concentration, is given to achieve therapeutic serum concentrations rapidly. If the patient is obese, lean or ideal body weight should be used because aminoglycosides are not significantly distributed in body fat. In patients with normal renal function, the recommended loading dose for gentamicin and tobramycin is 1 to 2.5 milligrams per kilogram of body weight; for amikacin the loading dose is 5 to 7.5 milligrams per kilogram.

*Maintenance doses* are based on serum drug concentrations. Peak serum concentrations should be assessed 30 to 60 minutes after drug administration (5–8 mcg/mL for gentamicin and tobramycin, 20–30 mcg/mL for amikacin). Measurement of both peak and trough levels helps to maintain therapeutic serum levels without excessive toxicity. For gentamicin and tobramycin, peak levels above 10 to 12 micrograms per milli-

## Patient Teaching Guidelines

### Oral Fluoroquinolones

#### General Considerations

- Avoid exposure to sunlight during and for several days after taking one of these drugs. Stop taking the drug and notify the prescribing physician if skin burning, redness, swelling, rash, or itching occurs. Sunscreen lotions do not prevent photosensitivity reactions.
- Be very careful if driving or doing other tasks requiring alertness or physical coordination. These drugs may cause dizziness or lightheadedness.

#### Self-Administration

- Take norfloxacin (Noroxin) levofloxacin solution and ofloxacin (Floxin) 1 hour before or 2 hours after meals on an

empty stomach. Ciprofloxacin (Cipro) may be taken with food to decrease GI upset. Gatifloxacin (Teguin), gemifloxacin (Factive), levofloxacin tabs, and moxifloxacin (Avelox) can be taken with or without regard to meals.

- Drink 2 to 3 quarts of fluid daily if able. This helps to prevent kidney problems.
- Do not take antacids containing magnesium or aluminum (e.g., Mylanta or Maalox); any products containing iron, magnesium, calcium (e.g., Tums), or zinc (e.g., multivitamins); sucralfate, or buffered didanosine preparations at the same time, or for several hours before or after a dose of the fluoroquinolone. (Consult product-specific information for individual drug recommendations.)

liter and trough levels above 2 micrograms per milliliter for prolonged periods have been associated with nephrotoxicity. For accuracy, blood samples must be drawn at the correct times and the timing of drug administration and blood sampling must be accurately documented and based on institutional recommendations.

With impaired renal function, dosage of aminoglycosides must be reduced. Methods of adjusting dosage include lengthening the time between doses or reducing doses. References should be consulted for specific recommendations on adjusting aminoglycoside doses for renal impairment. In urinary tract infections, smaller doses can be used than in systemic infections because the aminoglycosides reach high concentrations in the urine.

### Single Daily Dosing

The use of once-daily aminoglycoside (ODA) dosing has replaced the common multiple daily dosing in many individuals unless contraindicated. This dosing method uses high doses (e.g., gentamicin, 4 to 7 mg/kg) to produce high initial drug concentrations, but a repeat dose is not administered until the serum concentration is quite low. The rationale for this dosing approach is a potential increase in efficacy with a reduced incidence of nephrotoxicity. Most patients can be successfully treated with one daily dose using this approach. However, certain populations are not appropriate due to age, renal function, and special situations. In general, the following circumstances contraindicate the use of a *single daily dosing* regimen: individuals aged 18 years of age or less, those pregnant or in the postpartum period, and those with endocarditis.

This practice evolved from increased knowledge about the concentration-dependent bactericidal effects and postantibiotic effects of aminoglycosides. *Concentration-dependent bactericidal effects* mean that the drugs kill more microorganisms with a large dose and high peak serum concentrations. *Postantibiotic effects* mean that aminoglycosides continue killing microorganisms even with low serum concentrations. These characteristics allow administration of high doses to achieve high peak serum concentrations and optimal killing of microorganisms. The

longer interval until the next dose allows the patient to eliminate the drug to very low serum concentrations for approximately 6 hours. During this low-drug period, the postantibiotic effect is active while there is minimal drug accumulation in body tissues. Monitoring of random level (12-hour) serum evaluation in a single dosing regimen replaces traditional peak and trough serum monitoring. Reported advantages of this regimen include increased bactericidal effects, less nephrotoxicity, reduced need for serum drug concentration data, and reduced nursing time for administration.

### Guidelines for Reducing Toxicity of Aminoglycosides

In addition to the preceding recommendations, guidelines to decrease the incidence and severity of adverse effects include the following:

- Identify patients at high risk for adverse effects (e.g., neonates, older adults, patients with renal impairment, patients with disease processes or drug therapies that impair blood circulation and renal function).
- Keep patients well hydrated to decrease drug concentration in serum and body tissues. The drugs reach higher concentrations in the kidneys and inner ears than in other body tissues resulting in nephrotoxicity and ototoxicity. The goal of an adequate fluid intake is to decrease the incidence and severity of these adverse effects.
- Use caution with concurrent administration of diuretics. Diuretics may increase the risk of nephrotoxicity by decreasing fluid volume, thereby increasing drug concentration in serum and tissues. Dehydration is most likely to occur with loop diuretics such as furosemide.
- Give the drug for no longer than 10 days unless necessary for treatment of certain infections. Patients are most at risk when high doses are given for prolonged periods.
- Detect adverse effects early and reduce dosage or discontinue the drug. Changes in renal function tests that indicate nephrotoxicity may not occur until the patient has received an aminoglycoside for several days. If nephrotoxicity occurs,

it is usually reversible if the drug is stopped. Early ototoxicity is detectable only with audiometry and is generally not reversible.

### Applying Your Knowledge 31-2

Mr. Dallas's wound is not responding to treatment. Due to his need for surgery, he is hospitalized for IV antibiotic therapy. His physician orders gentamicin IV once every 24 hours, to be dosed by the pharmacist. The medication is dosed and Mr. Dallas receives doses for 3 days. What assessments should you perform to observe for toxicity?

## Drug Dosage: Fluoroquinolones

Recommended dosages of fluoroquinolones should not be exceeded in any patients, and dosages should be reduced in the presence of renal impairment.

## Use in Special Populations

### Use in Children

Aminoglycosides must be used cautiously in children as with adults. Dosage must be accurately calculated according to weight and renal function. Serum drug concentrations must be monitored and dosage adjusted as indicated to avoid toxicity. Neonates may have increased risk of nephrotoxicity and ototoxicity because of their immature renal function. Neomycin is not recommended for use in infants and children. Fluoroquinolones are not recommended for use in children if other alternatives are available because they have been associated with permanent damage in cartilage and joints in some animal studies.

### Use in Older Adults

Because of impaired renal function, other disease processes (e.g., diabetes), and multiple-drug therapy, older adults are at high risk for development of aminoglycoside-induced nephrotoxicity and ototoxicity.

Aminoglycosides should not be given to older adults with impaired renal function if less toxic drugs are effective against causative organisms.

When the drugs are given, extreme caution is required. A **BLACK BOX WARNING** emphasizes the increased risk for ototoxicity with kanamycin in older adults. Interventions to decrease the incidence and severity of adverse drug effects, listed earlier in the section "Guidelines for Reducing Toxicity of Aminoglycosides," are especially important with older adults. In addition, prolonged therapy (>1 week) increases risk of toxicity and should be avoided when possible.

Fluoroquinolones are commonly used in older adults for the same indications as in younger adults. In older adults with normal renal function, the drugs should be accompanied by an adequate fluid intake and urine output to prevent drug crystals from forming in the urinary tract. In addition, urinary alkalinizing agents should be avoided because drug crystals form more readily in alkaline urine. In those with impaired renal function, a common condition in older adults, the drugs should be used

cautiously and in reduced dosage. A **BLACK BOX WARNING** for fluoroquinolones has been issued by the FDA alerting health professionals to the increased risk of developing tendonitis and tendon rupture. The risk is greater for those over the age of 60, those with heart kidney and lung transplants, and those taking corticosteroidal medications; and necessitates discontinuation of the fluoroquinolone.

### Use in Patients With Renal Impairment

Aminoglycosides are nephrotoxic and must be used very cautiously in patients with renal impairment. Both aminoglycosides and fluoroquinolones require dosage adjustments in renal impairment. Dosage guidelines have been established according to creatinine clearance and often involve lower dosages and prolonged intervals between doses (e.g., 36–72 hours). Guidelines for reducing nephrotoxicity of aminoglycosides are as listed previously.

With fluoroquinolones, reported renal effects include azotemia, crystalluria, hematuria, interstitial nephritis, nephropathy, and renal failure. Nephrotoxicity occurs less often than with aminoglycosides, and most cases of acute renal failure have occurred in older adults. It is unknown whether renal failure is caused by hypersensitivity or is a direct toxic effect of fluoroquinolones. Crystalluria rarely occurs in acidic urine but may occur in alkaline urine. Guidelines for reducing nephrotoxicity include using lower dosages, having longer intervals between doses, receiving adequate hydration, and avoiding substances that alkalinize the urine.

### Use in Patients With Hepatic Impairment

With aminoglycosides, hepatic impairment is not a significant factor because the drugs are excreted through the kidneys. With fluoroquinolones, however, hepatotoxicity has been observed with some of the drugs. A **BLACK BOX WARNING** reports that trovafloxacin is associated with severe liver injury leading to liver transplantation or death and should be reserved for serious infections only. Clinical manifestations range from abnormalities in liver enzyme test results to hepatitis, liver necrosis, or hepatic failure.

### Use in Patients With Critical Illness

Aminoglycosides and fluoroquinolones are often used in critically ill patients because this population has a high incidence of serious and difficult-to-treat infections. Aminoglycosides are usually given with other antimicrobials to provide broad-spectrum activity. Because critically ill patients are at high risk for development of nephrotoxicity and ototoxicity with aminoglycosides, guidelines for safe drug usage should be strictly followed. Renal function should be monitored to assess for needed dosage reductions in patients with renal dysfunction receiving aminoglycosides or fluoroquinolones. Because fluoroquinolones may be hepatotoxic, hepatic function should be monitored during therapy.

Fluoroquinolones are usually infused IV in critically ill patients. However, administration orally or by GI tube (e.g., nasogastric, gastrostomy, jejunostomy) may be feasible in some patients. Concomitant administration of antacids or enteral feedings decreases absorption.

## Evidence-Based Practice

### 31-1 Home Antibiotic Therapy for Community-Acquired Pneumonia

An increasing number of individuals with community-acquired pneumonia (CAP) are being treated at home for a number of reasons, including increased availability and cost considerations of oral antibiotics. Oral drugs have demonstrated effectiveness and are the preferred route for individuals and family members, but management of individuals with oral drugs has widely varied. The American College of Chest Physicians position statement, cosponsored by the American Academy of Home Care Physicians, outlines recommendations for home care for patients with CAP. These include recommendations for evaluation and diagnosis in the home and the determination of the site of care and the plan of care and guidelines for monitoring and follow-up. Recommendations in the position statement take into consideration the best plan of care incorporating the best available evidence with clinician judgment and patient preferences.

### Use in Patients With Diabetes Mellitus

Fluoroquinolones are associated with hyperglycemia and hypoglycemia. Older patients may be more at risk for these glucose disturbances. Severe hypoglycemia has occurred in patients

receiving concomitant glyburide and fluoroquinolones. Although most cases have occurred in diabetic patients, severe cases of hyperglycemia have occurred in patients not previously diagnosed as diabetic. Gatifloxacin has been associated with hypoglycemic and hyperglycemic events more commonly than other fluoroquinolones. The explanation for an increased association with gatifloxacin is not currently known.

### Use in Home Care

Parenteral aminoglycosides are usually given in a hospital setting. Oral fluoroquinolones are often self-administered at home. An increasing number of individuals with community-acquired pneumonia (CAP) are being treated at home. In a position statement by the American College of Chest Physicians, recommendations are outlined for the range of aspects of home care for patients with this condition (see Evidence-Based Practice Box 31-1).

### Applying Your Knowledge 31-3

#### How Can You Avoid This Medication Error?

Taking into consideration Mr. Dallas's age and the concern about the possibility of heart disease, you restrict Mr. Dallas's fluid intake.

.....

## Nursing Actions Aminoglycosides and Fluoroquinolones

### NURSING ACTIONS

#### 1. Administer accurately

- a. With aminoglycosides:
  - (1) For intravenous (IV) administration, dilute the drug in 50–100 milliliters of 5% dextrose or 0.9% sodium chloride injection and infuse over 30–60 minutes. The concentration of gentamicin solution should not exceed 1 mg/mL.
  - (2) Give intramuscular aminoglycosides in a large muscle mass, and rotate sites.
- b. With fluoroquinolones:
  - (1) Give IV infusions of levofloxacin over 60 to 90 minutes; with 250 or 500 mg infuse over 60 minutes. At 750 mg dose infuse over 90 minutes.
  - (2) When giving ciprofloxacin, gatifloxacin, or levofloxacin IV into a primary IV line (e.g., using piggyback apparatus or Y connector), stop the primary solution until ciprofloxacin is infused.

#### 2. Observe for therapeutic effects

- a. Decreased signs and symptoms of the infection for which the drug is being given

#### 3. Observe for adverse effects

- a. With aminoglycosides, observe for:

### RATIONALE/EXPLANATION

To achieve therapeutic blood levels

To avoid local tissue irritation. This is less likely to occur with aminoglycosides than with most other antibiotics.

To decrease vein irritation and phlebitis

To avoid physical or chemical incompatibilities

See Chapter 29.

Adverse effects are more likely to occur with parenteral administration of large doses for prolonged periods. However, they may occur with oral administration in the presence of renal impairment and with usual therapeutic doses.

**NURSING ACTIONS**

- (1) Nephrotoxicity—casts, albumin, red or white blood cells in urine; decreased creatinine clearance; increased serum creatinine; increased blood urea nitrogen
- (2) Ototoxicity—deafness or decreased hearing, tinnitus, dizziness, ataxia
- (3) Neurotoxicity—respiratory paralysis and apnea
- (4) Hypersensitivity—skin rash, urticaria
- (5) Nausea, vomiting, diarrhea, peripheral neuritis, paresthesias
- b. With fluoroquinolones, observe for:
  - (1) Hepatotoxicity (abnormal liver enzyme tests, hepatitis, hepatic failure)
  - (2) Allergic reactions (anaphylaxis, urticaria)
  - (3) Nausea, vomiting, diarrhea, pseudomembranous colitis
  - (4) Headache, dizziness, confusion, tremors, hallucinations, depression, seizures
  - (5) Crystalluria
  - (6) Photosensitivity (skin redness, rash, itching)
  - (7) Glucose tolerance
  - (8) QT prolongation
  - (9) Other

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of aminoglycosides:
  - (1) Amphotericin B, cephalosporins, cisplatin, cyclosporine, enflurane, vancomycin
  - (2) Loop diuretics (furosemide, bumetanide)
  - (3) Neuromuscular blocking agents (e.g., pancuronium, vecuronium)
- b. Drugs that *decrease* effects of aminoglycosides:
  - (1) Penicillins, when admixed directly in same syringe with aminoglycosides
- c. Drugs that *increase* effects of fluoroquinolones:
  - (1) Cimetidine, probenecid
- d. Drugs that *decrease* effects of fluoroquinolones:
  - (1) Antacids, iron preparations, sucralfate, zinc preparations, buffered didanosine preparations, quinapril

**RATIONALE/EXPLANATION**

Renal damage is most likely to occur in clients who are elderly; receive high doses or prolonged therapy; have prior renal damage; or receive other nephrotoxic drugs. This is the most serious adverse reaction. Risks of kidney damage can be minimized by using the drugs appropriately, detecting early signs of renal impairment, and keeping clients well hydrated. This results from damage to the eighth cranial nerve. Incidence of ototoxicity is increased in older clients and in those with previous auditory damage; high doses or prolonged duration of therapy; and concurrent use of other ototoxic drugs. May be reversible with discontinuation of drug. This is caused by neuromuscular blockade and is more likely to occur after rapid IV injection, administration to a client with myasthenia gravis, or concomitant administration of general anesthetics or neuromuscular blocking agents (e.g., succinylcholine, tubocurarine). This effect also may occur if an aminoglycoside is administered shortly after surgery, due to the residual effects of anesthetics or neuromuscular blockers. Neostigmine or calcium may be given to counteract apnea. This is an uncommon reaction except with topical neomycin, which may cause sensitization in as many as 10% of recipients. Uncommon with parenteral aminoglycosides. Diarrhea often occurs with oral administration. The drugs are usually well tolerated. Hepatotoxicity has been observed with most of the drugs. Uncommon, but some fatalities have been reported. Nausea is the most common GI symptom. Uncommon, but may develop after first dose. Use caution in clients with known or suspected central nervous system disorders that lower seizure threshold. Uncommon, but may occur with an inadequate fluid intake. May occur with most fluoroquinolones with exposure to sunlight. Fluoroquinolones are associated with hyperglycemia and hypoglycemia. Older clients and those with diabetes are most at risk. QT prolongation may result in life threatening dysrhythmias. Adverse effects involving most body systems have been reported with one or more of the fluoroquinolones. Most have a low incidence (<1%) of occurrence. The listed drugs increase toxicity. These drugs are nephrotoxic alone and may increase nephrotoxicity of aminoglycosides. Increased ototoxicity. Increased neuromuscular blockade with possible paralysis of respiratory muscles and apnea. Chemical inactivation of PCN. Cimetidine inhibits hepatic metabolism and probenecid inhibits renal excretion of fluoroquinolones. These actions may increase serum drug levels. These drugs interfere with absorption of fluoroquinolones from the GI tract.

## Key Concepts

- The choice of aminoglycoside depends on local susceptibility patterns and specific organisms causing an infection.
- The major clinical use of parenteral aminoglycosides is to treat serious systemic infections caused by susceptible aerobic gram-negative organisms.
- Neomycin and kanamycin may be given to suppress intestinal bacteria before bowel surgery and to treat hepatic coma.
- Multiple-dose regimens (conventional dosing) of aminoglycosides must be carefully monitored with evaluation of peak and trough serum levels. Once-daily regimens are monitored with random level (12-hour) serum evaluation.
- Drugs reach higher concentrations in the kidneys and inner ears than in other body tissues; this is a major factor in nephrotoxicity and ototoxicity.
- Fluoroquinolones are associated with hyperglycemia and hypoglycemia and older patients may be more at risk for these glucose disturbances.

## Review and Application Exercises

### Short Answer Exercises

1. Why must aminoglycosides be given parenterally for systemic infections?
2. How are aminoglycosides excreted?
3. What are risk factors for aminoglycoside-induced nephrotoxicity and ototoxicity?
4. How would you assess a patient for nephrotoxicity or ototoxicity?
5. What is the reason for giving an aminoglycoside and an antipseudomonal penicillin in the treatment of serious infections caused by *P. aeruginosa*?
6. Why should an aminoglycoside and an antipseudomonal penicillin not be combined in a syringe or IV fluid for administration?
7. Which laboratory tests need to be monitored regularly for a patient receiving a systemic aminoglycoside?
8. What is the rationale for giving an oral aminoglycoside to treat hepatic coma?
9. What are the main clinical uses of fluoroquinolones?
10. What are adverse effects of fluoroquinolones, and how may they be prevented or minimized?
11. Why is it important to maintain an adequate fluid intake and urine output while taking a fluoroquinolone?
12. Why are fluoroquinolones not preferred drugs for children?

### NCLEX-Style Questions

13. A hospitalized patient is scheduled to receive levofloxacin 500 mg PO at 9:00 A.M. The medication administration record also indicates that Maalox 30 mL PO and hydrochlorothiazide 25 mg PO are due at 9:00 A.M. The nurse should
  - a. Administer all the medications as scheduled.
  - b. Hold the Maalox until 11:00 A.M.
  - c. Ask the physician to discontinue hydrochlorothiazide because of increased risk of ototoxicity.
  - d. Administer the Maalox and levofloxacin, but hold the hydrochlorothiazide.
14. A critically ill patient is receiving tobramycin 1.5 mg/kg IV every 8 hours. The patient has recently stopped making urine, and the most recent laboratory results indicate that the creatinine level has risen from normal to 3.6 mg/dL. At the next scheduled administration time for tobramycin, the nurse should
  - a. Administer half the prescribed dose.
  - b. Hold the tobramycin and notify the physician.
  - c. Administer tobramycin as prescribed.
  - d. Draw a blood sample for testing the tobramycin level before the dose and then administer as prescribed.
15. An outpatient client has just been given a prescription for moxifloxacin 400 mg PO once daily for acute bronchitis. The nurse should teach the patient
  - a. not to take moxifloxacin with a meal
  - b. to restrict fluid intake to avoid fluid overload
  - c. to take moxifloxacin with an antacid (e.g., Tums) to decrease the chance of stomach upset
  - d. to avoid prolonged exposure to sunlight

16. A nursing home patient is brought to the emergency department with acute pyelonephritis. The emergency room physician prescribes ciprofloxacin 500 mg PO twice daily. The patient has a history of seizures and bradycardia. The nurse should
- Counsel the patient's caregiver to avoid administering the ciprofloxacin with the patient's anticonvulsant.
  - Ask the physician to check blood levels of the patient's anticonvulsant(s) before giving the first dose of ciprofloxacin.
  - Call the patient's seizure and dysrhythmia history to the physician's attention and inquire whether another type of antibiotic might be selected.
  - Counsel the patient's caregiver to discontinue the ciprofloxacin after the patient's fever is gone.
17. A physician writes an order for gentamicin 7 mg/kg IV every 24 hours and ampicillin 500 mg IV every 6 hours. The patient has a diagnosis of endocarditis. This is not an ideal antibiotic regimen for endocarditis because
- Gentamicin should be dosed using the multiple daily dosing method for endocarditis.
  - The addition of gentamicin to ampicillin increases the risk of treatment failure in endocarditis.
  - The appropriate single daily dose of gentamicin is 15 mg/kg once daily.
  - Streptomycin is the recommended aminoglycoside for use in endocarditis.

# Tetracyclines, Sulfonamides, and Urinary Agents

## KEY TERMS

- Broad-spectrum
- Crystalluria
- Mottling
- Sulfonamides
- Tetracyclines
- Urinary antiseptics

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss major characteristics and clinical uses of tetracyclines.
2. Recognize doxycycline as the tetracycline of choice in renal failure.
3. Discuss characteristics, clinical uses, adverse effects, and nursing implications of selected sulfonamides.
4. Recognize trimethoprim-sulfamethoxazole as a combination drug that is commonly used for urinary tract and systemic infections.
5. Describe the use of urinary antiseptics in the treatment of urinary tract infections.
6. Teach patients strategies for preventing, recognizing, and treating urinary tract infections.

## Applying Your Knowledge

Sharon Dee is an 18-year-old college student. She comes to the health clinic with complaints of urinary frequency and burning on urination. Her medication history includes ongoing, long-term treatment of acne with a tetracycline. She takes 250 mg of the drug PO daily. The physician diagnoses her with a urinary tract infection and prescribes trimethoprim-sulfamethoxazole (Bactrim) 160/800 mg PO every 12 hours for 10 days.

## Introduction

Tetracyclines and sulfonamides are older, *broad-spectrum*, bacteriostatic drugs that are rarely used for systemic infections because of microbial resistance and the development of more effective or less toxic drugs. However, the drugs are useful in selected infections. Urinary antiseptics are used only in urinary tract infections (UTI). All of these drugs are described in this chapter and are listed in the Drugs at a Glance tables.

The *tetracyclines* are similar in pharmacologic properties and antimicrobial activity. They are effective against both gram-negative and gram-positive microorganisms, although they are usually not drugs of choice. Many gram-negative microorganisms have developed resistance to tetracyclines. Bacterial infections caused by *Brucella* and *Vibrio cholerae* are still treated by tetracyclines. The drugs also remain effective against rickettsiae, chlamydia, some protozoa, spirochetes, and others. Doxycycline (Vibramycin) is one of the drugs of choice for *Bacillus anthracis* (anthrax) and *Chlamydia trachomatis* and is used in respiratory tract infections due to *Mycoplasma pneumoniae*. Tetracyclines are widely distributed into most body tissues and fluids. The older tetracyclines are excreted mainly in

urine, doxycycline is eliminated in urine and feces, and minocycline is eliminated mainly by the liver. Table 32-1 provides pertinent information about various tetracyclines.

*Sulfonamides* are bacteriostatic against a wide range of gram-positive and gram-negative bacteria, although increasing resistance is making them less useful. Susceptibility should be documented by culture and sensitivity testing, but sulfonamides may be active against *Streptococcus pyogenes*, some staphylococcal strains, *Haemophilus influenzae*, *Nocardia*, *C. trachomatis*, and toxoplasmosis. The combination of trimethoprim-sulfamethoxazole (Bactrim, Septra) is useful in bronchi-

tis, UTIs due to Enterobacteriaceae, and *Pneumocystis jirovecii* infection (in high doses). Individual drugs vary in extent of systemic absorption and clinical indications. Some sulfonamides are well absorbed and can be used in systemic infections; others are poorly absorbed and exert more local effects. Table 32-2 summarizes key information about sulfonamides.

*Urinary antiseptics* may be bactericidal for sensitive organisms in the urinary tract because these drugs are concentrated in renal tubules and reach high levels in urine. They are not used in systemic infections because they do not attain therapeutic plasma levels. An additional drug, phenazopyridine

Table 32-1

## Drugs at a Glance: Tetracyclines

Generic/Trade Name	Comments	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Tetracycline</b> (Achromycin, others)	<ul style="list-style-type: none"> <li>Prototype drug</li> <li>Marketed under generic and numerous trade names</li> </ul>	PO 250-500 mg q6h	Older than 8 y: PO 25-50 mg/kg/d in 4 divided doses
<b>Demeclocycline</b> (Declomycin)	<ul style="list-style-type: none"> <li>The tetracycline most likely to cause photosensitivity</li> <li>Primarily used to treat inappropriate secretion of antidiuretic hormone</li> <li>No longer recommended for treatment of gonorrhea</li> </ul>	PO 150 mg q6h or 300 mg q12h	Older than 8 y: PO 8-12 mg/kg/d in 2-4 divided doses
<b>Doxycycline</b> (Vibramycin)	<ul style="list-style-type: none"> <li>Well absorbed from the gastrointestinal tract. Oral administration yields serum drug levels equivalent to those obtained by parenteral administration.</li> <li>Highly lipid soluble; therefore, reaches therapeutic levels in CSF, the eye, and the prostate gland</li> <li>Can be given in smaller doses and less frequently than other tetracyclines because of long serum half-life (approximately 18 h)</li> <li>Excreted by kidneys to a lesser extent than other tetracyclines and is considered safe for clients with impaired renal function</li> </ul>	PO/IV 100 - 200 mg/day, in 1-2 divided doses.	Older than 8 y: PO, IV Weight $\geq$ 45 kg: same as adults Weight <45 kg: PO, IV 2-5 mg/kg/day in 1-2 divided doses (maximum dose 200 mg/day).
<b>Minocycline</b> (Minocin)	<ul style="list-style-type: none"> <li>Well absorbed after oral administration</li> <li>Like doxycycline, readily penetrates CSF, the eye, and the prostate gland</li> <li>Metabolized more than other tetracyclines, and smaller amounts are excreted in urine and feces</li> </ul>	PO, 200 mg initially, then 100 mg q12h (maximum dose 400 mg/day).	Older than 8 y: PO, 4 mg/kg initially, then 2 mg/kg q12h

Table 32-2

## Drugs at a Glance: Sulfonamides

Generic/Trade Name	Characteristics	Clinical indications	ROUTES AND DOSAGE RANGES	
			Adults	Children
<b>Single Agents</b>				
<b>Sulfadiazine</b>	<ul style="list-style-type: none"> <li>A short-acting, rapidly absorbed, rapidly excreted agent for systemic infections</li> <li>The addition of folic acid may be recommended.</li> </ul>	<ul style="list-style-type: none"> <li>Nocardiosis</li> <li>Toxoplasmosis</li> </ul>	Toxoplasmosis, PO 2–6 g daily in divided doses q 6 h in conjunction with pyrimethamine Nocardiosis: 4–8 g/day for a minimum of 6 weeks	Toxoplasmosis, older than 2 mo: PO 75 mg/kg initially, then 150 mg/kg/d in conjunction with pyrimethamine in 4–6 divided doses; maximal daily dose, 6 g
<b>Sulfasalazine</b> (Azulfidine)	<ul style="list-style-type: none"> <li>Poorly absorbed</li> <li>Does not alter normal bacterial flora in the intestine. Effectiveness in ulcerative colitis may be due to antibacterial (sulfapyridine) and anti-inflammatory (aminosalicylic acid) metabolites.</li> </ul>	<ul style="list-style-type: none"> <li>Ulcerative colitis/Crohn's disease</li> <li>Rheumatoid arthritis</li> </ul>	Ulcerative colitis, PO 3–4 g daily in 4 divided doses initially; 2 g daily in divided doses for maintenance; maximal daily dose, 4 g Rheumatoid arthritis, maintenance, PO 2 g daily in divided doses, q12h	PO 30–60 mg/kg/d in 2–6 divided doses initially, followed by 30 mg/kg/d in 4 divided doses; maximum daily dose, 2 g
<b>Sulfisoxazole</b>	<ul style="list-style-type: none"> <li>Rapidly absorbed, rapidly excreted</li> <li>Highly soluble and less likely to cause crystalluria than most other sulfonamides</li> </ul>	<ul style="list-style-type: none"> <li>UTI</li> <li>Ocular infections</li> </ul>	PO 2–4 g initially, then 4–8 g daily in 4–6 divided doses	Older than 2 mo: PO 75 mg/kg of body weight initially, then 120–150 mg/kg/d in 4–6 divided doses; maximal daily dose, 6 g
<b>Combination Agent</b>				
<b>Trimethoprim-sulfamethoxazole</b> (Bactrim, Septra, others) Dosage based on Trimethoprim Component	<ul style="list-style-type: none"> <li>May exhibit synergistic effectiveness against many organisms (verify susceptibility first), including streptococci (<i>S. viridans</i>), staphylococci (<i>S. epidermidis</i>, <i>S. aureus</i>), <i>Escherichia coli</i>, <i>Salmonella</i>, <i>Shigella</i>, <i>Serratia</i>, <i>Klebsiella</i>, <i>Nocardia</i>, and others. Most strains of <i>Pseudomonas</i> are resistant.</li> </ul>	<ul style="list-style-type: none"> <li>Acute and chronic UTI</li> <li>Acute exacerbations of chronic bronchitis</li> <li>Acute otitis media caused by susceptible strains of <i>Hemophilus influenzae</i> and <i>Streptococcus pneumoniae</i></li> <li>Shigellosis</li> <li>Infection by <i>Pneumocystis jiroveci</i> (prevention and treatment)</li> </ul>	UTI, trimethoprim 160 mg and sulfamethoxazole 800 mg PO q12h for 10–14 d Shigellosis, same dose as above for 5 d Severe UTI, IV 8–10 mg (trimethoprim component)/kg/d in 2–4 divided doses, up to 14 d	UTI and otitis media, PO 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole in 2 divided doses q12h for 10 d Shigellosis, same dose as above for 5 d Severe UTI, IV 8–10 mg (trimethoprim component)/kg in 2–4 divided doses, q6–8h or q12h, up to 14 d

Generic/Trade Name	Characteristics	Clinical indications	ROUTES AND DOSAGE RANGES	
			Adults	Children
	<ul style="list-style-type: none"> <li>The two drugs have additive antibacterial effects because they interfere with different steps in bacterial synthesis and activation of folic acid, an essential nutrient.</li> <li>The combination is less likely to produce resistant bacteria than either agent alone.</li> <li>Oral preparations contain different amounts of the two drugs, as follows: <ul style="list-style-type: none"> <li>– “Regular” tablets contain trimethoprim 80 mg and sulfamethoxazole 400 mg.</li> <li>– Double-strength tablets (e.g., Bactrim D.S., Septra D.S.) contain trimethoprim 160 mg and sulfamethoxazole 800 mg.</li> <li>– Oral suspension contains trimethoprim 40 mg and sulfamethoxazole 200 mg in each 5 mL.</li> </ul> </li> <li>IV preparation contains trimethoprim 80 mg and sulfamethoxazole 400 mg in 5 mL.</li> <li>Dosage must be reduced in renal insufficiency.</li> <li>The preparation is contraindicated if creatinine clearance is &lt;15 mL/min.</li> </ul>	<ul style="list-style-type: none"> <li>IV preparation indicated for <i>P. jiroveci</i> pneumonia, severe UTI, and shigellosis</li> </ul>	<p><i>P. jiroveci</i> pneumonia, IV 15–20 mg (trimethoprim component)/kg/d in 3 or 4 divided doses, q6–8h up to 21 d; IV doses should be given over 60–90 min.</p>	<p><i>P. jiroveci</i> pneumonia, IV 15–20 mg (trimethoprim component)/kg/d in 3 or 4 divided doses, q6–8h up to 21 d</p>
<b>Topical Sulfonamides</b>				
<b>Mafenide</b> (Sulfamylon)	<ul style="list-style-type: none"> <li>Effective against most gram-negative and gram-positive organisms, especially <i>Pseudomonas aeruginosa</i></li> <li>Application causes pain and burning.</li> <li>Mafenide is absorbed systemically and may produce metabolic acidosis.</li> </ul>	Prevention of bacterial colonization and infection of severe burn wounds	Topical application to burned area, once or twice daily, in a thin layer	Same as adults

(continued on page 518)

Table 32-2

## Drugs at a Glance: Sulfonamides (continued)

Generic/Trade Name	Characteristics	Clinical indications	ROUTES AND DOSAGE RANGES	
			Adults	Children
<b>Silver sulfadiazine</b> (Silvadene)	<ul style="list-style-type: none"> <li>■ Effective against most <i>Pseudomonas</i> species, the most common pathogen in severe burn sepsis; <i>E. coli</i>; <i>Klebsiella</i>; <i>Proteus</i>; staphylococci; and streptococci</li> <li>■ Lower incidence of pain, burning, or itching than mafenide</li> <li>■ Does not cause electrolyte or acid-base imbalances</li> <li>■ Significant amounts may be absorbed systemically with large burned areas and prolonged use. Monitor for adverse effects common to sulfonamides.</li> </ul>	Same as mafenide. Usually the preferred drug	1–2 times daily cover burned area with cream.	Same as mafenide

UTI, urinary tract infection.

(Pyridium), is given to relieve pain associated with UTI. It has no antibacterial activity.

### Mechanisms of Action

Tetracyclines penetrate microbial cells by passive diffusion and an active transport system. Intracellularly, they bind to 30S ribosomes, like the aminoglycosides, and inhibit microbial protein synthesis. Sulfonamides act as antimetabolites of para-aminobenzoic acid (PABA), which microorganisms require to produce folic acid; folic acid, in turn, is required for the production of bacterial intracellular proteins. Sulfonamides enter into the reaction instead of PABA, compete for the enzyme involved, and cause formation of nonfunctional derivatives of folic acid. Thus, sulfonamides halt multiplication of new bacteria but do not kill mature, fully formed bacteria. With the exception of the topical sulfonamides used in burn therapy, the presence of pus, serum, or necrotic tissue interferes with sulfonamide action because these materials contain PABA. Some bacteria can change their metabolic pathways to use precursors or other forms of folic acid and thereby develop resistance to the antibacterial action of sulfonamides. After resistance to one sulfonamide develops, cross-resistance to others is common.

### Indications for Use

A tetracycline is the drug of choice or an alternate (sometimes as part of combination therapy) in a few infections (e.g., brucellosis, chancroid, cholera, granuloma inguinale, psittacosis, Rocky Mountain spotted fever, syphilis, trachoma, typhus, gastroenteritis due to *V. cholerae* or *Helicobacter pylori*). Tetracyclines are also useful in treating some animal bites and Lyme disease. Other drugs (e.g., penicillins) are usually preferred in gram-positive infections, and many gram-negative organisms are resistant to tetracyclines. However, a tetracycline may be used if bacterial susceptibility is confirmed. Specific clinical indications for tetracyclines include

- Treatment of uncomplicated urethral, endocervical, or rectal infections caused by *Chlamydia* organisms.
- Adjunctive treatment, with other antimicrobials, in the treatment of pelvic inflammatory disease and sexually transmitted diseases.
- Postexposure prophylaxis and treatment of anthrax. Doxycycline is the tetracycline of choice as part of a combination-drug regimen.

- Long-term treatment of acne. Tetracyclines interfere with the production of free fatty acids and decrease *Corynebacterium* in sebum. These actions decrease the inflammatory, pustular lesions associated with severe acne.
- As a substitute for penicillin in penicillin-allergic patients. Tetracyclines may be effective in treating syphilis when penicillin cannot be given. They should not be substituted for penicillin in treating streptococcal pharyngitis because microbial resistance is common, and tetracyclines do not prevent rheumatic fever. In addition, they should not be substituted for penicillin in any serious staphylococcal infection because microbial resistance commonly occurs.
- Doxycycline may be used to prevent traveler's diarrhea due to enterotoxigenic strains of *Escherichia coli*.
- Demeclocycline (Declomycin) may be used to inhibit antidiuretic hormone in the treatment of chronic inappropriate antidiuretic hormone secretion.

Sulfonamides are commonly used to treat UTI (e.g., acute and chronic cystitis, asymptomatic bacteriuria) caused by *E. coli* and *Proteus* or *Klebsiella* organisms. In acute pyelonephritis,

other agents are preferred. Trimethoprim-sulfamethoxazole is used in chronic bronchitis due to pneumococci, *H. influenzae*, and *Moraxella catarrhalis*. It is also the drug of choice for treatment and prophylaxis of *P. jiroveci* infection in patients with and without human immunodeficiency virus (HIV) infection. Additional uses of sulfonamides include ulcerative colitis and uncommon infections such as chancroid, lymphogranuloma venereum, nocardiosis, toxoplasmosis, and trachoma. Topical sulfonamides are used in prevention of burn wound infections and in treatment of ocular and other soft tissue infections. For specific clinical indications of individual drugs, see Table 32-2.

Urinary antiseptics are used only for UTI. Table 32-3 summarizes information about drugs used to treat UTI.

### Contraindications to Use

Both tetracyclines (except doxycycline) and sulfonamides are contraindicated in patients with renal failure. Tetracyclines are also contraindicated in pregnant women and in children up to 8 years of age. In the fetus and young child, tetracyclines are deposited in bones and teeth along with calcium. If given during active mineralization of these tissues, tetracyclines can

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Trimethoprim</b> (Proloprim)	<ul style="list-style-type: none"> <li>■ A folate antagonist drug with antibacterial effects</li> <li>■ Available as a single agent for treatment of UTI caused by susceptible strains of <i>E. coli</i>, and other gram-negative organisms</li> <li>■ Most often used in a fixed-dose combination with sulfamethoxazole (Bactrim, Septra)</li> <li>■ Contraindicated in clients with hypersensitivity to trimethoprim or megaloblastic anemia due to folate deficiency</li> <li>■ Rash and pruritus are the most common adverse effects. Nausea, vomiting, thrombocytopenia, and leukopenia occasionally occur.</li> </ul>	PO 100 mg q12h for 10 d or 200 mg q24h for 10 d	4 mg/kg/d in divided doses every 12 h

*UTI, urinary tract infection.*

interfere with tooth enamel formation, cause permanent discoloration (*mottling*) of tooth enamel, and depress bone growth. Increased photosensitivity is a common adverse effect, and patients should be warned to take precautions against sunburn while taking these drugs. Sulfonamides are also contraindicated in late pregnancy, lactation, children younger than 2 months of age (except for treatment of congenital toxoplasmosis), and people who have had hypersensitivity reactions to them or to chemically related drugs (e.g., thiazide diuretics, antidiabetic sulfonylureas). **Sulfasalazine** (Azulfidine) is contraindicated in people who are allergic to salicylates and in people with intestinal or urinary tract obstruction.

### Nursing Process

General aspects of the nursing process in antimicrobial drug therapy, as described in Chapter 29, apply to the patient receiving tetracyclines, sulfonamides, and urinary antiseptics. In this chapter, only those aspects related specifically to these drugs are included.

### Assessment

With tetracyclines, assess for conditions in which the drugs must be used cautiously or are contraindicated, such as impaired renal or hepatic function.

With sulfonamides, assess for signs and symptoms of disorders for which the drugs are used:

- For UTI, assess urinalysis reports for white blood cell and bacteria counts; urine culture reports for type of bacteria; and symptoms of dysuria, frequency, and urgency of urination.
- For burns, assess the size of the wound, amount and type of drainage, presence of edema, and amount of eschar.
- Ask patients specifically if they have ever taken a sulfonamide and, if so, whether they had an allergic reaction.

With urinary antiseptics, assess for signs and symptoms of UTI.

### Nursing Diagnoses

- Risk for Injury: Hypersensitivity reaction, kidney, liver, or blood disorders with sulfonamides
- Deficient Knowledge: Correct administration and use of tetracyclines, sulfonamides, and urinary antiseptics

### Planning/Goals

The patient will

- Receive or self-administer the drugs as directed

- Receive prompt and appropriate treatment if adverse effects occur

## Interventions

- During tetracycline therapy for systemic infections, monitor laboratory tests of renal function for abnormal values.
- During sulfonamide therapy, encourage sufficient fluids to produce a urine output of at least 1200 to 1500 mL daily. A high fluid intake decreases the risk of crystalluria (precipitation of drug crystals in the urine).
- Avoid urinary catheterization when possible. If catheterization is necessary, use sterile technique. The urinary tract is normally sterile except for the lower third of the urethra. Introduction of any bacteria into the bladder may cause infection.
- A single catheterization may cause infection. With indwelling catheters, bacteria colonize the bladder and produce infection within 2 to 3 weeks, even with meticulous care.
- When indwelling catheters must be used, measures to decrease UTI include using a closed drainage system; keeping the perineal area clean; forcing fluids, if not contraindicated, to maintain a dilute urine; and removing the catheter as soon as possible. Do not disconnect the system and irrigate the catheter unless obstruction is suspected. *Never* raise the urinary drainage bag above bladder level.
- Force fluids in anyone with a UTI unless contraindicated. Bacteria do not multiply as rapidly in dilute urine. In addition, emptying the bladder frequently allows it to refill with uninfected urine. This decreases the bacterial population of the bladder.
- Teach women to cleanse themselves from the urethral area toward the rectum after voiding or defecating to avoid contamination of the urethral area with bacteria from the vagina and rectum. Also, voiding after sexual intercourse helps cleanse the lower urethra and prevent UTI.

- Provide appropriate teaching related to any drug therapy (see accompanying displays).

## Evaluation

- Interview and observe for improvement in the infection being treated.
- Interview and observe for adverse drug effects.

### Applying Your Knowledge 32-1

Sharon needs to have adequate serum drug levels of Bactrim to treat her infection successfully. What instruction should you give Sharon in regard to fluid intake?

.....

## Principles of Therapy

### Tetracyclines

Culture and susceptibility studies are needed before tetracycline therapy is started because many strains of organisms are either drug resistant or vary greatly in drug susceptibility. Cross-sensitivity and cross-resistance are common among tetracyclines. The oral route of administration is usually effective and preferred. Intravenous (IV) therapy is used when oral administration is contraindicated or for initial treatment of severe infections.

Tetracyclines decompose with age, exposure to light, and extreme heat and humidity. Because the breakdown products may be toxic, it is important to store these drugs correctly. Also, the manufacturer's expiration dates on containers should be noted, and outdated drugs should be discarded.

### Sulfonamides and Urinary Antiseptics

Urine cultures and susceptibility tests are indicated in suspected UTI because of wide variability in possible pathogens and their susceptibility to antibacterial drugs. The best results

## Patient Teaching Guidelines

### General Considerations

- Because tetracyclines inhibit rather than kill bacteria, they must be administered around the clock to achieve desired effects.
- These drugs increase sensitivity to sunlight and risks of sunburn. Avoid sunlamps, tanning beds, and intense or prolonged exposure to sunlight; if unable to avoid exposure, wear protective clothing and a sunblock preparation.
- Report severe nausea, vomiting, diarrhea, skin rash, or perineal itching. These symptoms may indicate a need for changing or stopping the tetracycline.

## Oral Tetracyclines

### Self-Administration

- Take most tetracyclines on an empty stomach, at least 1 hour before or 2 hours after meals. Doxycycline and minocycline may be taken with food (except dairy products).
- Do not take with or within 2 hours of dairy products, antacids, or iron supplements. If an antacid must be taken, take at least 2 hours before or 4 hours after tetracycline.
- Take each dose with at least 8 ounces of water.

## Patient Teaching Guidelines

## Oral Sulfonamides

### General Considerations

- Sulfonamides inhibit rather than kill bacteria. Thus, it is especially important to take them as prescribed, for the length of time prescribed.
- These drugs increase sensitivity to sunlight and risks of sunburn. Avoid sunlamps, tanning beds, and intense or prolonged exposure to sunlight; if unable to avoid exposure, wear protective clothing and a sunblock preparation.
- Notify the prescribing physician if you have blood in urine, skin rash, difficulty in breathing, fever, or sore throat. These symptoms may indicate adverse drug effects and the need to change or stop the drug.

### Self-Administration

- Take oral sulfonamides with or without food with at least 8 ounces of water.
- With oral suspensions, shake well, refrigerate after opening, and discard the unused portion after 14 days.
- Drink 2 to 3 quarts of fluid daily, if able. A good fluid intake helps the drugs to be more effective, especially in urinary tract infections, and decreases the likelihood of damaging the kidneys.

are obtained with drug therapy indicated by the microorganisms isolated from each patient. With systemically absorbed sulfonamides, an initial loading dose may be given to produce therapeutic blood levels more rapidly. The amount is usually twice the maintenance dose.

Urine pH is important in drug therapy with sulfonamides and urinary antiseptics. With sulfonamide therapy, alkaline urine increases drug solubility and helps prevent *crystalluria*. It also increases the rate of sulfonamide excretion and the concentration of sulfonamide in the urine. The urine can be alkalinized by giving sodium bicarbonate. Alkalinization is not needed with sulfisoxazole (because the drug is highly soluble) or sulfonamides used to treat intestinal infections or burn wounds (because there is little systemic absorption).

### Applying Your Knowledge 32-2

Sharon mentions that she is going to Florida for spring break. What precaution should you teach Sharon?

.....

## Use in Special Populations

### Use in Children

Tetracyclines should not be used in children younger than 8 years of age because of their effects on teeth and bones. In teeth, the drugs interfere with enamel development and may cause a permanent yellow, gray, or brown discoloration. In bone, the drugs form a stable compound in bone-forming tissue and may interfere with bone growth.

Systemic sulfonamides are contraindicated during late pregnancy, lactation, and in children younger than 2 months of age. If a fetus or young infant receives a sulfonamide by placental transfer, in breast milk, or by direct administration, the drug displaces bilirubin from binding sites on albumin. As a result, bilirubin may accumulate in the bloodstream (hyperbilirubinemia) and central nervous system (kernicterus) and cause life-threatening toxicity.

Sulfonamides are often used to treat UTI in children older than 2 months of age. Few data are available regarding the effects of long-term or recurrent use of sulfamethoxazole in children younger than 6 years with chronic renal disease. Sulfamethoxazole is often given in combination with trimethoprim (Bactrim, Septra), although trimethoprim has not been established as safe and effective in children younger than 12 years of age.

Some clinicians recommend that asymptomatic bacteriuria be treated in children younger than 5 years of age to decrease risks of long-term renal damage. Treatment is the same as for symptomatic UTI.

### Use in Older Adults

A major concern with the use of tetracyclines and sulfonamides in older adults is renal impairment, which commonly occurs in this population. Sulfonamides may cause additional renal impairment. As with younger adults, a fluid intake of 2 liters daily is needed to reduce formation of crystals and stones in the urinary tract.

With the combination of trimethoprim-sulfamethoxazole, older adults are at increased risk for severe adverse effects. Severe skin reactions and bone marrow depression are most often reported. Folic acid deficiency may also occur because both of the drugs interfere with folic acid metabolism.

### Use in Patients With Renal Impairment

As discussed previously, most tetracyclines are contraindicated in patients with renal impairment. High concentrations of tetracyclines inhibit protein synthesis in human cells. This antianabolic effect increases tissue breakdown (catabolism) and the amount of waste products to be excreted by the kidneys. The increased workload can be handled by normally functioning kidneys, but waste products are retained when renal function is impaired. This leads to azotemia, increased blood urea nitrogen, hyperphosphatemia, hyperkalemia, and acidosis. If a tetracycline is necessary because of an organism's sensitivity or the host's inability to take other antimicrobial drugs, doxycycline or minocycline may be given.

Systemic sulfonamides should probably be avoided in patients with renal impairment, if other effective drugs are available. Acute renal failure (ARF) has occurred when the drugs or their metabolites precipitated in renal tubules and caused obstruction. ARF is rarely associated with newer sulfonamides, which are more soluble than older ones, but has increased with the use of sulfadiazine to treat toxoplasmosis in patients with acquired immunodeficiency syndrome (AIDS). Preventive measures include an intake of 2 to 3 liters of fluid daily.

### Use in Patients With Hepatic Impairment

Tetracyclines are generally contraindicated in pregnant women because they may cause fatal hepatic necrosis in the mother (as well as interfere with bone and tooth development in the fetus). However, there are some situations where the benefit to the mother may outweigh the risk of liver dysfunction (e.g., rickettsial infections, ehrlichiosis, inhalational anthrax, and malaria). Tetracyclines must be used cautiously in the presence of liver or kidney impairment. Because tetracyclines are metabolized in the liver, hepatic impairment or biliary obstruction slows drug elimination. In patients with renal impairment, high IV doses (>2 g/day) have been associated with death from liver failure. If the drug is necessary to treat patients with known or suspected renal and hepatic impairment, renal and liver function test results should be monitored. In addition, hepatotoxic drugs should be avoided.

Sulfonamides cause cholestatic jaundice in a small percentage of patients and should be used with caution in patients with hepatic impairment.

### Use in Patients With Critical Illness

Tetracyclines may be used to treat sepsis caused by rickettsial, chlamydial, or mycoplasma infection and pulmonary infection caused by *M. pneumoniae* or *Legionella pneumophila*. When necessary, doxycycline is the drug of choice because it can be given to patients with renal impairment, a common problem in critical care settings.

Sulfonamides are rarely used in critical care settings except topical silver sulfadiazine (Silvadene) used to treat burn wounds and trimethoprim-sulfamethoxazole used to treat *P. jiroveci* pneumonia. Although often given IV in critical care settings, oral or nasogastric tube administration of trimethoprim-sulfamethoxazole may be used in selected patients.

### Applying Your Knowledge 32-3

While Sharon is in the clinic it would be prudent to review what she knows about her other medication. What dietary concerns should Sharon be aware of with regard to tetracycline's food-drug and drug-drug interactions?

## Nursing Actions

## Tetracyclines, Sulfonamides, and Urinary Agents

### NURSING ACTIONS

#### 1. Administer accurately

##### a. With tetracyclines:

- (1) Give oral drugs with food that does not contain dairy products; do not give with or within 2 hours of dairy products, antacids, or iron supplements. Doxycycline and minocycline may be given with food.
- (2) For intravenous (IV) administration of Doxycycline, dilute with an appropriate type and amount of IV solution, and infuse over 1–4 hours. Avoid extravasation.

##### b. With sulfonamides:

- (1) Give oral drugs before or after meals, with a full glass of water.
- (2) Infuse IV trimethoprim-sulfamethoxazole (diluted in 125 mL of 5% dextrose in water) over 60–90 minutes. Do not mix with other drugs or solutions and flush IV lines to remove any residual drug.
- (3) For topical sulfonamides to burn wounds, apply a thin layer with a sterile gloved hand after the surface has been cleansed of previously applied medication.

##### c. Give nitrofurantoin with meals.

#### 2. Observe for therapeutic effects

- a. With tetracyclines, observe for decreased signs and symptoms of the infection for which the drug is being given.

### RATIONALE/EXPLANATION

To decrease nausea and other gastrointestinal (GI) symptoms. Tetracyclines combine with metallic ions (e.g., aluminum, calcium, iron, magnesium) and are not absorbed.

Rapid administration should be avoided. IV doses are usually mixed in hospital pharmacies. Doxycycline is very irritating to tissues.

Absorption is better when taken on an empty stomach; however, taking with food decreases GI upset. Manufacturer's recommendations

Burn wounds may be cleansed by whirlpool, shower, or spot cleansing with sterile saline, gauze pads, and gloves.

Food decreases nausea, vomiting, and diarrhea.

Therapeutic effects depend on the reason for use.

## Nursing Actions Tetracyclines, Sulfonamides, and Urinary Agents (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

- b. With sulfonamides, observe for decreased symptoms of urinary tract infection (UTI); decreased diarrhea when given for ulcerative colitis or bacillary dysentery; lack of fever and wound drainage, and absence of infection and evidence of healing in burn wounds.
- c. With urinary antiseptics, observe for decreased symptoms of UTI.

#### 3. Observe for adverse effects

- a. Nausea, vomiting, diarrhea
- b. Hematologic disorders—*anemia, neutropenia, thrombocytopenia*
- c. Hypersensitivity—*anaphylaxis, skin rash, urticaria, serum sickness*
- d. Photosensitivity—*sunburn reaction*

- e. Thrombophlebitis at IV infusion sites

- f. Nephrotoxicity—*increased blood urea nitrogen and serum creatinine; hematuria; proteinuria; crystalluria*

- g. Hepatotoxicity—*elevated aspartate aminotransferase and other enzymes*

- h. Superinfection—*sore mouth; white patches on oral mucosa; black, furry tongue; diarrhea; skin rash; itching in the perineal area; pseudomembranous colitis*

- i. Vertigo and dizziness

- j. Adverse effects of sulfonamides in human immunodeficiency virus (HIV)-infected patients—*rash, fever, leukopenia, elevated transaminases, thrombocytopenia*

#### 4. Observe for drug interactions

- a. Drugs that *decrease* effects of tetracyclines:

- (1) Aluminum, calcium, iron, or magnesium preparations (e.g., antacids, ferrous sulfate)
- (2) Cathartics, didanosine
- (3) Phenobarbital, carbamazepine, phenytoin, rifampin

- b. Drugs that *increase* effects of sulfonamides:

- (1) Alkalinizing agents (e.g., sodium bicarbonate)
- (2) Methenamine compounds, urinary acidifiers (e.g., ascorbic acid)
- (3) Salicylates (e.g., aspirin), nonsteroidal anti-inflammatory drugs (e.g., ibuprofen), oral anticoagulants, phenytoin, methotrexate

- c. Drugs that *alter* effects of nitrofurantoin:

- (1) Antacids
- (2) Acidifying agents

Commonly occur with tetracyclines, sulfonamides, and urinary antiseptics, probably from local irritation of GI mucosa. After several days of an oral tetracycline, diarrhea may be caused by superinfection.

This can be prevented or minimized by avoiding exposure to sunlight or other sources of ultraviolet light, wearing protective clothing, and using sunscreen lotions.

These drugs are irritating to tissues. Irritation can be decreased by diluting the drugs and infusing them at the recommended rates.

Nephrotoxicity is more likely to occur in people who already have impaired renal function. Keeping clients well hydrated may help prevent renal damage.

Hepatitis, cholestasis, and other serious liver disorders rarely occur with these drugs.

Superinfection may occur with tetracyclines because of their broad spectrum of antimicrobial activity. Signs and symptoms usually indicate monilial infection.

Meticulous oral and perineal hygiene helps prevent these problems. The drug should be stopped if severe diarrhea occurs, with blood, mucus, or pus in stools.

Occurs only with minocycline

Occurs in 20%–85% of HIV-infected patients

These metals combine with oral tetracyclines to produce insoluble, nonabsorbable compounds that are excreted in feces.

Decrease absorption

These drugs induce drug-metabolizing enzymes in the liver and may speed up metabolism of doxycycline.

Increase rate of urinary excretion, thereby raising levels of sulfonamides in the urinary tract and increasing effectiveness in UTIs

These drugs increase the risk of nephrotoxicity and should not be used with sulfonamides. They may cause precipitation of sulfonamide with resultant blockage of renal tubules.

Increase toxicity by displacing sulfonamides from plasma proteinbinding sites, thereby increasing plasma levels of free drug

May decrease absorption

Increase antibacterial activity of nitrofurantoin by decreasing renal excretion. Nitrofurantoin is most active against organisms causing UTI when urine pH is 5.5 or less.

## Key Concepts

- The tetracyclines are effective against both gram-positive and gram-negative organisms, although they are usually not drugs of choice. Many gram-negative organisms have developed resistance to tetracyclines.
- Sulfonamides are bacteriostatic against a wide range of gram-positive and gram-negative bacteria, although increasing resistance is making them less useful.
- Sulfasalazine (Azulfidine) is contraindicated in people who are allergic to salicylates.
- Urinary antiseptics may be bactericidal for sensitive organisms in the urinary tract because these drugs are concentrated in renal tubules and reach high levels in urine but are not used in systemic infections because they do not attain therapeutic plasma levels.
- Both tetracyclines (except doxycycline) and sulfonamides are contraindicated in patients with renal failure.

## Review and Application Exercises

### Short Answer Exercises

1. What foods and drugs interfere with absorption of oral tetracyclines? How can interference be prevented or minimized?
2. What are potentially serious adverse effects of tetracyclines?
3. What is the rationale for long-term, low-dose administration of a tetracycline for acne?
4. Which tetracyclines may be given to patients with renal impairment?
5. Why are sulfonamides often effective in UTI?
6. What are major adverse effects of sulfonamides, and how may they be prevented or minimized?
7. What is the rationale for combining sulfamethoxazole and trimethoprim?
8. What are important characteristics of urinary antiseptics?

### NCLEX-Style Questions

9. A 6-year-old child with bronchitis is being seen in the office by the pediatric nurse practitioner. The RN is asked to assess the child. During the nurse's assessment, the mother expresses concern about the expense of treatment. She asks if it is all right for her to use the leftover tetracycline that was prescribed for her 15-year-old son during his last bout of bronchitis. The appropriate response would *not* include:
  - a. counseling the mother about the need to complete the full prescribed regimen of any antibiotic
  - b. instructing the mother to use her son's old prescription, but at half the dose
  - c. informing the mother of the adverse effects on tooth enamel for young children
  - d. instructing the mother to discard her son's old tetracycline medication
10. An HIV-positive client is being seen for routine follow-up care in the physician's office. His chief complaints are fever and a severe rash. His medication regimen includes trimethoprim-sulfamethoxazole for prophylaxis of *P. jiroveci* (formerly called *carinii*) infection. The client asks if his symptoms could be due to his medication. The nurse's best response is
  - a. The likelihood of the patient's fever and rash being drug-related is very low.
  - b. A high percentage of patients with HIV receiving trimethoprim-sulfamethoxazole develop adverse reactions such as these.
  - c. Adverse effects of trimethoprim-sulfamethoxazole in HIV-infected patients are rarely serious and usually self-limiting.
  - d. The presence of fever and rash probably indicates that the trimethoprim-sulfamethoxazole regimen is ineffective.
11. Patient teaching about phenazopyridine should not include
  - a. instruction that the drug is not an antibiotic and only relieves the symptoms of a UTI
  - b. a warning that the drug causes a harmless orange-red discoloration of the urine
  - c. counseling to take the drug after meals
  - d. instruction that phenazopyridine will eradicate the UTI in 3 days
12. The nurse prepares to administer the 2:00 P.M. medications to a hospitalized patient. Scheduled for that time are doxycycline PO, Maalox PO, and ferrous sulfate PO. The nurse should
  - a. change the doxycycline to IV to avoid drug interactions
  - b. co-administer the doxycycline and ferrous sulfate but hold the Maalox until 4:00 P.M.
  - c. reschedule the Maalox and ferrous sulfate to 4:00 P.M.
  - d. give the medications with a glass of milk to decrease stomach irritation

13. Which of the following instructions should be given to clients prescribed either tetracycline or a sulfonamide medication?
- Take with at least 8 ounces of water.
  - Direct exposure to the sun should be avoided, but use of tanning beds is acceptable during therapy.
  - Take the antibiotic until no longer febrile.
  - These medications are safe in late pregnancy.

# Macrolides, Ketolides, and Miscellaneous Antibacterials

## KEY TERMS

- Glycylcycline
- Gray syndrome
- Ketolides
- Lincosamide
- Lipopeptide
- MAC
- Macrolides
- MRSA
- MSSA
- Myelosuppression
- Oxazolidinone
- Red man syndrome
- SSNA
- Streptogramins
- VRE
- VREF

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify characteristics and specific uses of macrolide and ketolide antibacterials.
2. Compare and contrast macrolides and ketolides with other commonly used antibacterial drugs.
3. Apply principles of using macrolides and ketolides in selected patient situations.
4. Discuss characteristics and clinical indications for using chloramphenicol, clindamycin, daptomycin, linezolid, metronidazole, quinupristin-dalfopristin, rifaximin, spectinomycin, and vancomycin.
5. Discuss the roles of metronidazole and oral vancomycin in the treatment of pseudomembranous colitis.

## Applying Your Knowledge

Juro Nikki is a 65-year-old man who has had chronic obstructive pulmonary disease for a number of years. He presents to the doctor's office with a respiratory tract infection. He is started on azithromycin 500 mg for one dose, then 250 mg PO daily for 4 days.

## Introduction

The drugs described in this chapter are heterogeneous in their antimicrobial spectra, characteristics, and clinical uses. Some are used often; some are used only in specific circumstances. The macrolides, ketolides, and selected miscellaneous drugs are described in the following sections; names, routes, and dosage ranges of individual drugs are listed in the Drugs at a Glance tables.

## Macrolides and Ketolides

Table 33-1 presents routes and dosage ranges for macrolides and ketolides.

The *macrolides*, which include erythromycin, **azithromycin** (Zithromax), and **clarithromycin** (Biaxin), have similar antibacterial spectra and mechanisms of action. Macrolides are widely distributed into body tissues and fluids and may be bacteriostatic or bactericidal, depending on drug concentration in infected tissues. They are effective against gram-positive cocci, including group A streptococci, pneumococci, and most staphylococci. They are also effective against species of

Table 33-1

## Drugs at a Glance: Macrolides and Ketolides

Generic/Trade Name	USUAL ROUTES AND DOSAGE RANGES	
	Adults	Children
Azithromycin (Zithromax)	Respiratory and skin infections: PO 500 mg as a single dose on day 1, then 250 mg once daily for 4 days (Zpak) Nongonococcal urethritis and cervicitis caused by <i>Chlamydia trachomatis</i> , 1 g as a single dose Prevention of MAC, PO 1200 mg once per week Treatment of MAC, PO 600 mg once daily Bacterial sinusitis: Tri-pak PO 500 mg daily for 3 days, or Zmax extended-release formula PO 2 g as a single dose CAP: IV 500 mg daily for at least 2 d followed by PO 500 mg daily for total of 7–10 d treatment	6 mo to 2 y: For otitis media, PO 10 mg/kg on day 1 (not to exceed 500 mg), then 5 mg/kg once daily for 4 days (not to exceed 250 mg/d) 2 y and older: For pharyngitis/tonsillitis, PO 12 mg/kg (not to exceed 500 mg) once daily for 5 d
Clarithromycin (Biaxin, Biaxin XL)	PO 250–500 mg q12h for 7–14 d Prevention/treatment of MAC: PO 500 mg q12h or 1000 mg XL daily Extended-release: bronchitis and CAP PO 1000 mg daily for 7 d Acute maxillary sinusitis: PO 1000 mg daily for 14 d	PO 7.5 mg/kg, not to exceed 500 mg every 12 h Prevention/treatment of MAC: same as above
Erythromycin base (E-mycin)	PO 250–500 mg q6–12h Severe infections: up to 4 g daily in divided doses	PO 30–50 mg/kg/d in divided doses q6–12h
Erythromycin ethylsuccinate (E.E.S.)	PO 400–800 mg q6–12h Severe infections: up to 4 g daily in divided doses	PO 30–50 mg/kg/d in 2–4 divided doses
Erythromycin lactobionate	IV 15–20 mg/kg/d in divided doses q6h or 500 mg–1 g q6h or may be given as a continuous infusion over 24 h (maximum dose 4 g/d) Severe infections: up to 4 g daily in divided doses	15–50 mg/kg/d in divided doses q6h, not to exceed 4 g/d
Erythromycin stearate (Erythrocin stearate)	PO 250 mg q6h or 500 mg q12h Severe infections: up to 4 g daily in divided doses	PO 30–50 mg/kg/d in 2–4 divided doses
Telithromycin (Ketek)	CAP: PO 800 mg once daily for 7–10 d	

CAP, community-acquired pneumonia; MAC, *Mycobacterium avium* complex.

*Corynebacterium*, *Treponema*, *Legionella*, *Chlamydia*, *Neisseria*, and *Mycoplasma* and against some anaerobic species of organisms such as *Bacteroides* and *Clostridia*. Azithromycin and clarithromycin also are active against the atypical mycobacteria that cause *Mycobacterium avium* complex (MAC) disease. MAC disease (see Chap. 34) is an opportunistic infection that occurs mainly in people with advanced human immunodeficiency virus (HIV) infection. *Helicobacter pylori*, a pathogen implicated in peptic ulcer disease, is also

treated by azithromycin or clarithromycin as part of a combination regimen (see Chap. 59).

**P Erythromycin**, the prototype, is now used less often because of microbial resistance, numerous drug interactions, and the development of newer macrolides. Erythromycin is metabolized in the liver and excreted mainly in bile; approximately 20% is excreted in urine. Depending on the specific salt formulation used, food can have a variable effect on the absorption of oral erythromycin. Compared with erythromycin, the

newer drugs have enhanced antibacterial activity, require less frequent administration, and cause less nausea, vomiting, and diarrhea. Azithromycin is excreted mainly in bile, and clarithromycin is metabolized to an active metabolite in the liver, which is then excreted in urine.

Erythromycin is available in several preparations. Ophthalmic and topical preparations are discussed in Chapters 63 and 64, respectively.

A relative of the macrolides, **telithromycin** (Ketek) is the first member of the ketolide class. In addition to sharing the general spectrum of activity of the newer macrolides, it offers better activity against macrolide-resistant strains of *Streptococcus pneumoniae*, an increasingly common cause of infections in children and adults. Telithromycin is excreted by the liver and kidneys. Food does not affect the absorption of telithromycin.

### Mechanism of Action

The macrolides and ketolides enter microbial cells and reversibly bind to the 50S subunits of ribosomes, thereby inhibiting microbial protein synthesis. *Ketolides* have a greater affinity for ribosomal RNA, expanding their antimicrobial spectrum compared with macrolides.

### Indications for Use

The macrolides are widely used for treatment of respiratory tract and skin/soft tissue infections caused by streptococci and staphylococci. Erythromycin is also used as a penicillin substitute in patients who are allergic to penicillin; for prevention of rheumatic fever, gonorrhea, syphilis, pertussis, and chlamydial conjunctivitis in newborns (ophthalmic ointment); and to treat other infections (e.g., Legionnaire’s disease, genitourinary infections caused by *Chlamydia trachomatis*, intestinal amebiasis caused by *Entamoeba histolytica*).

In addition, azithromycin is approved for treatment of urethritis and cervicitis caused by *C. trachomatis* organisms and is

being used for the prevention and treatment of MAC disease. For acute bacterial sinusitis, azithromycin is approved for an abbreviated 3-day treatment duration.

Clarithromycin is approved for prevention and treatment of MAC disease. Clarithromycin is also approved to treat *H. pylori* infections associated with peptic ulcer disease.

The ketolide telithromycin is approved only for community-acquired pneumonia (including multidrug-resistant *S. pneumoniae*). The U.S. Food and Drug Administration (FDA) recently rescinded approval for two other indications, citing the risk of adverse effects (e.g., liver toxicity, loss of consciousness, and visual disturbances) outweighed the benefit of the medication.

### Contraindications to Use

Macrolides and ketolides are contraindicated in people who have had hypersensitivity reactions. Telithromycin is contraindicated in people who have had hypersensitivity reactions to macrolides. All macrolides and telithromycin must be used with caution in patients with pre-existing liver disease. A **BLACK BOX WARNING** for erythromycin estolate and an FDA alert for telithromycin emphasizes the liver toxicity associated with these drugs. Use of erythromycin and telithromycin concurrently with drugs highly dependent on CYP3A4 liver enzymes for metabolism (e.g., pimozide) is contraindicated. The FDA has issued a **BLACK BOX WARNING** alerting health care professionals that telithromycin is contraindicated in patients with myasthenia gravis due to the potential for fatal and life-threatening respiratory failure.

## Miscellaneous Antibacterial Drugs

Table 33-2 summarizes pertinent information about miscellaneous antibacterial drugs.

Table 33-2

### Drugs at a Glance: Miscellaneous Antibacterials

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
Chloramphenicol (Chloromycetin)	IV 50–100 mg/kg/d in divided doses q6h (maximum dose 4 g/d)	Meningitis (infants older than 30 days and children): 50–100 mg/kg/d in divided doses q6h Other infections (infants older than 30 days and children): 50–75 mg/kg/d in divided doses q6h (maximum daily dose 4 g)
Clindamycin hydrochloride (Cleocin)	PO 150–450 mg q6–8h (maximum dose 1.8 g/d)	PO 8–16 mg/kg/d in divided doses q6–8h; up to 20 mg/kg/d in severe infections
Clindamycin phosphate (Cleocin phosphate)	IV, IM 1.2–1.8 g/d in 2–4 divided doses (maximum dose 4–8 g/d)	Neonates: 15–20 mg/kg/d in divided doses q6–8h

(continued on page 530)

Table 33-2

## Drugs at a Glance: Miscellaneous Antibacterials (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
		1 mo and older: IM, IV 20–40 mg/kg/d in divided doses q6–8h; up to 40 mg/kg/d in severe infections
Clindamycin palmitate (Cleocin pediatric-75 mg/mL)		PO 8–25 mg/kg/d in divided doses q6–8h, the minimum dose is 37.5 mg q8h
Daptomycin (Cubicin)	Skin/soft tissue infections: IV 4 mg/kg q24h for 7–14 d MSSA, MRSA bacteremia or R-sided endocarditis: 6 mg/kg/d for 2–6 wk	Dosage not established
Linezolid (Zyvox)	PO, IV 400–600 mg q12h for 10–28 d	Neonates under 7 d: PO, IV 10 mg/kg q12h Children 7 d–11 y: PO, IV 10 mg/kg q8h 12 y and older: PO, IV 600 mg q12h
Metronidazole (Flagyl)	Anaerobic bacterial infection: PO, IV 500 mg q6–8h, not to exceed 4 g/d Surgical prophylaxis, colorectal surgery: IV 500 mg infused over 30–60 min within 0.5–1 h before surgery C. difficile colitis: PO 250–500 mg q6–8h for 10–14 d	Anaerobic infections in children older than 7 d and weighing 1200–2000 g: PO, IV 15 mg/kg/d in divided doses q12h Anaerobic infections in children older than 7 d and weighing more than 2000 g: 30 mg/kg/d in divided doses q12h Children ≥ 1 mo: PO 15–35 mg/kg/d in divided doses q8h; IV 30 mg/kg/d in divided doses q6h
Quinupristin-dalfopristin (Synercid)	IV 7.5 mg/kg over 60 min q12h for skin and skin-structure infections and q8h for VREF bacteremia	Same as adult Shunt infection due to VRE: 7.5 mg/kg/dose q8h
Rifaximin (Xifaxan)	PO 200 mg three times daily for 3 d	12 y and older: same as adult
Spectinomycin (Trobicin)	IM 2 g in a single dose (or 4 g in a single dose where antibiotic resistance is prevalent)	45 kg and over: Same as adult under 45 kg: IM 40 mg/kg single dose, maximum dose 2 g
Tigecycline (Tygacil)	IV 100 mg single dose initially; maintenance dose 50 mg q12h for 5–14 d	Dosage not established
Vancomycin (Vancocin)	Antibiotic-associated pseudomembranous colitis: PO 100–500 mg q6h (PO dose not for treating systemic infections) IV 20–45 mg/kg/d in divided doses (dose must be adjusted for renal impairment)	Antibiotic-associated pseudomembranous colitis: PO 40 mg/kg/d in divided doses q6–8h (PO dose not for treating systemic infections) 1 mo and older: IV 10–15 mg/kg q6h

VREF, vancomycin-resistant *Enterococcus faecium*.

**Chloramphenicol** (Chloromycetin) is a broad-spectrum, bacteriostatic antibiotic that is active against most gram-positive and gram-negative bacteria, rickettsiae, chlamydiae, and treponemes. It acts by interfering with microbial protein synthesis. It is well absorbed and diffuses well into body tissues and fluids, including cerebrospinal fluid (CSF), but low drug levels are obtained in urine. It is metabolized in the liver and excreted in the urine.

Chloramphenicol is rarely used now to treat infections because of the effectiveness and low toxicity of alternative

drugs. It is used in serious infections for which no adequate substitute drug is available. Specific infections include meningococcal, pneumococcal, or *Haemophilus meningitis* in penicillin-allergic patients; anaerobic brain abscess; *Bacteroides fragilis* infections; and rickettsial infections and brucellosis when tetracyclines are contraindicated. In infections due to vancomycin-resistant enterococci (VRE), chloramphenicol is effective against some strains. The FDA has issued a **BLACK BOX WARNING** reporting the development of serious and fatal blood dyscrasias with its use.

**Clindamycin** (Cleocin), a *lincosamide*, is similar to the macrolides in its mechanism of action and antimicrobial spectrum. Bacteriostatic in usual doses, it is effective against gram-positive cocci, including group A streptococci, pneumococci, most staphylococci, and some anaerobes such as *Bacteroides* and *Clostridia*. Clindamycin enters microbial cells and attaches to 50S subunits of ribosomes, thereby inhibiting microbial protein synthesis.

Clindamycin is often used to treat infections caused by *B. fragilis*. Because these bacteria are usually mixed with gram-negative organisms from the gynecologic or gastrointestinal (GI) tracts, clindamycin is usually given with another drug, such as an aminoglycoside or a fluoroquinolone, to treat mixed infections. The drug may be useful as a penicillin substitute in patients who are allergic to penicillin and who have serious streptococcal (including prevention of perinatal group B streptococcal disease), staphylococcal, or pneumococcal infections in which the causative organism is susceptible to clindamycin. A topical solution is used in the treatment of acne, and a vaginal cream is available. Clindamycin does not reach therapeutic concentrations in the central nervous system (CNS) and cannot be used for treating meningitis.

Clindamycin is well absorbed with oral administration and reaches peak plasma levels within 1 hour after a dose. It is widely distributed in body tissues and fluids, except CSF, and crosses the placenta. It is highly bound (90%) to plasma proteins. It is metabolized in the liver, and the metabolites are excreted in bile and urine. Dosage may need to be reduced in patients with severe hepatic failure to prevent accumulation and toxic effects. The FDA has issued a **BLACK BOX WARNING** for clindamycin reporting the development of severe colitis with its use that can be life-threatening.

**Daptomycin** (Cubicin) belongs to the *lipopeptide* class, a new class of antibiotics. It is a bactericidal agent effective only for gram-positive infections due to *Staphylococcus aureus* (including oxacillin-resistant strains), *Streptococcus pyogenes*, group B streptococci, and *Enterococcus faecalis* (vancomycin-susceptible strains only). In combination with gentamicin, daptomycin is synergistic in killing staphylococci and enterococci. Its mechanism of action is unique. The drug kills bacteria by inhibiting synthesis of bacterial proteins, DNA, and RNA. Indications are limited to the treatment of complicated skin and skin structure infections caused by the above organisms.

Available only for IV administration, the drug reaches target concentrations by the third daily dose. Daptomycin is excreted primarily by the kidneys. Information on use in children or during pregnancy and lactation is not known. Adverse musculoskeletal effects have been seen, primarily as increased serum creatine kinase (CK) levels. These effects are usually asymptomatic, but the drug should be discontinued in patients who develop muscle pain or weakness. The most common adverse effects are constipation, nausea, diarrhea, and vomiting.

**Tigecycline** (Tygacil) is a member of the *glycylcycline* class and is currently the only member in its class. Glycylcyclines are structurally related to tetracyclines and share many of their

properties. Tigecycline binds to the 30S ribosomal subunit of susceptible bacteria, thus inhibiting protein synthesis. The drug is used for the treatment of complicated skin and skin structure infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-sensitive *Enterococcus faecalis* as well as for treatment of complicated intra-abdominal infections. It is generally considered bacteriostatic and has demonstrated activity against a variety of gram-positive and gram-negative bacteria. Tigecycline is only administered intravenously. Because tigecycline is structurally similar to tetracycline, caution must be used in patients with prior hypersensitivity or severe adverse reactions associated with the use of tetracycline.

Tigecycline may be associated with antianabolic effects, pancreatitis, photosensitivity, pseudotumor cerebri, or superinfection. These potential adverse effects are due to structural similarities with tetracyclines. In addition, tigecycline may be associated with photosensitivity, and safety and efficacy has not been established in children younger than 18 years of age. The most common adverse effects appear to be gastrointestinal and include nausea, vomiting, and diarrhea. Others include hypertension, fever, headache, hypoproteinemia, abdominal pain, thrombocytopenia, and increased liver enzymes. Use caution in patients with hepatic impairment. In severe impairment, a dosage adjustment may be necessary.

**Linezolid** (Zyvox) is a member of the *oxazolidinone* class, a newer class of antibiotics. It is active against aerobic gram-positive bacteria, in which it acts by inhibiting protein synthesis by a unique mechanism. Linezolid binds to the bacterial 23S ribosomal RNA of the 50S subunit, thus preventing an essential component of the bacterial translation process. The drug exhibits bactericidal activity against most staphylococci, enterococci, and streptococci. It is well absorbed orally, distributes widely, and undergoes hepatic elimination. Its effects in pregnancy and in children are largely unknown.

Linezolid is indicated for pneumonia (both community acquired and nosocomial), complicated and uncomplicated skin and skin structure infections, and vancomycin-resistant *Enterococcus faecium* (VREF) infections. The drug is bacteriostatic against enterococci (including *E. faecalis* and *E. faecium*) and staphylococci (including methicillin-resistant strains) and bactericidal for most streptococci.

*Myelosuppression* (e.g., anemia, leukopenia, pancytopenia, thrombocytopenia) is a serious adverse effect that may occur with prolonged therapy over 2 weeks. The patient's complete blood count should be monitored; if myelosuppression occurs, linezolid should be discontinued. Myelosuppression usually improves with drug discontinuation. Pseudomembranous colitis may also occur. Mild cases usually resolve with drug discontinuation; moderate or severe cases may require fluid and electrolyte replacement and an antibacterial drug that is effective against *Clostridium difficile* organisms. Hypertension may occur with the concomitant ingestion of linezolid and adrenergic drugs (e.g., dopamine, epinephrine). Patients receiving linezolid and selective serotonin reuptake inhibitors

(SSRIs) may be at risk for serotonin syndrome, characterized by fever and cognitive dysfunction. Because linezolid is a weak monoamine oxidase (MAO) inhibitor, patients should avoid food high in tyramine content (aged cheeses, fermented or air-dried meats, sauerkraut, soy sauce, tap beers, red wine) while taking the drug. An FDA alert (2007) noted an increased rate of deaths among individuals treated with linezolid for catheter-related bacteremia and catheter site infections and emphasized that linezolid is not approved for site infections or bacteremia due to catheters or for gram negative infections.

**Metronidazole** (Flagyl) is effective against anaerobic bacteria, including gram-negative bacilli such as *Bacteroides*, gram-positive bacilli such as *Clostridia*, and some gram-positive cocci. It is also effective against protozoa that cause amebiasis, giardiasis, and trichomoniasis (see Chap. 37). Metronidazole achieves therapeutic concentrations in body fluids and tissues and can be used to treat anaerobic brain abscesses. It is eliminated by the liver and kidneys.

Clinical indications for use include prevention or treatment of anaerobic bacterial infections (e.g., in colorectal surgery, intra-abdominal infections) and treatment of *C. difficile* infections associated with pseudomembranous colitis. As part of a combination regimen, it is also useful in treatment of infections due to *H. pylori*. It is contraindicated during the first trimester of pregnancy and must be used with caution in patients with CNS or blood disorders.

**Quinupristin-dalfopristin** (Synercid) belongs to a class of antimicrobials referred to as *streptogramins*. Both components are active antimicrobials that affect bacterial ribosomes to decrease protein synthesis. The combination is bacteriostatic against *E. faecium* (including vancomycin-resistant strains) and bactericidal against methicillin-susceptible strains of *S. aureus* (MSSA). It is not active against *E. faecalis*. The combination undergoes biliary excretion and fecal elimination.

Quinupristin-dalfopristin is indicated for skin and skin structure infections caused by *S. aureus* or group A streptococcus. It is also used for treatment of patients with serious or life-threatening infections associated with VREF bacteremia; however, a **BLACK BOX WARNING** reports that FDA approval for this use is based on the ability of the drug to clear bacteria from the bloodstream rather than its ability to cure the underlying infection. Further clinical studies are underway to verify the clinical benefits of quinupristin-dalfopristin for curing VREF infections.

Quinupristin-dalfopristin is a strong inhibitor of cytochrome P450 3A4 enzymes and therefore interferes with the metabolism of drugs such as cyclosporine, antiretrovirals, carbamazepine, and many others. Toxicity may occur with the inhibited drugs.

**Rifaximin** (Xifaxan) is a structural analog of rifampin. It is used in infectious (travelers') diarrhea due to *Escherichia coli* but is not effective in diarrhea due to *Campylobacter jejuni* (see Chap. 61). It is not known whether rifaximin is effective to treat diarrhea due to *Shigella* or *Salmonella* species. Because of its very limited systemic absorption (97% eliminated in feces),

rifaximin cannot be used to treat systemic infections, including infections due to invasive strains of *E. coli*. Therefore, diarrhea occurring with fever or bloody stools should be treated with alternative agents. After treatment with rifaximin is started, patients reporting worsening or persistent diarrhea for longer than 24 to 48 hours, fever, or blood in the stool should be treated with an alternative agent.

**Spectinomycin** (Trobicin) is used for treatment of gonococcal exposure or infection in people who are allergic to or unable to take the preferred regimen. It may be used during pregnancy when patients cannot tolerate cephalosporins. Spectinomycin has no activity against infections caused by *Chlamydia* organisms, which often accompany gonorrhea. Therefore, spectinomycin should be followed by adequate chlamydial treatment.

**Vancomycin** (Vancocin) is active only against gram-positive microorganisms. It acts by inhibiting cell wall synthesis. Parenteral vancomycin has been used extensively to treat infections caused by methicillin-resistant *S. aureus* (MRSA) and methicillin-resistant staphylococcal species non-aureus (SSNA, including *Staphylococcus epidermidis*) and endocarditis caused by *Streptococcus viridans* (in patients allergic to or with infections resistant to penicillins and cephalosporins) or *E. faecalis* (with an aminoglycoside).

*S. pneumoniae* remain susceptible to vancomycin, although vancomycin-tolerant strains have been identified. The drug has also been widely used for prophylaxis of gram-positive infections in patients who are at high risk of developing MRSA infections (e.g., those with diabetes, previous hospitalization, or MRSA in their nasal passages) and who require placement of long-term intravascular catheters and other invasive treatment or monitoring devices. Oral vancomycin is used only to treat staphylococcal enterocolitis and pseudomembranous colitis caused by *C. difficile*.

Partly because of this widespread use, VRE are being encountered more often, especially in critical care units, and treatment options for infections caused by these organisms are limited. To decrease the spread of VRE, the Centers for Disease Control and Prevention (CDC) recommend limiting the use of vancomycin. Specific recommendations include avoiding or minimizing use in empiric treatment of febrile patients with neutropenia (unless the prevalence of MRSA or SSNA is high), in initial treatment for *C. difficile* colitis (metronidazole is preferred), and as prophylaxis for surgery, low birth weight infants, intravascular catheter colonization or infection, and peritoneal dialysis.

For systemic infections, vancomycin is given IV and reaches therapeutic plasma levels within 1 hour after infusion. It is very important to give IV infusions slowly, over 1 to 2 hours, to avoid an adverse reaction characterized by hypotension, flushing, and skin rash. This reaction, sometimes called "red man syndrome," is attributed to histamine release. Vancomycin is excreted through the kidneys; dosage should be reduced in the presence of renal impairment. For bacterial colitis, vancomycin is given orally because it is not absorbed

from the GI tract and acts within the bowel lumen. Large amounts of vancomycin are excreted in the feces after oral administration.

## Nursing Process

### Assessment

- Assess for infections that macrolides, ketolides, and the designated miscellaneous drugs are used to prevent or treat.
- Assess each patient for signs and symptoms of the specific current infection.
- Assess culture and susceptibility reports when available.
- Assess each patient for risk factors that increase risks of infection (e.g., immunosuppression) or risks of adverse drug reactions (e.g., impaired renal or hepatic function).

### Nursing Diagnoses

- Deficient Knowledge related to type of infection and appropriate use of prescribed antimicrobial drugs
- Risk for Injury related to adverse drug effects
- Risk for Injury related to infection with antibiotic-resistant microorganisms

### Planning/Goals

#### The patient will

- Take or receive macrolides, ketolides, and miscellaneous antimicrobials accurately, for the prescribed length of time
- Experience decreased signs and symptoms of the infection being treated
- Be monitored regularly for therapeutic and adverse drug effects
- Verbalize and practice measures to prevent recurrent infection

### Interventions

- Use measures to prevent and minimize the spread of infection (see Chap. 29).
- Monitor for fever and other signs and symptoms of infection.
- Monitor laboratory reports for indications of the patient's response to drug therapy (e.g., white blood cell count [WBC], tests of renal function).
- Encourage fluid intake to decrease fever and maintain good urinary tract function.
- Provide foods and fluids with adequate nutrients to maintain or improve nutritional status, especially if febrile and hypermetabolic.
- Assist patients to prevent or minimize infections with streptococci, staphylococci, and other gram-positive organisms.
- Provide appropriate patient teaching for any drug therapy (see accompanying display).

## Evaluation

- Interview and observe for improvement in the infection being treated.
- Interview and observe for adverse drug effects.

### Applying Your Knowledge 33-1

What instructions should be given to Mr. Nikki with regard to drug–food or drug–drug interactions for him to accurately self-administer the azithromycin?

## Principles of Therapy

### Culture and Susceptibility Studies

Culture and susceptibility reports and local susceptibility patterns should be reviewed to determine if an antibiotic-resistant pathogen is present in the patient. This is particularly important before starting vancomycin, quinupristin-dalfopristin, daptomycin, or linezolid. These drugs have relatively narrow spectra of activity and appropriate indications for their use should be observed to decrease the likelihood of resistance.

### Effects of Macrolides on Other Drugs

Erythromycin is metabolized by the cytochrome P450 3A4 isoenzymes in the liver. It interacts with other drugs metabolized by the same isoenzyme and interferes with the elimination of several drugs. As a result, the affected drugs are eliminated more slowly, their serum levels are increased, and they are more likely to cause adverse effects and toxicity unless dosage is reduced. Erythromycin in combination with potent inhibitors of CYP3A4 (e.g., fluconazole, diltiazem) increases the risk of sudden cardiac death. A partial list of other interacting drugs includes carbamazepine (Tegretol), cyclosporine (Sandimmune), digoxin (Lanoxin), disopyramide (Norpace), lopinavir-ritonavir (Kaletra), lovastatin (Mevacor), nevirapine (Viramune), pimozide (Orap), quinidine, rifampin (Rifadin), ritonavir (Norvir), simvastatin (Zocor), theophylline (Theo-Dur), triazolam (Halcion), and warfarin (Coumadin). These drugs represent a variety of drug classes.

Although they are less potent inhibitors of CYP3A than erythromycin, clarithromycin and telithromycin also interact with many of these drugs. Azithromycin is not a potent inhibitor of the CYP3A4 isoenzyme and is less prone to drug–drug interactions. However, caution should be used with all these agents.

### Preventing Toxicity

#### Chloramphenicol

Blood dyscrasias (potentially serious and life-threatening) have occurred in patients taking chloramphenicol. The FDA has

## Patient Teaching Guidelines Macrolides and Ketolides

### General Considerations

- Complete the full course of drug therapy. The fastest and most complete relief of infections occurs with accurate usage of antibiotics. Moreover, inaccurate use may cause other, potentially more severe, infections.
- These drugs are often given for infections of the respiratory tract or skin (e.g., bronchitis, pneumonia, cellulitis). Good hand hygiene can help prevent the development and spread of these infections.
- Report symptoms of infection that recur or develop during antibiotic therapy. Such symptoms can indicate recurrence of the original infection (i.e., the antibiotic is not effective because it is the wrong drug or wrong dosage for the infection or it is not being taken accurately) or a new infection with antibiotic-resistant bacteria or fungi.
- Report nausea, vomiting, diarrhea, abdominal cramping or pain, yellow discoloration of the skin or eyes (jaundice), dark urine, pale stools, or unusual tiredness. These symptoms may indicate liver damage, which sometimes occurs with these drugs.
- Telithromycin (Ketek) may cause loss of consciousness and interfere with accommodation, resulting in visual disturbances such as blurred vision, difficulty focusing, and diplopia. This often occurs with the first or second

dose. Caution should be used while driving, operating machinery, or engaging in other potentially hazardous activities. Report loss of consciousness or visual disturbances to your health care provider.

### Self-Administration

- Take each dose with 6 to 8 ounces of water, at evenly spaced time intervals, preferably around the clock.
- With erythromycin, ask a health care provider if not instructed when to take the drug in relation to food. Erythromycin is available in several preparations. Some should be taken on an empty stomach (at least 1 hour before or 2 hours after meals) or may be taken with a small amount of food if gastrointestinal upset occurs. Some preparations may be taken without regard to meals.
- Take azithromycin (Zithromax) tablets and oral suspension without regard to meals. Do not take with an antacid. Azithromycin ER should be taken on an empty stomach.
- Take clarithromycin (Biaxin) regular tablets and the oral suspension without regard to meals. Take extended-release tablets (Biaxin XL) with food. With the oral suspension, do not refrigerate and shake well before measuring the dose.
- Take telithromycin (Ketek) without regard to meals.

issued a **BLACK BOX WARNING** regarding this adverse effect. Irreversible bone marrow depression, which may lead to aplastic anemia, may appear weeks or months after therapy. A dose-related reversible bone marrow depression usually responds to discontinuation of the drug. Patients should be monitored with a complete blood count, platelet count, reticulocyte count, and serum iron test every 2 days. In addition, periodic measurements of serum drug levels are recommended when possible. Therapeutic levels are 5 to 20 micrograms per milliliter. Therapy should be discontinued as soon as possible, and the drug should not be used for trivial infections or for prophylaxis of infections. During therapy, it is recommended that the patient be hospitalized to facilitate close monitoring.

### Clindamycin

If diarrhea develops in a patient receiving clindamycin, the drug should be stopped. The FDA has issued a **BLACK BOX WARNING** regarding the potential for severe and possible fatal colitis. If the diarrhea is severe and persistent, stools should be checked for WBCs, blood, mucus, and the presence of *C. difficile* toxin. Sigmoidoscopy can be done to more definitively determine whether the patient has pseudomembranous colitis, a potentially fatal adverse reaction. If lesions are seen on sigmoidoscopy, the drug should be stopped immediately. Although pseudomembranous colitis may occur with any antibiotic, it has often been associated with clindamycin therapy.

### Applying Your Knowledge 33-2

Juro Nikki returns to the office with severe diarrhea and a fever. He is diagnosed with pseudomembranous colitis. His stool is positive for *C. difficile* secondary to antibiotic therapy. He is prescribed metronidazole 500 mg PO three times a day for 7 days. What adverse effects should you assess for in a patient receiving metronidazole?

### Daptomycin

Unexplained increases in serum CK levels associated with symptoms of myopathy should prompt discontinuation of daptomycin. Concurrent use of daptomycin with other drugs that might produce rhabdomyolysis (e.g., statin cholesterol-lowering drug) may increase the risk of musculoskeletal toxicity. If possible, these drugs should not be used concomitantly.

### Use in Special Populations

#### Use in Children

Erythromycin is usually considered safe for treatment of infections caused by susceptible organisms. Azithromycin and clarithromycin are used in young children for some infections (e.g., pharyngitis/tonsillitis, acute otitis media). Safety and effectiveness of telithromycin have not been established for children.

Dosage of chloramphenicol must be reduced in premature infants and in full-term infants less than 2 weeks of age because immature metabolism may lead to accumulation and adverse effects, including fatalities (“gray syndrome”).

Clindamycin should be given to neonates and infants only if clearly indicated, and then liver and kidney function must be monitored. Diarrhea and pseudomembranous colitis may occur with topical clindamycin for treatment of acne. The safety and efficacy of metronidazole have been established in children only for the treatment of amebiasis, although the drug is used for other infections in pediatric patients without reported unusual adverse effects. Linezolid and vancomycin are used in children, including premature and full-term neonates, for the same indications as in adults. Monitoring serum drug levels is recommended with IV vancomycin.

With the newer drugs, such as daptomycin, quinupristin-dalfopristin, and rifaximin, there has been little or no experience with their use in children, and pediatric dosages have not been identified.

### Use in Older Adults

Erythromycin is generally considered safe. Because it is metabolized in the liver and excreted in bile, it may be an alternative in patients with impaired renal function. Dosage reductions are not indicated with azithromycin and telithromycin but may be needed if clarithromycin is given to older adults with severe renal impairment. Dosage of vancomycin should be adjusted for impaired renal function in older adults as in other age groups.

Daptomycin, quinupristin-dalfopristin, and linezolid do not require dosage adjustment in older adults. The miscellaneous antibacterial drugs are used in older adults for the same indications as in younger adults.

### Use in Patients With Renal Impairment

With the macrolides, dosage of erythromycin and azithromycin do not require reduction in renal impairment. However, clarithromycin dosage should be halved or the dosing interval doubled in patients with severe renal impairment (creatinine clearance [CrCl] < 30 mL/min). The dose of telithromycin for patients with severe renal impairment or those on dialysis has not been established.

Chloramphenicol concentrations may increase in patients with impaired renal function. Doses should be adjusted and serum levels monitored during therapy.

Dosage of clindamycin does not need reduction in renal impairment because it is excreted primarily by the liver. Daptomycin dosage should be reduced to every 48 hours in patients with CrCl of less than 30 milliliters per minute and in those undergoing dialysis. Dosage of vancomycin should be reduced because it is excreted mainly by the kidneys and accumulates in renal impairment. In addition, vancomycin may be nephrotoxic with IV administration, high serum concentrations, prolonged therapy, use in older adults or neonates, and concomitant use of other nephrotoxic drugs. Thus, in addition to reduced dosage, renal function and serum drug levels should

be monitored (therapeutic levels are 10–25 mcg/mL). Dosage of metronidazole, quinupristin-dalfopristin, and linezolid does not need to be reduced in patients with renal failure. The use of rifaximin in renal failure has not been studied.

### Use in Patients With Hepatic Impairment

Erythromycin should be used cautiously, if at all, in patients with hepatic impairment. It is metabolized in the liver to an active metabolite that is excreted in the bile. Avoiding the drug or dosage reduction may be needed in liver failure. It has also been associated with cholestatic hepatitis. Symptoms, which may include nausea, vomiting, fever, and jaundice, usually occur after 1 to 2 weeks of drug administration and subside when the drug is stopped.

Other macrolides vary in their hepatic effects. Azithromycin is mainly eliminated unchanged in bile and could accumulate with impaired liver function, but dosage recommendations have not been established. It should be used with caution. Clarithromycin is metabolized in the liver to an active metabolite that is then excreted through the kidneys. Dosage reduction is not recommended for patients with hepatic impairment. The ketolide, telithromycin, does not need dosage adjustment in liver disease.

Clindamycin, chloramphenicol, and metronidazole should be used cautiously, if at all, in the presence of liver disease. Because these drugs are eliminated through the liver, they may accumulate and cause toxic effects. When feasible, other drugs should be substituted. If no effective substitutes are available, dosage should be reduced. Tigecycline should be adjusted in patients with severe hepatic impairment, and liver enzymes should be monitored closely. With daptomycin, quinupristin-dalfopristin, rifaximin, and linezolid, there are currently no recommendations to alter dosage in hepatic impairment.

## Applying Your Knowledge 33-3

A common adverse reaction to many drugs is hepatotoxicity. This may occur with the administration of macrolides. What signs and symptoms should you teach the patient to monitor for and report to his primary care provider?

.....

### Use in Patients With Critical Illness

Erythromycin is seldom used in critical care settings, partly because broader spectrum bactericidal drugs are usually needed in critically ill patients and partly because it inhibits liver metabolism and slows elimination of several other drugs. For a critically ill patient who needs a macrolide antibiotic, one of the newer macrolides is preferred because they have broader spectra of antibacterial activity and fewer effects on the metabolism of other drugs.

Clindamycin should be used only when necessary (i.e., for serious infections caused by susceptible anaerobes) because critically ill patients may develop hepatic impairment and

pseudomembranous colitis (also called antibiotic-associated colitis). These patients are at high risk for development of pseudomembranous colitis (the FDA has issued a **BLACK BOX WARNING**) because they often receive aggressive antibiotic therapy with multiple or broad-spectrum antibacterial drugs that destroy normal bowel microorganisms. Metronidazole is often used in critically ill patients with mixed infections. These patients are at risk for drug toxicity from accumulation of active metabolites. Vancomycin penetrates tissues well in critically ill patients and achieves therapeutic levels well above the minimum inhibitory concentration (MIC) for most staphylococci and enterococci. Plasma drug levels and renal function should be monitored. Although usually given by IV infusion, vancomycin is given orally to treat pseudomembranous colitis.

Quinupristin-dalfopristin, daptomycin, and linezolid are often used in critically ill patients because infections with resistant pathogens commonly occur in this population.

### Use in Home Care

Most of the macrolides, telithromycin, and miscellaneous antibacterial drugs may be taken in the home setting. The role of the home care nurse is generally the same as with other antibiotic therapy; that is, the nurse may need to teach patients or caregivers about drug administration and expected effects. For patients taking oral metronidazole or vancomycin for pseudomembranous colitis, stool specimens may need to be collected and tested in the laboratory for the presence of *C. difficile* organisms or toxins.

## Nursing Actions Macrolides, Ketolides, and Miscellaneous Antibacterials

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give oral erythromycin preparations according to manufacturers' instructions, with 6–8 ounces of water, at evenly spaced intervals, around the clock.
- b. With azithromycin, give the tablets or oral suspension without regard to meals. Give Azithromycin ER on an empty stomach. Do not give oral azithromycin with aluminum- or magnesium-containing antacids.
- c. With clarithromycin, give regular tablets and the oral suspension with or without food. Give the extended-release tablets (Biaxin XL) with food. Shake the suspension well before measuring the dose.
- d. With telithromycin, give without regard to meals.
- e. For intravenous (IV) erythromycin, consult the manufacturer's instructions for dissolving, diluting, and administering the drug. Infuse continuously or intermittently (e.g., q6h over 30–60 min).
- f. With chloramphenicol:
  - (1) Mix IV chloramphenicol in 50–100 milliliters of 5% dextrose in water and infuse over 15–30 minutes.
- g. With clindamycin:
  - (1) Give capsules with a full glass of water.
  - (2) Do not refrigerate reconstituted oral solution.
  - (3) Give IM injections deeply, and rotate sites. Do not give more than 600 milligrams in a single injection.
  - (4) For IV administration, dilute 300–600 milligrams in 50 milliliters of IV fluid and give over 10–20 minutes, or dilute 900 milligrams in 50–100 milliliters and give over 20 minutes. Do not give clindamycin undiluted or by direct injection.
- h. With daptomycin:
  - (1) Mix with normal saline or lactated Ringer's IV solution only.
  - (2) Infuse over 30 minutes.
- i. With linezolid:
  - (1) Give oral tablets and suspension without regard to meals.

### RATIONALE/EXPLANATION

- Some should be taken on an empty stomach; some can be taken without regard to meals.  
Adequate water aids absorption; regular intervals help to maintain therapeutic blood levels.  
Antacids decrease absorption of tablets and the suspension.
- Manufacturer's recommendations  
All suspensions should be mixed well to measure accurately.
- The IV formulation has limited stability in solution, and instructions must be followed carefully to achieve therapeutic effects. Also, instructions differ for intermittent and continuous infusions. IV erythromycin is the treatment of choice for Legionnaire's disease. Otherwise, it is rarely used.
- Do not administer intramuscularly (IM).
- To avoid esophageal irritation  
Refrigeration thickens the solution, making it difficult to measure and pour accurately.  
To decrease pain, induration, and abscess formation
- Dilution decreases risks of phlebitis. Cardiac arrest has been reported with bolus injections of clindamycin.
- The drug is incompatible with dextrose-containing IV solutions.
- Manufacturer's recommendations

**NURSING ACTIONS**

- (2) For IV administration, the drug is compatible with 5% dextrose, 0.9% sodium chloride, and lactated Ringer's solutions.
- (3) Infuse the drug over 30–120 minutes. If other drugs are being given through the same IV line, flush the line with one of the above solutions before and after linezolid administration.
- j. With IV metronidazole, check the manufacturer's instructions.
- k. With quinupristin-dalfopristin:
  - (1) Give IV, mixed in a minimum of 250 milliliters of 5% dextrose solution and infused over 60 minutes.
  - (2) Do not mix the drug or flush the IV line with saline- or heparin-containing solutions.
- l. Give rifaximin without regard to meals.
- m. With spectinomycin, administer by deep IM injection in upper outer quadrant of the gluteal muscle.
- n. With tigecycline infuse IV over 30–60 min. Flush line before and after administration with 0.9 NaCl injection or 5% dextrose injection.
- o. With vancomycin, dilute 500-milligram doses in 100 milliliters, and 1-gram doses in 200 milliliters of 0.9% NaCl or 5% dextrose injection and infuse over at least 60 minutes.

**2. Observe for therapeutic effects**

- a. Decreased local and systemic signs of infection
- b. Decreased signs and symptoms of the specific infection for which the drug is being given

**3. Observe for adverse effects**

- a. With macrolides and ketolides:
  - (1) Nausea, vomiting, diarrhea
  - (2) With IV erythromycin, phlebitis at the IV infusion site
  - (3) Hepatotoxicity—nausea, vomiting, abdominal cramps, fever, leukocytosis, abnormal liver function, cholestatic jaundice
  - (4) Allergic reactions—anaphylaxis, skin rash, urticaria
- b. With chloramphenicol:
  - (1) Bone marrow depression—anemia, leukopenia, thrombocytopenia
  - (2) Clinical signs of infection or bleeding
- c. With clindamycin:
  - (1) Nausea, vomiting, diarrhea
  - (2) Pseudomembranous colitis (also called antibiotic-associated colitis)—severe diarrhea, fever, stools containing neutrophils and shreds of mucous membrane
- d. With daptomycin:
  - (1) Increases in serum creatine kinase, muscle pain or weakness

**RATIONALE/EXPLANATION**

Note: Yellow color of infusion may intensify over time; however, this does not affect potency of medication.

The drug requires specific techniques for preparation and administration.

Dilution in at least 250 milliliters of IV solution decreases venous irritation. A central venous catheter may also be used for drug administration to decrease irritation. Toxicity may increase with shorter infusion times.

The drug is incompatible with saline- and heparin-containing solutions.

Manufacturers recommendations

To decrease hypotension and flushing (i.e., “red man syndrome”) that may occur with more rapid IV administration. This reaction is attributed to histamine release and may be prevented by prior administration of diphenhydramine, an antihistamine, or decreased rate of infusion. Dilution also decreases pain and phlebitis at the injection site.

See Chapter 29.

These are the most frequent adverse reactions, reportedly less common with azithromycin, clarithromycin, and telithromycin than with erythromycin.

The drug is very irritating to body tissues. Phlebitis can be minimized by diluting the drug well, infusing it slowly, and not using the same vein more than 48–72 hours, if possible. More likely to occur with the estolate formulation of erythromycin; less likely to occur with the newer macrolides and ketolides than with erythromycin

Potentially serious but infrequent

Blood dyscrasias are the most serious adverse reaction to chloramphenicol.

These are the most frequent adverse effects and may be severe enough to require stopping the drug.

May occur with most antibiotics but is more common with oral clindamycin. It is caused by *Clostridium difficile*. The organism produces a toxin that kills mucosal cells and produces superficial ulcerations that are visible with sigmoidoscopy. Discontinuing the drug and giving oral metronidazole are curative measures. Do not give antidiarrheal medications.

Daptomycin discontinuation may be warranted.

## Nursing Actions

## Macrolides, Ketolides, and Miscellaneous Antibacterials (continued)

## NURSING ACTIONS

## RATIONALE/EXPLANATION

## e. With linezolid:

- (1) Nausea, vomiting, diarrhea
- (2) Bone marrow depression—*anemia, leukopenia, thrombocytopenia* (especially when used > 2wk)
- (3) Fever, cognitive dysfunction

These are common effects.

Complete blood counts (CBCs) are recommended weekly to monitor for myelosuppression. If it occurs, the drug should be discontinued.

Serotonin syndrome may occur if linezolid is taken in presence of SSRIs or tyramine containing foods.

## f. With metronidazole:

- (1) Central nervous system effects—*convulsive seizures, peripheral paresthesias, ataxia, confusion, dizziness, headache*
- (2) GI effects—*nausea, vomiting, diarrhea, unpleasant metallic taste*. Disulfiram (Antabuse) reaction with alcohol.
- (3) Dermatologic effects—*skin rash, pruritus, thrombophlebitis at infusion sites*

Convulsions and peripheral neuropathy may be serious effects.

GI effects are most common. Disulfiram reaction symptoms include flushing, headache, nausea, vomiting, chest/abdominal pain.

## g. With quinupristin-dalfopristin:

- (1) IV infusion site reactions—*pain, edema, inflammation*
- (2) Nausea, vomiting, diarrhea

The most common adverse effects during clinical trials. Moderate to severe venous irritation can occur with administration through peripheral veins. This can be prevented by infusion through a central venous IV line.

These effects occurred in 2.7%–4.6% of subjects in clinical trials. Most other adverse effects occurred in fewer than 1% of subjects.

## h. With rifaximin:

- (1) Flatulence, headache, abdominal pain, nausea, constipation, vomiting

Occurred in  $\geq 2\%$  of subjects in clinical trials; however, with exception of headache, symptom occurrence was less than placebo group.

## i. With vancomycin:

- (1) Nephrotoxicity—*oliguria, increased blood urea nitrogen and serum creatinine*
- (2) Ototoxicity—*hearing loss, tinnitus*
- (3) “Red man syndrome”—*hypotension, skin flushing*

Most likely to occur with large doses, concomitant administration of an aminoglycoside antibiotic, or pre-existing renal impairment. Usually resolves when vancomycin is discontinued.

Most likely to occur in people with renal impairment or a pre-existing hearing loss

Occurs with rapid infusion of IV vancomycin. Can be prevented by adequate dilution and infusing over 1–2 hours or premedicating with diphenhydramine (an antihistamine).

## 4. Observe for drug interactions

## a. Drugs that increase effects of erythromycin:

- (1) Chloramphenicol
- (2) Streptomycin

The combination is effective against some strains of resistant *Staphylococcus aureus*.

The combination is effective against the enterococcus in bacteremia, brain abscess, endocarditis, meningitis, and urinary tract infection.

May result in life-threatening dysrhythmias when taken with erythromycin.

- (3) Drugs that prolong the QT interval (e.g., cisapride, dofetilide, phenothiazines, pimozone, ranolazine)

## b. Drugs that increase effects of clarithromycin:

- (1) Atazanavir, delavirdine, fluconazole, lopinavir, omeprazole, ritonavir, saquinavir

Inhibits metabolism of clarithromycin; dosage reductions of clarithromycin sometimes recommended.

## c. Drugs that decrease effects of clarithromycin:

- (1) Efavirenz, nevirapine

Consider alternatives to clarithromycin.

## d. Drugs that decrease effects of azithromycin:

- (1) Antacids

Antacids decrease peak serum levels.

## e. Drugs that decrease effects of telithromycin:

- (1) Phenytoin, carbamazepine, phenobarbital, rifampin

Decrease in telithromycin levels may result, with loss of antibacterial effect.

## f. Drugs that decrease effects of chloramphenicol:

- (1) Enzyme inducers (e.g., rifampin, phenobarbital)

Reduce serum levels, probably by accelerating liver metabolism of chloramphenicol

NURSING ACTIONS	RATIONALE/EXPLANATION
g. Drug that <i>decreases</i> effects of clindamycin: (1) Erythromycin	Delays absorption
h. Drugs that <i>increase</i> effects of daptomycin: (1) HMG-CoA reductase inhibitors (e.g., statin cholesterol-lowering drugs)	Potential to increase the musculoskeletal adverse effects of daptomycin
i. Drug that <i>increases</i> effects of metronidazole: (1) Cimetidine	Inhibits hepatic metabolism of metronidazole
j. Drugs that <i>decrease</i> effects of metronidazole: (1) Enzyme inducers (phenobarbital, phenytoin, prednisone, rifampin)	These drugs induce hepatic enzymes and decrease effects of metronidazole by accelerating its rate of hepatic metabolism.

## Key Concepts

- Macrolides, which include erythromycin, azithromycin and clarithromycin, inhibit microbial protein synthesis.
- Erythromycin shares a similar antibacterial spectrum with penicillin, making it a good choice for patients with penicillin allergy.
- The ketolide, telithromycin, is approved only for community-acquired pneumonia. Its mechanism of action is inhibition of microbial protein synthesis.
- The ketolide, telithromycin, and a macrolide, erythromycin estolate, can cause severe liver injury.
- Telithromycin is contraindicated in patients with myasthenia gravis due to the potential for fatal and life-threatening respiratory failure.
- Chloramphenicol (Chloromycetin) is rarely used due to the possible development of serious and fatal blood dyscrasias with its use. It is effective against some strains of VRE.
- Clindamycin belongs to the lincosamide class of antimicrobials, similar to macrolides in its mechanism of action and antimicrobial spectrum. A life-threatening adverse effect of clindamycin is the development of pseudomembranous colitis.
- Daptomycin belongs to the lipopeptide class of antibiotics, which kills gram-positive bacteria by inhibiting synthesis of bacterial proteins, DNA, and RNA.
- Tigecycline belongs to the glycylcycline class of antibiotics. It is similar to tetracycline in structure and properties and can be used to treat skin infections due to MRSA.
- Linezolid belongs to the oxazolidinone class of antibiotics. It is effective against MRSA and VRE.
- Quinupristin-dalfopristin belongs to the streptogramin class of antibiotics. It is indicated for VREF and MSSA.
- Vancomycin is effective against gram-positive organisms only, including MRSA and SSNA.
- Rifaximin is prescribed for travelers' diarrhea due to *Escherichia coli* infection.
- Spectinomycin is an alternative treatment for gonococcal infection when patients are unable to take the preferred regime.
- Metronidazole is effective against infections with anaerobic bacteria and some protozoa.

## Review and Application Exercises

### Short Answer Exercises

1. Why is erythromycin called a “penicillin substitute”?
2. What are adverse effects with erythromycin, and how may they be prevented or minimized?
3. How do the newer macrolides differ from erythromycin?
4. How does the ketolide differ from the macrolides?
5. How would you recognize pseudomembranous colitis in a patient? What would you do if you thought a patient might have it? Why?
6. Why is metronidazole preferred over vancomycin for initial treatment of pseudomembranous colitis?
7. Which antibacterial drug is considered the drug of choice for MRSA and SSNA?
8. What is “red man syndrome” and how can it be prevented or minimized?
9. What is the main clinical importance of the newer drugs, tigecycline, linezolid, daptomycin, rifaximin, and quinupristin-dalfopristin?

### NCLEX-Style Questions

10. A 35-year-old man with HIV/AIDS is being seen for routine follow-up care. He is receiving highly active antiretroviral therapy (HAART). The patient was recently

hospitalized with an infection due to *Mycobacterium avium-intracellulare* (formerly known as *Mycobacterium avium* complex, or MAC) disease, and the physician now decides to place the patient on a preventive regimen.

The best choice of drug would be

- erythromycin
  - clarithromycin
  - azithromycin
  - telithromycin
11. A 19-year-old college student was seen in the student health center for severe diarrhea. The nurse practitioner diagnosed travelers' diarrhea based on the history given that the student had recently returned from Mexico. Rifaximin 200 mg orally three times daily for 3 days was prescribed. The student calls the office 4 days later and reports to the nurse that she has a fever and that the diarrhea has not resolved. The nurse should
- Advise the student to return to the clinic for further tests and a different antibiotic.
  - Call the pharmacy and authorize one refill of rifaximin.
  - Advise the student that it takes up to 48 to 72 hours after the completion of treatment for the diarrhea to completely resolve.
  - Tell the student to continue to drink plenty of fluids and report back in 24 hours.
12. An 89-year-old man is admitted to the hospital from a nursing home with the diagnosis of pneumonia. The most likely pathogen is *Staphylococcus aureus*. He is also in acute renal failure with an estimated creatine clearance of 20 mL/min. Which of the following regimens would not require dosage adjustment because of the renal failure?
- vancomycin + azithromycin
  - quinupristin-dalfopristin + azithromycin
  - daptomycin + telithromycin
  - linezolid + clarithromycin

13. A recent nurse graduate is preparing to administer vancomycin IV to a patient. She states the patient reported that he experienced flushing with his last dose of vancomycin. The nurse should
- Infuse the vancomycin over 30 minutes to decrease the chance of a reaction.
  - Hold the vancomycin dose until the physician's rounds the following morning.
  - Dilute the vancomycin in 50 mL of normal saline solution and infuse over 60 minutes.
  - Contact the physician, report the reaction, and request an order for diphenhydramine pretreatment.
14. A patient is started on clarithromycin extended-release tablets (Biaxin XL) 500 mg every 24 hours for 7 days. The teaching plan for this patient should not include telling him to
- Complete the full 7 days of treatment.
  - Perform thorough hand hygiene to decrease spread of infection.
  - Contact the physician if a rash, jaundice, or diarrhea develops.
  - Take on an empty stomach.

# Drugs for Tuberculosis and *Mycobacterium avium* Complex (MAC) Disease

## KEY TERMS

- Directly observed therapy (DOT)
- Extensively drug-resistant tuberculosis (XDR-TB)
- Hepatitis
- Jaundice
- Multidrug-resistant tuberculosis (MDR-TB)

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe characteristics of latent, active, and drug-resistant tuberculosis infections.
2. Identify populations at high risk for developing tuberculosis.
3. List characteristics, uses, effects, and nursing implications of using primary antitubercular drugs.
4. Describe the rationale for multiple-drug therapy in treatment of tuberculosis.
5. Discuss ways to increase adherence to antitubercular drug therapy regimens.
6. Discuss circumstances in which directly observed therapy (DOT) is needed.
7. Describe factors affecting drug therapy in multidrug-resistant (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB).
8. Describe *Mycobacterium avium* complex disease and the drugs used to prevent or treat it.

## Applying Your Knowledge

Ramon Diaz is a 58-year-old homeless man. He is spending the night at a shelter where one of your coworkers volunteers one evening a month. Ramon has a productive cough. Your coworker notes that he has visibly lost weight since he was in the shelter 1 month ago. When she asks him how he feels, Ramon says he sweats a lot at night and thinks he has a fever. He is sent to the free clinic the next day, where his sputum test is positive for *Mycobacterium tuberculosis*. From the clinic, Ramon is sent to the county jail, where he will stay until his sputum test is negative. He is started on the following regimen:

Isoniazid (INH) 300 mg PO daily for 6 months

Rifampin 600 mg PO daily for 6 months

Pyrazinamide 2000 mg daily for 2 months

The health department supplies his medication and is responsible for overseeing his course therapy. You are a nurse working for the health department.

## Introduction

Tuberculosis (TB) is an infectious disease that usually affects the lungs but may affect lymph nodes, pleurae, bones, joints, kidneys, and the gastrointestinal tract. It is caused by *Mycobacterium tuberculosis*, the tubercle bacillus. In general, these bacilli multiply slowly, they may lie dormant in the body for many years, they resist phagocytosis and survive in phagocytic cells, and they develop resistance to antitubercular drugs.

Tuberculosis commonly occurs in many parts of the world. Authorities estimate that one-third of the world's population is infected with tuberculosis organisms and that tuberculosis is the cause of death in almost 2 million people every year. In the United States, active disease has decreased to a low level in American-born people; most new cases occur in foreign-born immigrants. There are also large numbers of people with inactive or latent TB infection. Contributing factors include increased exposure during a resurgence of active disease between 1985 and 1992, immigration from countries where the disease commonly occurs (e.g., Mexico, the Philippines, Vietnam, India, China), and increasing numbers of people with conditions or medications that depress the immune system.

## Epidemiology of Tuberculosis

There are four phases in the initiation and progression of tuberculosis (Fig. 34-1):

1. **Transmission.** This occurs when an uninfected person inhales infected airborne particles that are exhaled by an infected person. Major factors affecting transmission are the number of bacteria expelled by the infected person and the closeness and duration of the contact between the infected and the uninfected person.
2. **Primary infection.** It is estimated that 30% of persons exposed to tuberculosis bacilli become infected and develop a mild, pneumonia-like illness that is often undiagnosed. About 6 to 8 weeks after exposure, those infected have positive reactions to tuberculin skin tests. Within approximately 6 months of exposure, spontaneous healing occurs as the bacilli are encapsulated in calcified tubercles.
3. **Latent tuberculosis infection (LTBI).** The immune system is able to stop bacterial growth in most people who become infected with TB bacteria. The bacteria become inactive, although they remain alive in the body and can become active later. People with inactive or latent TB infection have no symptoms, do not feel sick, do not spread TB to others, usually have a positive skin-test reaction, and can

**Figure 34-1** ■ Transmission of tuberculosis and progression from latent infection to reactivated disease. Among persons who are seronegative for the human immunodeficiency virus (HIV), approximately 30% of heavily exposed persons will become infected. In 5% of persons with latent infection, active disease will develop within 2 years, and in an additional 5%, progression to active disease will occur later. The rate of progression to active disease is dramatically increased among persons who are coinfecting with HIV. (Adapted from Small, P. M., & Fujiwara, P. I. [2001]. Management of tuberculosis in the United States. *New England Journal of Medicine*, 345, 189–200.)

develop active TB disease years later if the latent infection is not effectively treated. In many people with LTBI, the infection remains inactive throughout their lives. In others, the TB bacteria become active and cause tuberculosis, usually when a person's immune system becomes weak as a result of disease, immunosuppressive drugs, or aging.

4. **Active tuberculosis.** This has long been thought to result almost exclusively from reactivation of latent infection, with only a few cases from new primary infections. However, more recent studies indicate that almost half of new TB cases may result from new infections or reinfections from exogenous sources.

Both reactivated and new infections are more likely to occur in people whose immune system is depressed by disease (e.g., human immunodeficiency virus [HIV] infection, diabetes mellitus, cancer) or from drug therapy (e.g., for cancer or organ transplantation). Among people with LTBI, signs and symptoms of active disease (e.g., cough that is persistent and often productive of sputum, chest pain, chills, fever, hemoptysis, night sweats, weight loss, weakness, lack of appetite, positive skin test, abnormal chest radiograph, positive sputum smear or culture) are estimated to develop in 5% within 2 years and in another 5% after 2 years. Among people with both HIV infection and latent or new primary TB infection, TB progresses more rapidly, often involves extrapulmonary sites, is more severe, and is often fatal.

## Drug-Resistant Tuberculosis

In addition to LTBI, a major concern among public health and infectious-disease authorities is an increase in drug-resistant infections. Drug-resistant mutants of *M. tuberculosis* microorganisms are present in any infected person. When infected people receive antitubercular drugs, drug-resistant mutants are not killed or weakened by the drugs. Instead, they are able to reproduce in the presence of the drugs and to transmit the property of drug resistance to newly produced bacteria. Eventually, the majority of TB bacilli in the body are drug resistant. Once a drug-resistant strain of TB develops, it can be transmitted to other people just like a drug-susceptible strain.

The development of drug-resistant TB organisms has long been attributed mainly to poor patient adherence to prescribed antitubercular drug therapy, that is, when previously infected patients do not take the drugs and doses prescribed for the length of time prescribed. However, drug-resistant strains can be spread from one person to another, and there is increasing evidence that many drug-resistant infections are new infections, especially in people whose immune system is suppressed.

*Multidrug-resistant tuberculosis (MDR-TB)* indicates organisms that are resistant to isoniazid (INH) and rifampin, the most effective drugs available, with or without resistance to other antitubercular drugs. MDR-TB is associated with rapid progression, with 4 to 16 weeks from diagnosis to death, and a high death rate (50%–80%). It is also difficult and expensive to treat; most authorities recommend 24 months of drug therapy. Despite longer treatment with more drugs, the cure rate for

MDR-TB is about 50% or less, compared with a cure rate of 90% or more for drug-susceptible strains of TB.

Some MDR-TB cases are now being described as *extensively drug-resistant TB (XDR-TB)*, an even more worrisome threat to public health. XDR-TB indicates resistance to the second-line drugs used to treat MDR-TB. Some cases are resistant to six or seven drugs, and there are essentially no effective drugs for their treatment.

Drug-resistant TB has been identified in many parts of the world, especially in Africa and Asia, and is a major concern in HIV-infected persons. Most cases in the United States occur among foreign-born persons. Factors contributing to the development of drug-resistant disease, whether acquired or new infection, include delayed diagnosis and delayed determination of drug susceptibility, which may take several weeks. In addition, some countries lack adequate laboratory facilities or do not test TB organisms for susceptibility to second-line antituberculosis drugs. These delays in effective treatment allow rapid disease progression and rapid transmission to others, especially to those with impaired immune systems.

### Applying Your Knowledge 34-1

It is very important that the health department follow Mr. Diaz' treatment to ensure that he takes his prescribed medications. Why is it essential that Mr. Diaz take the full course of therapy?

## Tuberculosis Control

An official joint statement from the Centers for Disease Control and Prevention (CDC), the American Thoracic Society (ATS), and the Infectious Diseases Society of America (IDSA) emphasizes continued treatment of active disease and expanded efforts to identify and treat latent infection (LTBI). For identification, tuberculin skin testing is recommended only for high-risk groups (Box 34-1). When LTBI is found in these groups, it should be treated to eradicate this reservoir of infection (Box 34-2). In addition, the statement recommends techniques for TB control among particular populations (e.g., children and adolescents, foreign-born persons, persons with HIV infection, homeless persons) and particular settings (e.g., health care facilities, prisons).

Cain et al. disagree with the CDC/ATS/IDSA recommendation that for foreign-born persons only those who have entered the United States during the previous 5 years be tested for LTBI. These authors say that over 50% of all reported TB cases in the United States occur in foreign-born persons and almost 25% of all reported cases occur in foreign-born persons who have lived in the country for longer than 5 years. Thus, they recommend testing for LTBI in the latter group as well.

Although local health departments are largely responsible for TB control programs, some authorities urge increased testing and treatment in primary-care settings and in settings where high-risk groups are found (e.g., homeless shelters).

## Box 34-1

## Targeted Tuberculin Testing for Latent Tuberculosis Infection (LTBI)

**Purpose**

To identify people with latent tuberculosis infection (LTBI) who are at high risk of developing active tuberculosis and who would benefit from treatment of LTBI, if detected.

**Who Should Be Tested?**

Numerous high-risk groups have been identified, including persons with the following circumstances or conditions:

- Having recent infection with *Mycobacterium tuberculosis* organisms
- Having close contact with someone diagnosed with infectious pulmonary TB
- Immigrating from areas of the world with high rates of TB.
- Belonging to younger age groups. Young children (e.g., under 5 years) with a positive skin test are at high risk for progression to active disease. The risk is also increased in adolescents and young adults.
- Belonging to older age groups, especially if also living or working in institutions with high-risk populations (e.g., hospitals, homeless shelters, correctional facilities, nursing homes, residential homes for patients with acquired immune deficiency syndrome [AIDS])
- Being homeless
- Being an injection drug user
- Having HIV infection or AIDS. HIV infection greatly increases the risk for progression of LTBI to active TB.
- Having chest radiographs that show fibrotic lesions in the lungs. Such lesions are likely to stem from prior, untreated, healed TB.
- Being underweight, especially if more than 10%–15% under ideal weight
- Having silicosis (a pulmonary disorder caused by inhalation of dust particles from mining or stonecutting). People with silicosis and a positive tuberculin test are about 30 times more likely to develop active disease than the general population.
- Having chronic renal failure and being on hemodialysis. These people are 10 to 25 times more likely to develop active disease than the general population.
- Having diabetes mellitus. These people are 2 to 4 times more likely to develop active TB than those without diabetes, and the risk is probably greater in those with insulin-dependent or poorly controlled diabetes.
- Having a history of gastrectomy (which is often accompanied by weight loss and malabsorption), jejunioileal bypass, renal or cardiac transplantation, carcinoma of the head or neck, lung cancer, lymphoma, or leukemia.
- Receiving high-dose corticosteroid therapy (e.g., prednisone >15 mg/d or equivalent amounts of other drugs for several weeks). These people may be at risk for reactivation of TB, but the exact risk is unknown. Lower doses and intermittent administration of corticosteroids are not associated with TB.

**Where Should Testing Be Done?**

Traditionally, local health departments have been responsible for testing, interpreting, and providing follow-up care; some

institutions have tested residents and employees, and some large businesses have tested employees. More recently, the Centers for Disease Control and Prevention (CDC) and other authorities have recommended that more testing be done in primary care settings and any other locations where high-risk individuals are. Such testing sites include neighborhood health centers, jails, homeless shelters, inner-city sites, methadone clinics, syringe and needle-exchange programs, and other community-based social service organizations. In the latter situations, local health departments are urged to assist local providers in developing, implementing, and evaluating TB screening programs appropriate for their communities.

**Test Interpretation**

Positive reactions differ according to the amount of induration (a nodule or area of hardened tissue, not to be confused with the area of redness, which may be larger than the area of induration) and characteristics of the group being tested, as follows:

- **Induration of 5 mm or more.** Persons at highest risk (e.g., close contacts of someone with active, infectious TB; those with HIV infection or risk factors for HIV infection; and those with chest radiographs that are consistent with previous TB)
- **Induration of 10 mm or more.** Persons at high risk (e.g., those with conditions or characteristics such as diabetes mellitus; silicosis; immunosuppressive drug therapy; leukemia; lymphoma; head or neck cancer; chronic renal failure; gastrectomy; jejunioileal bypass; low body weight; injecting drug users known to be seronegative for HIV infection; recent immigrants from countries that have high TB rates; residents and employees of prisons, long-term care institutions, and other congregate settings for high-risk populations; low-income groups; high-risk racial and ethnic groups; migrant farm workers; and infants, children, and adolescents exposed to adults in high-risk categories)
- **Induration of 15 mm or more.** Persons who are at low risk for developing TB and do not meet the criteria listed for the above groups. Routine testing is not recommended for low-risk groups.
- **False-positive reactions.** These may occur with infections caused by nontuberculous strains of mycobacteria or a previous intradermal injection of bacillus Calmette-Guérin (BCG), a live attenuated strain derived from *Mycobacterium bovis*. In many parts of the world, BCG is used as a vaccine against tuberculosis, especially in children. There is currently no reliable way to differentiate tuberculin reactions caused by vaccination with BCG from those caused by infection with *M. tuberculosis*. However, large areas of induration (>20 mm) are unlikely to result from BCG.
- **False-negative reactions.** These may occur with HIV infection or other conditions that suppress the immune system and inhibit the ability to react to the tuberculin antigen. Thus, a negative skin test may occur in the presence of tuberculosis infection.

## Box 34-2

## Treatment of Latent Tuberculosis Infection (LTBI)

## Recommended Regimens for Adults

**Isoniazid (INH) daily or twice weekly for 9 months** is the preferred regimen, including persons with human immunodeficiency virus (HIV) infection or radiographic evidence of prior TB.

**Isoniazid daily or twice weekly for 6 months.** The main advantage of this regimen over the 9-month schedule is greater adherence because of the shorter length. It is also less costly. This regimen may be used for HIV-negative adults with normal chest radiographs; it is *not* recommended for HIV-positive persons, those less than 18 years of age, or those with fibrotic lesions as shown on chest radiographs.

**Rifampin and pyrazinamide (RIF-PZA) daily or twice weekly for 2 months.** This regimen may be used for contacts of patients with INH-resistant TB and for those who are unlikely to complete a longer course of treatment. Rifampin is contraindicated in HIV-positive patients who are receiving protease inhibitors or non-nucleoside reverse transcriptase inhibitors (NNRTIs), because rifampin greatly stimulates metabolism and decreases the effectiveness of the antiviral drugs. Rifabutin, which causes less enzyme induction than rifampin, may be substituted in some cases. Pyrazinamide is contraindicated during pregnancy.

This regimen was revised in 2001 because of several reports of liver failure and death. To reduce the risks of liver injury, the American Thoracic Society and the Centers for Disease Control and Prevention (CDC), with the endorsement of the Infectious Diseases Society of America, issued new recommendations for choosing patients and for more intensive clinical and laboratory monitoring, as follows:

1. The RIF-PZA regimen is not recommended for persons who have underlying liver disease or who have had INH-associated liver injury. It should be used with caution in patients who take other hepatotoxic medications or use alcohol, even if alcohol use is stopped during treatment. Persons being considered for treatment with this regimen should be informed about potential hepatotoxicity and asked whether they have had liver disease or adverse effects from INH.
2. The RIF-PZA regimen is recommended mainly for patients who are unlikely to complete longer courses of treatment and who can be monitored closely. (For other adults not infected with HIV, the 9-month daily regimen of INH is preferred, with 4 months of daily RIF as an acceptable alternative.)
3. The RIF-PZA regimen does increase risks of hepatotoxicity in patients with HIV infection. Still, INH daily for 9 months is the treatment of choice for HIV-infected persons with LTBI when completion of treatment can be assured.
4. Increase safety by limiting the pyrazinamide dose to less than 20 mg/kg/d and a maximum of 2 g/d; giving no more than a 2-week supply of rifampin and pyrazinamide at a time; and assessing patients at 2, 4, and 6 weeks of treatment for adherence, tolerance, and adverse effects, and at 8 weeks to document treatment completion. For non-English-speaking clients, health care providers who speak the patients' language should instruct them to stop taking the drugs immediately and seek medical care if abdominal pain, emesis, jaundice, or other symptoms of hepatitis develop. Provider continuity is recommended for monitoring.
5. Perform liver function tests (e.g., serum aspartate and alanine aminotransferases [AST and ALT] and bilirubin) at baseline and at 2, 4, and 6 weeks. RIF-PZA treatment should be stopped and not resumed if enzyme levels are higher than five times the upper limit of normal in an asymptomatic person, are higher than normal range if symptoms of hepatitis are present, or if a serum bilirubin level is above normal range.

**Rifampin daily for 4 months.** This regimen is used mainly for patients who cannot tolerate INH or pyrazinamide.

## Special Populations

1. Pregnant women. The preferred regimen for treatment of LTBI is INH, administered daily or twice weekly for 9 or 6 months. Pregnant women taking INH should also take pyridoxine supplementation. For HIV-positive women with higher risks of progression to active TB, treatment should not be delayed; for those with lower risks, some experts recommend waiting until after delivery to start treatment. In general, INH, rifampin, and ethambutol have good safety records in pregnancy. Pyrazinamide and streptomycin are contraindicated during pregnancy.
2. Children and adolescents. INH daily or twice weekly for 9 months is recommended. Infants and children under 5 years of age with LTBI are at high risk for progression to disease. They are also more likely than older children and adults to develop life-threatening forms of TB, including meningeal and disseminated disease. INH therapy appears to be more effective for children than adults, and the risk for INH-related hepatitis is minimal in infants, children, and adolescents, who generally tolerate the drug better than adults. Routine administration of pyridoxine is not recommended for children taking INH, but should be given to breast-feeding infants, children and adolescents with pyridoxine-deficient diets, and children who experience paresthesias when taking INH.
 

Although few studies have been done in infants, children, and adolescents, rifampin alone, rifampin with INH, and rifampin with pyrazinamide have been used to treat LTBI with effectiveness. Although the optimal length of rifampin therapy in children with LTBI is unknown, the American Academy of Pediatrics (AAP) recommends 6 months.

There have been no reported studies of any regimen for treatment for LTBI in HIV-infected children. The AAP recommends INH for 9 months; most experts recommend routine monitoring of serum liver enzyme concentrations and pyridoxine administration.
3. Contacts of patients with drug-susceptible TB and positive skin-test reactions (more than 5 mm) should be treated with one of the recommended regimens described above, regardless of age.

## Box 34-2

## Treatment of Latent Tuberculosis Infection (LTBI) (continued)

4. Contacts of patients with INH-resistant, rifampin-susceptible TB should generally be given rifampin and pyrazinamide for 2 months. For patients with intolerance to pyrazinamide, rifampin alone for 4 months is recommended. If rifampin cannot be used, rifabutin can be substituted.
5. Contacts of patients with multidrug-resistant (MDR)-TB who are at high risk for developing active TB are generally given pyrazinamide and ethambutol or pyrazinamide and a fluoroquinolone (levofloxacin or ofloxacin) for 6 to 12 months. Immunocompetent contacts may be observed without treatment or treated for 6 months; immunocompromised contacts (e.g., HIV-infected persons) should be treated for 12 months.

For children exposed to MDR-TB, pyrazinamide and ethambutol are recommended for 9 to 12 months if the isolate is susceptible to both drugs. If these drugs cannot be used, two other drugs to which the infecting organism is likely susceptible should be given.

6. HIV-infected persons. With INH, the 9-month regimen is recommended. With rifampin, the drug is contraindicated or should be used with caution in persons who are taking protease inhibitors or NNRTIs. Rifabutin can be substituted for rifampin in some circumstances, but it should be used cautiously with saquinavir and nevirapine. Dosage of rifabutin needs to be reduced to one half the usual daily dose (i.e., from 300 mg/d to 150 mg/d) with indinavir or nelfinavir and to one fourth the usual dose (i.e., 150 mg every other day or 3 times a week) with ritonavir. Usual dosage (300 mg/d) can be given with nevirapine and 450 or 600 mg/d are needed with efavirenz. Rifapentine is not recommended as a substitute for rifampin because its safety, effectiveness, and interactions with anti-HIV medication have not been established.
7. Bacillus Calmette-Guérin (BCG)-vaccinated persons. A history of BCG vaccination should not influence the decision to treat LTBI.

## Additional Recommendations

1. Before beginning treatment for LTBI, active TB should be ruled out by history, physical examination, chest radiography, and bacteriologic studies, if indicated.
2. Allow patients to participate in choosing a treatment regimen, when feasible, by discussing options and characteristics of each (e.g., the length and complexity, possible adverse effects, potential drug interactions).
3. Directly observed therapy (DOT) should be used consistently with intermittent regimens (e.g., twice weekly) and when possible with 2-month regimens and in certain settings (e.g., institutional settings, community outreach programs, and for persons living in households with patients who are receiving home-based DOT for active TB).
4. Try to ensure completion of treatment. This is determined by the total number of doses administered as well as the duration of therapy. For daily INH, the 9-month regimen should include at least 270 doses in 12 months and the 6-month regimen should include at least 180 doses in 9 months. For twice-weekly INH, the 9-month regimen should include at least 76 doses in 12 months and the 6-month regimen should include at least 52 doses in 9 months. For the 2-month regimen of daily rifampin (or rifabutin) and pyrazinamide, at least 60 doses should be given in 3 months. For the 4-month regimen of daily rifampin alone, at least 120 doses should be given in 6 months.

These schedules allow minor interruptions in therapy although, ideally, patients should receive medication on a regular schedule until the course of therapy is completed. When doses are missed, the duration of therapy should be lengthened. When restarting therapy after interruptions, the original regimen may be continued as long as needed to complete the recommended duration of the particular regimen or a new regimen may be needed if interruptions were frequent or prolonged. If treatment is interrupted for longer than 2 months, the patient should be reassessed for active TB before restarting drug therapy.

In addition, authorities urge recognition and effective management of language, social, economic, transportation, and other barriers that limit access to health care and inhibit diagnosis and treatment.

Nurses have important roles to play in TB control. One role is to know and follow recommendations to prevent transmission (See “Guidelines for preventing the transmission of *Mycobacterium tuberculosis* in health-care settings,” available at [www.cdc.gov](http://www.cdc.gov)). Other roles include performing and reading tuberculin skin tests; managing TB clinics; tracking contacts of patients with active disease; assessing patients, homes, and other settings for risk factors; educating patients and families about TB infection and its treatment; administering antitubercular drugs (e.g., *directly observed therapy [DOT]*, in which a health care provider watches the patient take each dose of medication); and maintaining records (e.g., skin-test results,

patients starting or completing drug therapy, adherence or lack of adherence to prescribed treatment regimens).

In the United States, all citizens need to support efforts to maintain public health organizations and infrastructures to identify, treat, and monitor tuberculosis. The resurgence of active disease that occurred in the mid-1980s was due, at least in part, to decreased funding and a weakening of TB control measures at all levels of government. Strengthening those control measures has contributed to the present low level of active disease.

Worldwide, much work is needed to prevent further development and spread of drug-resistant TB. The development of XDR-TB indicates failure to adequately diagnose, prevent, and treat MDR-TB. One problem may be that effective drugs are not correctly prescribed, administered consistently, or even available. Another problem is that susceptibility testing for second-line drugs is not available or not widely used. In general,

susceptibility testing of first-line drugs is performed, but testing of second-line drugs is usually limited to TB isolates from patients known or suspected to have drug-resistant TB. Drug-resistant TB is often not suspected until the patient has had 2 months or more of drug therapy (e.g., cultures remain positive for TB organisms after 2 or more months of treatment or susceptibility tests reveal drug resistance). The delay in identifying and treating drug-resistant TB allows additional spread of the disease. Additional problems include needs for better and internationally standardized tests for susceptibility testing of second-line drugs, new anti-TB drugs and drug therapy regimens, and better diagnostic tests for TB and MDR-TB. One newer diagnostic test, called microscopic-observation drug susceptibility (MODS), is reportedly faster and less expensive to perform.

## Antitubercular Drugs

Antitubercular drugs are divided into primary (first-line) and second-line agents. The main primary drugs (isoniazid,

rifampin, and pyrazinamide) are used to treat latent, active, and drug-resistant TB infection when possible. Ethambutol and streptomycin are also considered primary drugs. Because of their varied characteristics, these drugs are described individually below and their dosages are listed in Table 34-1.

Second-line drugs are used only for patients who are unable to tolerate first-line drugs or those who are infected with organisms that are resistant to first-line drugs. In general, second-line drugs are less effective, more toxic, or both.

### Primary Drugs

**P Isoniazid** (also called INH), the most commonly used anti-tubercular drug and the prototype, is bactericidal, relatively inexpensive and nontoxic, and can be given orally or by injection. Although it can be used alone for treatment of LTBI, it must be used with other antitubercular drugs for treatment of active disease.

INH penetrates body cells and mycobacteria, kills actively growing intracellular and extracellular organisms, and inhibits

Table 34-1

Drugs at a Glance: Primary Antitubercular Drugs

Name/Route	DOSAGE RANGES (MAXIMUM DOSE)				Comments
	ADULTS		CHILDREN		
	Daily	Twice/Wk	Daily	Twice/Wk	
<b>Isoniazid</b> (INH) PO or IM	5 mg/kg (300 mg)	15 mg/kg (900 mg)	10–20 mg/kg (300 mg)	20–40 mg/kg (900 mg)	LTBI: Given at least 6 mo; 9 mo preferred Active TB: Given at least 6 mo, with other drugs
<b>Rifampin</b> (Rifadin) PO or IV infusion	10 mg/kg (600 mg)	10 mg/kg (600 mg)	10–20 mg/kg (600 mg)	10–20 mg/kg (600 mg)	LTBI: Given 4 mo alone or 2 mo with pyrazinamide Active TB: Given for 6 mo, with other drugs
<b>Pyrazinamide</b> PO	15–30 mg/kg (2 g)	50–70 mg/kg (4 g)	15–30 mg/kg (2 g)	50–70 mg/kg (4 g)	LTBI: Given for 2 mo, with rifampin Active TB: Given for 2 mo, with INH and rifampin
<b>Streptomycin</b> IM	15 mg/kg (1 g)	25–30 mg/kg (1.5 g)	20–40 mg/kg (1 g)	25–30 mg/kg (1.5 g)	Used for active TB, with other drugs
<b>Ethambutol</b> (Myambutol) PO	15–25 mg/kg (2.5 g)	50 mg/kg (2.5 g)	15–25 mg/kg (2.5 g)	50 mg/kg (2.5 g)	Used for active TB, with other drugs, and MAC disease
<b>Rifabutin</b> (Mycobutin) PO	300 mg		Not established		Used to treat MAC dis- ease and to substitute for rifampin in patients taking certain anti-HIV medications
<b>Rifapentine</b> (Priftin) PO	150 mg twice a wk for 2 mo, then once a wk for 4 mo		Not established		May be used instead of rifampin, with other drugs

HIV, human immunodeficiency virus; LTBI, latent tuberculosis infection; MAC, *Mycobacterium avium* complex; TB, tuberculosis.

the growth of dormant organisms in macrophages and tuberculous lesions. Its mechanism of action is to inhibit formation of cell walls in mycobacteria.

INH is well absorbed from the GI tract, with peak serum concentrations occurring 1 to 2 hours after a 300-milligram dose. It penetrates and reaches therapeutic concentrations in essentially all body fluids and cavities. Its half-life is 1 to 4 hours. It is acetylated in the liver to acetylisoniazid, which is excreted by the kidneys. Metabolism of INH is genetically determined; some people are “slow acetylators” and others are “rapid acetylators.” A person’s rate of acetylation affects response to INH. Slow acetylators have less *N*-acetyltransferase, the acetylating enzyme, in the liver. In these patients, INH is more likely to accumulate to toxic concentrations, and the development of peripheral neuropathy is more likely. However, there is no significant difference in the clinical effectiveness of INH. Rapid acetylators may require unusually high doses of INH. They also may be more susceptible to serious liver injury because of rapid formation of hepatotoxic metabolites. The drug is excreted in urine.

Potentially serious adverse effects include hepatotoxicity and peripheral neuropathy. Hepatotoxicity may be manifested by symptoms of hepatitis (e.g., anorexia, nausea, fatigue, malaise, jaundice) or elevated liver enzymes. The drug should be stopped if hepatitis develops or liver enzymes (e.g., alanine and aspartate aminotransferases [ALT and AST]) are more than five times the normal values. Hepatitis is more likely to occur during the first 8 weeks of INH therapy and in people who use alcohol. Patients receiving INH should be monitored monthly for signs and symptoms of hepatitis. Because of the risk of hepatotoxicity, INH should be used cautiously in patients with pre-existing liver disease. Peripheral neuropathy may be manifested by numbness and tingling in the hands and feet. It is most likely to occur in patients who are malnourished or older or who have alcoholism, diabetes mellitus, or uremia. Pyridoxine, 25 to 50 milligrams daily, is usually given with INH to minimize peripheral neuropathy.

### Applying Your Knowledge 34-2

You will have multiple opportunities to assess Mr. Diaz when he receives his medication. For what adverse effects of INH do you plan to monitor Mr. Diaz?

**Rifampin** (Rifadin) is a rifamycin that is bactericidal for both intracellular and extracellular TB organisms. It kills mycobacteria by inhibiting synthesis of RNA and thereby causing defective, nonfunctional proteins to be produced. Its ability to penetrate intact cells contributes to its effectiveness in TB because mycobacteria are harbored in host cells. Rifampin and INH are synergistic in combination, eliminating tuberculosis bacilli from sputum and producing clinical improvement faster than any other drug regimen, unless organisms resistant to one or both drugs are causing the disease.

Rifampin is well absorbed with oral administration and diffuses well into body tissues and fluids, with highest concentrations occurring in the liver, lungs, gallbladder, and kidneys. Peak serum concentration occurs in 1 to 3 hours with oral administration and immediately with IV administration. The drug is metabolized in the liver and excreted primarily in bile; a small amount is excreted in urine. Its elimination half-life is approximately 3 hours with a 300-milligram dose and approximately 5 hours with a 600-milligram dose. Because it is a strong inducer of drug-metabolizing enzymes, its half-life becomes shorter with continued use.

Adverse effects include GI upset, skin rashes, hepatitis, and a harmless red-orange discoloration of urine, tears, sweat, and other body fluids. Soft contact lenses may be permanently stained.

Rifampin has many interactions with other drugs. It induces hepatic cytochrome P450 3A4 enzymes and accelerates the metabolism of numerous other drugs, thereby decreasing their serum concentrations, half-lives, and therapeutic effects. Affected drugs include anti-acquired immunodeficiency syndrome (AIDS) drugs (protease inhibitors [PIs] and non-nucleoside reverse transcriptase inhibitors [NNRTIs]; see Chap. 35), benzodiazepines, corticosteroids, cyclosporine, estrogens, fluconazole, methadone, metoprolol, phenytoin, propranolol, oral contraceptives, oral sulfonylureas, theophylline, verapamil, and warfarin. With warfarin, decreased anticoagulant effect occurs approximately 5 to 8 days after rifampin is started and lasts for 5 to 7 days after rifampin is stopped. With methadone, concurrent administration with rifampin may precipitate signs and symptoms of opiate withdrawal unless methadone dosage is increased.

### Applying Your Knowledge 34-3

You are teaching Mr. Diaz about his medication. What adverse effect of rifampin should you include in your teaching so that Mr. Diaz does not become alarmed and stop taking his medication?

**Rifabutin** (Mycobutin) is another rifamycin that is active against mycobacteria. However, most rifampin-resistant strains are also resistant to rifabutin. The drug’s two main uses are in patients with HIV infection, to treat *Mycobacterium avium* complex (MAC) disease; and to substitute for rifampin in patients who need both antitubercular and certain antiviral drugs. The major advantages of rifabutin over rifampin are a longer serum half-life (45 hours, on average) and reduced induction of hepatic drug-metabolizing enzymes. Rifabutin has no advantage over rifampin in treatment of TB but may be given concurrently with INH to patients who need prophylaxis against both *M. tuberculosis* and *M. avium*.

Rifabutin is well absorbed from the GI tract; a dose of 300 milligrams produces peak serum concentration in 23 hours. It is extensively metabolized in the liver (and to a lesser extent in the intestinal wall), and it is excreted in urine and bile.

Like rifampin, rifabutin causes a harmless red-orange discoloration of body fluids and permanent staining of soft contact lenses. Adverse effects include GI upset (nausea, vomiting, diarrhea), hepatitis, muscular aches, neutropenia, skin rash, and uveitis (an eye disorder with inflammation, pain, and impaired vision). Hepatotoxicity is rare. Adverse effects increase when rifabutin is administered with a drug that inhibits cytochrome P450 3A4 enzymes (e.g., clarithromycin) and inhibits rifabutin metabolism. Safety and effectiveness in children have not been established.

Also similarly to rifampin, but to a lesser extent, rifabutin induces drug-metabolizing enzymes in the liver and accelerates the metabolism of numerous drugs. This action decreases concentration and clinical efficacy of beta blockers, corticosteroids, cyclosporine, digoxin, hormonal contraceptives, itraconazole, methadone, NNRTIs, oral hypoglycemic agents, phenytoin, PIs, theophylline, warfarin, and zidovudine. If these drugs are administered with rifabutin, their dosage may need to be increased.

**Rifapentine** (Priftin) is similar to rifampin in effectiveness, adverse effects, and enzyme induction activity. It may be used in the treatment of pulmonary TB and must be used with at least one other drug to which the causative organisms are susceptible. Its action has a slow onset and peaks in 5 to 6 hours. It is metabolized in the liver and excreted in urine and feces. It has a half-life of 14 hours. Rifapentine is infrequently used; its advantage over rifampin is that it can be given once weekly in the 4-month continuation phase of treatment for drug-susceptible tuberculosis.

**Ethambutol** (Myambutol) is a tuberculostatic drug that inhibits synthesis of RNA and thus interferes with mycobacterial protein metabolism. It may be a component in a four-drug regimen for initial treatment of active TB that may be caused by drug-resistant organisms. When culture and susceptibility reports become available (usually after several weeks), ethambutol may be stopped if the causative organisms are susceptible to INH and rifampin or continued if the organisms are resistant to INH or rifampin and susceptible to ethambutol. Ethambutol is not recommended for young children (e.g., under 5 years of age) whose visual acuity cannot be monitored but may be considered for children of any age when organisms are susceptible to ethambutol and resistant to other drugs. Mycobacterial resistance to ethambutol develops slowly.

Ethambutol is well absorbed from the GI tract, even when given with food. Dosage is based on body weight and should be changed during treatment if significant changes in weight occur. To obtain therapeutic serum levels, the total daily dose is given at one time. Drug action has a rapid onset, peaks in 2 to 4 hours, and lasts 20 to 24 hours. The drug has a half-life of 3 to 4 hours, is metabolized in the liver, and is excreted primarily by the kidneys. Dosage must be reduced with impaired renal function.

A major adverse effect is optic neuritis, an inflammatory, demyelinating disorder of the optic nerve that decreases visual acuity and ability to differentiate red from green. Tests of visual acuity and red-green discrimination are recommended before

starting ethambutol and periodically during therapy. If optic neuritis develops, the drug should be promptly stopped. Recovery usually occurs when ethambutol is discontinued.

**Pyrazinamide** is used with INH and rifampin for the first 2 months of treating active TB. It is bactericidal against actively growing mycobacteria in macrophages, but its exact mechanism of action is unknown. It is well absorbed from the GI tract and penetrates most body fluids and tissues, including macrophages containing TB organisms. Its action has a rapid onset and it peaks in 2 hours. It is metabolized in the liver and excreted mainly through the kidneys. Its half-life is 9 to 10 hours.

The most common adverse effect is GI upset; the most severe adverse effect is hepatotoxicity, and the drug should not be given to a patient with pre-existing liver impairment unless it is considered essential. Patients without liver impairment should be assessed for symptoms of liver dysfunction every 2 weeks during the usual 8 weeks of therapy. If symptoms occur, liver enzymes (ALT and AST) should be measured. If significant liver damage is indicated, pyrazinamide should be stopped.

Pyrazinamide inhibits urate excretion. This characteristic causes hyperuricemia in most patients and may cause acute attacks of gout.

**Streptomycin**, an aminoglycoside antibiotic (see Chap. 31), acts only against extracellular organisms; it does not penetrate macrophages and tuberculous lesions. It may be used in a regimen of four drugs to treat active TB when the susceptibility of the causative organism is unknown or in a regimen of four to six drugs in the treatment of TB suspected or known to be resistant to INH, rifampin, or both. It may be discontinued when cultures become negative or after a few months of therapy.

## Combination Primary Drugs

**Rifamate** and **Rifater** are combination products developed to increase convenience to patients and promote adherence to the prescribed drug therapy regimen (for drug-susceptible TB). Each Rifamate tablet contains INH 150 milligrams and rifampin 300 milligrams, and two tablets daily provide the recommended doses for a 6-month, short-course treatment regimen. Rifater contains INH 50 milligrams, rifampin 120 milligrams, and pyrazinamide 300 milligrams and is approved for the first 2 months of a 6-month, short-course treatment regimen. Dosage depends on weight, with four tablets daily for patients weighing 44 kilograms or less, five tablets daily for those weighing 45 to 54 kilograms, and six tablets daily for those weighing 55 kilograms or more. Rifater not only reduces the number of pills a patient has to take each day, it also prevents the patient from taking only one of the three medications, which can lead to MDR-TB.

## Second-line Drugs

**Para-aminosalicylic acid** (PAS), **capreomycin** (Capastat), **cycloserine** (Seromycin), and **ethionamide** (Trecator SC) are diverse drugs that share tuberculostatic properties. They are

indicated for use in disease caused by organisms resistant to primary drugs. They must be given concurrently with other drugs to inhibit emergence of resistant mycobacteria. These drugs are more costly, more toxic, and less effective than first-line drugs.

Other drugs used for the treatment of MDR-TB include aminoglycoside antibiotics (amikacin and kanamycin) and fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin, ofloxacin). These drugs are not usually considered antitubercular drugs. However, they have activity against mycobacteria and may be a component of a four- to six-drug regimen to treat suspected or known MDR-TB.

## Treatment of Active Tuberculosis

Adequate drug therapy of patients with active disease usually produces improvement within 2 to 3 weeks, with decreased fever and cough, weight gain, improved well-being, and improved chest radiographs. Treatment should generally be continued for at least 6 months or 3 months after cultures become negative. Most patients have negative sputum cultures within 3 to 6 months. If the patient is symptomatic or if the culture is positive after 3 months, noncompliance or drug resistance must be considered. Cultures that are positive after 6 months often include drug-resistant organisms, and an alternative drug therapy regimen is needed. With the increasing prevalence of MDR-TB, guidelines for treatment have changed and continue to evolve in the attempt to promote patient adherence to treatment and to manage MDR-TB, two of the major problems in drug therapy of tuberculosis.

The most commonly used regimen consists of INH, rifampin, and pyrazinamide daily for 2 months (the initial phase), followed by INH and rifampin (daily, two times weekly, or three times weekly) for 4 additional months (the continuation phase). If 4% or more of the tuberculosis isolates in the community are INH-resistant organisms, ethambutol or streptomycin should also be given until susceptibility reports become available. If the causative strain of *M. tuberculosis* is susceptible to INH, rifampin, and pyrazinamide, the regimen is continued as with the three-drug regimen described and the fourth drug (ethambutol or streptomycin) is discontinued. If rifampin is not used, an 18-month course of therapy is considered the minimum. In the absence of drug resistance, INH and rifampin in a 9-month regimen are effective; adding pyrazinamide for the initial 2 months of therapy allows the regimen to be shortened to 6 months.

For INH-resistant TB, the recommended regimen is rifampin, pyrazinamide, and ethambutol for 6 months. For rifampin-resistant TB, recommended regimens are INH and ethambutol for 18 months or INH, pyrazinamide, and streptomycin for 9 months. For MDR-TB, there is no standardized drug therapy regimen. Treatment of each patient must

be individualized according to susceptibility reports. Such regimens usually include an aminoglycoside, a fluoroquinolone, and two to four additional drugs to which the causative organism is susceptible. The drugs should be given for 1 to 2 years after cultures become negative. Intermittent administration is not recommended for MDR-TB. For XDR-TB, it is difficult if not impossible to design a drug therapy program with a sufficient number of drugs known to be effective against the TB organism.

Directly observed therapy (DOT), in which a health care provider (or other responsible adult) observes the patient taking each dose of anti-TB drugs, is recommended for all drug regimens and considered mandatory in intermittent schedules, (e.g., two or three times weekly) and regimens for MDR-TB.

During pregnancy, a three-drug regimen of INH, rifampin, and ethambutol is usually used, with close monitoring of liver function tests. Pyrazinamide and streptomycin should not be used during pregnancy.

## *Mycobacterium avium* Complex Disease

*Mycobacterium avium* and *Mycobacterium intracellulare* are different types of mycobacteria that resemble each other so closely that they are usually grouped together as *Mycobacterium avium* complex (MAC). These atypical mycobacteria are found in water (including natural water sources, indoor water systems, pools, and hot tubs) and soil throughout the United States as well as in animals. The organisms are thought to be transmitted by inhalation of droplets of contaminated water; there is no evidence of spread to humans from animals or other humans.

MAC rarely causes significant disease in immunocompetent people but causes an opportunistic pulmonary infection in approximately 50% of patients with advanced HIV infection. Symptoms include a productive cough, weight loss, hemoptysis, and fever. As the disease becomes disseminated through the body, chronic lung disease develops and the organism is found in the blood, bone marrow, liver, lymph nodes, and other body tissues.

The main drugs used in prevention of MAC disease are the macrolides azithromycin and clarithromycin (see Chap. 33) and rifabutin (described earlier in this chapter). Prophylactic drug therapy is recommended to be lifelong. For treatment, a three-drug regimen of azithromycin 250 milligrams daily or clarithromycin 1000 milligrams daily, rifampin or rifabutin (300 mg daily), and ethambutol (25 mg/kg/d for 2 months, then 15 mg/kg/d) is often used. The drugs may also be given two or three times weekly. Drug dosages are the same for intermittent regimens except that the larger dose of ethambutol is continued throughout. Streptomycin 500 to 1000 milligrams twice weekly is usually added for the initial 3 months of treatment when extensive MAC disease is present.

## Nursing Process

### Assessment

Assess for latent or active tuberculosis infection.

- For latent infection, identify high-risk patients (i.e., people who are close contacts of someone with active TB; are elderly or undernourished; have diabetes mellitus, silicosis, Hodgkin's disease, leukemia, or AIDS; are alcoholics; are receiving immunosuppressive drugs; or are immigrants from Southeast Asia and other parts of the world where the disease is endemic).
- For active disease, clinical manifestations include fatigue, weight loss, anorexia, malaise, fever, and a productive cough. In early phases, however, there may be no symptoms. If available, check diagnostic test reports for indications of TB (chest radiograph, tuberculin skin test, sputum smear and culture).
- In children, initial signs and symptoms may occur within a few weeks after exposure, before skin tests become positive, and resemble those of bacterial pneumonia. In addition, indications of disease in lymph nodes, GI and urinary tracts, bone marrow, and meninges may be present.
- In older adults, signs and symptoms of TB are often less prominent than in younger adults, or are similar to those in other respiratory disorders. Thus, an older adult is less likely to have fever, a positive skin test, significant sputum production, hemoptysis, or night sweats. However, mental status changes and mortality rates are higher in older than in younger adults.
- In patients with HIV infection, skin tests showing 5 mm of induration are considered positive. In addition, disease manifestations in patients with AIDS differ from those in people with undamaged immune systems. For example, malaise, weight loss, weakness, and fever are prominent. Other symptoms often resemble those of bacterial pneumonia, involve multiple lobes of the lungs, and involve extrapulmonary sites of infection.
- Assess candidates for antitubercular drug therapy for previous exposure and reaction to the primary drugs and for the current use of drugs that interact with the primary drugs.
- Assess for latent or active tuberculosis infection
- Assess for signs and symptoms of MAC disease, especially in patients with advanced HIV infection who have a CD4+ cell count of 100/mm<sup>3</sup> or less.

### Nursing Diagnoses

- Anxiety or Fear related to chronic illness and long-term drug therapy
- Deficient Knowledge: Disease process and need for treatment

- Noncompliance related to adverse drug effects and need for long-term treatment
- Deficient Knowledge: Consequences of noncompliance with the drug therapy regimen
- Risk for Injury: Adverse drug effects

### Planning/Goals

The patient will

- Take drugs as prescribed
- Keep appointments for follow-up care
- Report adverse drug effects
- Act to prevent spread of TB

### Interventions

Assist patients to understand the disease process and the necessity for long-term treatment and follow-up. This is extremely important for the patient and the community, because lack of knowledge and failure to comply with the therapeutic regimen lead to disease progression and spread. The American Lung Association publishes many helpful pamphlets, written for the general public, that can be obtained from a local chapter and given to patients and their families. Do not use these as a substitute for personal contact, however.

Use measures to prevent the spread of tuberculosis:

- Isolate suspected or newly diagnosed hospitalized patients in a private room for 2 or 3 weeks, until drug therapy has rendered them noninfectious.
- Wear a mask with close contact, and perform thorough hand hygiene afterward.
- Have patients wear a mask when out of the room for diagnostic tests.
- Assist patients to take antitubercular drugs as prescribed, for the length of time prescribed.

### Evaluation

- Observe for improvement in signs and symptoms of TB and MAC disease.
- Interview and observe for adverse drug effects; check laboratory reports of hepatic and renal function, when available.
- Question regarding compliance with instructions for taking antitubercular and anti-MAC drugs.

## Principles of Therapy

### Goals of Therapy

In general, the goals for treatment of TB are to cure patients with latent or active infection, to avoid the development of drug-resistant TB, and to minimize transmission of TB to other

## Patient Teaching Guidelines

## Isoniazid, Rifampin, and Pyrazinamide

- Isoniazid (INH) is one of the most commonly used medications for tuberculosis infection. It is given to people with positive skin tests to prevent development of active disease. Vitamin B<sub>6</sub> (pyridoxine) is usually given along with the INH to prevent leg numbness and tingling. Take INH and pyridoxine in a single dose once daily. Take on an empty stomach if possible; if stomach upset occurs, the drugs may be taken with food.
- For treatment of active disease, INH, rifampin, and pyrazinamide are usually given daily or twice weekly for 2 months; then the pyrazinamide is stopped and the others are continued for an additional 4 months.
- For treatment of inactive or latent tuberculosis infection, various regimens of INH alone, rifampin and pyrazinamide, or rifampin alone may be used. Any one of these regimens can be effective in preventing active disease if the drugs are taken correctly and for the time prescribed.
- INH, rifampin, and pyrazinamide can all cause liver damage. As a result, you should avoid alcoholic beverages and watch for signs and symptoms of hepatitis (e.g., nausea, yellowing of skin or eyes, dark urine, light-colored stools). If such symptoms occur, you should stop taking the drugs and report the symptoms to the health care provider managing the tuberculosis infection immediately. Blood tests of liver function will also be ordered. In some cases, liver failure has occurred, most often when patients continued to take the medications for a week or longer after symptoms of liver damage occurred.
- Rifampin should be taken in a single dose, once daily or twice weekly, on an empty stomach, 1 hour before or 2 hours after a meal.
- Rifampin causes a reddish discoloration of urine, tears, saliva, and other body secretions. This is harmless, except that soft contact lenses may be permanently stained.
- Use all available resources to learn about tuberculosis and the medications used to prevent or treat the infection. This is extremely important because the information can help you understand the reasons long-term treatment and follow-up care are needed. In addition to personal benefit, taking medications as prescribed can help your family and community by helping to prevent spread of tuberculosis. The American Lung Association publishes many helpful pamphlets that are available from local health departments and health care providers. Additional information is available on the Internet (e.g., the Centers for Disease Control and Prevention at <http://www.cdc.gov>).
- Learn how to prevent spread of tuberculosis:
  - Cover mouth and nose when coughing or sneezing. This prevents expelling tuberculosis germs into the surrounding air, where they can be inhaled by and infect others.
  - Cough and expectorate sputum into at least two layers of tissue. Place the used tissues in a waterproof bag, and dispose of the bag, preferably by burning.
  - Wash hands after coughing or sneezing.
- A nourishing diet and adequate rest help healing of infection.
- Periodic visits to a health care provider are needed for follow-up care and to monitor medications.
- The importance of taking medications as prescribed cannot be overemphasized. If not taken in the doses and for the length of time needed, there is a high likelihood for development of tuberculosis infection that is resistant to the most effective antituberculosis drugs. If this happens, treatment is much longer, very expensive, and requires strong drugs that cause more adverse effects. In addition, this very serious infection can be spread to family members and other close contacts. Thus, avoiding drug-resistant tuberculosis should be a strong incentive to complete the full course of treatment.
- Rifampin decreases the effectiveness of oral contraceptive tablets; a different type of contraception should be used during rifampin therapy.

people. More specifically, the goal with latent TB infection is to prevent the development of active infection. The main goals with active infection are to decrease signs and symptoms, make the patient noninfectious, ensure adherence to the drug therapy regimen, and cure the patient (i.e., eliminate all TB organisms; at least 6 months of treatment are usually required). Secondary goals are to identify the person from whom the patient caught the infection (called the index case), identify other people infected by the index case or the new case of TB, and ensure that those persons are treated appropriately.

### Drug-Susceptible Tuberculosis

Sputum culture and susceptibility reports require 6 to 8 weeks because the tubercle bacillus multiplies slowly. Consequently, initial drug therapy is based on other factors, such as the extent of disease, whether the patient has previously received antitubercular drugs, and whether multidrug-resistant strains are being found in the particular community.

Some general guidelines for pharmacologic treatment of TB are as follows:

- Multiple drugs are required to effectively treat the infection and inhibit emergence of drug-resistant organisms.
- Duration of drug therapy varies with the purpose, extent of disease, adherence to the drug therapy regimen, and clinical response. The trend in recent years, for treatment of both latent and active disease, is to give short courses of treatment (e.g., 6 months) when possible. Such regimens are more likely to be completed, and completion decreases the prevalence of drug-resistant disease in a community. In addition to the number of months of treatment, however, the total number of medication doses is also important. For example, the usual 6-month regimen for drug-susceptible TB consists of 182 doses of INH and rifampin and 56 doses of pyrazinamide. If treatment is interrupted for any reason, it is recommended that the drugs be continued so that the total number of doses is administered within a maximum time period of 9 months.

- Fixed-dose combination tablets (e.g., Rifamate, Rifater) are recommended by some authorities, because they help to prevent the emergence of drug-resistant organisms. These formulations are more expensive than separate drugs.

## Multidrug-Resistant Tuberculosis

Multidrug-resistant strains may occur anywhere. However, in the United States, they have been most evident in populations with AIDS, in closed environments (e.g., hospitals, prisons, long-term care facilities, homeless shelters), and in large urban areas.

Drug therapy regimens for people exposed to someone with MDR-TB or suspected of having MDR-TB should be designed in consultation with infectious-disease or tuberculosis specialists.

Treatment of MDR-TB requires concurrent administration of more drugs (e.g., four to six), for a longer period of time (e.g., 2 years or longer), than for drug-susceptible TB. The specific regimen is derived from cultures of infecting strains and susceptibility tests with primary and second-line drugs. It should include two or three drugs to which the isolate is sensitive and that the patient has not taken before.

All drug therapy for suspected or known MDR-TB should involve daily administration and DOT. Treatment is extremely expensive, even in the non-HIV population, and costs many thousand dollars more than the treatment of drug-susceptible TB.

XDR-TB may occur when treatment of MDR-TB is ineffective, for whatever reasons. Drug therapy for XDR-TB is extremely limited, because of the extensive resistance to both primary and second-line drugs.

## Increasing Adherence to Antitubercular Drug Therapy

Failure to complete treatment regimens is a major problem in TB management because it increases the spread of the disease and the amount of drug-resistant disease in a community. There is more difficulty with getting patients to complete treatment for latent infection than for active disease. Identifying and treating LTBI requires several steps, including administering and reading skin tests; obtaining medical evaluations of infected persons; and initiating, monitoring, and completing treatment. Nonadherence is common in all of these aspects.

### Strategies to Increase Adherence in TB Management

*Supporting the use of short-course regimens, directly observed therapy (DOT), and intermittent drug administration.* An additional strategy is to combine DOT with incentives and enablers (e.g., transportation, tokens or food coupons that are given to patients each time they appear at the health care facility for treatment).

*Educating patients, family members, and contacts of patients.* This may be especially important with treatment of LTBI. Most people are more motivated to take medications

and schedule follow-up care when they have symptoms than when they feel well and have no symptoms. The importance of treatment for the future health of the individual, significant others, and the community must be emphasized. In addition, patients should be informed about common and potential adverse effects of drug therapy and what to do if they occur.

*Providing support services and resources.* These require substantial financial resources and may include more workers to provide DOT therapy at the patient's location; flexible clinic hours; reducing waiting times for patients; and assisting patients with child care, transportation, or other social service needs that encourage them to initiate and continue treatment. Lack of these services (e.g., clinics far from patients' homes, with inconvenient hours, long waiting times, unsupportive staff) may deter patients from being evaluated for a positive skin test, initiating treatment, or completing the prescribed treatment and follow-up care.

*Individualizing treatment regimens.* Treatment should be individualized whenever possible to increase patient convenience and minimize disruption of usual activities of daily living. Short-course regimens, intermittent dosing (e.g., two or three times weekly rather than daily), and fixed-dose combinations of drugs (e.g., Rifater, Rifamate) reduce the number of pills and the duration of therapy.

*Promoting communication and continuity of care.* With patients for whom English is not their primary language, it is desirable to have a health care worker who speaks their language or who belongs to their ethnic group. This worker may be able to more effectively teach patients and others, elicit cooperation with treatment, administer DOT, and be a consistent support person.

## Monitoring Antitubercular Drug Therapy

There are two main methods of monitoring patient responses to treatment: clinical and laboratory.

Clinical monitoring is indicated for all patients. It includes teaching patients about signs and symptoms of adverse drug effects and which effects require stopping drug therapy and obtaining medical care (e.g., hepatotoxicity). It also includes regular assessment by a health care provider. Clinical monitoring should be repeated at each monthly visit. Patients should be assessed for signs of liver disease (e.g., loss of appetite, nausea, vomiting, dark urine, jaundice, fatigue, abdominal tenderness, easy bruising or bleeding) at least monthly if receiving INH alone or rifampin alone and at 2, 4, and 8 weeks if receiving rifampin and pyrazinamide. In addition to detecting adverse effects, these ongoing contacts are opportunities to reinforce teaching, assess adherence with therapy since the last visit, and observe for drug interactions. A standardized interview form may be helpful in eliciting appropriate information.

Laboratory monitoring mainly involves liver function tests (ALT, AST, bilirubin). Baseline measurements are indi-

cated for patients with possible liver disorders, those infected with HIV, women who are pregnant or early postpartum (within 3 months of delivery), those with a history of liver disease (e.g., hepatitis or cirrhosis), those who use alcohol regularly, and those with risk factors for liver disease. Monitoring during therapy is indicated for patients who have abnormal baseline values or other risk factors for liver disease and those who develop symptoms of liver damage. Some clinicians recommend that INH be stopped for transaminase levels over three times the upper limit of normal if associated with symptoms and five times the upper limit of normal if the patient is asymptomatic.

## Effects of Antitubercular Drugs on Other Drugs

Isoniazid (INH) increases risks of toxicity with several drugs by inhibiting their metabolism and increasing their blood levels. These include carbamazepine, fluconazole, haloperidol, phenytoin (effects of rifampin are opposite to those of INH and tend to predominate if both drugs are given with phenytoin), and vincristine. INH increases the risk of hepatotoxicity with most of these drugs; concurrent use should be avoided when possible or blood levels of the inhibited drug should be monitored. With vincristine, INH may increase peripheral neuropathy.

The rifamycins (rifampin, rifabutin, rifapentine) induce cytochrome P450 drug-metabolizing enzymes and therefore accelerate the metabolism and decrease the effectiveness of many drugs. Rifampin is the strongest inducer and may decrease the effects of angiotensin-converting enzyme (ACE) inhibitors, anticoagulants, antidysrhythmics, some antifungals (e.g., fluconazole), anti-HIV protease inhibitors (e.g., indinavir), anti-HIV NNRTIs (e.g., efavirenz, nevirapine), benzodiazepines, beta blockers, corticosteroids, cyclosporine, digoxin, diltiazem, estrogens and oral contraceptives, fexofenadine, fluoroquinolones, fluvastatin, haloperidol, lamotrigine, losartan, macrolide antibiotics, narcotic analgesics (e.g., methadone, morphine), nifedipine, ondansetron, phenytoin, propafenone, sertraline, sirolimus, sulfonyleureas (e.g., glyburide), tacrolimus, tamoxifen, theophylline, thyroid hormones, toremifene, tricyclic antidepressants, verapamil, zaleplon, zidovudine, zolpidem, and other drugs. Rifapentine reportedly causes fewer drug interactions than rifampin but more than rifabutin. Rifabutin is a weaker enzyme inducer and may be substituted for rifampin in some cases, most often for patients who require anti-HIV medications.

Pyrazinamide may decrease effects of allopurinol and cyclosporine.

## Use in Special Populations

### Use in Patients With Human Immunodeficiency Virus (HIV) Infection

Tuberculosis is a common opportunistic infection in people with advanced HIV infection and may develop from an initial infection or reactivation of LTBI. For treatment of LTBI in

patients with positive skin tests, INH daily or twice weekly for 9 months is effective.

Treatment of active disease is similar to that in persons who do not have HIV infection. Those with HIV infection who adhere to standard treatment regimens do not have an increased risk of treatment failure. Thus, these patients are usually treated with antitubercular drugs for 6 months like HIV-seronegative patients. The regimen may be longer if the bacteriologic (e.g., negative cultures) or clinical response (e.g., improvement in symptoms) is slow or inadequate.

A major difficulty with treatment of TB in patients with HIV infection is that rifampin interacts with many PIs and NNRTIs. If the drugs are given concurrently, rifampin decreases blood levels and therapeutic effects of the anti-HIV drugs. Rifabutin has fewer interactions and may be substituted for rifampin. The PIs indinavir and nelfinavir and most of the NNRTIs can be used with rifabutin. Ritonavir (PI) should not be used with rifabutin. Also, indinavir increases risks of rifabutin toxicity. Dosage of rifabutin should be decreased if given with indinavir.

### Use in Children

Tuberculosis occurs in children of all ages. Infants and preschool children need early recognition and treatment because the disease can rapidly progress from primary infection to active pulmonary disease and perhaps to extrapulmonary involvement. TB is usually discovered during examination of a sick child or investigation of the contacts of someone with newly diagnosed active TB. Most children are infected in their home. Children in close contact with a patient with TB should receive skin testing, a physical examination, and a chest radiograph.

For treatment of LTBI, only one of the four regimens currently recommended for adults (INH for 9 months) is recommended for those under 18 years of age. For treatment of active disease, the prescribed regimens are similar to those used for adults. That is, the same primary drugs are used and may be given daily, twice weekly, or three times weekly with child-appropriate reductions in dosage. If the drug-susceptibility patterns of the *M. tuberculosis* strain causing the index case are known, the child is treated with those drugs; if this information is not available, the pattern of drug resistance in the community where the child likely became infected should be the guide for selecting the drug therapy regimen. As in adults, drug-susceptible TB is treated with INH, rifampin, and pyrazinamide for 2 months. Then, pyrazinamide is stopped and the INH and rifampin are continued for 4 more months. If drug-resistant organisms have been identified in the community, a fourth drug, ethambutol or streptomycin, should be given until the patient's culture and susceptibility reports become available. If pyrazinamide is not given, INH and rifampin are recommended for 9 months. When INH or rifampin cannot be used, therapy should continue for 12 to 24 months.

Drug-resistant TB in children is usually acquired from an adult family member or other close contact with active,

drug-resistant disease. For children exposed to MDR-TB, there is no proven preventive therapy. Several regimens are used empirically, including ethambutol and pyrazinamide or ethionamide and cycloserine. When INH and rifampin cannot be given because of MDR-TB, drug therapy should continue for 24 months after sputum smears or cultures become negative. Fluoroquinolones (e.g., levofloxacin, others) are used for treatment of MDR-TB in adults but are not recommended for use in children. Patients with MDR-TB may require months of treatment before sputum smears become negative, and they are infectious during this period. To guide dosage and minimize adverse drug effects, serum drug levels should be measured periodically, especially in patients with GI, renal, or hepatic disease or in those with advanced HIV infection.

In children with HIV infection, the American Academy of Pediatrics recommends three drugs for at least 12 months. If drug-resistant or extrapulmonary disease is suspected, four drugs are indicated.

Overall, as with adults, drug therapy regimens vary with particular circumstances and continue to evolve. Health care providers must follow current recommendations of pediatric infectious-disease specialists.

### Use in Older Adults

Although INH is the drug of choice for treatment of LTBI, its use is controversial in older adults. Because risks of drug-induced hepatotoxicity are higher in this population, some clinicians believe those patients with positive skin tests should have additional risk factors (e.g., recent skin-test conversion, immunosuppression, previous gastrectomy) before receiving INH. When INH is given, people who drink alcoholic beverages daily are most likely to sustain serious liver impairment.

For treatment of active disease caused by drug-susceptible organisms, INH, rifampin, and pyrazinamide are given, as in younger adults. Because all three drugs may cause hepatotoxicity, liver function tests should be monitored and the drugs discontinued if signs and symptoms of hepatotoxicity occur. For treatment of suspected or known MDR-TB, four to six drugs are used.

### Use in Patients With Renal Impairment

Rifampin is mainly eliminated by the liver. However, up to 30% of a dose is excreted by the kidneys and dose reduction may be needed in patients with renal impairment. In addition, dosage of amikacin, capreomycin, cycloserine, ethambutol, fluoroquinolones, and streptomycin should be reduced in patients with impaired renal function. Cycloserine is contraindicated in severe renal impairment.

### Use in Patients With Hepatic Impairment

Most antitubercular drugs are metabolized in the liver, and several (e.g., INH, rifampin, pyrazinamide) are hepatotoxic. Moreover, they are often used concomitantly, which increases risks of hepatotoxicity. To detect hepatotoxicity as early as

possible, patients should be thoroughly instructed to report any signs of liver damage and health care providers who administer DOT or have any patient contact should observe for and ask about symptoms. For patients at risk of developing hepatotoxicity, serum ALT and AST should be measured before starting and periodically during drug therapy. If hepatitis occurs, these enzyme levels usually increase before other signs and symptoms develop.

With INH, mild increases in AST and ALT occur in approximately 10% to 20% of patients but are not considered significant and usually resolve without stopping the drug. Hepatitis and liver damage are more likely to occur during the first 8 weeks of INH therapy and in middle-aged and older adults. Patients should be assessed monthly for symptoms of hepatitis (anorexia, nausea, fatigue, malaise, jaundice). If symptoms occur or if AST and ALT increase significantly (more than five times the normal values), INH should be discontinued. INH should be used cautiously in patients with pre-existing liver disease.

With rifampin, liver damage is most likely to occur with pre-existing liver disease or concurrent use of other hepatotoxic drugs. Patients should be monitored at least monthly for symptoms of hepatotoxicity. AST and ALT may be measured before starting and periodically during rifampin therapy. If signs of liver damage occur, the drug should be stopped, serum AST and ALT should be measured, and medical evaluation should be done.

With pyrazinamide, the drug should not be given to a patient with pre-existing liver impairment unless it is considered absolutely essential. For patients without liver impairment, clinical monitoring for signs and symptoms of hepatotoxicity are recommended every 2 weeks. Serum ALT and AST may also be measured periodically. If significant symptoms or elevations of serum ALT and AST levels occur, the drug must be stopped.

### Use in Home Care

The home care nurse has major roles to play in the health care of patients, families, and communities. With individual patients receiving antitubercular drugs for latent or active infection, the home care nurse needs to assist in taking the drugs as directed. Specific interventions vary widely and may include administering the drugs (DOT), teaching about the importance of taking the drugs and the possible consequences of not taking them (i.e., more severe disease, longer treatment regimens with more toxic drugs, spreading the disease to others), monitoring for adverse drug effects and assisting the patient to manage them or reporting them to the drug prescriber, assisting in obtaining the drugs and keeping follow-up appointments for blood tests and chest radiographs, and others. Family members may also need teaching related to preventing spread of the disease and assisting the patient to obtain adequate treatment. In relation to community needs, the nurse needs to be active in identifying cases, investigating contacts of newly diagnosed cases, and promoting efforts to manage tuberculosis effectively.

## Nursing Actions Antitubercular Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give isoniazid (INH), ethambutol, and rifampin in a single dose once daily, twice a week, or 3 times a week.
- b. Give INH and rifampin on an empty stomach, 1 hour before or 2 hours after a meal, with a full glass of water. INH may be given with food if gastrointestinal (GI) upset occurs.
- c. Give parenteral INH by deep intramuscular (IM) injection into a large muscle mass, and rotate injection sites.
- d. Give IV rifampin by infusion, over 1–3 hours, depending on dose and volume of IV solution.
- e. Give rifabutin 300 mg once daily; if GI upset occurs, may give 150 mg twice daily.
- f. Give rifapentine on an empty stomach when possible; may give with food if GI upset occurs.
- g. Give secondary anti-TB drugs daily. See drug literature for specific instructions.

#### 2. Observe for therapeutic effects

- a. With latent infection, observe for the absence of signs and symptoms.
- b. With active disease, observe for clinical improvement (e.g., decreased cough, sputum, fever, night sweats, and fatigue; increased appetite, weight, and feeling of well-being; negative sputum smear and culture results; improvement in chest radiographs).

#### 3. Observe for adverse effects

- a. Nausea, vomiting, diarrhea
- b. Neurotoxicity:
  - (1) Eighth cranial nerve damage—vertigo, tinnitus, hearing loss
  - (2) Optic nerve damage—decreased vision and color discrimination
  - (3) Peripheral neuritis—tingling, numbness, paresthesias
  - (4) Central nervous system changes—confusion, convulsions, depression
- c. Hepatotoxicity—increased serum alanine and aspartate aminotransferases (ALT and AST), and bilirubin; jaundice; other symptoms of hepatitis (e.g., anorexia, nausea, vomiting, abdominal pain)
- d. Nephrotoxicity—increased blood urea nitrogen and serum creatinine; cells in urine; oliguria
- e. Hypersensitivity—fever, tachycardia, anorexia, and malaise are early symptoms. If the drug is not discontinued, exfoliative dermatitis, hepatitis, renal abnormalities, and blood dyscrasias may occur.
- f. Miscellaneous—rifampin, rifabutin, and rifapentine can cause:
  - (1) a red-orange discoloration of body fluids, including urine and tears
  - (2) permanent staining of soft contact lenses
  - (3) increased sensitivity to sunlight
  - (4) unplanned pregnancy, most often associated with rifampin, which makes hormonal birth control pills and implants less effective

### RATIONALE/EXPLANATION

A single dose with the resulting higher blood levels is more effective. Also, less-frequent administration is more convenient for patients and more likely to be completed. Food delays absorption.

To decrease local pain and tissue irritation. Used only when patients are unable to take the medication orally. For a 600-mg dose, reconstitute with 10 mL of sterile water for injection; withdraw the entire amount and add it to 500 mL 5% dextrose or 0.9% sodium chloride solution; infuse over 3 hours.

Manufacturer's recommendation

Usually given twice weekly for 2 months, with 72 hours between doses, then once weekly for 4 months, along with other antitubercular drugs, for treatment of active TB. These drugs are used only to treat TB infection caused by organisms that are resistant to the primary anti-TB drugs.

Therapeutic effects are usually apparent within the first 2 or 3 weeks of drug therapy for active disease.

These symptoms are likely to occur with any of the oral antitubercular drugs.

A major adverse reaction to aminoglycoside antibiotics

The major adverse reaction to ethambutol

Often occurs with INH but can be prevented by administering pyridoxine (vitamin B<sub>6</sub>). Also may occur with ethambutol. More often associated with INH, but similar changes may occur with ethambutol

May occur with INH, rifampin, and pyrazinamide, especially if the patient already has liver damage. Report these symptoms to the prescriber immediately, to prevent possible liver failure and death.

A major adverse reaction to aminoglycosides

Hypersensitivity reactions are more likely to occur between the third and eighth weeks of drug therapy. Early detection and drug discontinuation are necessary to prevent progressive worsening of the patient's condition. Severe reactions can be fatal.

The color change is harmless, but patients should avoid wearing soft contact lenses during therapy.

Women who take rifampin should use a different form of birth control.

NURSING ACTIONS	RATIONALE/EXPLANATION

## Key Concepts

- TB is a worldwide problem. Although not as extensive in the United States as in many other countries, the public health infrastructure for diagnosing and treating TB needs to be maintained.
- Multidrug resistant and extensively-drug resistant tuberculosis (MDR-TB and XDR-TB) are of increasing concern.
- Directly observed therapy (DOT) is recommended to prevent inadequate drug therapy and development of drug-resistant TB organisms.
- INH is the treatment of choice for LTBI.
- In drug-susceptible active TB, the treatment of choice is 2 months of INH, rifampin, and pyrazinamide, followed by 4 months of INH and rifampin.
- In drug-resistant TB, there is no standardized treatment regimen; treatment must be individualized for each patient according to drug susceptibility reports.

## Review and Application Exercises

### Short Answer Exercises

1. How do tuberculosis infections differ from other bacterial infections?
2. Why are patients with AIDS at high risk for developing tuberculosis?
3. What are the main risk factors for development of drug-resistant tuberculosis?
4. Who should receive INH to prevent tuberculosis? Who should not be given INH? Why?
5. When INH is given alone for treatment of LTBI, how long should it be taken?
6. If you worked in a health department with patients taking INH for treatment of LTBI, what are some interventions to promote patient adherence to the drug regimen?
7. Why is active, symptomatic tuberculosis always treated with multiple drugs?
8. In a patient with tuberculosis newly started on drug therapy, how could you explain the emergence of drug-resistant organisms and the importance of preventing this problem?
9. What are advantages and disadvantages of short-course (6–9 months) treatment programs?
10. What adverse effects are associated with INH, rifampin, pyrazinamide, and ethambutol, and how may they be prevented or minimized?

### NCLEX-Style Questions

11. The nurse who is giving isoniazid (INH) anticipates an order for the following vitamin supplementation, which is usually given with isoniazid (INH).
  - a. niacin
  - b. pyridoxine
  - c. vitamin D
  - d. folate
12. The nurse knows to anticipate that the following adverse effect may be more likely to occur in patients receiving INH and rifampin.
  - a. neurotoxicity
  - b. hepatotoxicity
  - c. nephrotoxicity
  - d. ototoxicity

13. Patients taking INH should be taught by the nurse to avoid alcohol because of increased risks of
  - a. severe central nervous system depression
  - b. hepatitis
  - c. drug-resistant *M. tuberculosis* organisms
  - d. rapid drug metabolism
14. The family of a TB patient who is being treated asks the nurse when his symptoms will start to resolve with treatment. The nurse knows that the therapeutic effects of antitubercular drugs are usually evident in
  - a. 3–5 days
  - b. 7–10 days
  - c. 2–3 weeks
  - d. 6 weeks or longer
15. The nurse taking care of a patient with tuberculosis receives an order for a fluoroquinolone drug, ciprofloxacin. She knows that this drug may be used to treat
  - a. inactive or latent tuberculosis
  - b. active drug-susceptible tuberculosis
  - c. MDR-TB
  - d. nontuberculous mycobacterial infection

# Antiviral Drugs

## KEY TERMS

- Antiretroviral drugs
- Antiretroviral therapy (ART)
- Genital herpes
- HAART
- Herpesvirus
- Human immunodeficiency virus (HIV)
- Immunocompetent
- Immuno-compromised
- Retrovirus
- Viral hepatitis
- Viral load

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe characteristics of viruses and common viral infections.
2. Discuss difficulties in developing and using antiviral drugs.
3. Identify patients at risk for development of systemic viral infections.
4. Differentiate types of antiviral drugs used for various viral infections.
5. Describe selected antiviral drugs in terms of indications for use, adverse effects, and nursing process implications.
6. Discuss the rationale for using combinations of drugs in treating HIV infection.
7. Discuss guidelines for using antiviral drugs in special populations.
8. Teach patients strategies to prevent viral infections.

## Applying Your Knowledge

Tony Bronowicz is a 32-year-old man who is HIV positive. He is following a drug regimen that consists of Combivir one capsule PO twice a day and ritonavir 600 mg PO twice a day. Mr. Bronowicz is currently hospitalized and you are his nurse.

## Introduction

Viruses cause acquired immunodeficiency syndrome (AIDS), hepatitis, pneumonia, and other disorders that affect almost every body system. Many potentially pathogenic viral strains exist, including more than 150 that infect the human respiratory tract. Viruses can be spread by secretions from infected people, ingestion of contaminated food or water, breaks in skin or mucous membrane, sexual contact, pregnancy, breast-feeding, and organ transplantation. Viral infections vary from mild, localized disease with few symptoms to severe, systemic illness and death. Additional characteristics of viruses and viral infections are described in the following paragraphs; selected infections are described in Box 35-1.

- Viruses are intracellular parasites that gain entry to human host cells by binding to receptors on cell membranes. All human cells do not have receptors for all viruses; cells that lack receptors for a particular virus are resistant to infection by that virus. Thus, the locations and numbers of the receptors determine which host cells can be infected by a virus. For example, the mucous membranes lining the tracheobronchial tree have receptors for the influenza A virus; helper T lymphocytes and other white blood cells have CD4 molecules, which are the receptors for the *human immunodeficiency virus (HIV)*.
- Inside host cells, viruses use cellular metabolic activities for their own survival and replication. Viral replication involves dissolution of the protein coating and exposure of the genetic

## Box 35-1

## Selected Viral Infections

**Avian Influenza A (H5N1)**

In recent years, the highly pathogenic H5N1 subtype of influenza A has been found in numerous countries. It occurs mainly in birds and poultry, but a few hundred human cases have been confirmed. Most human cases occur after exposure to infected poultry or surfaces contaminated with poultry droppings. Because human infection may cause respiratory failure and has a high mortality rate, the possibility that these viral strains might mutate so that they infect humans more easily is a major public health concern. This virus is considered the most likely cause of a future worldwide influenza epidemic.

**Herpesvirus Infections***Cytomegalovirus Infection and Retinitis*

Cytomegalovirus (CMV) infection is common, and most people become infected by adulthood. Infection is usually asymptomatic in healthy, *immunocompetent* adults. Like other herpesviruses, CMV can cause a primary infection, then remain latent in body tissues, probably for life. This means the virus can be shed in secretions of an asymptomatic host and spread to others by contact with infected saliva, blood, urine, semen, breast milk, and cervical secretions. It also means the virus may lead to an opportunistic infection when the host becomes immunosuppressed. During pregnancy, CMV is transmitted to the fetus across the placenta and may cause infection in the brain, inner ears, eyes, liver, and bone marrow. Learning disabilities and mental retardation can result from congenital CMV infection. Children spread the virus to each other in saliva or urine, whereas adolescents and adults transmit the virus mainly through sexual contact.

Major populations at risk for development of active CMV infection are patients with cancer who receive immunosuppressant drugs and organ transplant recipients, who must receive immunosuppressant drugs to prevent their body's rejection of the transplanted organ. Patients with advanced HIV infection are also at risk, but the incidence has decreased with highly active antiretroviral therapy (HAART). Systemic CMV infection occurs mainly from reactivation of endogenous virus, although it may occur from an exogenous source. Active CMV infection may cause cellular necrosis and inflammation in various body tissues. Common manifestations of disease include pneumonitis, hepatitis, encephalitis, adrenal insufficiency, gastrointestinal inflammation, and gastric ulcerations.

In the eye, CMV infection produces retinitis, usually characterized by blurred vision and decreased visual acuity. Visual impairment is progressive and irreversible and, if untreated, may result in blindness. CMV retinitis may also indicate systemic CMV infection or may be entirely asymptomatic.

*Genital Herpes Infection*

*Genital herpes* infection is caused by the herpes simplex virus (HSV) and produces recurrent, painful, blister-like lesions on skin and mucous membranes. HSV is usually transmitted from person to person by direct contact with open lesions or secre-

tions, including genital secretions. Primary infection occurs at a site of viral entry, where the virus infects epithelial cells, produces progeny viruses, and eventually causes cell death. After primary infection, latent virus may become dormant within sensory nerve cells. In response to various stimuli (e.g., intense sunlight, emotional stress, febrile illness, menstruation), latent virus may become reactivated and lead to viral reproduction and shedding.

In the fetus, HSV may be transmitted from an infected birth canal, and neonatal herpes is a serious complication of maternal genital herpes. Neonatal herpes usually becomes evident within the first week of life and may be manifested by the typical clusters of blister-like lesions on skin or mucous membranes. Irritability, lethargy, jaundice, altered blood clotting, respiratory distress, seizures, or coma may also occur. The lesions may heal in 1 to 2 weeks, but neonatal herpes carries a high mortality rate. In immunosuppressed patients, HSV infection may result in severe, systemic disease.

*Herpes Zoster*

Herpes zoster is caused by the varicella-zoster virus, which is highly contagious and present worldwide. Most children in the United States are infected by early school age. The virus produces chickenpox on first exposure and is spread from person to person by the respiratory route or by contact with secretions from skin lesions. Recovery from the primary infection leaves latent infection in nerve cells. Reactivation of the latent infection (usually later in life) causes herpes zoster (more commonly known as "shingles"), a localized cluster of painful, blister-like skin lesions. The skin lesions have the same appearance as those of chickenpox and genital herpes. Over several days, the vesicles become pustules, then rupture and heal. Because the virus remains in sensory nerve cells, pain can persist for months after the skin lesions heal. Most cases of herpes zoster infection occur among the elderly and the immunocompromised.

**Human Immunodeficiency Virus Infection**

HIV infection is caused by a *retrovirus* that infects the immune system. Two types of HIV virus have been identified, HIV-1 and HIV-2. Most infections in the United States are caused by HIV-1; HIV-2 infections occur mainly in Africa. HIV binds to receptors on the surface of CD4+ cells (especially T lymphocytes or helper T cells). HIV entry and replication eventually results in cell death. Because CD4+ cells play major roles in regulating immune function, their destruction results in serious impairment of the immune system.

The initial phase of HIV infection is characterized by influenza-like symptoms (e.g., fever, chills, muscle aches) that may last several weeks. During this time, the virus undergoes rapid replication. The next phase is characterized by a dramatic decline in the rate of viral replication, attributed to a partially effective immune response. During this phase, no visible manifestations of HIV infection may be present. However, replication of HIV continues and antibodies may be detected

in the serum. During this period, the person is seropositive (HIV+) and infectious but asymptomatic. Eventually, the immune system is substantially damaged and the rate of viral reproduction accelerates. When viral load and immunodeficiency reach significant levels, the illness is termed acquired human immunodeficiency syndrome (AIDS) and serious opportunistic infections occur. With effective drug therapy, viral load decreases and the CD4+ cell count increases, so that HIV-infected people may live for many years without progression to AIDS.

HIV infection occurs in all age groups and can spread to a new host during any phase of infection. The virus is commonly spread by sexual intercourse, injection of intravenous drugs with contaminated needles, mucous membrane contact with infected blood or body fluids, and perinatally from mother to fetus. Although the virus is found in most body fluids, infection has primarily been associated with exposure to blood, semen, or vaginal secretions. The virus is not spread through casual contact. Health care workers may be infected by needle-stick injuries. They should be aware that postexposure prophylaxis is available and may significantly reduce the risk of transmission.

#### Human Papilloma Virus (HPV) Infection

HPV infection, the most common sexually transmitted infection, is spread by contact with infected lesions. It affects both men and women and can cause genital warts and several types of cancer (e.g., cervical, vaginal, vulvar, anal, and penile). In women, 80% reportedly become infected within 5 years of becoming sexually active.

#### Respiratory Syncytial Virus Infection

RSV is a highly contagious virus that is present worldwide and infects most children by school age. Epidemics of RSV infection often occur in nurseries, daycare centers, and pediatric hospital units during winter months. RSV infects and destroys respiratory epithelium in the bronchi, bronchioles, and alveoli. It is spread by respiratory droplets and secretions, direct contact with an infected person, and contact with fomites, including the hands of caregivers.

RSV is the most common cause of bronchiolitis and pneumonia in infants and causes severe illness in those younger than 6 months of age. These infants usually have wheezing, cough, respiratory distress, and fever. The infection is usually self-limited and resolves in 1 to 2 weeks. Antiviral therapy with ribavirin is used in some cases. The mortality rate from RSV infection is low in children who are generally healthy but increases substantially in those with congenital heart disease or immunosuppression. Recurrent infection occurs but is usually less severe than primary infection. In older children, RSV infection produces much milder disease but may be associated with acute exacerbations of asthma.

In adults, RSV infection causes colds and bronchitis, with symptoms of fever, cough, and nasal congestion. Infection occurs most often in those with household or other close contact with children, including pediatric health care workers. In

older adults, RSV infection may cause pneumonia requiring hospitalization. In immunocompromised patients, RSV infection may cause severe and potentially fatal pneumonia.

#### Viral Hepatitis

There are several types of *viral hepatitis*, and new hepatitis viruses are still being identified. Worldwide, viral hepatitis has increased in recent years. All hepatitis viruses have similar effects on the liver, although they differ in some other characteristics. Common types of viral hepatitis are described below. Vaccines are available to prevent hepatitis A and B (see Chap. 39).

**Hepatitis A virus (HAV)** is transmitted mainly by the fecal–oral route and close contact with an infected person; foodborne outbreaks also occur, usually from infected food handlers or contaminated produce in the United States. The virus survives for long periods in the environment (e.g., in water and soil) and on human hands and inanimate objects. It resists freezing, detergents, and acids but can be inactivated by chlorine and temperatures above 185°F.

The HAV reproduces only in liver and gastrointestinal cells, from which viral particles are released into blood and bile. The average incubation period is 25 to 30 days. The patient is infectious during the incubation period and for 7 to 10 days after symptoms develop. In infected adults, about 70% develop symptoms, including fever and jaundice, that may last as long as 2 months. Most recover without treatment and develop immunity against future HAV infections; 10% to 20% require hospitalization. In children, many are asymptomatic or develop flu-like or nonspecific symptoms without jaundice. However, even children with few or no symptoms may shed virus in their stools and be a source of community infection for as long as 6 months. The availability of hepatitis A vaccine has greatly decreased the number of reported cases. The vaccine is recommended for children and adults at increased risk of contracting the disease (e.g., travelers to certain countries, men who have sex with men, drug abusers, recipients of clotting factor replacement) and for persons with chronic liver disease.

**Hepatitis B virus (HBV)** can be transmitted by contact with contaminated blood and other body fluids (e.g., perinatally, during sexual contact with an infected person, by sharing needles during IV drug use, and undergoing acupuncture, hemodialysis, tattooing, or ear and body piercing). In addition, health care and public safety workers are at increased risk of developing HBV infection from injuries with contaminated equipment (e.g., contaminated needles) and from other exposures to infected body fluid. Any person exposed to infected body fluids should be evaluated for HBV infection; any person diagnosed with HBV infection should be evaluated for liver disease and for HIV infection. It is estimated that 70,000 Americans become infected with HBV every year and approximately 5,000 of them will die of the complications caused by the infection. Many Americans have chronic HBV infection; asymptomatic chronic carriers of HBV may transmit the infection to others. Hepatitis B can lead to cirrhosis, liver cancer, liver failure, and death.

## Box 35-1

## Selected Viral Infections (continued)

The HBV can live up to 3 days on various surfaces that appear clean. The incubation period is 30 to 180 days. Increased hepatitis B surface antigens and liver enzymes (ALT, AST) occur before symptoms of HBV infection develop. After symptoms develop, antibodies to the viral antigens are produced and the presence of antigens and viral DNA in the patient's blood indicate that the patient is infectious.

**Hepatitis C virus (HCV)** can be transmitted by contact with contaminated blood or other body fluids. Persons at high risk of exposure include health care and public safety workers; IV drug users; those with multiple sex partners; those undergoing hemodialysis, tattoos, or body piercings; and those who received blood transfusions before 1990, when screening blood for HCV was started. In addition, pregnant women may trans-

mit the virus to their infants, and mothers with symptoms and high viral titers may transmit the virus to nursing infants.

The HCV incubation period is 14 to 80 days; infection is diagnosed by testing for viral DNA or antibodies. HCV infection affects people of all ages but is most often found among 20- to 39-year-olds. Infected persons can be asymptomatic for years, but most eventually develop chronic liver disease. In the United States, HCV infection is the leading cause of cirrhosis, liver cancer, and liver transplants. Effective drug therapy may cure HCV infection.

**Other hepatitis viruses** (e.g., D, G, and a “transfusion-transmissible” virus) have been identified; they, like HBV and HCV, are transmitted through contact with infected blood and body fluids.

material (deoxyribonucleic acid [DNA] or ribonucleic acid [RNA]). With DNA viruses, the viral DNA enters the host cell's nucleus, where it becomes incorporated into the host cell's chromosomal DNA. Then, host cell genes are coded to produce new viruses. In addition, the viral DNA incorporated with host DNA is transmitted to the host's daughter cells during host cell mitosis and becomes part of the inherited genetic information of the host cell and its progeny. With RNA viruses (e.g., HIV), viral RNA must be converted to DNA by an enzyme called reverse transcriptase before replication can occur.

After new viruses are formed, they are released from the infected cell either by budding out and breaking off from the cell membrane (leaving the host cell intact) or by causing lysis of the cell. When the cell is destroyed, the viruses are released into the blood and surrounding tissues, from which they can transmit the viral infection to other host cells.

- Viruses induce antibodies and immunity. Antibodies are proteins that defend against microbial or viral invasion. They are very specific (i.e., an antibody protects only against a specific virus or other antigen). For example, in a person who has had measles, antibody protection (immunity) develops against future infection by the measles virus, but immunity does not develop against other viral infections, such as chickenpox or hepatitis.

The protein coat of the virus allows the immune system of the host to recognize the virus as a “foreign invader” and to produce antibodies against it. This system works well for most viruses but does not work for the influenza A virus, which can alter its protein covering so much and so often that the immune system does not recognize it as foreign to the body. Thus, last year's antibody cannot recognize and neutralize this year's virus.

Antibodies against infecting viruses can prevent the viruses from reaching the bloodstream or, if they are already

in the bloodstream, prevent their invasion of host cells. After the virus has penetrated the cell, it is protected from antibody action, and the host depends on cell-mediated immunity (lymphocytes and macrophages) to eradicate the virus along with the cell harboring it.

- Viral infection may occur without signs and symptoms of illness. If illness does occur, the clinical course is usually short and self-limited. Recovery occurs as the virus is eliminated from the body. Some viruses (e.g., *herpesvirus*) can survive in host cells for many years and cause a chronic, latent infection that periodically becomes reactivated. Also, autoimmune diseases may be caused by viral alteration of host cells so that lymphocytes recognize the host's own tissues as being foreign.
- Symptoms usually associated with acute viral infections include fever, headache, cough, malaise, muscle pain, nausea and vomiting, diarrhea, insomnia, and photophobia. White blood cell counts usually remain normal. Other signs and symptoms vary with the type of virus and body organs involved.

## Antiviral Drugs

Numerous vaccines have been developed (see Chap. 39) to prevent viral infections, and numerous drugs have been developed to treat HIV and other viral infections. Most antivirals inhibit viral reproduction but do not eliminate viruses from tissues. In general, available drugs are expensive, relatively toxic, and effective in a limited number of infections. Some may be useful in treating an established infection if given promptly and in chemoprophylaxis if given before or soon after exposure. Protection conferred by chemoprophylaxis is immediate but lasts only while the drug is being taken. Subgroups of antiviral drugs are described in the following sections; additional characteristics and dosage ranges are listed in Tables 35-1 and 35-2.

Table 35-1

## Drugs at a Glance: Drugs for Prevention or Treatment of Selected Viral Infections

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Herpesvirus Infections</b>			
<b>Acyclovir</b> (Zovirax)	Oral mucocutaneous lesions (e.g., cold sores, fever blisters) Genital herpes Herpes simplex encephalitis Varicella (chickenpox) in immunocompromised hosts Herpes zoster (shingles) in normal and immunocompromised hosts	Genital herpes, PO 200 mg q4h, 5 times daily for 10 d for initial infection; 400 mg 2 times daily to prevent recurrence of chronic infection; 200 mg q4h 5 times daily for 5 d to treat recurrence Herpes zoster, PO 800 mg q4h 5 times daily for 7–10 d Chickenpox, PO 20 mg/kg (maximum dose 800 mg) 4 times daily for 5 d Mucosal and cutaneous HSV infections in ICH, IV 5 mg/kg infused over 1 h, q8h for 7 d Varicella-zoster infections in ICH, IV 10 mg/kg, infused over 1 h, q8h for 7 d HSV encephalitis, IV 10 mg/kg, infused over 1 h, q8h for 10 d Topically to lesions q3h, 6 times daily for 7 d	Under 12 y: IV 10 or 20 mg/kg q8h for 7 or 10 d, depending on the condition being treated Chickenpox, weight above 40 kg, PO 800 mg 4 times daily for 5 d Chickenpox, 2 y and older and weight 40 kg or less, PO 20 mg/kg 4 times daily for 5 d 12 y and older: topical, same as adults
<b>Famciclovir</b> (Famvir)	Acute herpes zoster Genital herpes	Herpes zoster, PO 500 mg q8h for 7 d Genital herpes, PO 125 mg twice daily for 5 d	
<b>Foscarnet</b> (Foscavir)	Treatment of CMV retinitis in persons with AIDS Treatment of acyclovir-resistant mucocutaneous HSV infections in ICH	CMV retinitis, IV 60 mg/kg q8h for 2–3 wk, depending on clinical response, then 90–120 mg/kg/d for maintenance HSV infections, IV 40 mg/kg q8–12h for 2–3 wk or until lesions are healed	Dosage not established
<b>Ganciclovir</b> (Cytovene)	CMV retinitis in ICH Prevention of CMV disease in patients with organ transplants or advanced HIV infection	CMV retinitis, IV 5 mg/kg q12h for 14–21 d, then 5 mg/kg once daily for 7 d/wk or 6 mg/kg once daily for 5 d/wk or PO 1000 mg 3 times daily for maintenance Prevention in transplant recipients, IV 5 mg/kg once daily 7 d/wk or 6 mg/kg once daily 5 d/wk Prevention in patients with HIV infection, PO 1000 mg 3 times daily	Dosage not established
<b>Trifluridine</b> (Viroptic)	Keratoconjunctivitis caused by herpes viruses	Topically to eye, 1% ophthalmic solution, 1 drop q2h while awake (maximum 9 drops/d) until re-epithelialization of corneal ulcer occurs; then 1 drop q4h (maximum 5 drops/d) for 7 d	Older than 6 y, same as adults

(continued on page 564)

Table 35-1

## Drugs at a Glance: Drugs for Prevention or Treatment of Selected Viral Infections (continued)

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Valacyclovir</b> (Valtrex)	Herpes labialis, herpes zoster, and recurrent genital herpes in immunocompetent patients	Herpes labialis, PO 2 g twice daily for 1 d Herpes zoster, PO 1 g q8h for 7 d Recurrent genital herpes, PO 500 mg q12h daily for 5 d Reduce dosage with renal impairment	Herpes labialis, adolescents, PO, same as adults Dosage not established for children
<b>Valganciclovir</b> (Valcyte)	Prevention and treatment of CMV retinitis	PO 900 mg twice daily for 21 d	Dosage not established
<b>Influenza Virus Infection</b> <b>Amantadine</b> (Symmetrel)	Prevention or treatment of influenza A infection	PO 200 mg once daily or 100 mg twice daily Reduce dosage with renal impairment	1–10 y and weight less than 40 kg: PO 5 mg/kg/d; maximum dose 150 mg/d 10 y and older and weight 40 kg or over: PO 100 mg twice daily
<b>Oseltamivir</b> (Tamiflu)	Prevention or treatment of influenza A infection	PO 75 mg once daily	13 y and older or weight above 40 kg: PO same as adults 1–12 y: PO twice daily according to weight: 15 kg or less, 30 mg; above 15 kg to 23 kg or less, 45 mg; above 23 kg to 40 kg or less, 60 mg
<b>Rimantadine</b> (Flumadine)	Prevention or treatment of influenza A infection in adults Prophylaxis of influenza A in children	PO 100 mg twice daily	10 y and older: same as adults Under 10 y: 5 mg/kg once daily; maximum dose 150 mg
<b>Zanamivir</b> (Relenza)	Treatment of influenza A or B infection	Oral inhalation, 2 inhalations twice daily for 5 d	7 y and older: same as adults
<b>Respiratory Syncytial Virus Infection</b> <b>Ribavirin</b> (Virazole)	Treatment of hospitalized infants and young children with severe lower respiratory tract infections		Inhalation: diluted to a concentration of 20 mg/mL for 12–18 h/d for 3–7 d
<b>Viral Hepatitis</b> <b>Adefovir</b> (Hepsera)	Treatment of chronic hepatitis B	PO 10 mg once daily	Dosage not established
<b>Entecavir</b> (Baraclude)	Treatment of chronic hepatitis B	PO 0.5 mg once daily for patients beginning treatment; 1 mg daily for those who have developed resistance to lamivudine	Dosage not established
<b>Lamivudine</b> (Epivir HBV)	Treatment of chronic hepatitis B	PO 100 mg once daily	2–17 y: 3 mg/kg once daily; maximum dose, 100 mg
<b>Ribavirin</b> (Virazole)	Treatment of chronic hepatitis C (with peginterferon alfa 2a)	PO 800–1200 mg twice daily	PO 15 mg/kg twice daily
<b>Telbivudine</b> (Tyzeka)	Treatment of chronic hepatitis B	PO 600 mg once daily	16 y and older: same as adults

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; HSV, herpes simplex virus; ICH, immunocompromised host.

Table 35-2

## Drugs at a Glance: Drugs for Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Nucleoside Reverse Transcriptase Inhibitors (NRTIs)</b> <b>Abacavir</b> (Ziagen)	Well absorbed; 50% bound to plasma proteins; metabolized to inactive metabolites that are excreted in urine and feces  <b>BBW:</b> Risks of serious hypersensitivity reactions, lactic acidosis, and hepatomegaly with steatosis	PO 300 mg twice daily	Over 3 mo: PO 8 mg/kg twice daily (maximum 300 mg twice daily)
<b>Emtricitabine</b> (Emtriva)	Well absorbed; metabolized in the liver and excreted mainly in urine  <b>BBW:</b> Risks of lactic acidosis and hepatomegaly with steatosis	PO 200 mg (1 capsule) or 240 mg (24 mL of oral solution) once daily	3 mo to 17 y: Weight above 33 kg and can swallow capsule, PO 1 capsule once daily  Oral solution, PO 6 mg/kg once daily (maximum dose, 240 mg or 24 mL daily)
<b>Lamivudine</b> (EpiVir)	Used to treat HIV infection and chronic hepatitis B Well absorbed; mainly eliminated unchanged in urine Dosage should be reduced with renal impairment.  <b>BBW:</b> Risks of lactic acidosis and hepatomegaly with steatosis	PO 150 mg twice daily Weight 60 kg (110 lbs) or less: PO 2 mg/kg twice daily	12–16 y: PO same as adults 3 mo to 12 y: PO 4 mg/kg twice daily
<b>P Zidovudine</b> (AZT, ZVD, Retrovir)	Prototype NRTI Well absorbed, metabolized in the liver to an inactive metabolite, which is excreted in urine  May cause peripheral neuropathy and pancreatitis  <b>BBW:</b> Risks of severe anemia, neutropenia, lactic acidosis, and hepatomegaly with steatosis	PO 300 mg twice daily	3 mo to 12 y: 180 mg/m <sup>2</sup> q6h (not to exceed 200 mg q6h)  Neonate born of HIV-infected mother who took the drug during pregnancy, labor, and delivery: PO 2 mg/kg q6h starting within 12 h of birth and continuing until 6 wk of age; IV 1.5 mg/kg q6h if unable to take oral drug
<b>Nucleotide Reverse Transcriptase Inhibitor</b> <b>Tenofovir DF</b> (Viread)	Used for salvage therapy after multiple drug failures  Efficacious against hepatitis B  <b>BBW:</b> Risks of lactic acidosis and hepatomegaly with steatosis	300 mg once daily	Dosage not established

(continued on page 566)

Table 35-2

## Drugs at a Glance: Drugs for Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome (continued)

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)</b>			
<b>Efavirenz</b> (Sustiva)	Well absorbed; induces drug-metabolizing enzymes in the liver. May cause central nervous system side effects.	PO 600 mg at bedtime	Weight over 40 kg: PO same as adults Age 3 y and over and weight 10–40 kg (22–88 lb): PO 200–400 mg, depending on weight
<b>Nevirapine</b> (Viramune)	Well absorbed; induces drug-metabolizing enzymes in the liver <b>BBW:</b> Risks of hepatitis, hepatic necrosis, hepatic failure, and severe skin reactions	PO 200 mg once daily for 2 wk, then 200 mg twice daily	2 mo to 8 y: 4 mg/kg once daily for 14 d, then 7 mg/kg twice daily 8 y and older: 4 mg/kg once daily for 14 d, then 4 mg/kg twice daily
<b>Protease Inhibitors</b>			
<b>Atazanavir</b> (Reyataz)	Well absorbed with few adverse effects May cause hyperbilirubinemia	PO 400 mg daily	Dosage not established
<b>Darunavir</b> (Prezista)	Must be taken with ritonavir and food to achieve therapeutic blood levels Highly bound to plasma proteins; metabolized in liver and excreted mainly in feces	PO 600 mg twice daily, with ritonavir 100 mg and food	Dosage not established
<b>Fosamprenavir</b> (Lexiva)	Prodrug formulation of amprenavir that allows for a reduced pill burden. A 700-mg tablet contains the equivalent of 600 mg of amprenavir.	Treatment-naïve: PO 1400 mg twice daily Treatment-experienced: PO 700 mg twice daily (with ritonavir 100 mg twice daily)	Dosage not established
<b>Indinavir</b> (Crixivan)	Well absorbed; metabolized in the liver; excreted mainly in feces May cause GI upset and kidney stones	PO 800 mg q8h	Dosage not established
<b>Nelfinavir</b> (Viracept)	Most common adverse effect is diarrhea, which can be controlled with over-the-counter drugs such as loperamide	PO 1250 mg twice daily	1–13 y: PO 20–30 mg/kg/dose, 3 times daily
<b>Ritonavir</b> (Norvir)	Metabolized in the liver; slows metabolism of many drugs <b>BBW:</b> Risk of serious adverse effects if given with certain other drugs, including antidysrhythmics (amiodarone, flecainide, propafenone, others), sedative-hypnotics (midazolam, triazolam), ergot derivatives, alfuzosin, voriconazole	PO 600 mg twice daily	PO 400 mg/m <sup>2</sup> daily

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Saquinavir</b> (Invirase)	Not well absorbed; highly protein bound; metabolized in liver; excreted mainly in feces May produce fewer drug interactions than indinavir and ritonavir	PO 1200 mg 3 times daily	16 y and older: same as adults
<b>Tipranavir</b> (Aptivus)	Absorption increased with food; highly protein bound; metabolized in the liver mainly by CYP3A4 enzymes	PO 500 mg with ritonavir 200 mg twice daily	Dosage not established
<b>Entry Inhibitors</b>			
<b>Enfuvirtide</b> (Fuzeon)	Highly protein bound Adverse effects include injection site reactions, nausea, and diarrhea.	Sub-Q 90 mg (1 mL) twice daily into upper arm, anterior thigh, or abdomen	6-16 y: Sub-Q 2 mg/kg (maximum, 90 mg) twice daily, into upper arm, anterior thigh, or abdomen
<b>Maraviroc</b> (Selzentry)	Given with other antiretroviral drugs May cause hepatotoxicity	PO 150–600 mg twice daily, depending on other medications being taken	Dosage not established for children under 16 years of age
<b>Combination Products</b>			
<b>Atripla</b>	Tablets contain efavirenz 600 mg, emtricitabine 200 mg and tenofovir 300 mg	PO 1 tablet once daily	Not recommended
<b>Combivir</b>	Tablets contain zidovudine 300 mg and lamivudine 150 mg	PO 1 tablet twice daily	12 y and older: same as adults
<b>Epzicom</b>	Tablets contain abacavir 600 mg and lamivudine 300 mg	PO 1 tablet daily	Dosage not established
<b>Kaletra</b>	Tablets contain lopinavir 200 mg and ritonavir 50 mg Oral solution contains lopinavir 80 mg and ritonavir 20 mg/mL	PO 3 tablets twice daily	Weight 7–15 kg: 12/3 mg/kg twice daily Weight 15–40 kg: 10/2.5 mg/kg twice daily
<b>Trizivir</b>	Tablets contain zidovudine 300 mg, lamivudine 150 mg, and abacavir 300 mg	PO 1 tablet twice daily	Dosage not established
<b>Truvada</b>	Tablets contain emtricitabine 200 mg and tenofovir 300 mg	PO 1 tablet once daily	Dosage not established

BBW, black box warning; GI, gastrointestinal.

## Drugs for Herpesvirus Infections

**Acyclovir**, **famciclovir**, and **valacyclovir** penetrate virus-infected cells, become activated by an enzyme, and inhibit viral DNA reproduction. They are used in the treatment of herpes simplex and herpes zoster infections. Acyclovir is used to treat genital herpes, in which it decreases viral shedding and the duration of skin lesions and pain. It does not eliminate inactive virus in the body and thus does not prevent recurrence of the disease unless oral drug therapy is continued. Acyclovir is also used for treatment of herpes simplex infections in *immunocompromised* patients. Prolonged or repeated courses of acyclovir therapy may result in the emergence of acyclovir-

resistant viral strains, especially in immunocompromised patients. Acyclovir can be given orally, intravenously (IV), or applied topically to lesions. IV use is recommended for severe genital herpes in nonimmunocompromised patients and any herpes infections in immunocompromised patients. Oral and IV acyclovir are excreted mainly in urine, and dosage should be decreased in patients who are older or who have renal impairment.

Famciclovir and valacyclovir are oral drugs for herpes zoster and recurrent genital herpes. Famciclovir is metabolized to penciclovir, its active form, and excreted mainly in the urine. Valacyclovir is metabolized to acyclovir by enzymes in the liver and/or intestine and is eventually excreted in the

urine. As with acyclovir, dosage of these drugs must be reduced in the presence of renal impairment.

**Foscarnet, ganciclovir, and valganciclovir** also inhibit viral reproduction after the drugs are activated by a viral enzyme found in virus-infected cells. The drugs are used to treat cytomegalovirus (CMV) retinitis. In addition, foscarnet is used to treat acyclovir-resistant mucocutaneous herpes simplex infections in people with impaired immune function. Valganciclovir and ganciclovir are used to prevent CMV disease, mainly in patients with organ transplants or HIV infection. Dosage of these drugs must be reduced with renal impairment. Ganciclovir causes granulocytopenia and thrombocytopenia in 20% to 40% of recipients, often during the first 2 weeks of therapy. If severe bone marrow depression occurs, ganciclovir should be discontinued; recovery usually occurs within a week of stopping the drug. Foscarnet should be used cautiously in patients with renal disease.

**Trifluridine** is applied topically to treat keratoconjunctivitis and corneal ulcers caused by the herpes simplex virus (herpetic keratitis). Trifluridine should not be used longer than 21 days because of possible ocular toxicity.

## Drugs for HIV Infection (Antiretrovirals)

*Antiretroviral therapy (ART)* for treatment of HIV infection continues to evolve. In general, newer drugs and drug combinations are more effective in viral suppression, cause fewer serious adverse effects, and are more convenient for patients to take. Some of the older drugs are not recommended for initial treatment but may be used when drug-resistant infections develop with the newer drugs or are transmitted to other people. Testing for drug resistance is more often used; interactions among *antiretroviral drugs* and between antiretrovirals and other drugs continue to be complex.

Five classes of antiretroviral drugs currently exist: nucleoside reverse transcriptase inhibitors (NRTIs), nucleotide reverse transcriptase inhibitor, non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors, and entry inhibitors (see Table 35-2). The first four groups inhibit enzymes required for viral replication in human host cells; the entry inhibitors prevent the HIV from entering cells and causing infection (Fig. 35-1). To increase effectiveness and decrease viral mutations and emergence of drug-resistant viral strains, combinations of drugs are used. Recommendations for drug regimens change often; a good source for keeping up-to-date is [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov).

### Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

The NRTIs are structurally similar to DNA components (adenosine, cytosine, guanosine, or thymidine) and thus easily enter human cells and viruses in human cells. For example, **zidovudine**, the prototype, is able to substitute for thymidine. In infected cells, these drugs inhibit reverse transcriptase, an enzyme required by retroviruses to convert RNA to DNA and allow replication. The drugs are more active in slowing the

**Figure 35-1** ■ Human immunodeficiency virus (HIV) entry into cells and replication; actions of anti-HIV drugs. (1) The virus attaches to receptors (e.g., CD4 molecules) and coreceptors (CCR5 molecules) on the host cell membrane. (2) The virus becomes uncoated and releases its RNA into the host cell. (3) The enzyme reverse transcriptase converts RNA to DNA, which is necessary for viral replication. (4) The DNA codes for protein synthesis, which produces immature viral particles. (5) The enzyme protease assembles the immature viral particles into mature viruses. (6) Mature viruses are released from the host cell.

progression of acute infection than in treating chronically infected cells. Thus, they do not cure HIV infection or prevent transmission of the virus through sexual contact or blood contamination. Didanosine (Videx) and stavudine (Zerit) are infrequently used and are not discussed further in this chapter.

### Nucleotide Reverse Transcriptase Inhibitor

The one drug in this group, **tenofovir** (Viread), is similar to the NRTIs in that it inhibits the reverse transcriptase enzyme. However, it differs structurally, and this difference helps to prevent the development of drug-resistant viral strains.

### Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

The NNRTIs inhibit viral replication in infected cells by directly binding to reverse transcriptase and preventing its function. They are used in combination with NRTIs to treat HIV infection. Because the two types of drugs inhibit reverse transcriptase by different mechanisms, they may have synergistic antiviral effects. **Efavirenz** (Sustiva) is the most commonly used NNRTI, with **nevirapine** (Viramune) as an acceptable

substitute in some circumstances. **Delavirdine** (Rescriptor) is the least effective of these drugs. It is not recommended for initial treatment but may be used to treat drug-resistant HIV strains. It is not discussed further in this chapter.

### Protease Inhibitors (PIs)

The PIs exert their effects against HIV at a different phase of its life cycle than reverse transcriptase inhibitors. Protease is an HIV enzyme required to process viral protein precursors into mature particles that are capable of infecting other cells. The drugs inhibit the enzyme by binding to its protease-active site and cause the production of immature, noninfectious viral particles. These drugs are active in both acutely and chronically infected cells because they block viral maturation.

Two major concerns with PIs are viral resistance and drug interactions. Viral resistance develops fairly rapidly, with resistant strains developing in approximately half of the recipients within a year of drug therapy. Most PIs are metabolized in the liver by the cytochrome P450 enzyme system and should be used cautiously in patients with impaired liver function. In relation to drug interactions, PIs interfere with metabolism, increase plasma concentrations, and increase risks of toxicity of numerous other drugs metabolized by the cytochrome P450 enzymes in the liver.

**Indinavir**, **ritonavir**, and **saquinavir** are the oldest PIs. Ritonavir, the most potent cytochrome P450 inhibitor in the group, interacts with other PIs to increase their blood levels and therapeutic effectiveness. Thus, ritonavir is often given with other PIs (except nelfinavir) as a “booster.” This usage allows fewer pills and less frequent administration but also increases risks of hyperlipidemia and drug interactions.

With other drugs, ritonavir may increase plasma concentrations of amiodarone, bupropion, clozapine, flecainide, meperidine, piroxicam, propafenone, propoxyphene, quinidine, rifabutin, and voriconazole. None of these drugs should be given concomitantly with ritonavir because high plasma concentrations may cause cardiac dysrhythmias, hematologic abnormalities, seizures, and other potentially serious adverse effects. In addition, ritonavir may increase sedation and respiratory depression when used concurrently with benzodiazepines (e.g., alprazolam, diazepam, triazolam) and zolpidem.

Indinavir increases plasma concentrations of several of the same drugs listed previously and should not be given concomitantly with them because of potential cardiac dysrhythmias or prolonged sedation. Saquinavir may produce fewer interactions because it inhibits the cytochrome P450 enzyme system to a lesser extent than indinavir and ritonavir. However, if saquinavir is given with clindamycin, quinidine, triazolam, or a calcium channel blocker, patients should be monitored closely for increased plasma levels and adverse drug effects.

### Entry Inhibitors

HIV entry into human host cells requires two sequential steps, and a drug has been developed to block each step. First, the virus contains a glycoprotein on its surface that allows it to attach itself to CD4 receptors on human cells and fuse with the cell membrane. This initial binding and fusion is blocked by

**enfuvirtide** (Fuzeon), which is also called a fusion inhibitor. Second, the HIV binds to another molecule on the surface of host cell membranes. This molecule, CCR5, is a co-receptor that enhances viral binding and fusion. **Maraviroc** (Selzentry) blocks the binding of the HIV to CCR5 and is also called a CCR5 antagonist.

### Combination Drugs

Early antiretroviral drug regimens were very complex and involved the ingestion of many pills daily. Current regimens are simpler, partly because of newer drugs and partly because of more fixed-dose combinations of commonly used drugs. Combination products decrease the “pill burden” and promote adherence. A high degree of adherence is required to produce therapeutic effects and prevent the development of drug resistance.

## Applying Your Knowledge 35-1

### How Can You Avoid This Medication Error?

Mr. Bronowicz complains of severe pain, so you notify the resident and receive an order for meperidine 50 mg IM for one dose. You prepare and administer the medication

.....

## Drugs for Influenza

**Amantadine** and **rimantadine** inhibit replication of the influenza A virus and are used to prevent or treat influenza A infections. Postexposure prophylaxis with these drugs may protect persons who have had direct contact with people infected with influenza A. Seasonal prophylaxis may be used in high-risk patients if the influenza vaccine cannot be given or may be ineffective. In epidemics, use of one of the drugs is recommended for patients at high risk who have not been vaccinated. The high-risk population includes older adults, those who have chronic lung disease, and those who have immunodeficiency disorders. During an epidemic, amantadine or rimantadine may be given for 2 weeks if the patient is vaccinated at the beginning of drug therapy or 4 to 8 weeks if the patient is unvaccinated. Protection is lost within a few days after drug therapy is stopped. For treatment of influenza A infection, either drug may shorten the illness if started soon after onset and continued for 5 days. The drugs may also decrease viral shedding and spread.

Amantadine and rimantadine are well absorbed after oral administration. Amantadine is excreted in the urine unchanged. It accumulates in the body of older adults and others with impaired renal function, and dosage therefore should be reduced in these groups. Rimantadine is extensively metabolized, with small amounts excreted in the urine. The most common adverse effects of the drugs are gastrointestinal (anorexia, nausea) and central nervous system (CNS: nervousness, lightheadedness, difficulty concentrating) symptoms. CNS effects are more likely to occur with amantadine than rimantadine, and high plasma levels of amantadine have been

associated with delirium, hallucinations, seizures, coma, and cardiac dysrhythmias. Amantadine has also been associated with exacerbations of pre-existing seizure disorders and psychiatric symptoms. Amantadine is teratogenic in animals, and neither drug has been established as safe for pregnant women.

Amantadine is also used in the treatment of Parkinson's disease and for extrapyramidal symptoms associated with the use of certain antipsychotic drugs (see Chap. 12).

**Oseltamivir** (Tamiflu) and **zanamivir** (Relenza) are approved for prevention or treatment of influenza A or B in patients with symptoms for 2 days or less. They may be more effective for prevention than treatment, with some reports indicating that they reduce symptoms by only 1 day and viral shedding by 2 days. When used, therapy should last for 5 days. Oseltamivir is an oral drug; zanamivir is a powder form for oral inhalation with a device called a Diskhaler. Zanamivir may cause bronchospasm in patients with asthma or chronic obstructive pulmonary disease. The drugs also have activity against avian influenza A (H5N1).

## Drug for Respiratory Syncytial Virus Respiratory Tract Infections

**Ribavirin** is used mainly for the treatment of bronchiolitis or pneumonia caused by the respiratory syncytial virus (RSV). It is used in hospitalized infants and young children and given by inhalation with an aerosol device. The drug is not recommended for patients on ventilators because it precipitates and may block breathing tubes, including endotracheal tubes. Deterioration of pulmonary function is a common adverse effect. The drug is absorbed systemically after administration by aerosol. Most infants and children with RSV infections have mild, self-limited disease that does not involve the lower respiratory tract and therefore does not require hospitalization or ribavirin therapy.

## Drugs for Viral Hepatitis Infections

Vaccines are available to prevent hepatitis A and hepatitis B, and the incidence of these infections has decreased with use of the vaccines. Still, viral hepatitis is an important cause of disability and death from liver disease as well as the major reason for liver transplantation. People at high risk of developing hepatitis include men who have sex with men, users of illicit drugs, and international travelers.

For treatment of hepatitis B, several drugs have been developed, including **adefovir**, **entecavir**, **interferon** (see Chap. 40), **lamivudine** (Epivir HBV), and **telbivudine**. Entecavir, lamivudine, and telbivudine are nucleoside analogs, all of which have **BLACK BOX WARNINGS** about increased risks of lactic acidosis and severe enlargement and accumulation of fat in the liver, including fatal cases. Because some patients experience exacerbation of hepatitis B symptoms when drug therapy is stopped, they should be monitored for several months. For treatment of chronic hepatitis C, a combination of ribavirin and peginterferon alfa-2a (see Chap. 40) is effective and may cure the infection.

## Nursing Process

### Assessment

- Assessment varies with the type of viral infection that is present or suspected.
- Assess renal function and adequacy of fluid intake.
- With HIV infection, assess baseline data to assist in monitoring response to drug therapy. Baseline data may include vital signs, weight and nutritional status, signs and symptoms of the disease, signs and symptoms of opportunistic infections associated with the disease and immunosuppression, and available reports of laboratory tests (e.g., complete blood count; CD4+ lymphocyte counts; plasma levels of viral RNA, blood urea nitrogen, and serum creatinine; liver function tests).
- With viral hepatitis, assess for risk factors, possible sources of exposure, and signs and symptoms of liver dysfunction.

### Nursing Diagnoses

- Anxiety related to a medical diagnosis of serious viral infection (e.g., HIV infection, viral hepatitis)
- Altered Sexuality Patterns related to sexually transmitted viral infections (HIV infection, genital herpes)
- Disturbed Body Image related to sexually transmitted infection
- Social Isolation related to a medical diagnosis of HIV infection or genital herpes
- Deficient Knowledge: Disease process and methods of spread; availability of vaccines and other prophylactic interventions
- Risk for Injury: Recurrent infection; adverse drug effects; adverse drug interactions; infections and other problems associated with a compromised immune system in HIV infection; liver damage or failure with viral hepatitis

### Planning/Goals

The patient will

- Receive or take antiviral drugs as prescribed
- Be safeguarded against new or recurrent infection
- Act to prevent spread of viral infection to others and recurrence in self
- Avoid preventable adverse drug effects and drug interactions
- Receive emotional support and counseling to assist in coping with HIV infection or genital herpes

### Interventions

- Follow recommended policies and procedures for preventing spread of viral infections.

- Assist patients in learning ways to control spread and recurrence of viral infections.
- Assist patients to maintain immunizations against viral infections.
- For patients receiving systemic antiviral drugs, monitor serum creatinine and other tests of renal function, complete blood count, and fluid balance.
- For patients with HIV infection, assist to schedule their drug therapy regimen as conveniently as possible (to promote adherence), monitor for changes in baseline data during each contact, prevent opportunistic infections (e.g., herpes infections) when possible, and manage adverse effects of drug therapy to promote quality of life.

### Evaluation

- Observe for improvement in signs and symptoms of the viral infection for which a drug is given.
- Interview outpatients regarding their compliance with instructions for taking antiviral drugs.
- Interview and observe for use of infection control measures.
- Interview and observe for adverse drug effects.
- Observe the extent and severity of any symptoms in patients with HIV infection or viral hepatitis.

### Applying Your Knowledge 35-2

Mr. Bronowicz has been having a hard time with his drug regimen. He has difficulty with the proper timing of his medications. He also has complained about an upset stomach. What patient education should you provide to Mr. Bronowicz?

.....

## Principles of Therapy

### Prevention of Viral Infections

General preventive measures include vaccination, hand hygiene, teaching patients with respiratory infections to cover their mouth and nose when coughing or sneezing, treatment of symptoms, and recognition and treatment of complications.

With sexually transmitted viral infections, spread of genital herpes can be prevented by avoiding sex when skin lesions are present and using condoms. HIV infection can be prevented by the consistent use of condoms and use of clean needles by IV drug users. In addition, anti-HIV medications can be given to prevent HIV infection after occupational (e.g., contaminated needle-stick injuries of health care personnel) or nonoccupational (e.g., sexual, drug use, accidental) exposure. For the latter group, those with high-risk exposure to an HIV-infected person should seek treatment within 72 hours. Drug therapy should be started as soon as possible and continued for 4 weeks. With human papilloma virus (HPV) infections, consistent use of condoms can prevent HPV infection. Although lesions may develop outside the area covered by a condom, such lesions are not considered a common or major source of infection spread. With hepatitis, prevention strategies include rigorous hand hygiene, avoiding contaminated water and food, avoiding contact with blood and body fluids, and avoiding injections, tattooing, or body piercing with contaminated needles.

### Viral Vaccines

Viral vaccines are used to produce active immunity in patients before exposure or to control epidemics of viral disease in a community. Vaccines for prevention of cervical cancer, chickenpox, hepatitis A and B, herpes zoster, measles, mumps, poliomyelitis, rubella, smallpox, and yellow fever and for protection against influenza A, B, and avian influenza A (H5N1) and rabies are available (see Chap. 39). Live attenuated viral vaccines are generally safe and nontoxic. However, they should not be used in patients who are pregnant; immunodeficient; receiving high-dose, long-term corticosteroids; or receiving

## Patient Teaching Guidelines

### General Considerations

- Prevention is better than treatment, partly because medications used to treat viral infections may cause serious adverse effects. Thus, whenever possible, techniques to prevent viral infections should be employed.
  - Wash hands frequently and thoroughly; this helps prevent most infections.
  - Maintain immunizations against viral infections as indicated.
  - With genital herpes, avoid sexual intercourse when visible lesions are present and always wash hands after touching any lesion.
- Drugs may relieve symptoms but do not cure viral infections. For example, treatment of genital herpes does not

## Miscellaneous Antiviral Drugs

prevent transmission to others, and treatment of cytomegalovirus (CMV) retinitis may not prevent disease progression.

- Ask a health care provider for information about managing adverse drug effects.
- If taking foscarnet or ganciclovir for CMV retinitis, have eye examinations approximately every 6 weeks.

### Self-Administration

- With acyclovir, famciclovir, and valacyclovir for genital herpes, start oral drugs for recurrent lesions as soon as signs and symptoms begin.
- Use gloves to apply acyclovir ointment to lesions.

## Patient Teaching Guidelines Antiretroviral Drugs

### General Considerations

- Prevention is better than treatment, partly because medications used to treat viral infections may cause serious adverse effects. Thus, whenever possible, techniques to prevent viral infections should be used.
  - Wash hands frequently and thoroughly; this helps prevent most infections.
  - Maintain immunizations against viral infections as indicated.
  - Always practice safer sex by using a condom.
  - In cases of intravenous drug use, use and promote the use of clean needles.
- Drugs may relieve symptoms but do not cure human immunodeficiency virus (HIV) infection, prevent transmission of the virus, or prevent other illnesses associated with advanced HIV infection.
- Effective treatment of HIV infection requires close adherence to drug therapy regimens involving several drugs and daily doses. Missing as few as one or two doses can decrease blood levels of antiretroviral drugs and result in increased HIV replication and development of drug-resistant viral strains.
- It is generally recommended that herbal products not be used with antiretroviral medications. St. John's wort may decrease blood levels of some anti-HIV medications and make them less effective; echinacea should be avoided because it may stimulate viral replication.
- Request information about adverse effects associated with the specific drugs you are taking and what you should do if they occur. Adverse effects vary among the drugs; some are potentially serious.
- Have regular blood tests including viral load, CD4+ cell count, complete blood count, and others as indicated (e.g., tests of kidney and liver function).

- Keep your health care providers informed about all medications being taken; do not take any other drugs (including drugs of abuse, herbal preparations, vitamin/mineral supplements, nonprescription drugs) without consulting a health care provider. These preparations may make anti-HIV medications less effective or more toxic.

### Self-Administration

- Take the medications exactly as prescribed. Do not change doses or stop the medications without consulting a health care provider. If a dose is missed, do not double the next dose. The drugs must be taken consistently to suppress HIV infection and minimize adverse drug effects.
- These medications vary in their interactions with food and should be taken appropriately for optimal benefit. Unless otherwise instructed, take the drugs as follows:
  - Abacavir, Combivir, emtricitabine, famciclovir, fosamprenavir, Kaletra tablets, lamivudine, nevirapine, tenofovir, Trizivir, valacyclovir and zidovudine may be taken with or without food. However, do not take abacavir or efavirenz with a high-fat meal.
  - Take Atripla, efavirenz, entecavir, or indinavir on an empty stomach, 1 hour before or 2 hours after a meal.
  - Take atazanavir, darunavir, ganciclovir, Kaletra oral solution, nelfinavir, ritonavir, and tipranavir with food.
  - Take saquinavir within 2 hours after a meal.
- To give nelfinavir to infants and young children, the oral powder can be mixed with a small amount of water, milk, or formula. After it is mixed, the entire amount must be taken to obtain the full dose. Acidic foods or juices (e.g., applesauce, orange juice, apple juice) should not be used because they produce a bitter taste.

antineoplastic or immunosuppressive drugs or radiation. Vaccines for influenza A and influenza B prevent infection in most patients. If infection does occur, less virus is shed in respiratory secretions. Thus, vaccination reduces transmission of influenza by decreasing the number of susceptible people and by decreasing transmission by immunized people who still become infected. The multiplicity of rhinoviruses (common cold), enteroviruses, and respiratory viruses hinders development of vaccines for these common diseases.

### Use of Antibacterial Drugs in Viral Infections

Antibacterial drugs (e.g., antibiotics) should not be used to treat viral infections. They do have a role, however, in treating bacterial complications of viral infections. For example, bacterial pneumonia may develop as a complication of influenza.

### Use of Antiretroviral Drugs in HIV Infection

- The goals of drug therapy include reducing HIV-related morbidity and mortality, decreasing viral load to unde-

etectable levels (<400 copies/mL) as long as possible, halting disease progression, restoring immune function, and improving quality of life.

- Treatment of HIV infection is complex, and recommendations change often as new drugs, new drug regimens, and research reports become available. Thus, when possible, clinicians with expertise in the care of HIV-infected patients should prescribe, supervise, and monitor drug therapy. Before starting drug therapy, clinicians should consult current treatment guidelines and individualize the regimen according to health status (e.g., impaired liver function, psychiatric illness, tuberculosis), dosing convenience (e.g., number of pills daily and frequency of administration), presence or absence of drug-resistant viral strains, potential adverse drug effects and drug interactions, the patient's likelihood of adhering to the drug therapy regimen, and other factors. Updated treatment guidelines are readily available via the Internet at [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov) and should be consulted regularly by health care personnel involved in treatment of patients with HIV infection.

- Benefits and risks of drug therapy must be clear to patients initiating drug therapy. A high degree of adherence to the prescribed regimen is required for viral suppression; nonadherence may lead to a lack of effectiveness and emergence of drug-resistant viral strains. Factors contributing to nonadherence include active substance abuse, depression, and lack of social support. The patient must also be able to tolerate or manage adverse drug effects.
- Evidence-based drug therapy for adults and adolescents is described in Evidence-Based Practice Box 35-1. Additional considerations include the following:
  - Combination antiretroviral therapy is the standard of care. A commonly used three-drug regimen includes two NRTIs and a protease inhibitor. Other options include two NRTIs and one NNRTI (most commonly efavirenz) or three NRTIs.
  - Potentially serious drug interactions, especially between protease inhibitors and other agents, are extensive and may require drug substitution or dose reduction to avoid toxicity.
  - Patients should be assessed for signs and symptoms of adverse drug effects approximately every 3 months during therapy.
  - Effective drug therapy usually produces significantly reduced plasma HIV RNA levels by 2 months and undetectable levels by 4 to 6 months. In addition, the CD4+ cell count usually increases faster during the first 3 months, then at an average of 100 to 150 cells/mm<sup>3</sup> per year. Failure to obtain an undetectable viral load may result from nonadherence to the medication regimen, inadequate drugs or doses, drug-resistant viral strains, and other factors.
  - Laboratory tests are used to determine when to initiate drug therapy and to assess adherence and response to therapy. *Viral load* is a measure of the number of HIV RNA particles within the blood; it does not measure viral levels in tissues, where viral reproduction may be continuing. In untreated clients, measurement is recommended at the time of diagnosis, then every 3 to 4 months. In treated patients, HIV RNA levels should be assessed before and 2 to 8 weeks after starting drug therapy, then every 3 to 4 months.
 

CD4+ cell counts are also assessed and used to monitor drug therapy. CD4+ cell counts should be measured at the time of diagnosis and every 3 to 6 months thereafter. Complete blood counts, electrolyte levels, fasting blood glucose and lipids, and tests of renal and hepatic function are also recommended.
  - Drug therapy should be continuous when at all possible. Studies indicate that interruptions in treatment allow viral growth and disease progression. In addition, patients receiving drug therapy for advanced HIV infection should continue medications during an opportunistic infection or malignancy, unless there are significant drug intolerances, toxicities, or interactions.

## Evidence-Based Practice

### 35-1 Drug Therapy for HIV Infection in Adults and Adolescents

#### Treatment-Naïve Patients

- Initial antiretroviral drug therapy is recommended for all symptomatic patients and for asymptomatic patients with a CD4+ T-cell count below 350/mL, **before** the count falls to 200 cells/mL (Level of evidence A).
- A combination of three antiretroviral drugs is recommended for initial treatment of a previously untreated patient. Several combinations, often called highly active antiretroviral therapy (HAART), are possible. As of October 2006, the preferred regimen (Level of evidence A for all drugs) was
  - Efavirenz plus one of the following combinations:
    - Atazanavir + ritonavir
    - Fosamprenavir + ritonavir twice daily
    - Lopinavir/ritonavir twice daily
    - Tenofovir/emtricitabine
    - Zidovudine/lamivudine
- An alternative regimen (Level of evidence B for all drugs) consists of nevirapine rather than efavirenz, plus one of the following single drugs or combinations:
  - Atazanavir
  - Fosamprenavir
  - Fosamprenavir + ritonavir once daily
  - Lopinavir/ritonavir once daily
  - Abacavir/lamivudine
  - Didanosine + lamivudine
- Other options may be acceptable for individual patients, including nelfinavir, ritonavir-boosted saquinavir, and a combination of abacavir, zidovudine, and lamivudine.

#### Treatment-Experienced Patients

Treatment-experienced patients are those who have developed retroviral strains that are resistant to the drugs used earlier. Tests of drug susceptibility and design of a new drug therapy regimen with at least two active antiretroviral drugs is recommended (Level of evidence A). If two fully active drugs cannot be identified, clinicians may choose one of the following regimens (Level of evidence B):

- Add ritonavir to other protease inhibitors (except nelfinavir).
- Add a drug with activity against drug-resistant virus (e.g., a ritonavir-boosted protease inhibitor) and a drug with a new mechanism of action (e.g., HIV entry inhibitors such as enfuvirtide) to the current antiretroviral regimen. (Note: Tipranavir and darunavir are newer protease inhibitors approved for patients who are highly treatment-experienced or have HIV-1 strains resistant to multiple protease inhibitors.)

Treatment for adult HIV infection: 2006 Recommendations of the International AIDS Society—USA panel. *Journal of the American Medical Association*, 296, 827–843.

### Applying Your Knowledge 35-3

During the course of therapy for Mr. Bronowicz, periodic laboratory tests will be done to monitor the effectiveness of drug therapy. What cell count is assessed and how often should it be monitored?

## Use in Special Populations

### Use in Children

The use of systemic antiviral drugs is more problematic in children because several of the available drugs have not been tested in this group, are not available in pediatric formulations, and/or do not have pediatric dosages.

Amantadine may be given to prevent or treat influenza A in children 1 year of age or older, and rimantadine is given only for prevention in children. Oseltamivir may be used in children 1 year and older. However, some serious adverse effects have been reported in children 16 years and younger who were taking oseltamivir. The adverse effects include neurologic and psychiatric problems (e.g., delirium, hallucinations, confusion, abnormal behavior, seizures, encephalitis) and a few severe skin reactions. Zanamivir may be used in children 7 years and older.

Clinicians using anti-HIV drugs in children need to be experienced and up-to-date regarding recommendations. Some HIV infections in children result from perinatal transmission and HIV testing of pregnant women should be a part of routine perinatal care. HIV-seropositive females should receive zidovudine to prevent perinatal transmission. At 14 to 34 weeks of gestation, zidovudine should be administered at a dose of 100 milligrams PO five times a day until delivery. At delivery, a loading dose of 2 milligrams per kilogram of body weight should be given, followed by 1 milligram per kilogram every hour until birth. The infant is then given zidovudine 2 milligrams per kilogram every 6 hours for the first 6 weeks of life. If perinatal infection occurs, the infant usually develops symptoms (e.g., an opportunistic infection, failure to thrive) within the first 3 to 8 months of life. Zidovudine, which is approved for treatment of HIV infection in children, is usually the drug of choice. As in adults, anemia and neutropenia are common adverse effects of zidovudine.

In addition to zidovudine, several other drugs can be used in children, including abacavir, emtricitabine, enfuvirtide, efavirenz, lamivudine, nelfinavir, nevirapine, ritonavir, and the combination products Combivir, Kaletra, and Trizivir. Current drug literature should be consulted for age and weight ranges for individual drugs.

For older children and adolescents with HIV infection, additional factors need to be considered. A few are long-term survivors of perinatal HIV infection and their clinical course may differ from those infected later in life. However, many

become infected during their teen years. The Centers for Disease Control and Prevention (CDC) estimate that half of the 40,000 new cases diagnosed each year occur in people 13 to 24 years of age.

In general, adult guidelines for anti-HIV drug therapy are appropriate for adolescents because those infected sexually or by injecting drugs follow a clinical course similar to that of adults. However, pediatric doses of antiretroviral drugs should be used for those in early puberty, and adult doses should usually be given for those in late puberty. Persuading adolescents to adhere to the drug therapy regimen may be especially difficult as they may not see the need for medications when they are asymptomatic, may experience adverse drug effects, want to fit in with their peer groups rather than being different, or have other barriers. Clinicians need to make the drug regimen as user friendly as possible and to use all available resources to promote adherence.

All adolescents with HIV infection, who are often sexually active, need information about prevention of HIV transmission. Female adolescents need additional information about contraception and drug interactions between anti-HIV medications and birth control pills.

### Use in Older Adults

Antiviral drug selection and dosing should proceed cautiously with older adults, who often have impaired organ function, concomitant diseases, and other drug therapy. Most systemic antiviral drugs are excreted by the kidneys and renal impairment is common in older adults. Therefore, greater risks of toxicity exist. These risks may be minimized by dose reduction when indicated by decreased creatinine clearance. When amantadine is given to prevent or treat influenza A, dosage should be reduced with renal impairment, and older adults should be closely monitored for CNS (e.g., hallucinations, depression, confusion) and cardiovascular (e.g., congestive heart failure, orthostatic hypotension) effects.

HIV infection is increasing in those over 50 years of age, and there is little information about the effects of anti-HIV medications in older adults. As potent antiretroviral therapy extends the lifespan of HIV-infected patients, clinicians can expect to encounter greater numbers of older adults who take these medications. As a general rule, renal impairment may necessitate adjustment of NRTI and NNRTI doses, and hepatic impairment may affect dosing of protease inhibitors.

### Use in Patients With Renal Impairment

Antiviral drugs should be used cautiously in patients with impaired renal function because some are nephrotoxic, most are eliminated by the kidneys, and many require dosage reductions because their elimination may be decreased. All patients with renal impairment should be monitored closely for abnormal renal function tests and drug-related toxicity. Renal effects and guidelines for usage of selected drugs are described in the following sections.

### Nephrotoxic Drugs

- Acyclovir may precipitate in renal tubules and cause renal impairment with high doses of oral drug or IV administration (e.g., to treat acute herpes zoster). This is most likely to occur in patients who are dehydrated and may be minimized by maintaining a high urine output. Although patients on hemodialysis usually need reduced doses, an additional dose is needed after dialysis because treatment removes up to 51% of serum acyclovir.
- Foscarnet may cause or worsen renal impairment and should be used with caution in all patients. Manifestations of renal impairment are most likely to occur during the second week of induction therapy but may occur any time during treatment. Renal impairment may be minimized by monitoring renal function (e.g., at baseline; 2 or 3 times weekly during induction; at least every 1 or 2 weeks during maintenance therapy) and reducing dosage accordingly. The drug should be stopped if creatinine clearance drops below 0.4 milliliters per minute per kilogram. Adequate hydration should also be maintained throughout the course of drug therapy.
- Indinavir may cause nephrolithiasis, flank pain, and hematuria. Symptoms usually subside with increased hydration and drug discontinuation. To avoid nephrolithiasis, patients on indinavir should consume 48 to 64 ounces of water or other fluid daily.

### Drugs That Require Dosage Reduction

- Amantadine, emtricitabine, entecavir, famciclovir, ganciclovir, lamivudine, telbivudine, and valacyclovir are eliminated mainly through the kidneys. In patients with renal impairment, they may accumulate, produce higher blood levels, have longer half-lives, and cause toxicity. For all of these drugs except famciclovir and emtricitabine, dosage should be reduced with creatinine clearance (CrCl) levels below 50 milliliters per minute. With famciclovir, dosage should be decreased with CrCl below 60 milliliters per minute. For patients receiving hemodialysis, dosages should be calculated according to CrCl, with daily doses given after dialysis. With emtricitabine, dosage is reduced by extending the dosage interval. Prescribers should consult manufacturers' recommendations.
- Zidovudine dosage should be decreased in cases of severe renal impairment. Zidovudine is mainly metabolized in the liver to an inactive metabolite that is then eliminated renally (approximately 60%–75% of a dose); another 20% is excreted as unchanged drug in the urine. Thus, mild to moderate renal impairment does not lead to drug accumulation or a need for reduced dosage. With severe impairment, however, drug half-life is prolonged. Also, patients with renal impairment may be more likely to experience zidovudine-induced hematologic adverse effects because of decreased production of erythropoietin. Because of these

factors, it is recommended that the daily dosage be reduced by approximately 50% in patients with severe renal impairment ( $\text{CrCl} < 25 \text{ mL/minute}$ ) and patients on hemodialysis.

### Use in Patients With Hepatic Impairment

The antiviral drugs of most concern in hepatic impairment are the anti-HIV agents, especially the protease inhibitors. Although most antiretroviral drugs have not been studied in patients with hepatic impairment, several are primarily metabolized in the liver and may produce high blood levels and cause adverse effects in the presence of liver dysfunction. In addition, patients with HIV infection may have concomitant liver disease that further impairs hepatic metabolism and elimination of the drugs. Although few guidelines are available, dosages should be individualized according to the severity of hepatic impairment and HIV infection, other drug therapies (for HIV infection, opportunistic infections, or other conditions), additional risk factors for drug toxicity, and the potential for drug interactions. In addition, all patients with hepatic impairment should be monitored closely for abnormal liver function tests (LFTs) and drug-related toxicity. Hepatic effects and considerations for usage of selected drugs are as follows:

- Atazanavir, fosamprenavir, nelfinavir, nevirapine, ritonavir, saquinavir, and tenofovir may need dosage reductions in patients with impaired hepatic function.
- Nevirapine may cause abnormal LFTs, and a few cases of fatal hepatitis have been reported. If moderate or severe LFT abnormalities occur, nevirapine administration should be discontinued until LFTs return to baseline. If liver dysfunction recurs when the drug is resumed, nevirapine should be discontinued permanently.
- Zidovudine is eliminated slowly and has a longer half-life in patients with moderate to severe liver disease. Thus, daily doses should be reduced by 50% in patients with hepatic impairment.

### Use in Home Care

Most antiviral drugs are self-administered or dosed by caregivers in the home. Precautions to prevent viral infections from occurring or spreading are important because of the close contact among members of a household. The home care nurse may need to teach infection-control precautions and to assess the immunization status of all household members. If immunizations are indicated, the nurse may need to teach about, encourage, provide, or facilitate their administration.

Home care of patients with HIV infection may include teaching patients and caregivers about the disease and its treatment, assisting with drug therapy for HIV or opportunistic infections, coordinating medical and social services, managing symptoms of infection or adverse drug effects, and preventing or minimizing opportunistic infections.

## Nursing Actions Antiviral Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give oral drugs as recommended in relation to meals:
  - (1) Give abacavir, Combivir, emtricitabine, famciclovir, fosamprenavir, Kaletra tablets, lamivudine, nevirapine, tenofovir, Trizivir, valacyclovir, and zidovudine with or without food. However, do not give abacavir with a high-fat meal. Avoid antacids in combination with atazanavir.
  - (2) Give Atripla, efavirenz, entecavir, or indinavir on an empty stomach, 1 hour before or 2 hours after a meal.
  - (3) Give atazanavir, darunavir, ganciclovir, Kaletra oral solution, nelfinavir, ritonavir, and tipranavir with food.
  - (4) Give saquinavir within 2 hours after a meal.
- b. To give nelfinavir to infants and young children, the oral powder can be mixed with a small amount of water, milk, or formula. After it is mixed, the entire amount must be taken to obtain the full dose.
- c. Give intravenous (IV) acyclovir, foscarnet, ganciclovir, and zidovudine over 1 hour.
- d. Give enfuvirtide Sub-Q in upper arm, anterior thigh or abdomen; apply ice or heat and massage the site after the injection.
- e. When applying topical acyclovir, wear a glove.

#### 2. Observe for therapeutic effects

- a. With acyclovir for genital herpes, observe for fewer recurrences when given for prophylaxis; observe for healing of lesions and decreased pain and itching when given for treatment.
- b. With amantadine, observe for absence of symptoms when given for prophylaxis of influenza A, and decreased fever, cough, muscle aches, and malaise when given for treatment.
- c. With ganciclovir or foscarnet for cytomegalovirus retinitis, observe for improved vision.
- d. With antiretroviral drugs, observe for improved clinical status and improved laboratory markers (e.g., decreased viral load, increased CD4+ cell count).

#### 3. Observe for adverse effects

- a. General effects—*anorexia, nausea, vomiting, diarrhea, fever, headache*
- b. With IV acyclovir—*phlebitis at injection site; skin rash; urticaria; increased blood urea nitrogen or serum creatinine; encephalopathy manifested by confusion, coma, lethargy, seizures, tremors*
- c. With topical acyclovir—*burning or stinging and pruritus*
- d. With amantadine and rimantadine—*central nervous system (CNS) effects with anxiety, ataxia, dizziness, hyperexcitability, insomnia, mental confusion, hallucinations, slurred speech*
- e. With ganciclovir and foscarnet—*bone marrow depression, renal impairment, neuropathy*
- f. With protease inhibitor antiretroviral drugs—*gastrointestinal distress, increased serum cholesterol and triglycerides*
- g. With NRTI antiretroviral drugs—*hypersensitivity skin rash, peripheral neuropathy. Additional effects with zidovudine—severe anemia and neutropenia, pancreatitis*

### RATIONALE/EXPLANATION

Manufacturers' recommendations to promote absorption and bioavailability

Acidic foods or juices (e.g., orange juice, apple juice, applesauce) should not be used because they produce a bitter taste.

To decrease tissue irritation and increased toxicity from high plasma levels

See the manufacturer's instructions for reconstituting the drug powder.

To decrease local tissue irritation

These effects occur with most systemic antiviral drugs and may range from mild to severe.

Encephalopathy is rare but potentially serious; other effects commonly occur.

These effects are usually transient.

CNS symptoms are more likely with amantadine and may be similar to those caused by atropine and CNS stimulants.

Adverse reactions are more likely to occur in older adults and those with renal impairment.

The most frequent adverse effects are the general ones listed above. Most are relatively mild. The dyslipidemia may increase risks of heart attack or stroke.

Anemia may occur within 2–4 weeks of starting zidovudine, neutropenia after 6–8 weeks. A complete blood count should be performed every 2 weeks. Filgrastim or sargramostim may be given to aid recovery of bone marrow function; blood transfusions may be given for anemia.

NURSING ACTIONS	RATIONALE/EXPLANATION
h. With enfuvirtide—injection site pain, hypersensitivity reactions	Hematologic effects may occur in newborn infants when the mothers received zidovudine during pregnancy. Injection site discomfort can be minimized by applying ice or heat and massaging the site after injection.
<b>4. Observe for drug interactions</b>	Antiviral drugs are given concurrently with many other drugs, especially in treatment of HIV infection, and significant interactions may occur.
a. Drugs that <i>increase</i> effects of amantadine and rimantadine: (1) Anticholinergics—atropine, first-generation antihistamines, antipsychotics, tricyclic antidepressants  (2) CNS stimulants	These drugs add to the anticholinergic effects (e.g., blurred vision, mouth dryness, urine retention, constipation, tachycardia) of the antiviral agents. These drugs add to the CNS-stimulating effects (e.g., confusion, insomnia, nervousness, hyperexcitability) of the antiviral agents.
b. Drugs that <i>increase</i> effects of ganciclovir: (1) Imipenem-cilastatin (2) Nephrotoxic drugs (e.g., amphotericin B, cyclosporine)	Increased risk of seizures; avoid the combination if possible. Increased serum creatinine and potential nephrotoxicity
c. Drugs that <i>increase</i> effects of protease inhibitors:	In addition to the interactions listed here as occurring with PIs as a group, individual drugs may have additional interactions.
(1) Azole antifungals (fluconazole, itraconazole) (2) Clarithromycin (3) Other antiretrovirals	May decrease blood levels of PIs Accelerate metabolism of PIs by inducing drug-metabolizing enzymes in the liver
d. Drugs that <i>decrease</i> effects of protease inhibitors: (1) Anticonvulsants (carbamazepine, phenytoin) (2) Rifamycins (rifampin, rifabutin)	Decreases elimination of lamivudine
(3) Other antiretrovirals	Increased bone marrow depression (anemia, neutropenia) May increase blood levels Increased neutropenia May increase blood levels
e. Drug that <i>increases</i> the effects of lamivudine: (1) Trimethoprim-sulfamethoxazole	May decrease blood levels Accelerate metabolism of zidovudine and decrease blood levels
f. Drugs that <i>increase</i> effects of zidovudine:	Accelerate metabolism and decrease blood levels
(1) Doxorubicin, vincristine, vinblastine (2) Fluconazole (3) Ganciclovir (4) Phenytoin, valproic acid	
g. Drugs that <i>decrease</i> effects of zidovudine:	
(1) Acetaminophen (2) Rifampin, rifabutin	
h. Drugs that <i>decrease</i> effects of nevirapine and efavirenz:	
(1) Rifamycins	

## Key Concepts

- Viral infections commonly occur in all age groups.
- Vaccinations, avoiding contact with people who have viral infections, and thorough hand hygiene are effective ways to prevent viral infections.
- Viral infections for which drug therapy is available include genital herpes, hepatitis B and C, HIV infection, and influenza.
- Because viruses are intracellular parasites, antiviral drugs are relatively toxic to human cells.
- Antiretroviral drugs are given in combination to increase effectiveness and decrease emergence of drug-resistant viruses.

## Review and Application Exercises

### Short Answer Exercises

1. What are the predominant effects of antiviral drugs on susceptible viruses?
2. Which viral infections may be prevented by administration of antiviral drugs?
3. What are the major adverse effects associated with commonly used antiviral drugs? How would you assess for each of these adverse effects?
4. Why is it important to monitor renal function in any patient receiving a systemic antiviral drug?
5. What is the advantage of combination drug therapy for HIV infection?
6. List nursing interventions to prevent or minimize adverse effects of anti-HIV drugs.

### NCLEX-Style Questions

7. The nurse is admitting a patient transferred from a nursing home who has just been diagnosed with influenza type A. The nurse anticipates an immediate order for
  - a. ganciclovir (Cytovene)
  - b. amantadine (Symmetrel)
  - c. nevirapine (Viramune)
  - d. ritonavir (Norvir)
8. When counseling a patient with a first outbreak of genital herpes who has been prescribed 10 days of acyclovir (Zovirax), you tell her that this medication is being used to
  - a. decrease fever
  - b. decrease pain
  - c. prevention of recurrence
  - d. reduce number of lesions in recurrences
9. In caring for a pregnant woman who is HIV positive, which of the following drugs would you anticipate administering to prevent transmission of HIV to the fetus?
  - a. zidovudine (AZT)
  - b. adefovir (Hepsera)
  - c. Fosamprenavir (Lexiva)
  - d. ribavirin (Virazole)
10. A 21-year-old man is being started on a combination of antiretroviral drugs for treatment of AIDS. Which of the following statements indicates that he understands the nurse's accurate patient teaching?
  - a. "The medicines inactivate the virus and prevent recurrence of the disease."
  - b. "The medicines do not promote the development of drug-resistant viral strains."
  - c. "The medicines slow the progression of the disease but do not cure it."
  - d. "The medicines prevent the occurrence of opportunistic infections."
11. The nurse is preparing to administer enfuvirtide (Fuzeon) to a patient. He wants to know how it works. The nurse explains that it exerts its anti-HIV viral effects by
  - a. inhibiting reverse transcriptase enzymes
  - b. inhibiting protease enzymes
  - c. having direct toxic effects on the virus in the bloodstream
  - d. preventing the virus from attaching to human cells

# Antifungal Drugs

## KEY TERMS

- Candidiasis
- Dermatophytes
- Fungi
- Immunocompromised
- Molds
- Mycoses
- Yeasts

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe characteristics of fungi and fungal infections.
2. Discuss antibacterial drug therapy and immunosuppression as risk factors for development of fungal infections.
3. Describe commonly used antifungal drugs in terms of indications for use, adverse effects, and nursing process implications.
4. Differentiate between adverse effects associated with systemic and topical antifungal drugs.
5. Teach patients about prevention and treatment of fungal infections.

## Applying Your Knowledge

Charlotte Angelo, age 21, is on antibiotic therapy for a urinary tract infection. During the course of her therapy, she develops vaginal discharge and is diagnosed with a *Candida albicans* vaginal infection. The primary care provider prescribes fluconazole (Diflucan) 150 mg PO, one dose.

## Introduction

### Fungi

*Fungi* are *molds* and *yeasts* that are widely dispersed in the environment and are either saprophytic (i.e., obtain food from dead organic matter) or parasitic (i.e., obtain nourishment from living organisms). Molds are multicellular organisms composed of colonies of tangled strands. They form a fuzzy coating on various surfaces (e.g., the mold that forms on spoiled food, the mildew that forms in damp environments). Yeasts are unicellular organisms. Some fungi, called *dermatophytes*, can grow only at the cooler temperatures of body surfaces. Other fungi, called dimorphic, can grow as molds outside the body and as yeasts in the warm temperatures of the body. As molds, these fungi produce spores that can persist indefinitely in the environment and can be carried by the wind to distant locations. When these mold spores enter the body, most often by inhalation, they rapidly become yeasts that can invade body tissues. Dimorphic fungi include a number of human pathogens such as those that cause blastomycosis, histoplasmosis, and coccidioidomycosis.

Fungi that are pathogenic in humans exist in soil, decaying plants, and other environmental habitats or as part of the endogenous human flora. For example, *Candida albicans* organisms are part of the normal microbial flora of the skin, mouth, gastrointestinal (GI) tract, and vagina. Growth of *Candida* organisms is normally restrained by intact immune mechanisms and bacterial competition for nutrients. When these restraining forces are altered (e.g., by suppression of the immune system, antibacterial drug therapy), fungal overgrowth and opportunistic infection can occur. In addition, some fungi have characteristics that enhance their ability to cause disease. *Cryptococcus neoformans*

organisms, for example, can become encapsulated, which allows them to evade the normal immune defense mechanism of phagocytosis. *Aspergillus* organisms produce protease, an enzyme that allows them to destroy structural proteins and penetrate body tissues.

Structurally, fungi are larger and more complex than bacteria. They have a thick, rigid cell wall, of which glucan is one of the components. Glucan is formed by the fungal enzyme, glucan synthetase. Fungi also have a cell membrane composed mainly of ergosterol, a lipid that is similar to cholesterol in human cell membranes. Within the cell membrane, structures are mostly the same as those in human cells (e.g., a nucleus, mitochondria, Golgi apparatus, ribosomes attached to endoplasmic reticulum, a cytoskeleton with microtubules and filaments).

### Fungal Infections (Mycoses)

Fungal infections may be mild and superficial or life-threatening and systemic. Dermatophytes cause superficial infections of the skin, hair, and nails. They obtain nourishment from keratin, a protein in skin, hair, and nails. Dermatophytic infections include tinea pedis (athlete's foot) and tinea capitis (ringworm of the scalp) (see Chap. 64).

Systemic or invasive mycoses include the endemic mycoses that can cause disease (e.g., blastomycosis, coccidioidomycosis, histoplasmosis, sporotrichosis) in healthy hosts

who are exposed to them in the environment and the opportunistic mycoses (e.g., aspergillosis, candidiasis, cryptococcosis) that cause serious infection mainly in immunosuppressed hosts. The fungi that cause endemic mycoses exist as molds in the environment; they grow in soil and decaying organic matter. Infection is acquired by inhalation of airborne spores from contaminated soil. Histoplasmosis, coccidioidomycosis, and blastomycosis usually occur as pulmonary disease but may be systemic. These infections often mimic common bacterial infections, and their severity is determined both by the extent of the exposure to the organism and by the immune status of the host. The fungi that cause opportunistic mycoses may be part of the normal body flora (e.g., *Candida* species) or exist in the environment (*Aspergillus*, *Cryptococcus*). Infection occurs after inhalation or inoculation of the fungus into body tissues.

Most fungal infections occur in healthy people but are more severe and invasive in *immunocompromised* hosts. Serious infections are increasing in incidence, largely because of human immunodeficiency virus (HIV) infections, the use of immunosuppressant drugs to treat patients with cancer or organ transplants, the use of indwelling intravenous catheters for prolonged drug therapy or parenteral nutrition, implantation of prosthetic devices, and widespread use of broad-spectrum antibacterial drugs. Characteristics of selected fungal infections are described in Box 36-1.

#### Box 36-1

#### Selected Fungal Infections

**Aspergillosis** occurs in debilitated and immunocompromised people, including those with leukemia, lymphoma, or acquired immunodeficiency syndrome (AIDS), and those with neutropenia. Invasive aspergillosis is a serious illness characterized by inflammatory granulomatous lesions, which may develop in the bronchi, lungs, ear canal, skin, or mucous membranes of the eye, nose, or urethra. It may extend into blood vessels, which leads to infection of the brain, heart, kidneys, and other organs. It is associated with thrombosis, ischemic infarction of involved tissues, and progressive disease. It is often fatal.

Allergic bronchopulmonary aspergillosis, an allergic reaction to inhaled aspergillus spores, may develop in people with asthma and cause bronchoconstriction, wheezing, dyspnea, cough, muscle aches, and fever. The condition is aggravated if the spores germinate and grow in the airways, thereby producing chronic exposure to the antigen and permanent fibrotic damage.

*Aspergillus* mold is widespread in the environment; spores are released into the air during soil excavations (e.g., for construction of buildings) or handling of decaying plant matter and are carried into most human environments. Spores have been found in water (e.g., hot water faucets, saunas, shower heads, swimming pools), public buildings and private homes (e.g., basements, bedding, humidifiers, ventilation ducts, potted plants, house dust), and foods (e.g., peppers and spices, pasta, peanuts, cashews, coffee beans). In hospitals, sources

of infection include contaminated air from building renovations and new construction; hospital water, which may become aerosolized during activities such as patient showering; and cereals, powdered milk, tea, and soy sauce ingested by neutropenic patients. As *Aspergillus* molds grow, they produce toxins (e.g., aflatoxin, one of the strongest carcinogens known) that contaminate the food chain.

There are several species that cause invasive disease in humans, but *Aspergillus fumigatus* is the most common. *A. fumigatus* reproduces by releasing spores, which are small enough to reach the alveoli when inhaled. Most aspergillus organisms enter the body through the respiratory system, and pulmonary aspergillosis is acquired by inhalation of the spores. Other potential entry sites include damaged skin (e.g., burn wounds, intravenous catheter insertion sites), operative wounds, the cornea, and the ear.

**Blastomycosis** occurs with inhalation of spores from a fungus that grows in soil and decaying organic matter. The organism is widespread in the United States. Sporadic cases most often occur in adult males who have extensive exposure to woods and streams with vocational or recreational activities. The infection may be asymptomatic or produce pulmonary symptoms resembling pneumonia, tuberculosis, or lung cancer. It may also be systemic and involve other organs, especially the skin and bone. Skin lesions (e.g., pustules, ulcerations, abscesses) may progress over a period of years and

eventually involve large areas of the body. Bone invasion, with arthritis and bone destruction, occurs in 25% to 50% of patients.

Blastomycosis can occur in healthy people with sufficient exposure but is more severe and more likely to involve multiple organs and central nervous system (CNS) disease in immunocompromised patients.

**Candidiasis** occurs in patients with malignant lymphomas, diabetes mellitus, or AIDS and in patients receiving antibiotic, antineoplastic, corticosteroid, and immunosuppressant drug therapy. *Candida* organisms are found in soil, on inanimate objects, in hospital environments, and in food. In the human body, they are found on skin and in the gastrointestinal (GI) and genitourinary tracts, including the urine of patients with indwelling bladder catheters. Historically, most infections arose from the normal endogenous organisms of the GI tract and were caused by *Candida albicans*. In recent years, however, the incidence of infections caused by other candidal strains has greatly increased. Oral, intestinal, vaginal, and systemic candidiasis can occur. Early recognition and treatment of local infections may prevent systemic candidiasis.

- Oral candidiasis (thrush) produces painless white plaques on oral and pharyngeal mucosa. It often occurs in newborn infants who become infected during passage through an infected or colonized vagina. In older children and adults, thrush may occur as a complication of diabetes mellitus, as a result of poor oral hygiene, or after taking antibiotics or corticosteroids. It may also occur as an early manifestation of AIDS.
- GI candidiasis often occurs after broad-spectrum antibacterial therapy, which destroys a large part of the normal flora of the intestine. The main symptom is diarrhea.
- Vaginal candidiasis occurs in women who are pregnant, have diabetes mellitus, or take oral contraceptives or antibacterial drugs. The main symptom is a yellowish vaginal discharge. The infection may produce inflammation of the perineal area and spread to the buttocks and thighs.
- Skin candidiasis occurs in people with continuously moist skinfolds or moist surgical dressings. The organism also may cause diaper rash and perineal rashes. Skin lesions are red and macerated.
- Systemic or invasive candidiasis occurs when the organism gets into the bloodstream and is circulated throughout the body, with the brain, heart, kidneys, and eyes as the most common sites of infection. It occurs as a nosocomial infection in patients with serious illness or who are undergoing drug therapy that suppresses the immune system and may be fatal. Invasive infections may be present in any organ and may produce such disorders as urinary tract infection, endocarditis, and meningitis. It may be diagnosed by positive cultures of blood or tissue. Signs and symptoms depend on the severity of the infection and the organs affected and are indistinguishable from those occurring with bacterial infections.

The incidence of severe candidal infections has increased in recent years, in part because of increased numbers of neutropenic and immunodeficient patients. In addition, the frequent use of broad-spectrum antibiotics leads to extensive candidal colonization in debilitated patients, and the wide-

spread use of medical devices (e.g., intravascular catheters, monitoring equipment, endotracheal tubes, urinary catheters) allows the organisms to reach sites that are normally sterile. People who use IV drugs also develop invasive candidiasis because the injections inoculate the fungi directly into the bloodstream.

**Coccidioidomycosis** is caused by an organism that grows as a mold in soil and decaying organic matter and is commonly found in the southwestern United States and northern Mexico. Infection results from inhalation of spores that convert to yeasts in the warm environment of the body and often cause asymptomatic or mild respiratory infection. However, the organism may cause acute pulmonary infection with fever, chest pain, cough, headache, and loss of appetite. Radiographs may show small nodules in the lung like those seen in tuberculosis. In some cases, chronic disease develops in which the organisms remain localized and cause large, organism-filled cavities in the lung. These cavities may become fibrotic and require surgical excision. In a few cases, severe, disseminated disease occurs, either soon after the primary infection or after years of chronic pulmonary disease. Disseminated coccidioidomycosis may produce acute or chronic meningitis or a generalized disease with lesions in many internal organs. Skin lesions appear as granulomas that may eventually heal or become ulcerations. Most patients with primary infection recover without treatment; patients with disseminated disease require long-term treatment.

Coccidioidomycosis may occur in healthy or immunocompromised people but is more severe and more likely to become systemic in immunocompromised patients. For example, patients with AIDS who live in endemic areas are highly susceptible to this infection. The severity of the disease also increases with intensity of exposure.

**Cryptococcosis** is caused by inhalation of spores of *Cryptococcus neoformans*, an organism found worldwide, especially in bird droppings. The spores have also been found in fruits, vegetables, and dairy products.

When cryptococcosis occurs in healthy people, the primary infection is localized in the lungs, is asymptomatic or produces mild symptoms, and heals without treatment. However, pneumonia may occur and lead to spread of the organisms by the bloodstream. When cryptococcosis occurs in immunocompromised people, it is likely to be more severe and to become disseminated to the CNS, skin, and other organs. People with AIDS are highly susceptible, and cryptococcosis is a frequent opportunistic infection in this population. Infection most often affects the lungs and CNS. Cryptococcal pneumonia in patients with AIDS has a high mortality rate. Cryptococcal meningitis, the most common manifestation of disseminated disease, often produces abscesses in the brain. Clinical manifestations include headache, dizziness, and neck stiffness, and the condition is often mistaken for brain tumor. Later symptoms include coma, respiratory failure, and death if the meningitis is not treated effectively.

**Histoplasmosis** is a common infection that occurs worldwide, especially in the central and mideastern United States. The causative fungus is found in soil and organic debris around chicken houses, bird roosts, and caves inhabited by bats. Exposure to spores may result from activities such as demolishing or

## Box 36-1

## Selected Fungal Infections (continued)

remodeling old buildings or cleaning chicken coops. Spores can be picked up by the wind and spread over large areas. Histoplasmosis develops when the spores are inhaled into the lungs, where they rapidly develop into the tissue-invasive yeast cells that reach the bloodstream and become distributed throughout the body. In most cases, the organisms are destroyed or encapsulated by the host's immune system. The lung lesions heal by fibrosis and calcification and resemble the lesions of tuberculosis. Some people develop histoplasmosis years after the primary infection, probably from reactivation of a latent infection.

Clinical manifestations may vary widely. In people with a normal immune response, manifestations can be correlated with the extent of exposure. Most infections are asymptomatic or produce minimal symptoms for which treatment is not sought. When symptoms occur, they usually resemble an acute, influenza-like respiratory infection and improve within a few weeks. However, people exposed to large amounts of spores may have a high fever and severe pneumonia, which usually resolves with a low mortality rate. Some people, most often adult men with emphysema or other lung diseases, develop chronic pulmonary histoplasmosis with recurrent episodes of cough, fever, and weakness. In addition, histoplasmosis occasionally infects the liver, spleen, and other organs and is rapidly fatal if not treated effectively. The severe, disseminated form usually occurs in patients whose immune system is suppressed by diseases or drugs.

**Pneumocystosis** is caused by *Pneumocystis jirovecii*, an organism formerly considered a protozoan but now identified

as a fungus. The organism is widespread in the environment, and most people are exposed at an early age. Infections are mild or asymptomatic in immunocompetent people. However, the organism can form cysts in the lungs, persist for long periods, and become activated in immunocompromised hosts. Activation produces an acute, life-threatening pneumonia (PCP) characterized by cough, fever, dyspnea, and presence of the organism in sputum. Groups at risk include human immunodeficiency virus (HIV) seropositive persons, those receiving corticosteroids or antineoplastics and other immunosuppressive drugs, and caregivers of infected people.

**Sporotrichosis** occurs when contaminated soil or plant material is inoculated into the skin through small wounds (e.g., thorn pricks) on the fingers, hands, or arms. It is most likely to occur among people who handle sphagnum moss, roses, or baled hay. Thus, infection is a hazard for gardeners and greenhouse workers. It can occur in both healthy and immunocompromised people but is more severe and disseminated in immunocompromised hosts.

Initial lesions, which are usually small, painless bumps resembling insect bites, occur 1 week to 6 months after inoculation. The subcutaneous nodule develops into a necrotic ulcer, which heals slowly as new ulcers appear in adjacent areas. Local lymphatic channels and lymph nodes also develop abscesses, nodules, and ulcers that may persist for years if the disease is not treated effectively. In immunocompromised people, sporotrichosis may spread to various tissues, including the meninges.

## Antifungal Drugs

Development of drugs that are effective against fungal cells without being excessively toxic to human cells has been limited because fungal cells are similar to human cells. Most of the available drugs target the fungal cell membrane and produce potentially serious toxicities and drug interactions. In general, antifungal drugs disrupt the structure and function of fungal cell components (Fig. 36-1).

Polyenes (e.g., amphotericin B), azoles (e.g., fluconazole), and terbinafine act on ergosterol to disrupt fungal cell membranes. Amphotericin B (and nystatin) binds to ergosterol and forms holes in the membrane, causing leakage of fungal cell contents and lysis of the cell. The azole drugs bind to an enzyme that is required for synthesis of ergosterol. This action causes production of a defective cell membrane, which also allows leakage of intracellular contents and destruction of the cell. Both types of drugs also affect cholesterol in human cell membranes, a characteristic considered mainly responsible for the drugs' adverse effects.

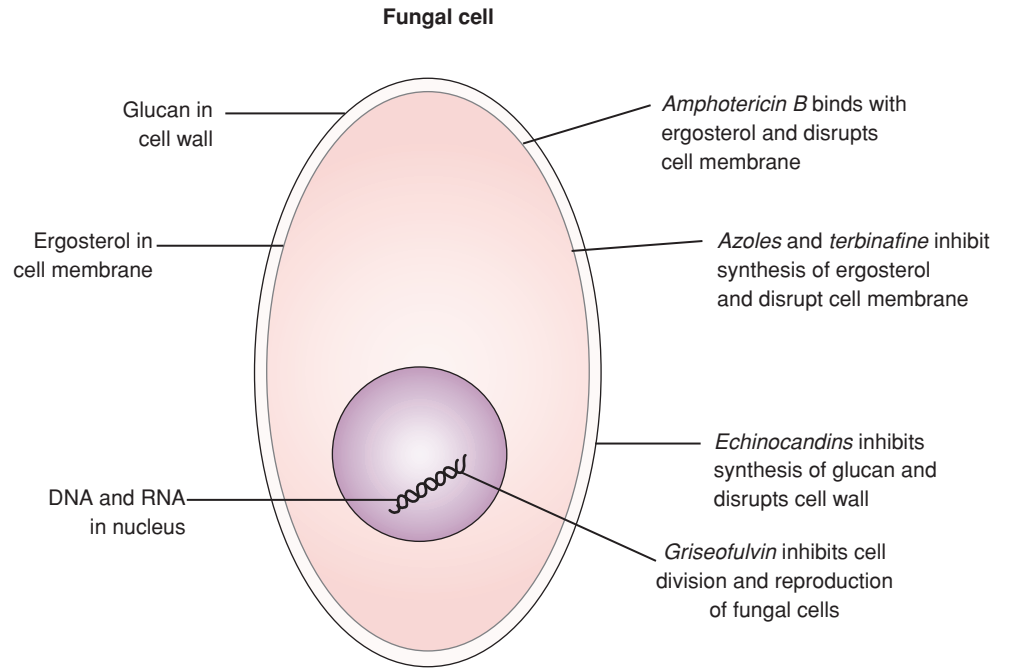

Echinocandins (e.g., caspofungin) disrupt fungal cell walls rather than fungal cell membranes. They inhibit glucan

synthetase, an enzyme required for synthesis of glucan. Glucan is a component of the fungal cell wall; its depletion leads to leakage of cellular contents and cell death. Because human cells do not contain cell walls, these drugs are less toxic than the polyene and azole antifungals.

Drugs for superficial fungal infections of skin and mucous membranes are often applied topically. Numerous preparations are available, many without a prescription. Drugs for systemic infections are given IV or orally. Patients with HIV infection or severe neutropenia due to treatment with cytotoxic cancer drugs require aggressive treatment of fungal infections, because they are at high risk for developing life-threatening systemic mycoses. Selected antifungal drugs are further described in the following sections. In addition, indications for use and dosage ranges are listed in Table 36-1.

### Polyenes

**Amphotericin B** is active against most types of pathogenic fungi and is fungicidal or fungistatic, depending on the concentration in body fluids and the susceptibility of the causative fungus. Because of its toxicity, the drug is used only for serious fungal infections. It is usually given for 4 to 12 weeks.

**Figure 36-1** ■ Actions of anti-fungal drugs on fungal cells.

**Table 36-1**

**Drugs at a Glance: Selected Antifungal Drugs**

Generic/Trade Name	Indications For Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Amphotericin B deoxycholate</b> (Fungizone)	Serious, systemic fungal infections (e.g., candidiasis, histoplasmosis) Cutaneous candidiasis Oral candidiasis	IV, individualized according to disease severity and patient tolerance. Initial dose often 0.25 mg/kg/d, gradually increased to 0.5–1 mg/kg/d, infused over 2–6 h Topically to skin lesions, 2–4 times daily for 1–4 wk Oral suspension (100 mg/mL), 1 mL “swish and swallow” 4 times daily	Same as for adults for IV, skin preparations, and oral suspension
<b>Amphotericin B lipid complex</b> (Abelcet)	Systemic infections in patients who do not tolerate Fungizone	IV 5 mg/kg/d	Same as adults
<b>Liposomal amphotericin B</b> (AmBisome)	Systemic infections in patients who do not tolerate Fungizone Empiric treatment of presumed fungal infections in febrile, neutropenic patients	IV 3–5 mg/kg/d	Same as adults

(continued on page 586)

Table 36-1

## Drugs at a Glance: Selected Antifungal Drugs (continued)

Generic/Trade Name	Indications For Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Amphotericin B cholesteryl</b> (Amphotec)	Systemic infections in patients who do not tolerate Fungizone	IV 3–4 mg/kg/d	Same as adults
<b>Anidulafungin</b> (Eraxis)	Treatment of candidemia, esophageal candidiasis, and other <i>Candida</i> infections	Candidemia IV infusion 200 mg initially, then 100 mg daily Esophageal candidiasis IV infusion 100 mg initially, then 50 mg daily	Dosage not established
<b>Butoconazole</b> (Femstat, Gynazole)	Vaginal candidiasis	Intravaginally, once daily for 3 d	
<b>Caspofungin</b> (Cancidas)	Invasive aspergillosis Candidiasis	IV infusion over 1 h, 70 mg initially, then 50 mg daily Hepatic impairment, 70 mg initially, then 35 mg daily	Safety and efficacy not established
<b>Ciclopirox</b> (Loprox, Penlac Nail Lacquer)	Tinea infections, cutaneous candidiasis, onychomycosis of fingernails and toenails	Tinea and candidal infections topically to skin lesions twice daily for 2–4 wk Onychomycosis topically once daily to affected nails	Safety not established for (1) cream or suspension under 10 years of age (2) Penlac for any age child (3) gel or shampoo under 16 years of age
<b>Clotrimazole</b> (Lotrimin, Mycelex, Gyne-Lotrimin)	Cutaneous dermatophytosis; oral, cutaneous, and vaginal candidiasis	Orally, 1 troche dissolved in mouth 5 times daily Topically to skin daily for 2–4 wk Intravaginally, once daily for 3–7 d	Same as adults
<b>Econazole</b> (Spectazole)	Tinea infections, cutaneous candidiasis	Topically to skin lesions, once or twice daily for 2–4 wk	Dosage not established
<b>Fluconazole</b> (Diflucan)	Oropharyngeal, esophageal, vaginal, and systemic candidiasis Prevention of candidiasis after bone marrow transplantation Cryptococcal meningitis	Oropharyngeal candidiasis, PO, IV 200 mg first day, then 100 mg daily for 2 wk Esophageal candidiasis, PO, IV, 200 mg first day, then 100 mg daily for at least 3 wk Vaginal candidiasis, PO 150 mg as a single dose Systemic candidiasis, PO, IV 400 mg first day, then 200 mg daily for at least 4 wk Prophylaxis, PO, IV 400 mg once daily Cryptococcal meningitis, PO, IV, 400 mg first day, then 200–400 mg/d for 10–12 wk	Oropharyngeal candidiasis, PO, IV 6 mg/kg first day, then 3 mg/kg/d for at least 2 wk Esophageal candidiasis, PO, IV, 6 mg/kg first day, then 3 mg/kg/d for at least 3 wk Systemic candidiasis, PO, IV 6–12 mg/kg/d Cryptococcal meningitis, PO, IV 12 mg/kg first day, then 6 mg/kg/d for 10–12 wk
<b>Griseofulvin</b>	Dermatophytosis (skin, hair, nails)	PO 250–500 mg daily	PO 5–10 mg/kg/d

Generic/Trade Name	Indications For Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Itraconazole (Sporanox)</b>	Systemic fungal infections, including aspergillosis, in neutropenic and immunocompromised hosts Onychomycosis Tinea infections	Systemic infection, PO 200 mg once or twice daily for 3 mo Blastomycosis, histoplasmosis, aspergillosis, IV 200 mg twice daily for 4 doses, then 200 mg/d Onychomycosis, Fingernail, PO 200 mg twice daily for 1 wk, no drug for 3 wk, then repeat dosage for 1 wk; toenail, PO 200 mg once daily for 12 consecutive wk Oral solution, 100–200 mg daily (10–20 mL), swish and swallow 3 times daily for 3–5 d Tinea infections, PO 100–200 mg daily for 1–4 wk	Safety and efficacy not established. 3–16-y-old patients have been treated with 100 mg daily for systemic infections and patients 6 mo–12 y have been treated with 5 mg/kg once daily for 2 wk without serious or unusual adverse effects.
<b>Ketoconazole (Nizoral)</b>	Candidiasis, histoplasmosis, coccidioidomycosis Cutaneous candidiasis Tinea infections	PO 200 mg once daily, increased to 400 mg once daily if necessary in severe infections Topically, once daily for 2–6 wk	2 y and older: PO 3.3–6.6 mg/kg/d as a single dose
<b>Micafungin (Mycamine)</b>	Treatment of esophageal candidiasis Prevention of <i>Candida</i> infections in patients undergoing hematopoietic stem cell transplantation (HSCT)	Treatment : IV infusion 150 mg daily Prevention: IV infusion 50 mg daily	Dosage not established
<b>Miconazole (Monistat)</b>	Dermatophytosis, cutaneous and vulvovaginal candidiasis	Topically, twice daily for 2–4 wk Intravaginally, vaginal cream, once daily at bedtime for 3–7 d; vaginal suppository, once daily at bedtime (1 d for 1200 mg; 3 d for 200 mg; 7 d for 100 mg)	
<b>Naftifine (Naftin)</b>	Tinea infections (athlete's foot, jock itch, ringworm)	Topically, once daily (cream) or twice daily (gel)	Safety and efficacy not established
<b>Natamycin (Natacyn)</b>	Fungal infections of the eye	Topically, 1 drop q1–2h for 3–4 d, then 1 drop 6–8 times daily for 14–24 d	Safety and efficacy not established
<b>Nystatin (Mycostatin)</b>	Candidiasis of skin, mucous membrane, and intestinal tract	Oral or intestinal infection, PO tablets 1–2 (500,000–1,000,000 units) 3 times daily; oral suspension, 4–6 mL (400,000–600,000 units) 4 times daily; oral troches 1–2 (200,000–400,000 units) 4–5 times daily Topically to skin lesions, 2–3 times daily Intravaginally, 1 vaginal tablet once daily for 14 d	Older than 1 y: PO oral suspension, same as adults; infants, 2 mL (200,000 units) 4 times daily Oral troches, same as adults for children old enough to suck on the lozenge until it dissolves

(continued on page 588)

Table 36-1

## Drugs at a Glance: Selected Antifungal Drugs (continued)

Generic/Trade Name	Indications For Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Oxiconazole</b> (Oxistat)	Tinea infections	Topically to skin lesions, once or twice daily for 2–4 wk	Safety and efficacy not established
<b>Posaconazole</b> (Noxafil)	Treatment of oropharyngeal candidiasis Prevention of invasive fungal infection	Prevention: PO 200 mg 3 times daily Oropharyngeal candidiasis PO 100 mg twice daily initially, then 200 mg once daily for 13 days	Dosage not established
<b>Sulconazole</b> (Exelderm)	Tinea infections	Topically to skin lesions, once or twice daily for 3–4 wk	Safety and efficacy not established for children younger than 12 y
<b>Terbinafine</b> (Lamisil)	Tinea infections Onychomycosis of fingernails or toenails	Tinea infections, topically to skin, once or twice daily for at least 1 wk and no longer than 4 wk Fingernail infections, PO 250 mg daily for 6 wk Toenail infections, PO 250 mg daily for 12 wk	
<b>Terconazole</b> (Terazol)	Vaginal candidiasis	Intravaginally, 1 applicator once daily at bedtime for 7 doses (0.4% cream) or 3 doses (0.8% cream) Vaginal suppository, 1 daily at bedtime for 3 d	
<b>Tioconazole</b> (Vagistat)	Vaginal candidiasis	Intravaginally, 1 applicator at bedtime	
<b>Tolnaftate</b> (Tinactin)	Cutaneous mycoses (dermatophytosis)	Topically to skin lesions, twice daily for 2–6 wk	
<b>Triacetin</b> (Fungoid)	Dermatophytosis (e.g., athlete's foot), cutaneous candidiasis	Topically to skin lesions, 3 times daily	
<b>Voriconazole</b> (Vfend)	Esophageal candidiasis Invasive aspergillosis Other serious fungal infections	Esophageal candidiasis, PO 200 mg q12h for weight of $\geq 40$ kg; 100 mg q12h for weight $< 40$ kg. Give at least 14 d or 7 d after symptoms resolve. Aspergillosis and other serious infections, IV 6 mg/kg q12h for 2 doses (loading dose), then 4 mg/kg q12h (maintenance dose)	Safety and efficacy not established for children younger than 12 y
<b>Zinc undecylenate</b> (Desenex)	Dermatophytosis	Topically to skin twice daily for 2–4 wk	Same as for adults

Lipid formulations (Abelcet, AmBisome, Amphotec) reach higher concentrations in diseased tissues than in normal tissues, so that larger doses can be given to increase therapeutic effects. At the same time, they cause less damage to normal tissues and decrease adverse effects. These products are much more expensive than the deoxycholate formulation (Fungizone). They are most likely to be used for patients with pre-existing renal impairment or conditions in which other nephrotoxic drugs are routinely given (e.g., bone marrow transplant recipients) and when high doses are needed for difficult-to-treat infections. The lipid preparations differ in their characteristics and cannot be used interchangeably.

Amphotericin B must be given IV for systemic infections. After infusion, the drug is rapidly taken up by the liver and other organs. It is then slowly released back into the bloodstream. Despite its long-term use, little is known about its distribution and metabolic pathways. Drug concentrations in most body fluids are higher in the presence of inflammation; concentrations in cerebrospinal fluid (CSF) are low with or without inflammation. The drug has an initial serum half-life of 24 hours, which represents redistribution from the bloodstream to tissues. This is followed by a second elimination phase, with a half-life of 15 days, which represents elimination from tissue storage sites. Most of the drug is thought to be metabolized in the tissues; some is excreted in the urine and can be detected for several weeks.

Adverse effects include an infusion reaction (e.g., fever, chills, tachypnea). Nephrotoxicity is the most common and the most serious long-term adverse effect. The drug constricts afferent renal arterioles and reduces blood flow to the kidneys. Several strategies may decrease nephrotoxicity, such as keeping the patient well hydrated, giving 0.9% sodium chloride IV before drug administration, and avoiding the concomitant administration of other nephrotoxic drugs (e.g., aminoglycoside antibiotics). Hypokalemia and hypomagnesemia also occur and may require oral or IV mineral replacement. Additional adverse effects include anorexia, nausea, vomiting, anemia, and phlebitis at peripheral infusion sites. A central vein is preferred for administration.

**Nystatin** has the same mechanism of action as amphotericin B. However, it is used only for topical therapy of oral, intestinal, and vaginal candidiasis because it is too toxic for systemic use. Although given orally for oral or intestinal infections, the drug is not absorbed systemically and is excreted in the feces. With oral use, adverse effects include nausea, vomiting, and diarrhea; with vaginal application, adverse effects include local irritation and burning.

## Azoles

The azoles are the largest group of commonly used antifungal agents. Many are used topically and some are available without a prescription for dermatologic (see Chap. 64) or vaginal use (e.g., butoconazole, clotrimazole, miconazole, terconazole, tioconazole). The main drugs discussed in this chapter are used systemically or both topically and systemically.

Systemic azoles include ketoconazole, fluconazole, itraconazole, posaconazole, and voriconazole. Compared with ketoconazole, the first azole, the other drugs have a broader spectrum of antifungal activity, better absorption with oral administration, better drug distribution in body tissues, fewer adverse effects, and fewer drug interactions. The most common adverse effects are nausea, diarrhea, and skin rash. In addition, all azoles may cause hepatotoxicity (e.g., hepatitis). Patients with impaired liver function or chronic use must be monitored closely. Azoles are contraindicated during pregnancy. The drugs also interact with cytochrome P450 enzymes to produce significant interactions with many other drugs (in which they usually decrease the metabolism and increase the risks of toxicity with affected drugs).

### Applying Your Knowledge 36-1

What assessment should be made before Charlotte takes fluconazole (Diflucan)?

**Ketoconazole** (Nizoral) has largely been replaced by the newer drugs. It may still be used for long-term therapy, because it is less expensive than other azoles. It may also be used with cyclosporine and tacrolimus because it increases blood levels of these immunosuppressant drugs and allows smaller dosages in patients with organ transplants.

**Fluconazole** (Diflucan) is often the drug of choice for localized candidal infections (e.g., urinary tract infections, thrush) and is useful for systemic candidiasis. However, resistant strains of *Candida* organisms occur with extensive use of fluconazole. In vaginal candidiasis, a single oral dose of 150 milligrams is usually effective. Fluconazole is also used for long-term suppression of cryptococcal meningitis in patients with acquired immunodeficiency syndrome (AIDS), after initial use of amphotericin B.

Fluconazole can be given orally or IV. Oral drug is well absorbed, and the drug reaches therapeutic levels in most body fluids and tissues, including meninges. With a one-time loading dose of twice the usual daily dose, steady-state blood levels are reached in about 2 days; without a loading dose, 5 to 10 days are required. Once-daily dosing may be effective in some patients with normal renal function. Most of the drug is excreted as unchanged drug in urine; dosage may need to be reduced in patients with impaired renal function.

Fluconazole is usually well tolerated but may cause nausea, vomiting, diarrhea, abdominal pain, headache, and skin rash. In addition, elevation of liver enzymes and hepatic necrosis have been reported, and alopecia often occurs in patients receiving prolonged, high-dose treatment. Fluconazole increases the effects of several drugs, including cyclosporine, phenytoin, oral sulfonylureas, and warfarin, but has fewer interactions than ketoconazole and itraconazole.

**Itraconazole** (Sporanox) is a drug of choice for many fungal infections. It can be given orally or IV. Drug absorption

may be decreased in patients with achlorhydria and in those receiving a concurrent antacid, histamine H<sub>2</sub> antagonist, or proton pump inhibitor. Serum levels should be measured to ensure adequate absorption. Drug concentrations are higher in visceral organs than in serum; little drug appears in urine or CSF.

Usual doses may cause GI upset and higher doses may cause hypokalemia, hypertension, edema, and heart failure. Itraconazole has many drug interactions. Drugs that increase the pH of gastric acid (e.g., antacids, histamine H<sub>2</sub> blockers, proton pump inhibitors) decrease absorption of itraconazole and should be given at least 2 hours after itraconazole. Drugs that induce drug-metabolizing enzymes (e.g., carbamazepine, phenytoin, rifampin) decrease serum levels of itraconazole. Itraconazole increases serum levels of cyclosporine, digoxin, oral sulfonyleureas, and warfarin; it decreases serum levels of carbamazepine, phenytoin, and rifampin. There is a **BLACK BOX WARNING** about the risks of heart failure and drug interactions.

**Posaconazole** (Noxafil) is a second-generation azole with activity against *Candida* and *Aspergillus* species. It is available as an oral suspension; after administration, it reaches maximum concentration in the body in 3 to 5 hours and steady state in 7 to 10 days. It is highly protein bound and eliminated mainly in feces. Patients with severe vomiting and diarrhea or renal impairment should be monitored for breakthrough fungal infections. If given with drugs metabolized by the CYP3A4 enzymes in the liver, posaconazole increases blood levels and risks of adverse effects with the other drugs.

**Voriconazole** (Vfend) is a second-generation azole with activity against species of *Candida* and *Aspergillus*. It is well absorbed with oral administration and reaches peak serum levels in less than 2 hours. It is widely distributed in body tissues and metabolized in the liver by cytochrome P450 enzymes 2C9, 2C19, and 3A4. The metabolites are excreted renally. Transient visual disturbance is a common adverse effect, occurring in approximately 30% of recipients. Significant drug interactions include reduced voriconazole levels with enzyme inducers (e.g., rifampin, rifabutin, carbamazepine) and increased sirolimus levels with voriconazole administration, possibly to toxic levels. These drugs are contraindicated during voriconazole therapy and concomitant cyclosporine, tacrolimus, or warfarin administration requires vigilant monitoring. Dosage of voriconazole should be reduced with impaired liver function.

### Applying Your Knowledge 36-2

The dose of Diflucan is not effective, and Charlotte returns to the office 2 weeks later with an active *C. albicans* infection. The primary care provider prescribes Diflucan 200 mg PO for one dose, then 100 mg PO daily for 14 days. What adverse effects should you monitor for in the patient taking Diflucan?

## Echinocandins

The echinocandins have fungicidal activity against *Candida*, including azole-resistant organisms, and fungistatic activity against *Aspergillus*.

**Anidulafungin** (Eraxis) is used for *Candida* infections. It is moderately protein bound, has an elimination half-life of about 24 hours, and is excreted mainly in feces. It should be used cautiously with hepatic impairment. Adverse effects include a possible histamine-related reaction with dyspnea, flushing, hypotension, itching, and urticaria. This reaction is less likely to occur if the recommended infusion rate is not exceeded.

**Caspofungin** (Cancidas) is used for systemic *Candida* and *Aspergillus* infections. It is highly bound to plasma albumin, metabolized slowly, and excreted in feces and urine. It is usually well tolerated with doses of 50 milligrams per day. Adverse effects include fever, headache, nausea, skin rash, vomiting, and phlebitis at injection sites. Dosage must be reduced with moderate hepatic impairment; no dosage reduction is needed for renal impairment.

Cyclosporine increases the effects of caspofungin, including potential liver damage, and concomitant use is not recommended. Drugs that decrease effects include anti-HIV drugs (e.g., efavirenz, nelfinavir, nevirapine), anticonvulsants (e.g., carbamazepine, phenytoin), dexamethasone, and rifampin. Concurrent administration may significantly reduce caspofungin blood levels and therapeutic effectiveness unless dosage is increased (e.g., from the usual 50 mg to 70 mg daily).

**Micafungin** (Mycamine) is used to prevent or treat *Candida* infections. It is highly protein bound, metabolized in the liver, has an elimination half-life of 11 to 21 hours, and is excreted mainly in feces. It should be used cautiously with hepatic impairment. Adverse effects include liver and renal function changes and a possible histamine-related reaction with rash, itching, facial swelling, and vasodilation. Micafungin may increase blood levels and risks of toxicity of nifedipine and sirolimus.

## Miscellaneous Antifungal Drugs

**Griseofulvin** is occasionally used for dermatophyte infections of the scalp and nails. Tinea infections of skin (e.g., ringworm) improve in 3 to 8 weeks; onychomycosis of toenails may require a year or more. Common adverse effects include GI upset (e.g., nausea, vomiting, diarrhea), fatigue, headache, insomnia, and skin rash. Hepatotoxicity may also occur.

**Terbinafine** (Lamisil) is a broad-spectrum antifungal that inhibits an enzyme needed for synthesis of ergosterol, a structural component of fungal cell membranes. It has fungicidal activity against dermatophytes and has been used mainly for topical treatment of ringworm infections and oral treatment of onychomycosis. Therapeutic effects may not be evident until months after drug therapy is stopped, because of the time required for growth of healthy nail. The drug is metabolized to inactive metabolites and excreted in the urine.

Common adverse effects with oral terbinafine include headache, diarrhea, and abdominal discomfort; skin reactions

and liver failure may also occur with long-term use for onychomycosis. Hepatotoxicity is uncommon but has occurred in people with and without pre-existing liver disease and has led to liver transplant or death. The drug is not recommended for patients with chronic or active liver disease, and serum ALT and AST should be checked before starting the drug. There is a **BLACK BOX WARNING** regarding the risk of hepatotoxicity.

## Nursing Process

### Assessment

Assess for fungal infections. Specific signs and symptoms vary with location and type of infection as well as the immune state of the patient.

- Superficial lesions of skin, hair, and nails are usually characterized by pain, burning, and itching. Some lesions are moist; others are dry and scaling. They also may appear inflamed or discolored.
- Candidiasis occurs in warm, moist areas of the body. Skin lesions are likely to occur in perineal and intertriginous areas. They are usually moist, inflamed, pruritic areas with papules, vesicles, and pustules. Oral lesions are white patches that adhere to the buccal mucosa. Vaginal infection causes a cheesy vaginal discharge, burning, and itching. Intestinal infection causes diarrhea. Systemic infection causes chills and fever, myalgia, arthralgia, and prostration.
- Blastomycosis, coccidioidomycosis, and histoplasmosis may be asymptomatic or mimic influenza, pneumonia, or tuberculosis, with cough, fever, malaise, and other pulmonary manifestations. Severe histoplasmosis may also cause fever, anemia, enlarged spleen and liver, leukopenia, and GI tract ulcers.
- Cryptococcosis may involve the lungs, skin, and other body organs. In patients with AIDS or other immunosuppressant disorders, it often involves the central nervous system (CNS) and produces mental status changes, headache, dizziness, and neck stiffness.
- Sporotrichosis involves the skin and lymph nodes. It usually produces small nodules that look like insect bites initially and ulcerations later. Nodules and ulcers also may develop in local lymphatic channels and nodes. The infection can spread to other parts of the body in immunocompromised patients.
- Systemic mycoses produce severe symptoms and may be life-threatening. They are confirmed by recovery of organisms from specimens of body tissues or fluids.

### Nursing Diagnoses

- Risk for Injury related to fungal infection
- Deficient Knowledge: Prevention of fungal infection; accurate drug usage

- Noncompliance related to the need for long-term therapy
- Risk for Injury: Adverse drug effects with systemic antifungal drugs

### Planning/Goals

#### The patient will

- Take or receive systemic antifungal drugs as prescribed
- Apply topical drugs accurately
- Act to prevent recurrence of fungal infection
- Avoid preventable adverse effects from systemic drugs

### Interventions

Use measures to prevent spread of fungal infections.

- Observe Standard Precautions while assessing or providing care to patients with skin lesions. Superficial infections (e.g., ringworm) are highly contagious and can be spread by sharing towels and hairbrushes. Systemic mycoses are not usually contagious.
- Decrease patient exposure to environmental fungi. For inpatients who are neutropenic or otherwise immunocompromised, do not allow soil-containing plants in the room and request regular cleaning and inspection of air-conditioning systems. Aspergillosis has occurred after inhalation of airborne mold spores from air-conditioning units and hospital water supplies. For outpatients, assist to identify and avoid areas of potential exposure (e.g., soil contaminated by chicken, bird, or bat droppings; areas where buildings are being razed, constructed, or renovated). If exposure is unavoidable, instruct to spray areas with water to minimize airborne spores and to wear disposable clothing and a face mask. For patients at risk of exposure to sporotrichosis (e.g., those who garden or work in plant nurseries), assist to identify risk factors and preventive measures (e.g., wearing gloves and long sleeves).
- For obese patients with skin candidiasis, apply dry padding to intertriginous areas to help prevent irritation and candidal growth.
- For patients with oropharyngeal ulcerations, provide soothing oral hygiene, nonacidic fluids, and soft, bland foods.
- For patients with systemic fungal infections, monitor respiratory, cardiovascular, and neurologic status at least every 8 hours. Provide comfort measures and medications (e.g., analgesics, antihistamines, antipyretics, antiemetics) for patients receiving IV amphotericin B.

### Evaluation

- Observe for relief of symptoms for which an antifungal drug was prescribed.
- Interview outpatients regarding their compliance with instructions for using antifungal drugs.
- Interview and observe for adverse drug effects with systemic antifungal agents.

## Patient Teaching Guidelines

## Oral and Topical Antifungal Drugs

### General Considerations

- If you have a condition or take a medicine that suppresses your immune system (e.g., bone marrow or organ transplant, leukemia, lymphoma, diabetes mellitus, human immunodeficiency virus [HIV] infection, cancer chemotherapy, corticosteroid therapy), avoid exposure to molds and fungi when possible, because serious, life-threatening infection may occur. To minimize exposure, avoid areas of building construction or renovation, avoid cleaning carpets or potentially moldy areas, and avoid potted plants and live flowers.
- With skin lesions, wash hands often and do not share towels, hairbrushes, or other personal items.
- With vaginal yeast infections, do not use over-the-counter medications repeatedly without consulting a health care provider. Recurrent infections may indicate inadequate treatment, reinfection, or a bacterial infection (for which an antifungal drug is not effective), and a different treatment may be needed.
- With histoplasmosis and other potentially serious fungal infections, avoid or minimize future exposure to chicken, pigeon, and bat droppings.
- If you work with plants (e.g., roses, sphagnum moss) or baled hay, prevent sporotrichosis by wearing gloves and long sleeves and avoiding injuries that cause breaks in the skin.

### Self-Administration

- Use antifungal drugs as prescribed, to increase benefit and decrease adverse drug effects.

- With topical skin preparations, wash and dry the area before each application of medication.
- With vaginal antifungal preparations:
  - Read instructions.
  - Insert high into the vagina (except during pregnancy).
  - Continue use through menstruation (wear a minipad to avoid staining clothing; do not use a tampon).
  - Wash applicator with mild soap and rinse after each use.
  - Avoid sexual intercourse.
- With itraconazole (Sporanox) capsules, take after a full meal for best absorption. With the oral suspension, take on an empty stomach, usually by swishing in the mouth and then swallowing it.
- With oral posaconazole (Noxafil), take with a meal.
- With oral voriconazole (Vfend), take 1 hour before or after a meal.
- With nystatin suspension for mouth lesions (thrush), swish the medication around in the mouth (to increase drug contact with the lesions), then swallow the medication.
- With oral fluconazole (Diflucan), itraconazole (Sporanox), or terbinafine (Lamisil), notify a health care provider of unusual fatigue, loss of appetite, nausea, vomiting, jaundice, dark urine, pale stools, fever, abdominal pain, or diarrhea. These may be signs of liver damage or other adverse drug effects. Drug therapy may need to be discontinued.
- With griseofulvin, avoid prolonged exposure to sunlight or sunlamps; the drug may cause photosensitivity.
- With voriconazole, do not drive at night because vision may be blurred.

## Principles of Therapy

### Nonpharmacologic Treatment

Some fungal infections are asymptomatic or resolve spontaneously without treatment. In addition, some candidal infections respond to the removal of predisposing factors such as antibacterial drugs, corticosteroids or other immunosuppressant drugs, and indwelling IV or bladder catheters.

### Drug Selection

Drug therapy for potentially serious fungal infections should be planned in consultation with an infectious-disease specialist when possible. Drug selection is determined mainly by the type of fungal infection. For serious infections, amphotericin B has long been the drug of choice, especially for invasive aspergillosis and systemic infections in immunocompromised hosts. However, azoles (e.g., fluconazole, itraconazole, voriconazole) and echinocandins (e.g., anidulafungin, caspofungin, micafungin) are increasingly being used for first-line treatment. The azoles are also used for initial therapy in less acutely ill patients and as long-term treatment after a brief initial course of amphotericin B. However, all azoles are contraindicated during pregnancy.

### Drug Dosage and Administration

Dosages depend on illness severity, with large amounts required for systemic infections, especially in immunocompromised hosts. Routes are determined mainly by location and severity of infection. For example, local infections can often be treated by topical applications, whereas more serious or systemic infections require oral or IV routes.

### Duration of Therapy

When antifungal drug therapy is required, it is usually long term, over weeks to months. In some cases, it may be continued for years or lifelong. If drug therapy is stopped too soon, relapse of the infection often occurs. However, in patients with AIDS, who often require long-term antifungal drug therapy, drug-resistant infections may develop. Fluconazole-resistant candidiasis is becoming increasingly recognized in this population. Patients with an impaired immune response often become reinfected after effective antifungal drug therapy and may require repeated courses.

### Drug Treatment of Specific Infections

**Aspergillosis.** Itraconazole for approximately 1 year may be effective in mild to moderate infection. Amphotericin B

is indicated for serious invasive disease, and large doses are required. Voriconazole or caspofungin may also be used.

**Blastomycosis.** Patients with skin, pulmonary, or other manifestations of systemic disease should receive systemic antifungal drug therapy to prevent further progression. Mild to moderate disease may be treated with itraconazole for 6 to 12 months. For severe disease and patients with CNS infection or immunosuppression, amphotericin B is the drug of first choice. After initial amphotericin B therapy and clinical improvement, itraconazole may be given for 6 to 12 months.

**Candidiasis.** Most mucocutaneous infections may be treated with local applications of drug. For oral candidiasis, clotrimazole troches are preferred; oral fluconazole, itraconazole, or nystatin suspension may also be used. Vaginal candidiasis may be treated with a single oral dose of fluconazole or multiple doses of vaginal tablets, creams, or suppositories containing butoconazole, clotrimazole, miconazole, terconazole, or tioconazole. Some of these preparations are available over-the-counter. One concern about self-treatment with nonprescription products is an incorrect diagnosis. Antifungal preparations do not help a bacterial vaginal infection. Pregnant patients should consult their obstetrician before using these drugs. Esophageal candidiasis should be treated with a systemically absorbed agent such as fluconazole or itraconazole. Systemic candidiasis may be treated with amphotericin B, an azole (e.g., fluconazole, itraconazole, voriconazole), or an echinocandin (e.g., anidulafungin, caspofungin). Fluconazole is usually preferred; amphotericin B may be preferred if the patient has previously received fluconazole or if the infection is caused by non-albicans *Candida*. Chronic systemic candidiasis usually requires months of drug therapy.

**Coccidioidomycosis.** Many coccidioidal infections are chronic in nature and require long-term drug therapy to control disease activity. Mild infections are usually treated with an oral azole (e.g., fluconazole, itraconazole) for 6 to 12 months. Amphotericin B is preferred for severe or disseminated disease and is usually given for 1 to 3 months. Patients with meningitis may require lifelong therapy with an azole drug to prevent recurrence.

**Cryptococcosis.** Amphotericin B followed by 6 to 12 months of oral fluconazole is used for treatment of meningitis. Patients with AIDS are usually given fluconazole long term to suppress recurrence.

**Histoplasmosis.** Itraconazole is the drug of choice for mild to moderate histoplasmosis, and amphotericin B is the drug of choice for severe disease. Patients who also have AIDS may be given itraconazole twice daily for 12 weeks, and then maintained on daily itraconazole to suppress recurrence.

**Pneumocystis pneumonia (PCP).** Trimethoprim-sulfamethoxazole (TMP-SMZ, Bactrim) (see Chap. 32) is the drug of choice for prevention and treatment of PCP. Prophylaxis may be indicated for adults and adolescents with

HIV and CD4+ cell counts of less than 200, organ transplant recipients, patients with leukemia or lymphoma who are receiving cytotoxic chemotherapy, and patients receiving high doses of corticosteroids (equivalent to 20 mg or more daily of prednisone) for longer than 2 weeks. Other drugs that may be used to prevent or treat PCP, usually in people who cannot tolerate TMP-SMZ, include atovaquone (Mepron), dapsone, pentamidine (Pentam 300, NebuPent), and trimethoprim (Neutrexin).

**Sporotrichosis.** Itraconazole, for 3 to 6 months, is the drug of choice for localized lymphocutaneous infection. Amphotericin B may be used to treat pulmonary, disseminated, and relapsing infections.

## Characteristics and Usage of Amphotericin B

Amphotericin B has long been the gold standard of drug therapy for serious fungal infections. However, its use is problematic because of different preparations, special requirements for administration, and toxicity. These aspects are summarized below.

**Preparations.** The deoxycholate preparation (Fungizone), often called “conventional amphotericin B,” is the oldest, most widely used form. Lipid preparations were developed to decrease the toxicity of the deoxycholate form, and three are currently available. These preparations have similar antifungal spectra, but they differ from the deoxycholate formulation and from each other in other respects.

**Administration.** These drugs should be reconstituted and prepared for IV administration in a pharmacy. Additional factors include the following:

- A test dose may be used to assess the patient’s tolerance of the drug. Some authorities question the need for a test dose.
- Maintenance doses can be doubled and infused on alternate days. However, a single daily dose of Fungizone should not exceed 1.5 milligram per kilogram; overdoses can result in cardiorespiratory arrest.
- Small initial doses (e.g., 5–10 mg/day) are recommended for patients with impaired cardiovascular or renal function or a severe reaction to the test dose.
- Larger doses of lipid preparations are needed to achieve therapeutic effects similar to those of the deoxycholate preparation.
- Administer through a separate IV line when possible. If injecting into an existing IV line, the line should be flushed with 5% dextrose solution before and after drug administration (both deoxycholate and lipid formulations).
- An in-line filter may be used with Fungizone and AmBisome but should not be used with Abelcet or Amphotec.
- Prepared solutions should be infused within 8 hours of reconstitution.

**Decreasing adverse effects.** There are several recommendations for reducing toxicity of IV amphotericin B, but most have not been tested in controlled studies. Recommendations to decrease nephrotoxicity are listed below in “Use in Patients With Renal Impairment”; those to decrease fever and chills include premedication with acetaminophen, diphenhydramine, and a corticosteroid; and those to decrease phlebitis at injection sites include administering on alternate days, adding 500 to 2000 units of heparin to the infusion, rotating infusion sites, administering through a central vein, removing the needle after infusion, and using a pediatric scalp vein needle. Supplemental potassium may be used to treat hypokalemia, and recombinant erythropoietin may be used to treat anemia if the patient has a low plasma level of erythropoietin.

### Applying Your Knowledge 36-3

A fungal infection that is severe or systemic may need to be treated with amphotericin B. Proper administration and assessment for adverse effects are part of the nurse's role. What adverse effects do you assess for in Charlotte while her amphotericin B is infusing?

## Effects of Antifungals on Other Drugs

Amphotericin B increases effects of cyclosporine (nephrotoxicity), digoxin (risk of hypokalemia and cardiac dysrhythmias), nephrotoxic drugs (e.g., aminoglycoside antibiotics), skeletal muscle relaxants (amphotericin B–induced hypokalemia may enhance muscle relaxation), and thiazide and loop diuretics (risk of hypokalemia). Serum potassium levels should be monitored.

Azoles inhibit the metabolism of many drugs (by inhibiting cytochrome P450 drug-metabolizing enzymes in the liver and small intestine, especially 3A4 enzymes) and therefore increase their effects and risks of toxicity. These drugs include benzodiazepines (alprazolam, midazolam, triazolam), calcium channel blockers (felodipine, nifedipine), cyclosporine, phenytoin, statin cholesterol-lowering drugs (atorvastatin, simvastatin), sulfonyleureas, tacrolimus, theophylline, warfarin, vincristine, and zidovudine.

Although the main concern about azole drug interactions is increased toxicity of inhibited drugs, ketoconazole may be given with cyclosporine and tacrolimus to decrease dosages and costs of the immunosuppressant drugs. There may also be a reduced risk of fungal infections, which commonly occur in people with an impaired immune system.

Fluconazole is apparently a less potent inhibitor of cytochrome P450 3A4 enzymes than ketoconazole and itraconazole. As a result, drug interactions with fluconazole are of lesser magnitude and usually occur only with dosages of 200 milligrams per day or more. However, fluconazole is a strong

inhibitor of cytochrome P450 2C9 enzymes, and concurrent administration of losartan, phenytoin, or warfarin results in greater risks of toxicity with the inhibited drugs.

Caspofungin decreases serum levels of tacrolimus; serum levels of tacrolimus should be monitored. Miconazole increases blood levels and risks of toxicity with nifedipine and sirolimus. No significant interactions have been reported with anidulafungin.

Griseofulvin decreases the effects of cyclosporine, oral contraceptives, salicylates, and warfarin, probably by inducing hepatic drug-metabolizing enzymes and accelerating their metabolism.

Terbinafine is a strong inhibitor of cytochrome P450 2D6 enzymes and may increase the effects of propafenone, metoprolol, and desipramine and nortriptyline.

## Use in Special Populations

### Use in Children

Guidelines for the use of topical antifungal drugs in children are generally the same as those for adults. With most oral and intravenous agents for treatment of systemic fungal infections, safety, effectiveness, and guidelines for use have not been established. In addition, some agents have no established pediatric dosages and others have age restrictions. Despite these limitations, most antifungal drugs, including amphotericin B and the azoles, have been used successfully to treat children with serious fungal infections, without unusual or severe adverse effects. The safety and efficacy of echinocandins in children have not been established. Children receiving systemic antifungal drugs should be given the lowest effective dosage and be monitored closely for adverse effects.

### Use in Older Adults

Specific guidelines for the use of antifungal drugs have not been established. The main concern is with oral or parenteral drugs because topical agents produce few adverse effects.

Virtually all adults receiving IV amphotericin B experience adverse effects. With the impaired renal and cardiovascular functions that usually accompany aging, older adults are especially vulnerable to serious adverse effects. They must be monitored closely to reduce the incidence and severity of nephrotoxicity, hypokalemia, and other adverse drug reactions. Lipid formulations of amphotericin B are less nephrotoxic than the conventional deoxycholate formulation and may be preferred for older adults. Azole drugs should probably be stopped if hypertension, edema, or hypokalemia occur. In addition, itraconazole has been associated with heart failure, a common condition in older adults. There is little information available about the effects of posaconazole, voriconazole, and the echinocandins (e.g., caspofungin) in older adults.

### Use in Patients With Cancer

Patients with cancer are at high risk for development of serious, systemic fungal infections. In patients receiving cytotoxic anticancer drugs, antifungal therapy is often used to prevent or

treat infections caused by *Candida* and *Aspergillus* organisms. For prophylaxis, topical, oral, or IV agents are given before and during periods of drug-induced neutropenia, often to prevent recurrence of infection that occurred during previous neutropenic episodes. For treatment, oral or IV drugs may be given at the onset of fever and neutropenia, when fever persists or recurs in a neutropenic patient despite appropriate antimicrobial therapy, or when maintenance therapy is needed after initial treatment of coccidioidomycosis, cryptococcosis, or histoplasmosis. These infections often relapse if antifungal drugs are discontinued. Patients must be closely monitored for adverse effects of antifungal drugs.

### Use in Patients With Renal Impairment

Amphotericin B deoxycholate (Fungizone) is nephrotoxic. Renal impairment occurs in most patients (up to 80%) within the first 2 weeks of therapy but usually subsides with dosage reduction or drug discontinuation. Permanent impairment occurs in a few patients. Recommendations to decrease nephrotoxicity include hydrating patients with a liter of 0.9% sodium chloride solution IV and monitoring serum creatinine and blood urea nitrogen (BUN) at least weekly. If BUN exceeds 40 milligrams per deciliter or serum creatinine exceeds 3 milligrams per deciliter, the drug should be stopped or dosage should be reduced until renal function recovers. Another strategy is to give a lipid formulation (e.g., Abelcet, AmBisome, Amphotec), which is less nephrotoxic. For patients who already have renal impairment or other risk factors for development of renal impairment, a lipid formulation is indicated. Renal function should still be monitored frequently.

Caspofungin does not require dosage reduction for renal impairment and is not removed by hemodialysis. Fluconazole is mainly excreted in the urine as unchanged drug. For patients with a creatinine clearance (CrCl) above 50 milliliters per minute, full dosage may be given. For those with a CrCl of 50 milliliters per minute or less, dosage should be reduced by one half. However, for patients receiving hemodialysis, an extra dose may be needed because 3 hours of hemodialysis lowers plasma drug levels by approximately 50%. Itraconazole can be given to patients with mild to moderate renal impairment but is contraindicated in those with a CrCl of 30 milliliters per minute or less. It is not removed by hemodialysis. Voriconazole has been associated with acute renal failure; renal function should be closely monitored during use. Terbinafine clearance is reduced by 50% in patients with a CrCl of 50 milliliters per minute or less. Its use is not recommended.

### Use in Patients With Hepatic Impairment

Although the main concern with amphotericin B is nephrotoxicity, it is recommended that liver function tests be monitored during use. Caspofungin dosage must be reduced with moderate hepatic impairment; the drug has not been studied in patients with severe hepatic impairment.

The azole antifungals may cause hepatotoxicity, ranging from mild elevations in ALT and AST to clinical hepatitis, cholestasis, hepatic failure, and death. Fatal hepatic damage

has occurred mainly in patients with serious underlying conditions, such as AIDS or malignancy, and with multiple concomitant medications. The drugs are relatively contraindicated in patients with increased liver enzymes, active liver disease, or a history of liver damage with other drugs. They should be given only if expected benefits outweigh risks of liver injury. ALT, AST, and serum bilirubin should be checked before drug use, after several weeks of drug use, and every 1 to 2 months during long-term therapy. If ALT and AST increase to more than three times the normal range, the azole should be discontinued. Hepatotoxicity may be reversible if drug therapy is stopped.

Griseofulvin may cause hepatotoxicity, especially if given in large doses for prolonged periods. Terbinafine has been associated with liver failure, and its clearance is reduced by 50% in patients with hepatic cirrhosis. Its use is not recommended for patients with chronic or active liver disease, and liver function tests should be done in all patients before starting therapy. Hepatotoxicity has been reported in patients with and without pre-existing liver disease.

### Use in Patients With Critical Illness

Amphotericin B, caspofungin, and the azoles are often used for serious fungal infections. Amphotericin B penetrates tissues well, except for CSF, and only small amounts are excreted in urine. With prolonged administration, the half-life increases from 1 to 15 days. Hemodialysis does not remove the drug. Lipid formulations may be preferred in critically ill patients because of less nephrotoxicity. Fluconazole penetrates tissues well, including CSF. Although IV administration may be necessary in many critically ill patients, the drug is well absorbed when administered orally or by nasogastric tube. Significantly impaired renal function may require reduced dosage, and impaired hepatic function may require discontinuation. When itraconazole is used in critically ill patients, a loading dose of 200 milligrams three times daily may be given for the first 3 days. Treatment should be continued for at least 3 months; inadequate treatment may lead to recurrent infection.

### Use in Home Care

Antifungal drugs may be taken at home by various routes. For topical and oral routes, the role of the home care nurse may be teaching correct usage and encouraging patients to persist with the long-term treatment usually required. With IV antifungal drugs for serious infections, the home care nurse may need to assist in managing the environment, administering the drug, and monitoring for adverse effects. Because the immune function of these patients is often severely suppressed, protective interventions are needed. These may include teaching about frequent and thorough hand hygiene by patients, all members of the household, and visitors; safe food preparation and storage; removing potted plants and fresh flowers; and avoiding activities that generate dust in the patient's environment. In addition, air conditioning and air filtering systems should be kept meticulously clean and any plans for renovations should be postponed or canceled.

## Nursing Actions Antifungal Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give intravenous (IV) amphotericin B (Fungizone, Abelcet, AmBisome, and Amphotec) according to manufacturers' recommendations for each product:
  - (1) Follow recommendations for administration of test doses, if ordered.
  - (2) Use an infusion pump.
  - (3) Use a separate IV line if possible; if using an existing line, flush with 5% dextrose in water before and after each infusion.
  - (4) Fungizone IV—give in 5% dextrose in water, over 2–6 hours; use an in-line filter; do not mix with other IV medications.
  - (5) Abelcet—give over 2 hours; do not use an in-line filter.
  - (6) AmBisome—give over 2 hours or longer; may use an in-line filter.
  - (7) Amphotec—give over at least 2 hours; do not use an in-line filter.
  - (8) Apply cream or lotion liberally to skin lesions and rub in gently.
- b. Give azoles according to manufacturers' recommendations:
  - (1) Give IV fluconazole as a continuous infusion at a maximum rate of 200 mg/h. Give IV voriconazole over 1 to 2 hours.
  - (2) Shake oral suspensions of fluconazole, posaconazole, voriconazole before measuring the dose.
  - (3) Give itraconazole capsules after a full meal; give the oral solution on an empty stomach and ask the patient to swish the medication in the mouth, then swallow it.
  - (4) With posaconazole suspension, shake well and give with a full meal or liquid nutritional supplement.
  - (5) Give oral voriconazole 1 h before or 2 h after a meal.
- c. Review and follow manufacturers' instructions for IV administration of anidulafungin, caspofungin, and micafungin.

#### 2. Observe for therapeutic effects

- a. Decreased fever and malaise with systemic mycoses
- b. Healing of lesions on skin and mucous membranes
- c. Diminished diarrhea with intestinal candidiasis
- d. Decreased vaginal discharge and discomfort with vaginal candidiasis

#### 3. Observe for adverse effects

- a. With IV amphotericin B, observe for fever, chills, anorexia, nausea, vomiting, renal damage (elevated blood urea nitrogen and serum creatinine), hypokalemia, hypomagnesemia, headache, stupor, coma, convulsions, anemia from bone marrow depression, phlebitis at venipuncture sites, and anaphylaxis.
- b. With fluconazole, itraconazole, posaconazole, and voriconazole, observe for unusual fatigue, loss of appetite, nausea, vomiting, jaundice, dark urine, pale stools, fever, abdominal pain, or diarrhea.

### RATIONALE/EXPLANATION

This drug is given for serious, systemic fungal infections and unlikely to be commonly used in many health care settings.

Preparation, concentration, and infusion times vary among formulations. Solutions, including test doses, should be prepared in a pharmacy. Some clinicians may not use a test dose. To regulate flow accurately

To resuspend medication in the liquid vehicle and ensure accurate dosage

To decrease GI upset and increase absorption. The oral solution is used to treat oropharyngeal and esophageal candidiasis, and correct administration enhances contact with mucosal lesions.

To increase absorption

Manufacturer's recommendation

These drugs are given for serious, systemic fungal infections and unlikely to be commonly used in many health care settings.

Most antifungal drug therapy is long term, over weeks, months, or years. With skin infections, optimal therapeutic effects may occur 2–4 weeks after drug therapy is stopped. With nail infections, optimal effects may occur 6–9 months after drug therapy is stopped.

This is a highly toxic drug and most recipients develop adverse effects, including renal damage. Antipyretic and antiemetic drugs may decrease adverse reactions and promote patient comfort. Adequate hydration and lipid formulations may decrease renal damage. Anaphylaxis is uncommon; however, emergency medications and supplies should be available during infusions. If severe respiratory distress occurs, the drug should be stopped immediately.

These may be signs of liver damage or other adverse effects. Drug therapy may need to be discontinued.

**NURSING ACTIONS**

- c. With caspofungin 50 mg daily, observe for nausea, vomiting, and phlebitis at infusion sites. With larger doses (50–70 mg daily), observe for the above plus fever, headache, and abnormal laboratory reports (e.g., decreased white blood cells, hemoglobin, and hematocrit; increased serum potassium and liver aminotransferase enzymes).
- d. With griseofulvin, observe for GI symptoms, hypersensitivity (urticaria, photosensitivity, skin rashes, angioedema), headache, mental confusion, fatigue, dizziness, peripheral neuritis, and blood dyscrasias (leukopenia, neutropenia, granulocytopenia).
- e. With oral terbinafine, observe for diarrhea, dyspepsia, headache, skin rash or itching, and liver enzyme abnormalities.
- f. With topical drugs, observe for skin rash and irritation.

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of amphotericin B:
  - (1) Antineoplastic drugs
  - (2) Corticosteroids
  - (3) Zidovudine
  - (4) Nephrotoxic drugs (e.g., aminoglycoside antibiotics, cyclosporine)
- b. Drug that *increases* effects of fluconazole:
  - (1) Hydrochlorothiazide
- c. Drugs that *decrease* effects of fluconazole and posaconazole:
  - (1) Cimetidine
  - (2) Rifampin
- d. Drugs that *decrease* effects of itraconazole:
  - (1) Antacids, histamine H<sub>2</sub> antagonists, proton pump inhibitors
  - (2) Phenytoin, rifampin
- e. Drugs that *increase* effects of voriconazole:
  - (1) Cimetidine
  - (2) Proton pump inhibitors
  - (3) Protease inhibitors (anti-HIV drugs)
- f. Drugs that *decrease* effects of voriconazole
  - (1) Phenytoin
  - (2) Rifampin
- g. Drug that *increases* effects of caspofungin:
  - (1) Cyclosporine
- h. Drugs that *decrease* effects of caspofungin:
  - (1) Enzyme inducers (efavirenz, nelfinavir, nevirapine, dexamethasone, carbamazepine, phenytoin, rifampin)
- i. Drugs that *decrease* effects of griseofulvin:
  - (1) Enzyme inducers (e.g., rifampin)
- j. Drug that *increases* effects of terbinafine:
  - (1) Cimetidine
- k. Drug that *decreases* effects of terbinafine:
  - (1) Rifampin

**RATIONALE/EXPLANATION**

- The drug is usually well tolerated.
- The incidence of serious reactions is low.
- Elevated liver enzymes (alanine and aspartate aminotransferases [ALT and AST]) may indicate liver damage and may occur in patients with or without pre-existing liver disease. Adverse reactions are usually minimal with topical drugs, although hypersensitivity may occur.
- May increase risks of nephrotoxicity, hypotension, and bronchospasm
- May potentiate hypokalemia and precipitate cardiac dysfunction
- Increases renal and hematologic adverse effects of the liposomal formulation. Renal and hematologic functions should be monitored closely.
- Increase nephrotoxicity
- Increases serum levels of fluconazole, attributed to decreased renal excretion
- Decreased absorption
- Accelerated metabolism from enzyme induction
- These drugs decrease gastric acid, which inhibits absorption. If required, they should be given at least 2 hours after the azole drug.
- Accelerate metabolism and decrease blood levels
- Decrease serum levels, probably from accelerated metabolism
- Increases serum levels
- Decrease serum levels by accelerating caspofungin metabolism. The daily dose of caspofungin may need to be increased if given with one of these drugs.
- Increase metabolism of griseofulvin
- Slows metabolism and elimination of terbinafine so that serum levels are increased
- Causes rapid metabolism and clearance of terbinafine

## Key Concepts

- Serious fungal infections and infections with non-albicans *Candida* strains are increasing.
- Patients whose immune systems are suppressed are at high risk of serious fungal infections.
- Fungal infections often require long-term drug therapy.

- Systemic antifungal drugs may cause serious adverse effects. Nephrotoxicity is associated with amphotericin B; hepatotoxicity is associated with azole drugs.
- Liver function should be monitored with all systemic antifungal drugs; both hepatic and renal function should be monitored with amphotericin B.

## Review and Application Exercises

### Short Answer Exercises

1. What environmental factors predispose patients to development of fungal infections?
2. What signs and symptoms occur with candidiasis, and how would you assess for these?
3. Which fungal infections often mimic other respiratory infections?
4. What are the clinical indications for use of IV amphotericin B?
5. What are nursing interventions to decrease adverse effects of IV amphotericin B?
6. What are the differences between amphotericin B deoxycholate and the lipid formulations?
7. What are the clinical indications for use of oral antifungal drugs?
8. What are some early indications that a patient is developing nephrotoxicity or hepatotoxicity?
9. Which population groups are at high risk of developing serious fungal infections and what can be done to protect them?

### NCLEX-Style Questions

10. The nurse caring for a patient with a serious fungal infection is aware that a major risk factor for these fungal infections is
  - a. immunosuppression
  - b. mild exposure to a causative organism
  - c. poor hand hygiene technique
  - d. taking an antibacterial drug for 5 days
11. The nurse knows that the following drug may be used to treat oral candidiasis (thrush)?
  - a. terbinafine (Lamisil)
  - b. flucytosine (Ancobon)
  - c. fluconazole (Diflucan)
  - d. butoconazole (Gynazole)
12. The nurse caring for a patient who has just been diagnosed with a serious fungal infection received an order to start IV amphotericin B. Which of the following is a major adverse effect of IV amphotericin B?
  - a. bone marrow depression
  - b. nephrotoxicity
  - c. hepatotoxicity
  - d. neurotoxicity
13. In administering an azole antifungal medication to a patient, as the nurse you are aware that a major adverse effect of the azole antifungal drugs is
  - a. bone marrow depression
  - b. nephrotoxicity
  - c. hepatotoxicity
  - d. neurotoxicity
14. Which of the following medications is often ordered to be given with IV amphotericin B to decrease infusion reactions?
  - a. an antihistamine
  - b. an antibacterial
  - c. a diuretic
  - d. a local anesthetic

# Antiparasitics

## KEY TERMS

- Amebicides
- Anthelmintics
- Giardiasis
- Larvae
- Parasite
- Pediculicides
- Plasmodia

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe environmental and other major factors in prevention and recognition of selected parasitic diseases.
2. Discuss assessment and treatment of pinworm infestations and pediculosis in school-age children.
3. Teach preventive interventions to patients planning travel to a malarious area.

## Applying Your Knowledge

Lacy Michelsen is a 35-year-old woman who is a missionary. She has just returned from a 2-year stay in a developing country. Ms. Michelsen comes to the clinic today with severe diarrhea, fever, chills, headache, and myalgia. She is diagnosed with giardiasis and malaria and is prescribed chloroquine 500 mg daily for 3 weeks and metronidazole 250 mg PO three times a day for 7 days.

## Introduction

A *parasite* is a living organism that survives at the expense of another organism, called the host. Parasitic infestations are common human ailments worldwide. The effects of parasitic diseases on human hosts vary from minor to major and life threatening. Parasitic diseases discussed in this chapter are those caused by protozoa, helminths (worms), scabies, and pediculi (lice). Protozoa and helminths can infect the digestive tract and other body tissues; scabies and pediculi affect the skin.

## Protozoal Infections

### Amebiasis

Amebiasis is a common disease in Africa, Asia, and Latin America, but it can occur in any geographic region. In the United States, it is most likely to occur in residents of institutions for the mentally challenged, men who have sex with men, and residents or travelers in countries with poor sanitation.

Amebiasis is caused by the pathogenic protozoan *Entamoeba histolytica*, which exists in two forms, cysts and trophozoites. Cysts are inactive; resistant to drugs, heat, cold, and drying; and can survive outside the body for long periods. Amebiasis is transmitted by ingestion of food or water contaminated with human feces containing amebic cysts. After they are ingested, some cysts remain intact to be expelled in feces and continue the chain of infection, and some open in the ileum to release amebae, which produce trophozoites. Trophozoites are active amebae that feed, multiply, move about, and produce clinical manifestations of amebiasis. Trophozoites produce an

enzyme that allows them to invade body tissues. They may form erosions and ulcerations in the intestinal wall with resultant diarrhea (this form of the disease is called intestinal amebiasis or amebic dysentery), or they may penetrate blood vessels and be carried to other organs, where they form abscesses. These abscesses are usually found in the liver (hepatic amebiasis) but also may occur in the lungs or brain.

Drugs used to treat amebiasis (*amebicides*) are classified according to their site of action. For example, chloroquine is a tissue or extraintestinal amebicide because it acts in the bowel wall, liver, and other tissues. Metronidazole (Flagyl) is effective in both intestinal and extraintestinal amebiasis. No amebicides are currently recommended for prophylaxis of amebiasis.

### Giardiasis

Giardiasis is caused by *Giardia lamblia*, a common intestinal parasite. It is spread by food or water contaminated with human feces containing encysted forms of the organism or by contact with infected people or animals. Person-to-person spread often occurs among children in daycare centers, people in institutions, and men who have sex with men. The organism is also found in people who camp or hike in wilderness areas or who drink untreated well water in areas where sanitation is poor. Giardiasis may affect children more than adults and may cause community outbreaks of diarrhea.

Giardial infections occur 1 to 2 weeks after ingestion of the cysts and may be asymptomatic or produce diarrhea, abdominal cramping, and distention. If untreated, giardiasis may resolve spontaneously or progress to a chronic disease with anorexia, nausea, malaise, weight loss, and continued diarrhea with large, foul-smelling stools. Deficiencies of vitamin B<sub>12</sub> and fat-soluble vitamins may occur. Adults and children older than 8 years of age with symptomatic giardiasis are usually treated with oral metronidazole.

### Malaria

Malaria is a common cause of morbidity and mortality in many parts of the world, especially in tropical regions. In the United States, malaria is rare and affects travelers or immigrants from malarious areas.

Malaria is caused by four species of protozoa of the genus *Plasmodium*. The human being is the only natural reservoir of these parasites. All types of malaria are transmitted only by *Anopheles* mosquitoes. *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium ovale* cause recurrent malaria by forming reservoirs in the human host. In these types of malaria, signs and symptoms may occur months or years after the initial attack. *Plasmodium falciparum* causes the most life-threatening type of malaria but does not form a reservoir. This type of malaria may be cured and prevented from recurring.

*Plasmodia* have a life cycle in which one stage of development occurs within the human body. When a mosquito bites a person with malaria, it ingests blood that contains gametocytes (male and female forms of the protozoan parasite). From these forms, sporozoites are produced and transported to the mosquito's salivary glands. When the mosquito bites the next person, the sporozoites are injected into that person's bloodstream.

From the bloodstream, the organisms lodge in the liver and other tissues, where they reproduce and form merozoites. The liver cells containing the parasite eventually rupture and release the merozoites into the bloodstream, where they invade red blood cells. After a period of growth and reproduction, merozoites rupture red blood cells, invade other erythrocytes, form gametocytes, and continue the cycle. After several cycles, clinical symptoms of malaria occur because of the large parasite burden. The characteristic cycles of chills and fever correspond to the release of merozoites from erythrocytes.

Antimalarial drugs act at different stages in the life cycle of plasmodial parasites. Some drugs (e.g., chloroquine) are effective against erythrocytic forms and are therefore useful in preventing or treating acute attacks of malaria. These drugs do not prevent infection with the parasite, but they do prevent clinical manifestations. Other drugs (e.g., primaquine) act against exoerythrocytic or tissue forms of the parasite to prevent initial infection and recurrent attacks or to cure some types of malaria. Combination drug therapy, administered concomitantly or consecutively, is common with antimalarial drugs.

### Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii*, a parasite spread by ingesting undercooked meat or other food containing encysted forms of the organism, by contact with feces from infected cats, and by congenital spread from mothers with acute infection. After infection, the organism may persist in tissue cysts for the life of the host. However, symptoms rarely occur unless the immune system is impaired or becomes impaired at a later time. Although symptomatic infection may occur in anyone with immunosuppression (e.g., people with cancer or organ transplantation), it is especially common and serious in people with AIDS, in whom it often causes encephalitis and death.

### Trichomoniasis

The most common form of trichomoniasis is a vaginal infection caused by *Trichomonas vaginalis*. The disease is usually spread by sexual intercourse. Antitrichomonal drugs may be administered systemically (i.e., metronidazole) or applied locally as vaginal creams. Because trichomoniasis is transmitted by sexual intercourse, partners should be treated simultaneously to prevent reinfection.

### Helminthiasis

Helminthiasis, or infestation with parasitic worms, often occurs in many parts of the world. Helminths are most often found in the gastrointestinal (GI) tract. However, several types penetrate body tissues or produce *larvae* that migrate to the blood, lymph channels, lungs, liver, and other body tissues. Helminthic infections are described in Box 37-1.

Drugs used for treatment of helminthiasis are called *anthelmintics*. Most anthelmintics act locally to kill or cause expulsion of parasitic worms from the intestines; some anthelmintics act systemically against parasites that have penetrated various body tissues. The goal of anthelmintic therapy

## Box 37-1

## Helminthic Infections

**Hookworm infections** are caused by *Necator americanus*, a species found in the United States, and *Ancylostoma duodenale*, a species found in Europe, the Middle East, and North Africa. Hookworm is spread by ova-containing feces from infected people. Ova develop into larvae when deposited on the soil. Larvae burrow through the skin (e.g., if the person walks on the soil with bare feet), enter blood vessels, and migrate through the lungs to the pharynx, where they are swallowed. Larvae develop into adult hookworms in the small intestine and attach themselves to the intestinal mucosa.

**Pinworm infections** (enterobiasis), caused by *Enterobius vermicularis*, are the most common parasitic worm infections in the United States. They are highly communicable and often involve schoolchildren and household contacts. Infection occurs from contact with ova in food or water or on bed linens. The female pinworm migrates from the bowel to the perianal area to deposit eggs, especially at night. Touching or scratching the perianal area deposits ova on hands and any objects touched by the contaminated hands.

**Roundworm infections** (ascariasis), caused by *Ascaris lumbricoides*, are the most common parasitic worm infections in the world. They occur most often in tropical regions but may occur wherever sanitation is poor. The infection is transmitted by ingesting food or water contaminated with feces from infected people. Ova are swallowed and hatch into larvae in the intestine. The larvae penetrate blood vessels and migrate through the lungs before returning to the intestines, where they develop into adult worms.

**Tapeworms** attach themselves to the intestinal wall and may grow as long as several yards. Segments called *proglottids*, which contain tapeworm eggs, are expelled in feces. Tapeworms are transmitted by ingestion of contaminated, raw, or improperly cooked beef, pork, or fish. Beef and fish tapeworm infections are not usually considered serious illnesses. Pork tapeworm, which is uncommon in the United States, is more serious because it produces larvae that enter the bloodstream and migrate to other body tissues (i.e., muscles, liver, lungs, and brain).

**Threadworm infections** (strongyloidiasis), caused by *Strongyloides stercoralis*, are potentially serious infections. This worm burrows into the mucosa of the small intestine, where the female lays eggs. The eggs hatch into larvae that can penetrate all body tissues.

**Trichinosis**, a parasitic worm infection caused by *Trichinella spiralis*, occurs worldwide. It is caused by ingestion of inadequately cooked meat, especially pork. Encysted larvae are ingested in infected pork. In the intestine, the larvae excyst, mature, and produce eggs that hatch into new larvae. The larvae enter blood and lymphatic vessels and are transported throughout the body. They penetrate various body tissues (e.g., muscles and brain) and evoke inflammatory reactions. Eventually, the larvae are re-encysted or walled off in the tissues and may remain for 10 years or longer.

**Whipworm infections** (trichuriasis) are caused by *Trichinella trichiura*. Whipworms attach themselves to the wall of the colon.

may be to eradicate the parasite completely or to decrease the magnitude of infestation (“worm burden”).

## Scabies and Pediculosis

Scabies and pediculosis are parasitic infestations of the skin. Scabies is caused by the “itch mite” (*Sarcoptes scabiei*), which burrows into the skin and lays eggs that hatch in 4 to 8 days. The burrows may produce visible skin lesions, most often between the fingers and on the wrists.

Pediculosis may be caused by one of three types of lice. *Pediculosis capitis* (head lice) is the most common type in the United States. It is diagnosed by finding louse eggs (nits) attached to hair shafts close to the scalp. *Pediculosis corporis* (body lice) is diagnosed by finding lice in clothing, especially in seams. *Pediculosis pubis* (pubic or crab lice) is diagnosed by the presence of nits in the pubic and genital areas. Although scabies and pediculosis are caused by different parasites, the conditions have several common characteristics:

- They are more likely to occur in areas of poverty, overcrowding, and poor sanitation. However, they may occur in any geographic area and socioeconomic group.
- They are highly communicable and transmitted by direct contact with an infected person or the person’s personal effects (e.g., clothing, combs and hairbrushes, bed linens).

- Pruritus is usually the major symptom. It results from an allergic reaction to parasite secretions. In addition to the intense discomfort associated with pruritus, scratching is likely to cause skin excoriation with secondary bacterial infection and formation of vesicles, pustules, and crusts.
- They are treated with many of the same topical medications.

## Antiparasitic Drugs

Antiparasitic drugs include amebicides, antimalarials, other antiprotozoal agents, anthelmintics, scabicides, and *pediculicides*. They are described below and in Table 37-1.

### Antiprotozoal Agents

#### Amebicides

**Chloroquine** (Aralen) is used mainly for its antimalarial effects. When used as an amebicide, the drug is effective in extraintestinal amebiasis (i.e., hepatic amebiasis) but usually ineffective in intestinal amebiasis. Treatment is usually combined with an intestinal amebicide.

**Iodoquinol** (Yodoxin) is an iodine compound that acts against active amebae (trophozoites) in the intestinal lumen. It

Table 37-1

Drugs at a Glance: Antiparasitic Drugs

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Amebicides</b>			
Chloroquine (Aralen)	Extraintestinal amebiasis	PO 1 g/d for 2 d, then 500 mg/d for 2–3 wk	PO 20 mg/kg/d, in 2 divided doses, for 2 d, then 10 mg/kg/d for 2–3 wk
Iodoquinol (Yodoxin)	Intestinal amebiasis	Asymptomatic carriers, PO 650 mg/d Symptomatic intestinal amebiasis, PO 650 mg 3 times daily after meals for 20 d; repeat after 2–3 wk if necessary	PO 40 mg/kg/d in 3 divided doses for 20 d (maximum dose, 2 g/d); repeat after 2–3 wk if necessary
Metronidazole (Flagyl)	Intestinal and extraintestinal amebiasis Giardiasis Trichomoniasis	Amebiasis, PO 500–750 mg 3 times daily for 5–10 d Giardiasis, PO 250 mg 3 times daily for 7 d Trichomoniasis, PO 250 mg 3 times daily for 7 d, 1 g twice daily for 1 d, or 2 g in a single dose. Repeat after 4–6 wk, if necessary. <i>Gardnerella vaginalis</i> vaginitis, PO 500 mg twice daily for 7 d	Amebiasis, PO 35–50 mg/kg/d in 3 divided doses, for 10 d Giardiasis, PO 15 mg/kg/d in 3 divided doses, for 7 d
Tetracycline (Sumycin) and doxycycline (Vibramycin)	Intestinal amebiasis	PO 250–500 mg q6h, up to 14 d	PO 25–50 mg/kg/d in 4 divided doses, for 7 to 10 d
Tinidazole (Tindamax)	Amebiasis Giardiasis Trichomoniasis	Amebiasis, PO 2 g daily for 3–5 d Giardiasis and trichomoniasis, PO 2 g as a single dose	Amebiasis, 3 y and older, PO 50 mg/kg, up to 2 g, daily for 3–5 d Giardiasis and trichomoniasis, PO 50 mg/kg, up to 2 g, as a single dose
<b>Antimalarial Agents</b>			
Atovaquone/proguanil (Malarone)	Prevention and treatment of malaria	Prophylaxis, one adult tablet daily 1–2 d before and 7 d after travel Treatment, 4 adult tablets daily for 3 d	Prophylaxis, weight 11–40 kg, PO 1–3 pediatric tablets 1–2 d before and 7 d after travel Treatment, weight 40 kg or above, PO 1–4 adult tablets daily for 3 d; weight under 40 kg, PO 8 mg/kg according to the schedule for adults
Chloroquine phosphate (Aralen)	Prevention and treatment of malaria	Prophylaxis, PO 5 mg/kg weekly (maximum of 300 mg/wk), starting 2 wk before entering a malarious area and continuing for 8 wk after return Treatment, PO 1 g initially, then 500 mg after 6–8 h, then 500 mg daily for 2 d (total of 2.5 g in 4 doses)	Treatment, PO 10 mg/kg initially, then 5 mg/kg after 6 h, then 5 mg/kg/d for 2 d (total of 4 doses)

(continued on page 604)

Table 37-1

## Drugs at a Glance: Antiparasitic Drugs (continued)

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
Chloroquine with primaquine	Prophylaxis of malaria	PO 1 tablet weekly for 2 wk before entering and 8 wk after leaving malarious areas	PO same as adults for weight above 45 kg; 1/2 tablet for weight of 25–45 kg. For younger children, a suspension is prepared (e.g., 40 mg of chloroquine and 6 mg of primaquine in 5 mL). Dosages are then 2.5 mL for weight of 5–7 kg; 5 mL for 8–11 kg; 7.5 mL for 12–15 kg; 10 mL for 16–20 kg; and 12.5 mL for 21–24 kg. Dosages are given weekly for 2 wk before entering and 8 wk after leaving malarious areas.
Hydroxychloroquine (Plaquenil)	Erythrocytic malaria	Prophylaxis, PO 5 mg/kg, not to exceed 310 mg, once weekly for 2 wk before entering and 8 wk after leaving malarious areas Treatment of acute malaria, PO 620 mg initially, then 310 mg 6 h later, and 310 mg/d for 2 d (total of 4 doses)	Prophylaxis, PO 5 mg/kg once weekly for 2 wk before entering and 8 wk after leaving malarious areas Treatment of acute malaria, PO 10 mg/kg initially, then 5 mg/kg 6 h later, and 5 mg/kg/d for 2 doses (total of 4 doses)
Mefloquine (Lariam)	Prevention and treatment of malaria	Prophylaxis, PO 250 mg 1 wk before travel, then 250 mg weekly during travel and for 4 wk after leaving a malarious area Treatment, 1250 mg (5 tablets) as a single dose	Prophylaxis, PO 1/4 tablet for 15–19 kg weight; 1/2 tablet for 20–30 kg; 3/4 tablet for 31–45 kg; and 1 tablet for above 45 kg, according to the schedule for adults
Primaquine	Prevention of malaria	PO 26.3 mg (15 mg of primaquine base) daily for 14 d, beginning immediately after leaving a malarious area, or 79 mg (45 mg of base) once weekly for 8 wk. To prevent relapse, the same dose is given with chloroquine or a related drug daily for 14 d.	PO 0.3 mg of base/kg/d for 14 d, according to the schedule for adults, or 0.9 mg of base/kg/wk for 8 wk
Quinine	Treatment of malaria	PO 650 mg q8h for 10–14 d	PO 25 mg/kg/d in divided doses q8h for 10–14 d
<b>Other Antiprotozoal Agent</b>			
Nitazoxanide (Alinia)	Diarrhea caused by giardiasis or cryptosporidiosis	PO 500 mg q12h	12 y and older, PO 1 tab (500 mg) or 25 mL oral suspension q12h for 3 d 4–11 y, PO 10 mL q12h for 3 d 12–47 mo, 5 mL q12h for 3 d
<b>Anthelmintics</b>			
Mebendazole (Vermox)	Treatment of hookworm, pinworm, roundworm, whipworm, and tapeworm infections	Most infections, PO 100 mg morning and evening for 3 consecutive d For pinworms, a single 100-mg dose may be sufficient. A second course may be given in 3 wk, if necessary	Same as adults

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
Pyrantel (Pin-Rid)	Treatment of roundworm, pinworm, and hookworm infections	Roundworms and pinworms, PO 11 mg/kg (maximum dose, 1 g) as a single dose; for hookworms, the same dose is given daily for 3 consecutive d. The course of therapy may be repeated in 1 mo, if necessary.	Same as adults
Ivermectin (Stromectol)	Treatment of strongyloidiasis	PO 200 mcg/kg as a single dose	5 y and older, PO 150 mcg/kg as a single dose
<b>Scabicides and Pediculicides</b>			
Lindane	Pediculosis Scabies	Scabies, apply to entire skin except the face, neck, and scalp; leave in place for 24 h; then remove by shower. Pediculosis, rub cream or lotion into affected area, leave in place for 12 h, then wash or shampoo (rub into the affected area for 4 min and rinse thoroughly).	Same as adults
Permethrin (Nix, Elimite)	Pediculosis Scabies	Scabies, massage Elimite into the skin over the entire body except the face, leave on for 8–14 h, wash off. Pediculosis, apply Nix after shampooing, rinsing, and towel-drying hair. Saturate hair and scalp, leave on for 10 min, rinse off with water.	Same as adults
Malathion (Ovide)	Pediculosis (head lice)	Apply to hair, rub in well to wet hair, then dry hair without covering or using a hair dryer. After 8–12 h, shampoo, rinse, and comb hair with a fine-toothed comb to remove dead lice and eggs. If necessary, treatment can be repeated in 7–9 d.	Above 2 y of age, same as adults; below 2 y, safety and effectiveness not established

may be used alone in asymptomatic intestinal amebiasis to decrease the number of amebic cysts passed in the feces. When given for symptomatic intestinal amebiasis (e.g., amebic dysentery), it is usually given with other amebicides in concurrent or alternating courses. Iodoquinol is ineffective in amebic hepatitis and abscess formation. Its use is contraindicated with iodine allergy and liver disease.

**Metronidazole** (Flagyl) is effective against protozoa that cause amebiasis, giardiasis, and trichomoniasis and against anaerobic bacilli, such as *Bacteroides* and *Clostridia* (see Chap. 33). In amebiasis, metronidazole is amebicidal at intestinal and extraintestinal sites of infection. It is a drug of choice for all forms of amebiasis except asymptomatic intestinal amebiasis (in which amebic cysts are expelled in the feces). In trichomoniasis, metronidazole is more effective than any locally active agent.

Metronidazole is contraindicated during the first trimester of pregnancy and must be used with caution in patients with central nervous system (CNS) or blood disorders. Patients should also avoid all forms of ethanol while on this medication.

**Tetracycline** and **doxycycline** are antibacterial drugs (see Chap. 32) that act against amebae in the intestinal lumen by altering the bacterial flora required for amebic viability. One of these drugs may be used with other amebicides in the treatment of all forms of amebiasis except asymptomatic intestinal amebiasis.

**Tinidazole** (Tindamax), a chemical relative of metronidazole, is approved for the treatment of amebiasis, giardiasis, and trichomoniasis. It is metabolized in the liver by cytochrome P450 3A4 enzymes and should be used cautiously in people with impaired liver function. The most common adverse effects are a metallic/bitter taste and nausea.

## Applying Your Knowledge: 37-1

What important information about contraindications to metronidazole should you teach to Ms. Michelsen?

### Antimalarial Agents

**Chloroquine** is a widely used antimalarial agent. It acts against erythrocytic forms of plasmodial parasites to prevent or treat malarial attacks. When used for prophylaxis, it is given before, during, and after travel or residence in endemic areas. When used for treatment of malaria caused by *P. vivax*, *P. malariae*, or *P. ovale*, chloroquine relieves symptoms of the acute attack. However, the drug does not prevent recurrence of malarial attacks because it does not act against the tissue (exoerythrocytic) forms of the parasite. When used for treatment of malaria caused by *P. falciparum*, chloroquine relieves symptoms of the acute attack and eliminates the parasite from the body because *P. falciparum* does not form tissue reservoirs. Concern about chloroquine-resistant strains of *P. falciparum* has developed in many areas.

Chloroquine is also used in protozoal infections other than malaria, including extraintestinal amebiasis and giardiasis. It should be used with caution in patients with hepatic disease or severe neurologic, GI, ocular, or blood disorders.

**Hydroxychloroquine** (Plaquenil) is a derivative of chloroquine with essentially the same actions and uses with fewer adverse effects. It has also been used to treat rheumatoid arthritis and lupus erythematosus.

**Chloroquine with primaquine** is a mixture available in tablets containing chloroquine phosphate 500 milligrams (equivalent to 300 mg of chloroquine base) and primaquine phosphate 79 milligrams (equivalent to 45 mg of primaquine base). This combination is effective for prophylaxis of malaria and may be more acceptable to patients. It also may be more convenient for use in children because no pediatric formulation of primaquine is available.

**Atovaquone and proguanil** (Malarone) is a combination product with adult and pediatric formulations. The drugs inhibit different pathways in plasmodial reproduction. Malarone is used for prevention and treatment of malaria, including chloroquine-resistant strains.

**Mefloquine** (Lariam) is used to prevent *P. falciparum* malaria, including chloroquine-resistant strains, and to treat acute malaria caused by *P. falciparum* or *P. vivax*.

**Primaquine** is used to prevent the initial occurrence of malaria; to prevent recurrent attacks of malaria caused by *P. vivax*, *P. malariae*, and *P. ovale*; and to achieve “radical cure” (i.e., eradicating the tissue forms of the plasmodium and preventing survival of the blood forms) of these three types of malaria. It is especially effective in *P. vivax* malaria. When used to prevent initial occurrence of malaria (causal prophylaxis), primaquine is given concurrently with a suppressive agent (e.g., chloroquine, hydroxychloroquine) after the patient has returned from a malarious area.

Primaquine is not effective for treatment of acute attacks of malaria.

**Quinine** was the primary antimalarial drug for many years but has been largely replaced by synthetic agents that cause fewer adverse reactions. However, it may still be used in the treatment of chloroquine-resistant *P. falciparum* malaria. Quinine also relaxes skeletal muscles and has been used for prevention and treatment of nocturnal leg cramps.

### Other Antiprotozoal Agent

**Nitazoxanide** (Alinia) is approved for treatment of diarrhea caused by giardiasis or cryptosporidiosis. It is the first drug approved for treatment of cryptosporidiosis, which may be life threatening in immunocompromised hosts.

### Anthelmintics

**Ivermectin** (Stromectol) is used for numerous parasitic infections and is most active against strongyloidiasis. Ivermectin has also been used for the oral treatment of resistant lice infestations. The drug has relatively few adverse effects but may cause some nausea and vomiting.

**Mebendazole** (Vermox) is a broad-spectrum anthelmintic that is usually the drug of choice for treatment of hookworm, pinworm, roundworm, and whipworm infestations. It is also useful in tapeworm infection. The drug kills helminths by preventing uptake of the glucose necessary for parasitic metabolism. The helminths become immobilized and die slowly, so they may be expelled from the GI tract up to 3 days after drug therapy is completed. Mebendazole acts locally in the GI tract, and little drug is absorbed systemically. The drug is contraindicated during pregnancy because of teratogenic effects in rats; it is relatively contraindicated in children younger than 2 years of age.

**Pyrantel** (Pin-Rid) is effective in infestations of roundworms, pinworms, and hookworms. The drug acts locally to paralyze worms in the intestinal tract. Pyrantel is poorly absorbed from the GI tract, and most of an administered dose may be recovered in feces. Pyrantel is contraindicated in pregnancy and is not recommended for children younger than 1 year of age.

### Scabicides and Pediculicides

**Permethrin** is the drug of choice for both pediculosis and scabies. Although a single application eliminates parasites and ova, two applications are generally recommended. For pediculosis, permethrin is available as a 1% over-the-counter liquid (Nix). For scabies, a 5% permethrin cream (Elimite) is available by prescription and a single application is curative. Permethrin is safer than other scabicides and pediculicides, especially for infants and children.

Permethrin is derived from a chrysanthemum plant, and people with a history of allergy to ragweed or chrysanthemum flowers should use it cautiously. The most frequent adverse effect is pruritus.

To avoid reinfection, close contacts should be treated simultaneously. With pediculosis, clothing and bedding should

be sterilized by boiling or steaming, and seams of clothes should be examined to verify that all lice are eliminated.

**Lindane** is a second-line drug for scabies and pediculosis. It may be used for people who have hypersensitivity reactions or resistance to treatment with permethrin. It is applied topically, and substantial amounts are absorbed through intact skin. CNS toxicity has been reported with excessive use, especially in infants and children. The drug is available in a 1% concentration in a cream, lotion, and shampoo.

**Malathion** (Ovide) is a pediculicide used in the treatment of resistant head lice infestations, and **pyrethrin** preparations (e.g., RID) are available over-the-counter for treatment of pediculosis. These preparations require two applications approximately 10 days apart.

## Nursing Process

### Assessment

Assess for conditions in which antiparasitic drugs are used.

- Assess for exposure to parasites. Although exposure is influenced by many variables (e.g., geographic location, personal hygiene, environmental sanitation), some useful questions may include the following:
  - Does the person live in an institution, an area of poor sanitation, an underdeveloped country, a tropical region, or an area of overcrowded housing? These conditions predispose to parasitic infestations with lice, scabies, protozoa, and worms.
  - Are parasitic diseases present in the person's environment? For example, head lice, scabies, and pinworm infestations often affect school-age children and their families.
  - Has the person recently traveled (within the previous 1–3 weeks) in malarious regions? If so, were prophylactic measures used appropriately?
  - With vaginal trichomoniasis, assess in relation to sexual activity. The disease is spread by sexual intercourse, and sexual partners need simultaneous treatment to prevent reinfection.
  - With pubic (crab) lice, assess sexual activity. Lice may be transmitted by sexual and other close contact and by contact with infested bed linens.
- Assess for signs and symptoms. These vary greatly, depending on the type and extent of parasitic infestation.
  - **Amebiasis.** The person may be asymptomatic; have nausea, vomiting, diarrhea, abdominal cramping, and weakness; or experience symptoms from ulcerations of the colon or abscesses of the liver (amebic hepatitis) if the disease is severe, prolonged, and untreated. Amebiasis is diagnosed by identifying cysts or trophozoites of *E. histolytica* in stool specimens.

- **Malaria.** Initial symptoms may resemble those produced by influenza (e.g., headache, myalgia). Characteristic paroxysms of chills, fever, and copious perspiration may not be present in early malaria. During acute malarial attacks, the cycles occur every 36 to 72 hours. Additional manifestations include nausea and vomiting, splenomegaly, hepatomegaly, anemia, leukopenia, thrombocytopenia, and hyperbilirubinemia. Malaria is diagnosed by identifying the plasmodial parasite in peripheral blood smears (by microscopic examination).
- **Trichomoniasis.** Women usually have vaginal burning, itching, and yellowish discharge; men may be asymptomatic or have symptoms of urethritis. The condition is diagnosed by finding *T. vaginalis* organisms in a wet smear of vaginal exudate, semen, prostatic fluid, or urinary sediment (by microscopic examination). Cultures may be necessary.
- **Helminthiasis.** Light infestations may be asymptomatic. Heavy infestations produce symptoms according to the particular parasitic worm. Hookworm, roundworm, and threadworm larvae migrate through the lungs and may cause symptoms of pulmonary congestion. The hookworm may cause anemia by feeding on blood from the intestinal mucosa; the fish tapeworm may cause megaloblastic or pernicious anemia by absorbing folic acid and vitamin B<sub>12</sub>. Large masses of roundworms or tapeworms may cause intestinal obstruction. The major symptom usually associated with pinworms is intense itching in the perianal area (pruritus ani). Helminthiasis is diagnosed by microscopic identification of parasites or ova in stool specimens. Pinworm infestation is diagnosed by identifying ova on anal swabs, obtained by touching the sticky side of cellophane tape to the anal area. (Early-morning swabs are best because the female pinworm deposits eggs during sleeping hours.)
- **Scabies and pediculosis.** Pruritus is the primary symptom. Secondary symptoms result from scratching and often include skin excoriation and infection (i.e., vesicles, pustules, and crusts). Pediculosis is diagnosed by visual identification of lice or ova (nits) on the patient's body or clothing.

### Nursing Diagnoses

- Deficient Knowledge: Management of disease process and prevention of recurrence
- Deficient Knowledge: Accurate drug administration
- Imbalanced Nutrition: Less Than Body Requirements related to parasitic disease or drug therapy
- Self-Esteem Disturbance related to a medical diagnosis of parasitic infestation
- Noncompliance related to need for hygienic and other measures to prevent and treat parasitic infestations

Nursing Process continues on page 608

## Planning/Goals

### The patient will

- Experience relief of symptoms for which antiparasitic drugs were taken
- Self-administer drugs accurately
- Avoid preventable adverse effects
- Act to prevent recurrent infestation
- Keep appointments for follow-up care

## Interventions

Use measures to avoid exposure to or prevent transmission of parasitic diseases.

- Environmental health measures include the following:
  - Sanitary sewers to prevent deposition of feces on surface soil and the resultant exposure to helminths
  - Monitoring of community water supplies, food-handling establishments, and food-handling personnel
  - Follow-up examination and possibly treatment of household and other close contacts of people with helminthiasis, amebiasis, trichomoniasis, scabies, and pediculosis
  - Mosquito control in malarious areas and prophylactic drug therapy for travelers to malarious areas. In addition, teach travelers to decrease exposure to mosquito bites (e.g., wear long-sleeved, dark clothing; use an effective insect repellent such as DEET; sleep in well-screened rooms or under mosquito netting). These measures are especially needed at dusk and dawn, the maximal feeding times for mosquitoes.
- Personal and other health measures include the following:
  - Maintain personal hygiene (i.e., regular bathing and shampooing, performing hand hygiene before eating or handling food and after defecation or urination).

- Avoid raw fish and undercooked meat. This is especially important for anyone with immunosuppression.
- Avoid contaminating streams or other water sources with feces.
- Control flies and avoid foods exposed to flies.
- With scabies and pediculosis infestations, drug therapy must be accompanied by measures to avoid reinfection or transmission to others. For example, close contacts should be examined carefully and treated if indicated. Clothes, bed linens, and towels should be washed and dried on hot cycles. Clothes that cannot be washed should be dry cleaned. With head lice, combs and brushes should be cleaned and disinfected; carpets and upholstered furniture should be vacuumed.
- With pinworms, clothing, bed linens, and towels should be washed daily on hot cycles. Toilet seats should be disinfected daily.
- Ensure follow-up measures, such as testing of stool specimens; vaginal examinations; anal swabs; smears; and cultures.
- With vaginal infections, avoid sexual intercourse, or have the male partner use a condom.

## Evaluation

- Interview and observe for relief of symptoms.
- Interview outpatients regarding compliance with instructions for taking antiparasitic drugs and measures to prevent recurrence of infestation.
- Interview and observe for adverse drug effects.
- Interview and observe regarding food intake or changes in weight.

## Patient Teaching Guidelines Antiparasitic Drugs

### General Considerations

- Use measures to prevent parasitic infection or reinfection:
  - Support public health measures to maintain a clean environment (i.e., sanitary sewers, clean water, regulation of food-handling establishments and food-handling personnel).
  - When traveling to wilderness areas or to tropical or underdeveloped countries, check with the local health department about precautions needed to avoid parasitic infections.
  - Practice good hand hygiene and other personal hygienic practices.
  - When a family member or other close contact contracts a parasitic infection, be sure appropriate treatment and follow-up care are completed.
  - Avoid raw fish and undercooked meat.
  - With vaginal infections, avoid sexual intercourse or use a condom.

### Self- or Caregiver Administration

- Use antiparasitic drugs as prescribed; their effectiveness depends on accurate use.
- Take atovaquone/proguanil, chloroquine and related drugs, iodoquinol, oral metronidazole, and tinidazole with or after meals. Food increases absorption of atovaquone and decreases gastrointestinal irritation with the other drugs.
- Avoid alcoholic beverages while taking metronidazole or tinidazole and for 3 days after the drugs are stopped. Flushing, headache, nausea, sweating, and vomiting, may occur if alcohol is ingested.
- Take or give most anthelmintics without regard to meal-times or food ingestion. Mebendazole tablets should be chewed or crushed and mixed with food.
- Use pediculicides and scabicides as directed on the label or product insert. Instructions vary among preparations.

### Applying Your Knowledge: 37-2

Ms. Michelsen should be taught measures to prevent parasitic infection or reinfection. What would you include in your teaching plan?

## Principles of Therapy

Antiparasitic drugs should be used along with personal and public health control measures to prevent the spread of parasitic infestations. Specific measures vary according to the type of organism, the environment, and the host.

Many of the drugs described in this chapter are quite toxic; they should be used only when clearly indicated (i.e., laboratory documentation of parasitic infection).

### Use in Special Populations

#### Use in Children

Children often receive an antiparasitic drug for head lice or worm infestations. These products should be used exactly as

directed and with appropriate precautions to prevent reinfection. Malaria is usually more severe in children than in adults, and children should be protected from exposure when possible. When chemoprophylaxis or treatment for malaria is indicated, the same drugs are used for children as for adults, with appropriate dosage adjustments. The tetracyclines are an exception and should not be given to children younger than 8 years of age.

#### Use in Older Adults

Older adults are more likely to experience adverse effects of antiparasitic drugs because they often have impaired renal and hepatic function.

#### Use in Home Care

Most antiparasitic drugs are given in the home setting. The home care nurse may need to examine close contacts of the infected person and assess their need for treatment, assist parents and patients so that drugs are used appropriately, and teach personal and environmental hygiene measures to prevent reinfection. When children have parasitic infestations, the home care nurse may need to collaborate with daycare centers and schools to prevent or control outbreaks.

## Nursing Actions Antiparasitics

### NURSING ACTIONS

#### 1. Administer accurately

- Give atovaquone/proguanil, chloroquine and related drugs, iodoquinol, oral metronidazole, and tinidazole with or after meals.
- Give anthelmintics with or without food. Mebendazole tablets may be chewed, swallowed, or crushed and mixed with food.
- For pediculicides and scabicides, follow the label or manufacturer's instructions.

#### 2. Observe for therapeutic effects

- With chloroquine for acute malaria, observe for relief of symptoms and negative blood smears.
- With amebicides, observe for relief of symptoms and negative stool examinations.
- With anthelmintics, observe for relief of symptoms, absence of the parasite in blood or stool for three consecutive examinations, or a reduction in the number of parasitic ova in the feces.
- With pediculicides, inspect affected areas for lice or nits.

#### 3. Observe for adverse effects

- With amebicides, observe for anorexia, nausea, vomiting, epigastric burning, diarrhea.
- With antimalarial agents, observe for nausea, vomiting, diarrhea, pruritus, skin rash, headache, central nervous system (CNS) stimulation.

### RATIONALE/EXPLANATION

Food improves absorption of atovaquone and decreases gastrointestinal (GI) irritation with the other drugs.

Food does not decrease effectiveness of most anthelmintics.

Instructions vary among preparations.

Fever and chills usually subside within 24–48 hours, and blood smears are negative for plasmodia within 24–72 hours.

Relief of symptoms does not indicate cure of amebiasis; laboratory evidence is required. Stool specimens should be examined for amebic cysts and trophozoites periodically for 6 months.

The goal of anthelmintic drug therapy may be complete eradication of the parasite or reduction of the “worm burden.”

For most patients, one treatment is effective; for some, a second treatment may be needed.

GI effects may occur with all amebicides.

These effects may occur with most antimalarial agents. However, adverse effects are usually mild because small doses are used for prophylaxis, and the larger doses required for treatment of acute attacks are given only for short periods.

## Nursing Actions Antiparasitics (continued)

### NURSING ACTIONS

- c. With metronidazole and tinidazole, observe for GI upset (e.g., nausea, diarrhea, unpleasant taste), dizziness, headache, peripheral neuropathy, seizures.
- d. With topical antitrichomonal agents, observe for hypersensitivity reactions (e.g., rash, inflammation), burning, and pruritus.
- e. With permethrin, observe for pruritus, burning, or tingling; with Lindane, observe for CNS stimulation (nervousness, tremors, insomnia, convulsions).

#### 4. Observe for drug interactions

- a. Drugs that alter effects of chloroquine:
  - (1) Acidifying agents (e.g., ascorbic acid)
  - (2) Alkalinizing agents (e.g., sodium bicarbonate)
  - (3) Monoamine oxidase (MAO) inhibitors
- b. Drugs that alter effects of metronidazole and tinidazole:
  - (1) Enzyme inducers (e.g., phenytoin, rifampin)
  - (2) Enzyme inhibitors (e.g., cimetidine)
- c. Drugs that decrease effects of atovaquone/proguanil:
  - (1) Rifampin and other drugs that induce cytochrome P450 drug-metabolizing enzymes in the liver

### RATIONALE/EXPLANATION

CNS effects are most serious; GI effects are most common.

Hypersensitivity reactions are the major adverse effects.

Antihistamines or topical corticosteroids may be used to decrease itching. CNS toxicity is more likely to occur with excessive use of Lindane (i.e., increased amounts, leaving in place longer than prescribed, or applying more frequently than prescribed).

Few clinically significant drug interactions occur because many antiparasitic agents are administered for local effects in the GI tract or on the skin. Most of the drugs also are given for short periods.

Accelerate urinary excretion

Slow urinary excretion

Increase risk of toxicity and retinal damage by inhibiting metabolism

Decrease effects by accelerating hepatic metabolism

Increase effects by inhibiting hepatic metabolism

Although few interactions have been reported, any enzyme-inducing drug can potentially decrease effects by accelerating hepatic metabolism.

## Key Concepts

- Parasitic infestations injure host tissues.
- Travelers to malarious regions should generally receive chloroquine to prevent malaria and take precautions to avoid or minimize exposure to the causative mosquito.
- Personal and public health hygienic practices can prevent many parasitic infections and should be followed diligently.
- Antiparasitic drugs are usually given for local effects in the GI tract or on the skin.

## Review and Application Exercises

### Short Answer Exercises

1. What groups are at risk for development of parasitic infections (e.g., amebiasis, giardiasis, malaria, pediculosis, helminthiasis)?
2. What interventions are needed to prevent parasitic infections?
3. How would you assess for a parasitic infection in a patient who has been in an environment associated with a particular infestation?
4. How can you assess a patient's personal hygiene practices and environmental sanitation facilities?
5. How would you instruct a child's mother regarding treatment and prevention of reinfection with head lice or pinworms?
6. What are adverse effects of commonly used antiparasitic drugs, and how might they be prevented or minimized?

### NCLEX-Style Questions

7. A patient being treated for amebiasis should be informed by the nurse that which of the following adverse drug effects may occur?
  - a. dizziness and numbness of extremities
  - b. weight gain and reduced urine output
  - c. nausea, vomiting, and diarrhea
  - d. low blood pressure and tachycardia, or a feeling of racing heartbeat
8. For a patient taking metronidazole (Flagyl) for trichomoniasis, which of the following statements indicates understanding of the nurse's instructions for safe drug usage?
  - a. "I will limit my intake of caffeine."
  - b. "I will eat a low-sodium diet for a week."
  - c. "I will increase my daily intake of potassium."
  - d. "I will not drink any alcoholic beverages."
9. The drug of choice for prevention or treatment of *Pneumocystis pneumonia* is
  - a. trimethoprim-sulfamethoxazole (Bactrim)
  - b. trimetrexate (Neutrexin)
  - c. mebendazole (Vermox)
  - d. permethrin (Nix, Elimate)
10. A usual drug of choice for prevention or treatment of malaria is
  - a. chloroquine (Aralen)
  - b. metronidazole (Flagyl)
  - c. pentamidine (Pentam 300)
  - d. pyrantel (Pin-Rid)
11. Patients taking antiparasitic drugs should be taught
  - a. that adverse drug effects are often severe
  - b. to have blood tests weekly
  - c. ways to prevent reinfection
  - d. that prior infection confers immunity to most parasitic infections

## Drugs Affecting Hematopoiesis and the Immune System

### Chapter Outline

- 38** ■ Physiology of the Hematopoietic and Immune Systems
- 39** ■ Immunizing Agents
- 40** ■ Hematopoietic and Immunostimulant Drugs
- 41** ■ Immunosuppressants
- 42** ■ Drugs Used in Oncologic Disorders

# Physiology of the Hematopoietic and Immune Systems

## KEY TERMS

- Acquired immunity
- Active immunity
- Antibody
- Antigen
- Complement
- Cytokines
- Hematopoiesis
- Immunoglobulins
- Innate or natural immunity
- Macrophage
- Phagocytosis
- Passive immunity

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review hematopoiesis, body defense mechanisms, and immune mechanisms.
2. Differentiate between cellular and humoral types of immunity.
3. Describe the antigen–antibody reaction.
4. Discuss roles of various white blood cells in the immune response.
5. Describe the functions and roles of cytokines and hematopoietic growth factors.
6. Discuss selected factors that affect hematopoietic and immune system functions.
7. Discuss selected connections between the immune system and cancer.

## Introduction

Hematopoietic and immune blood cells originate in bone marrow in stem cells, which are often called pluripotent stem cells because they are capable of becoming different types of cells. As these stem cells reproduce, some cells are exactly like the original cells and are retained in bone marrow to maintain a continuing supply. However, most reproduced stem cells differentiate to form other types of cells. The early offspring are committed to become a particular type of cell, and a committed stem cell that produces a cell type is called a colony-forming unit (CFU) (e.g., CFU-erythrocyte, CFU-granulocyte). Hematopoietic growth factors or cytokines control the reproduction, growth, and differentiation of stem cells and CFUs. They also initiate the processes required to produce fully mature cells. Overall, cytokines are involved in numerous physiologic responses, including *hematopoiesis*, cellular proliferation and differentiation, inflammation, wound healing, and cellular and humoral immunity.

## Hematopoietic Cytokines

*Cytokines* are diverse substances produced mainly by bone marrow and white blood cells. They regulate many cellular activities by acting as chemical messengers among cells and as growth factors for blood cells.

Cytokines act by binding to receptors on target cells. After binding, the cytokine–receptor complexes trigger signal-transduction pathways that alter gene expression in the target cells. Cytokine actions and functions are affected by several factors. First, cytokines affect any cells they encounter that have cytokine receptors and are able to respond; they do not act in response to specific

antigens. However, cytokine receptors are often expressed on a cell only after that cell has interacted with an *antigen*, so that cytokine activation is limited to antigen-activated lymphocytes. Second, the actions of most cytokines have been determined in laboratories by analysis of the effects of recombinant cytokines, often at nonphysiologic concentrations, and added individually to *in vitro* systems. Within the human body, however, cytokines rarely, if ever, act alone. Instead, a target cell is exposed to an environment containing a mixture of cytokines, which may have synergistic or antagonistic effects on each other. Third, cytokines often induce the synthesis of other cytokines. The resulting interactions among cytokines may profoundly alter physiologic responses. Fourth, proteins that act as cytokine antagonists are found in the bloodstream and other extracellular fluids. These proteins may bind directly to a cytokine and inhibit its activity or bind to a cytokine receptor but fail to activate the cell. The main groups of cytokines are colony-stimulating factors (CSFs), interferons, and interleukins. Especially important or clinically relevant cytokines are emphasized in this chapter.

### Colony-Stimulating Factors (CSFs)

CSFs stimulate the production of red blood cells (erythropoietin), platelets (thrombopoietin), granulocytes (G-CSF), granulocyte–macrophages (GM-CSF), and monocyte–macrophages (M-CSF). In addition to granulocytes (neutrophils, basophils, and eosinophils), G-CSF also affects other blood cells (e.g., erythrocytes, platelet precursors, macrophages). Interleukin-3 (IL-3) is sometimes called multi-CSF because it stimulates the production of all types of blood cells.

### Interferons

Interferons “interfere” with the ability of viruses in infected cells to replicate and spread to uninfected cells. They also inhibit reproduction and growth of other cells, including tumor cells, and activate natural killer (NK) cells. These antiproliferative and immunomodulatory activities play important roles in normal host defense mechanisms.

### Interleukins (ILs)

ILs were initially named because they were thought to be produced by and to act only on leukocytes. However, they can be produced by body cells other than leukocytes and they can act on nonhematopoietic cells. Eighteen interleukins have been characterized and more have been identified. Especially important ILs include IL-3 (stimulates growth of stem-cell precursors of all blood cells), IL-2 (stimulates T and B lymphocytes), IL-12 (stimulates hematopoietic cells and lymphocytes), and IL-11 (stimulates platelets and other cells). Interleukin action may occur only when combined with another factor, may be suppressive rather than stimulatory (e.g., IL-10), or may involve a specific function (e.g., IL-8 mainly promotes movement of leukocytes into injured tissues as part of the inflammatory response).

## Overview of Body Defense Mechanisms

The immune system is one of several mechanisms that protect the body from potentially harmful substances, including pathogenic microorganisms. The body’s primary external defense mechanism is intact skin, which prevents entry of foreign substances and produces secretions that inhibit microbial growth. The mucous membranes lining the gastrointestinal (GI) and respiratory tracts are internal defense mechanisms that act as physical barriers and produce mucus that traps foreign substances so they may be expelled from the body. Mucous membranes also produce other secretions (e.g., gastric acid) that kill ingested microorganisms. Additional internal mechanisms include the normal microbial population, which is usually nonpathogenic and controls potential pathogens; and secretions (e.g., perspiration, tears, saliva) that contain lysozyme, an enzyme that destroys the cell walls of gram-positive bacteria.

If a foreign substance gets through defenses to penetrate body tissues and cause cellular injury, an inflammatory response begins immediately. Cellular injury may be caused by chemicals, hypoxia, ischemia, microorganisms, excessive heat or cold, radiation, and nutritional deficiencies or excesses. The cellular response to injury involves inflammation, a generalized reaction to any tissue damage, which attempts to remove the damaging agent and repair the damaged tissue. The hemodynamic aspect of inflammation includes vasodilation, which increases blood supply to the injured area, and increased capillary permeability, which allows fluid to leak into tissue spaces. The cellular aspect involves the movement of white blood cells (WBCs) into the area of injury. WBCs are attracted to the injured area by bacteria, tissue debris, plasma protein fractions (complement), and other substances, in a process called chemotaxis. After they reach the area, they phagocytize causative agents and tissue debris.

The final defense mechanism is the immune response, and an effective response involves lymphoid cells, inflammatory cells, and hematopoietic cells. The immune response stimulates production of antibodies and activated lymphocytes to destroy foreign invaders and mutant body cells (e.g., abnormal cells, cancer cells).

Inflammatory and immune responses interact in complex ways and share a number of processes, including phagocytosis. They produce their effects indirectly, through interactions among cytokines and other chemical mediators. Cytokines induce WBC replication, phagocytosis, antibody production, fever, inflammation, and tissue repair. Other chemical mediators (e.g., histamine, prostaglandins) are synthesized or released by mast cells and other cells. After they are activated, mediators may exert their effects on tissues locally or at distant target sites. They also may induce or enhance other mediators.

## Immunity

Immunity indicates protection from a disease, and the main function of the immune system is host protection. To this end, the immune system detects and eliminates foreign substances that may cause tissue injury or disease. It also regulates tissue homeostasis and repair as cells of the immune system identify and remove injured, damaged, dead, or malignant cells.

To perform these functions, the immune system must be able to differentiate body tissues (self) from foreign substances (non-self). Self tissues are recognized by distinctive protein molecules on the surface membranes of body cells. These molecules or markers are encoded by a group of genes called the major histocompatibility complex (MHC). MHC markers are essential to immune system function because they regulate the antigens to which a person responds and allow immune cells (e.g., lymphocytes, *macrophages*) to recognize and communicate with each other. Non-self or foreign antigens are also recognized by distinctive molecules, called epitopes, on their surfaces. Epitopes vary widely in type, number, and ability to elicit an immune response.

A normally functioning immune system does not attack body tissues labeled as self but attacks non-self substances. An abnormally functioning immune system causes numerous diseases. When the system is hypoactive, immunodeficiency disorders develop because the person is highly susceptible to infectious and neoplastic diseases. When the system is hyperactive, it perceives ordinarily harmless environmental substances (e.g., foods, plant pollens) as harmful and induces allergic reactions. When the system is inappropriately activated (it loses its ability to distinguish between self and non-self, so an immune response is aroused against the host's own body tissues), the result is autoimmune disorders such as rheumatoid arthritis and systemic lupus erythematosus (SLE). Many other disorders, including diabetes mellitus, myasthenia gravis, and inflammatory bowel diseases, are thought to involve autoimmune mechanisms. To aid understanding of the immune response and drugs used to alter immune response, more specific characteristics, processes, and functions of the immune system are described.

### Types of Immunity

*Innate or natural immunity*, which is not produced by the immune system, includes the general protective mechanisms described.

Adaptive or *acquired immunity* develops during gestation or after birth and may be active or passive. *Active immunity* is produced by the person's own immune system in response to a disease caused by a specific antigen or administration of an antigen (e.g., a vaccine) from a source outside the body, usually by injection. The immune response stimulated by the antigen produces activated lymphocytes and antibodies against the antigen. When an antigen is present for the first time, production of antibodies requires several days. As a result, the serum concentration of antibodies does not reach protective levels for

7 to 10 days, and the disease develops in the host. When the antigen is eliminated, the antibody concentration gradually decreases over several weeks.

The duration of active immunity may be brief (e.g., to influenza viruses), or it may last for years or a lifetime. Long-term active immunity has a unique characteristic called memory. When the host is re-exposed to the antigen, lymphocytes are activated and antibodies are produced rapidly, and the host does not contract the disease. This characteristic allows "booster" doses of antigen to increase antibody levels and maintain active immunity against some diseases.

*Passive immunity* occurs when antibodies are formed by the immune system of another person or animal and transferred to the host. For example, an infant is normally protected for several months by maternal antibodies received through the placenta during gestation. Also, antibodies previously formed by a donor can be transferred to the host by an injection of immune serum. These antibodies act against antigens immediately. Passive immunity is short-term, lasting only a few weeks or months.

### Cellular and Humoral Immunity

Types of adaptive immunity are separated into cellular immunity (mainly involving activated T lymphocytes in body tissues) and humoral immunity (mainly involving B lymphocytes and antibodies in the blood). However, the two types are closely connected so that virtually all antigens elicit both cellular and humoral responses and most humoral (B cell) responses require cellular (T cell) stimulation.

Although most humoral responses occur when antibodies or B cells encounter antigens in blood, some occur when antibodies or B cells encounter antigens in other body fluids (e.g., tears, sweat, saliva, mucus, breast milk). The antibodies in body fluids other than blood are produced by a part of humoral immunity sometimes called the secretory or mucosal immune system. The B cells of the mucosal system migrate through lymphoid tissues of tear ducts, salivary glands, breasts, bronchi, intestines, and genitourinary structures. The antibodies (mostly immunoglobulin A [IgA]) secreted at these sites act locally rather than systemically. This local protection combats foreign substances, especially pathogenic microorganisms, that are inhaled, swallowed, or otherwise come in contact with external body surfaces. When the foreign substances bind to local antibodies, they are unable to attach to and invade mucosal tissue.

### Antigens

Antigens are the foreign (non-self) substances (e.g., microorganisms, other proteins, polysaccharides) that initiate immune responses. Antigens have specific sites that interact with immune cells to induce the immune response. The number of antigenic sites on a molecule depends largely on its molecular weight. Large protein and polysaccharide molecules are complete antigens because of their complex chemical structure and multiple antigenic sites. Smaller molecules (e.g., animal danders, plant pollens, most drugs) are incomplete antigens (called

haptens) and cannot act as antigens by themselves. However, they have antigenic sites and can combine with carrier substances to become antigenic. In discussions of hypersensitivity (allergic) conditions, antigens are often called allergens.

### Immune Responses to Antigens

The immune response involves antigens that induce the formation of antibodies or activated T lymphocytes. The initial response occurs when an antigen is first introduced into the body. B lymphocytes recognize the antigen as foreign and develop antibodies against it. Antibodies are proteins called *immunoglobulins* (Ig) that interact with specific antigens.

Antigen–antibody interactions may result in formation of antigen–antibody complexes, agglutination (clumping) of cells, neutralization of bacterial toxins, destruction of pathogens or cells, attachment of antigen to immune cells, coating of the antigen so that it is more readily recognized by phagocytic cells (opsonization), or activation of *complement* (a group of plasma proteins activated by recognition of an antigen–antibody complex, bacteria, or viruses and essential to normal inflammatory and immunologic responses). Activated complement stimulates chemotaxis (movement of monocytes, neutrophils, basophils, and eosinophils toward the antigen) and the release of hydrolytic enzymes, actions that result in the destruction or inactivation of the invading antigen. With a later exposure to the antigen, *antibody* is rapidly produced. The number of exposures required to produce enough antibodies to bind a significant amount of antigen is unknown. Thus, an allergic reaction may occur with the second exposure or after several exposures, when sufficient antibodies have been produced.

Antigen–T lymphocyte interactions stimulate production and function of other T lymphocytes and help to regulate antibody production by B lymphocytes. T cells are involved in delayed hypersensitivity reactions, rejection of tissue or organ transplants, and responses to neoplasms and some infections.

## Immune Cells

Immune cells (Fig. 38-1) are WBCs that circulate in the blood and lymphatic vessels or reside in lymphoid tissues. These cells are present in virtually all body tissues, and their ability to circulate throughout the body and to migrate between blood and lymphoid tissues are major components of host defenses. The cells are activated by exposure to an antigen. Although all WBCs play a role, neutrophils, monocytes, and lymphocytes are especially important in phagocytic and immune processes.

### Neutrophils

Neutrophils are the major WBCs in the bloodstream and the body's main defense against pathogenic bacteria. They usually arrive at sites of tissue injury within 90 minutes. They localize the area of injury and phagocytize organisms or particles by releasing digestive enzymes and oxidative metabolites that kill

engulfed pathogens or destroy other types of foreign particles. The number of neutrophils increases greatly during the inflammatory process. These cells circulate in the bloodstream for approximately 10 hours, then move into tissues, where they live for 1 to 3 days.

### Eosinophils and Basophils

Eosinophils increase in number and activity during allergic reactions and parasitic infections. In parasitic infections, they bind to and kill the parasites. In hypersensitivity reactions, they produce enzymes that inactivate histamine and leukotrienes and may produce other enzymes that destroy antigen–antibody complexes. Despite these generally beneficial effects, eosinophils also may aggravate tissue damage by releasing cytotoxic substances. Basophils release histamine, a major chemical mediator in inflammatory and immediate hypersensitivity reactions. However, the function of basophils in normal immune responses is not well understood.

### Monocytes

Monocytes arrive several hours after injury and usually replace neutrophils as the predominant WBC within 48 hours. They are the largest WBCs, and their lifespan is much longer than that of the neutrophils. Monocytes can phagocytize larger sizes and amounts of foreign material than neutrophils. In addition to their activity in the bloodstream, monocytes can leave blood vessels and enter tissue spaces, and are then called tissue macrophages. Tissue macrophages are widely distributed in connective tissue and in other areas (e.g., Kupffer's cells in the liver, alveolar macrophages in the lungs, others in the lymph nodes and spleen) and form the mononuclear phagocyte system. Both mobile and fixed monocyte–macrophages are important in inflammatory processes, and both can initiate the immune response by activating lymphocytes. They perform this function as part of *phagocytosis*, in which they engulf a circulating antigen (e.g., foreign material, cellular debris), break it into fragments, combine the fragments with MHC molecules, and return the antigenic fragments to the cell surface. The antigenic fragments are recognized as foreign material by circulating T and B lymphocytes, and an immune response is initiated. Because the monocytes prepare the antigen to interact with T and B lymphocytes, they are called antigen-presenting cells (APCs). In addition to phagocytosis, activated macrophages also secrete many products (e.g., enzymes, cytokines), remove antigen–antibody complexes, remove dying and dead host cells, and can destroy virus-infected cells and tumor cells.

### Dendritic Cells

Dendritic cells are surface macrophages found in peripheral lymphoid and other tissues through which antigens enter the body (e.g., skin, mucosa, bronchial airways). They are star-shaped, with a large surface area through which they can recognize, capture, and ingest antigens. Their main function is the presentation of antigen to T lymphocytes, which activates the T cells and initiates the adaptive immune response. Dendritic

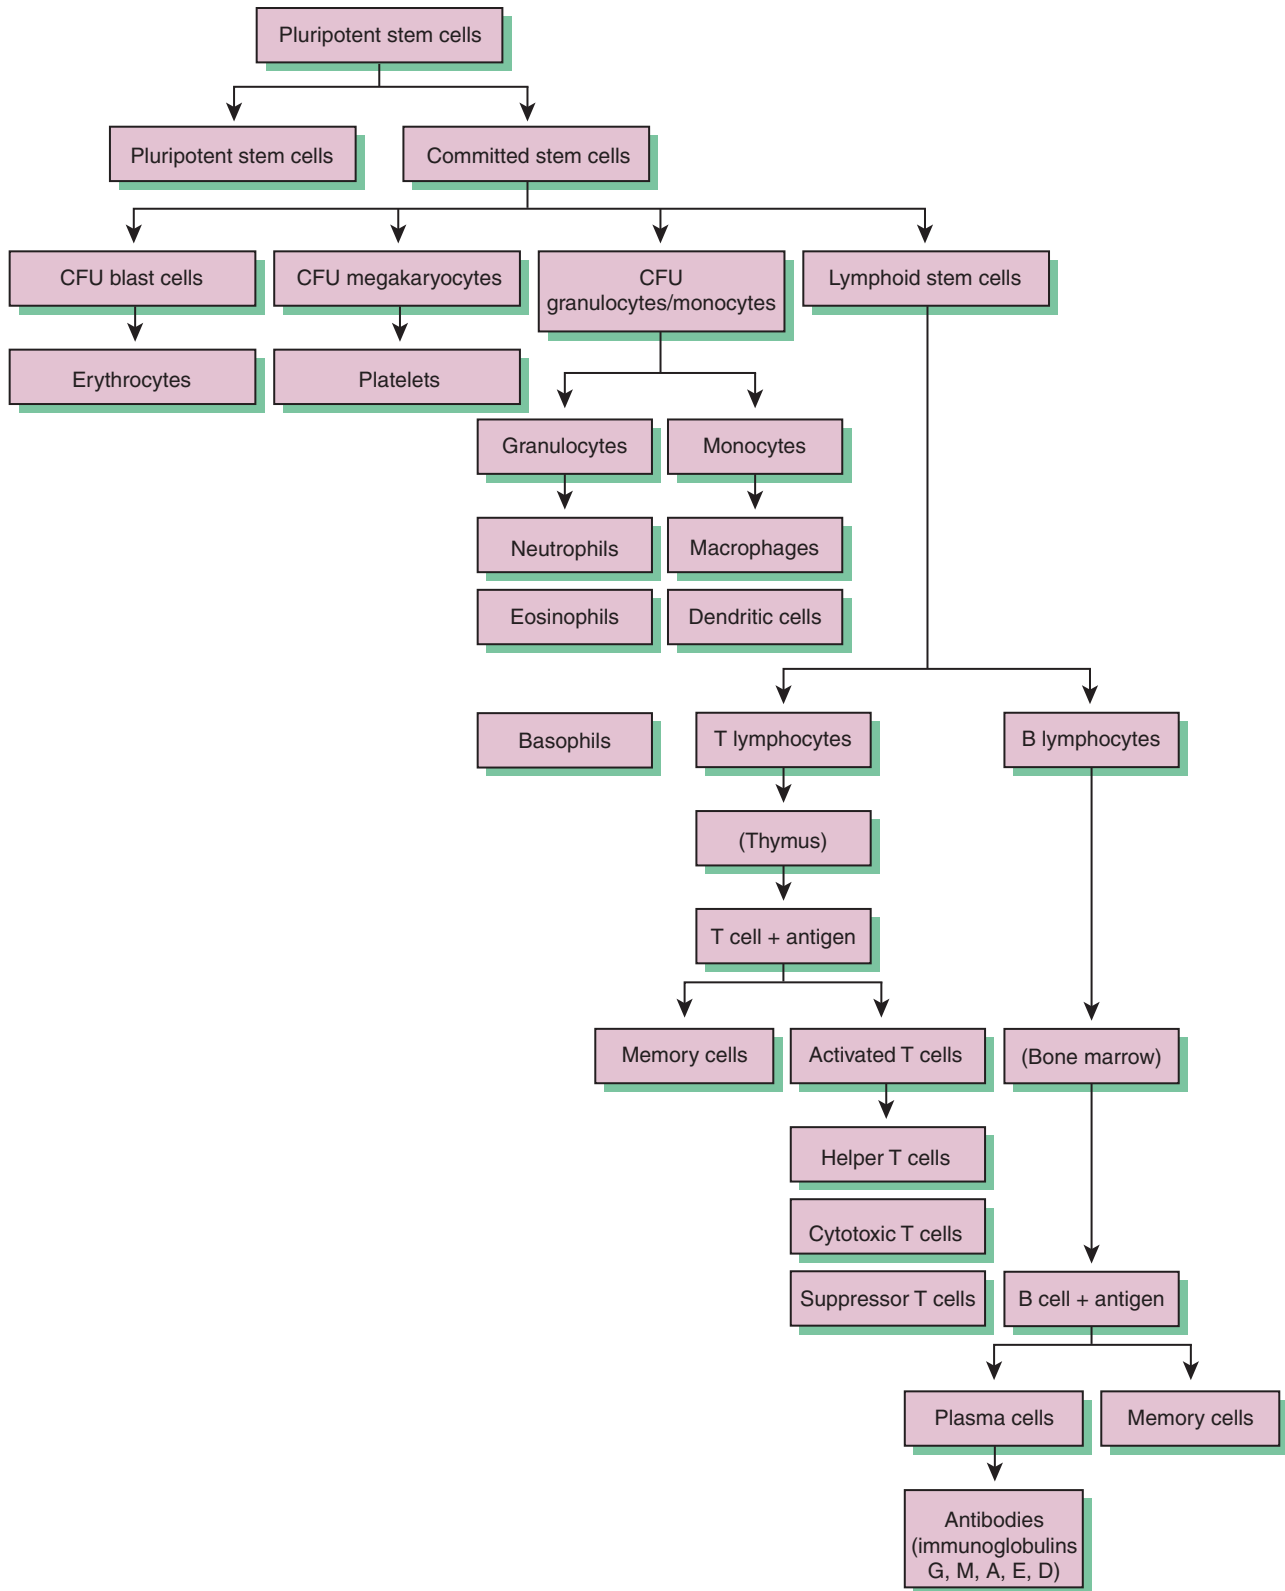

Figure 38-1 ■ Hematopoiesis and formation of immune cells. CFU, colony-forming unit.

cells become active APCs when stimulated by injury or cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) or interferon  $\alpha$ . Activation also causes the antigen-containing cells to enter lymph vessels and migrate to regional lymph nodes, where T cells are located.

## Lymphocytes

Lymphocytes are the main immune cells, and those in tissues are in dynamic equilibrium with those in circulating blood. These cells continuously travel through blood and lymph vessels from one lymphoid organ to another. The three types of lymphocytes are NK cells, T cells, and B cells.

### Natural Killer Cells

Natural killer cells, so called because they do not need to interact with a specific antigen to become activated, destroy infectious microorganisms and malignant cells by releasing powerful chemicals. These cells are thought to provide the first line of defense against viral infections and other intracellular pathogens while adaptive immune responses are being generated. NK cells are sensitized by cytokines released from macrophages and dendritic cells. They function mainly by secreting interferon gamma, which activates macrophages and other cells. In addition to their ability to kill virus-infected cells, they are thought to kill certain tumor cells.

### T Lymphocytes

T lymphocytes, the main regulators of the immune response, are involved in both cell-mediated and humoral immunity because they direct the activities of B cells and macrophages. T cells must be activated by antigens before they can fulfill their immune functions, and they have proteins on their cell-membrane surfaces that act as receptors for antigens.

Each T cell reacts only with a specific type of antigen and is capable of forming only one type of T cell. When a specific antigen attaches to cell-membrane receptors to form an antigen-antibody complex, the complex activates the T cell to form tremendous numbers of duplicate T cells (clones) that are exactly like the parent cell. T-cell clones are sensitized or activated T cells that are released into lymphatic ducts, carried to the blood, circulated through all tissue fluids, then returned to lymphatic ducts and recirculated. Additional participants in the activation process are phagocytic macrophages and helper T cells, which secrete cytokines that regulate the growth, reproduction, and function of lymphocytes.

T lymphocytes originate in stem cells in the bone marrow and differentiate into immune cells in the thymus gland. The thymus produces a substance called thymosin, which is necessary for T-cell maturation. When T cells bind with an antigen, specific genes are activated to produce substances that direct T-cell proliferation and differentiation. One such substance is IL-2, which stimulates T-cell DNA replication and mitosis. Cell division is necessary for production of large numbers of antigen-reactive cells and for cellular changes associated with the different subgroups of T cells. Specific types and functions of T cells include the following:

- Helper T cells (also called  $T_h$  or CD4+ cells), the largest subgroup, regulate virtually all immune functions by producing cytokines. The cytokines stimulate the growth of bone marrow and other cells of the immune system (e.g., cytotoxic T and B cells). They also activate macrophages and facilitate phagocytosis. Important cytokines include IL-2, -3, -4, -5, and -6; GM-CSF; and interferon gamma.

Subsets of helper T cells have recently been identified as  $T_{h1}$ ,  $T_{h2}$ , and suppressor T cells. Both  $T_{h1}$  and  $T_{h2}$  cells secrete IL-3 and GM-CSF but differ in the other cytokines they secrete. The  $T_{h1}$  subset is responsible for many cell-mediated functions (e.g., delayed-type hypersensitivity reactions, activation of cytotoxic T cells) and for the production of IgG antibodies that promote recognition of antigens. These cells are also associated with excessive inflammation and tissue injury. The  $T_{h2}$  subset stimulates the activation of eosinophils and stimulates B cells (e.g., to produce immunoglobulins such as IgM and IgE). These cells are also associated with hypersensitivity reactions. Suppressor T cells are thought to stop the immune response (i.e., decrease the activities of B cells and other T cells) when an antigen has been destroyed. This activity is important in preventing further tissue damage.

- Cytotoxic T cells (also called TC or CD8+ cells) are recruited and activated by helper T cells (i.e., helper T cells secrete IL-2, which is necessary for activation and proliferation of cytotoxic T cells). When activated by antigen and IL-2, cytotoxic T cells bind to antigens on the surfaces of target cells and damage or kill the target cells. After damaging the target cells, the cytotoxic cells can detach themselves and attack other target cells.

Cytotoxic T cells persist in tissues for months and are especially lethal to virus-infected cells because virus particles become entrapped in the membranes of the cells and act as strong antigens that attract the T cells. These T cells can also destroy malignant cells, transplanted organs, and play a role in delayed hypersensitivity reactions.

### B Lymphocytes

B cells are involved in humoral immunity; they secrete antibodies that can neutralize pathogens before their entry into host cells. B cells must be activated by antigens before they can fulfill their immune functions, and they have proteins on their cell-membrane surfaces that act as receptors for antigens. Each B lymphocyte reacts only with a specific type of antigen and is capable of forming only one type of antibody. When a specific antigen attaches to cell-membrane receptors to form an antigen-antibody complex, the complex activates the lymphocyte to form tremendous numbers of duplicate lymphocytes (clones) that are exactly like the parent cell. Clones of a B lymphocyte eventually secrete antibodies that circulate throughout the body.

B lymphocytes originate in stem cells in the bone marrow, differentiate into cells capable of forming antibodies (also in the bone marrow), and migrate to the spleen, lymph nodes, or other lymphoid tissue. In lymphoid tissue, the cells may be

dormant until exposed to an antigen. In response to an antigen and IL-2 from helper T cells, B cells multiply rapidly, enlarge, and differentiate into plasma cells, which then produce antibodies (immunoglobulins [Ig]) to oppose the antigen. Immunoglobulins are secreted into lymph and transported to the bloodstream for circulation throughout the body. There are five main classes of immunoglobulins:

1. IgG is the most abundant immunoglobulin. It protects against bacteria, toxins, and viruses as it circulates in the bloodstream. Molecules of IgG combine with molecules of antigen, and the antigen–antibody complex activates complement. Activated complement causes an inflammatory reaction, promotes phagocytosis, and inactivates or destroys the antigen. IgG also crosses the placenta to provide maternally acquired antibodies (passive immunity) to the infant.
2. IgA is the main immunoglobulin in mucous membranes and body secretions. It is found in saliva, breast milk, and nasal, respiratory, prostatic, and vaginal secretions. It protects against antigens that gain access to these areas (e.g., it prevents attachment of viruses and bacteria to mucous membranes).
3. IgM protects against bacteria, toxins, and viruses that gain access to the bloodstream. It acts only in the bloodstream, because its large molecular size prevents its movement through capillary walls. It activates complement to destroy microorganisms.
4. IgE binds to mast cells and basophils. It is present in body fluids and readily enters body tissues. It is involved in parasitic infections and hypersensitivity reactions, including anaphylaxis. IgE sensitizes mast cells, which then release histamine and other chemical mediators that cause bronchoconstriction, edema, urticaria, and other manifestations of allergic reactions. IgE does not activate complement. The production of IgE is stimulated by T lymphocytes and IL-4, -5, and -6 and is inhibited by the interferons. Small amounts of IgE are present in the serum of nonallergic people; larger amounts are produced by people with allergies.
5. IgD is found on the cell membranes of B lymphocytes. It functions as an antigen receptor for initiating the differentiation and maturation of B lymphocytes.

## Immune System Cytokines

Cytokines (Fig. 38-2) regulate the immune response by stimulating or inhibiting the activation, proliferation, and differentiation of various cells and by regulating the secretion of antibodies or other cytokines. They are secreted when immune cells are activated by antigens or other cytokines and are the primary means of communication between immune cells and other body tissues. Although the hematopoietic cytokines described include the immune system cytokines, the emphasis here is on those that affect immune cells. It is thought that

cytokines formed by activated macrophages enter the bone marrow, where they induce the synthesis and release of other cytokines that activate resting stem cells to produce more granulocytes and monocytes–macrophages. Newly formed granulocytes and monocytes leave the bone marrow and enter the circulating blood in approximately 3 days.

Cytokine binding to target cells elicits wide-ranging effects, including increased production of other cytokines. In general, the cytokines secreted by antigen-activated lymphocytes can affect the activity of most cells involved in the immune response. For example, cytokines produced by activated helper T cells influence the activity of B cells, cytotoxic T cells, NK cells, macrophages, granulocytes, and hematopoietic stem cells. As a result, a network of interacting cells is activated.

Some cytokines increase macrophage activity and phagocytosis. Some, especially IL-2, stimulate helper T cells and enhance the antiantigenic activity of the entire immune system. IL-4, -5, and -6 are especially important in B-cell activities.

*Tumor necrosis factors* (TNFs) are produced by activated macrophages and other cells and act on many immune and nonimmune target cells. They stimulate the inflammatory response and have cytotoxic effects on tumor cells. TNF-alpha stimulates production of cytokines; TNF-beta increases phagocytic activity of macrophages and neutrophils.

## Patient-Related Factors That Influence Immune Function

### Age

#### Fetuses and Neonates

During the first few months of gestation, the fetal immune system is deficient in antibody production and phagocytic activity. During the last trimester, the fetal immune system may be able to respond to infectious antigens, such as cytomegalovirus, rubella virus, and *Toxoplasma*. However, most fetal protection against infectious microorganisms is by maternal antibodies that reach the fetal circulation through the placenta.

At birth, the neonatal immune system is still immature, but IgG levels (from maternal blood) are near adult levels in umbilical cord blood. However, the source of maternal antibodies is severed at birth. Antibody titers in infants decrease over approximately 6 months as maternal antibodies are catabolized. Although the infant does start producing IgG, the rate of production is lower than the rate of breakdown of maternal antibodies. Cell-mediated immunity is functional at birth.

#### Older Adults

Both humoral and cell-mediated immune functions decline with aging, and this decline is probably a major factor in the older adult's increased susceptibility to infections and neoplasms. Lymphocytes are less able to proliferate in response

**Figure 38-2** ■ Macrophage and T-cell cytokines, their target cells, and the products of target cells. These elements overlap and interact to regulate the immune response. CSF, colony-stimulating factor; G-CSF, granulocyte-colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; Ig, immunoglobulin; IL, interleukin; M-CSF, monocyte-macrophage colony-stimulating factor; RBCs, red blood cells; Tc, cytotoxic T cell; Th, helper T cell; TNF, tumor necrosis factor; WBCs, white blood cells.

to antigenic stimulation, and a relative state of immunodeficiency prevails. With T lymphocytes, function is impaired, and the numbers in peripheral blood may be decreased. The functional impairment includes decreased activity of helper T cells. With B lymphocytes, the cells are less able to form antibodies in response to antigens. Abnormal antibody production results

from impaired function of B cells and helper T cells. Other aspects of immune system function also decline with age. For example, older adults have increased blood levels of antibodies against their own tissues (autoantibodies), which may account for the greater frequency of autoimmune diseases in this age group.

Impaired immune mechanisms have several implications for clinicians who care for older patients, including the following:

- Older adults are more likely to develop infections (including reactivation of tuberculosis and herpes zoster) and less able to recover from them. Therefore, older adults need protective measures, such as rigorous personal hygiene; good nutrition; adequate exercise, rest, and sleep; minimal exposure to potential pathogens, when possible; and appropriate immunizations (e.g., influenza, pneumonia, tetanus). When an infection develops in older adults, signs and symptoms (e.g., fever, drainage) may be absent or less pronounced than in younger adults.
- Older adults have impaired immune responses to antigens. Thus, achieving protective antibody titers may require higher doses of immunizing antigens in older adults than in younger adults.
- Older adults often exhibit a less intense positive reaction in skin tests for tuberculosis (indicating a decreased delayed hypersensitivity response).

## Nutritional Status

Nutritional status can have profound effects on immune function. Adequate nutrient intake contributes to immunocompetence (ability of the immune system to function effectively). Malnutrition contributes to immunodeficiency. A severe lack of calories or protein decreases numbers and functions of T cells, complement activity, neutrophil chemotaxis, and phagocytosis. An inadequate zinc intake can depress the functions of T and B cells. Zinc is a cofactor for many enzymes, some of which are found in lymphocytes and are required for lymphocyte function. Zinc deficiency also may result from inadequate absorption in the GI tract or excessive losses in urine, feces, or through the skin with such disorders as chronic renal disease, chronic diarrhea, burns, or severe psoriasis. Vitamin deficiencies may also depress T- and B-cell function because several (e.g., A, E, folic acid, pantothenic acid, pyridoxine) also are enzyme cofactors in lymphocytes.

## Stress

There is evidence that stress depresses immune function and therefore increases risks for development of infection and cancer. The connection between the stress response and the immune response is thought to involve neuroendocrine mechanisms. The stress response is characterized by increased activity of catecholamine neurotransmitters in the central and autonomic nervous systems (e.g., norepinephrine, epinephrine) and increased secretion of cortisol from the adrenal cortex. Cortisol and other corticosteroids are well known to suppress immune function and are used therapeutically for that purpose. The immune response is affected by these neuroendocrine influences on lymphoid organs and lymphocyte functions because lymphocytes have receptors for many neurotransmitters and hormones.

## Immune Disorders

Dysfunction of the immune system is related to many disease processes, including allergic, autoimmune, immunodeficiency, and neoplastic disorders. These disorders are described below to assist in understanding the use of drugs to alter immune functions.

### Allergies

In allergic disorders, the body perceives normally harmless substances (e.g., foods, pollens) as antigens and mounts an immune response. More specifically, IgE binds to antigen on the surface of mast cells and causes the release of chemical mediators (e.g., histamine) that produce the allergic manifestations. These reactions may cause tissue damage ranging from mild skin rashes to life-threatening anaphylaxis.

### Autoimmune Disorders

In autoimmune disorders, the body perceives its own tissues as antigens and elicits an immune response, usually chronic and inflammatory in nature. Hashimoto's thyroiditis, multiple sclerosis, myasthenia gravis, rheumatoid arthritis, systemic lupus erythematosus, and type 1 diabetes mellitus are considered autoimmune disorders. Autoimmune processes, which are similar to the processes elicited by pathogenic microorganisms and environmental antigens, may damage virtually every body tissue.

### Immunodeficiency Disorders

Defects in any immune system components can compromise host protection and increase susceptibility to infections and malignant neoplasms. Immunodeficiency disorders can be inherited or acquired. Common causes of acquired disorders include infection with HIV, advanced age, cytotoxic anticancer chemotherapy, and immunosuppressive drugs used to treat transplant rejection or autoimmune disorders. The HIV paralyzes the immune system by targeting helper T cells, macrophages, and dendritic cells. More specifically, it decreases the numbers and almost all functions of T lymphocytes and several functions of B lymphocytes and monocytes. Advanced age is associated with reduced ability to produce T cells, and chemotherapy is often associated with permanent deficits in the numbers and functions of T cells.

### Neoplastic Disorders

In neoplastic disease, immune cells lose their ability to recognize and destroy mutant cells or early malignant cells. This effect could result from immunodeficiency states or from cancer cells that are overwhelming in number or highly malignant. Mutant cells constantly occur during cell division, but few survive or lead to cancer. Most mutant cells simply die, some survive but retain the normal controls that prevent excessive growth, and some are destroyed by immune processes activated by the abnormal proteins found in most mutant cells.

## Drugs That Alter Hematopoietic and Immune Responses

Drugs that modify the immune system (often called immunomodulators) can enhance or restrict immune responses to various disease processes. Thus, they may be immunostimulants or immunosuppressants. Specific drug groups include hematopoietic growth factors, interferons, interleukins, and monoclonal antibodies. Interferons have antiviral and antiproliferative actions as well as immunomodulatory functions.

These drugs are heterogenous in their uses and characteristics. They are used to prevent or treat symptoms (e.g., anemia, neutropenia) caused by disease processes or their treatments, prevent or treat infections, prevent or treat rejection of transplanted tissues or organs, treat autoimmune disorders, and treat immunodeficiency disorders and cancer. In cancer, the drugs are used to modify host responses, to destroy

tumor cells by suppressing their growth or killing the cells, or to modify tumor cell biology. Vaccines for melanoma and prostate cancer are being investigated.

Methods of modifying immune functions include administering exogenous antigens (e.g., immunizations, desensitization procedures), strengthening antigens (e.g., an antigen that is too weak to elicit an immune response), or suppressing the normal response to an antigen. In desensitization procedures, weak extracts of antigenic substances (e.g., foods, plant pollens, penicillin) are prepared as drugs and administered in small, increasing amounts so the patient develops a tolerance for the substances and avoids serious allergic reactions.

Overall, drugs can be given to stimulate immune responses (see Chap. 39), stimulate hematopoiesis and immune responses (see Chap. 40), suppress normal immune responses (see Chap. 41), and manage various aspects of oncologic disorders (see Chap. 42).

## Key Concepts

- All hematopoietic and immune blood cells are derived from stem cells in the bone marrow.
- Hematopoietic growth factors include G-CSF, M-CSF, GM-CSF, erythropoietin, and thrombopoietin.
- Interferons alfa, beta, and gamma have antiviral and immunomodulating effects.
- Interleukins are important regulators of immune and inflammatory responses.
- T lymphocytes are major regulators of both humoral and cellular immunity.
- B cells produce antibodies in response to antigens. Immunoglobulins (Ig) A, D, G, E, and M are important in immune responses, including allergic disorders.
- Autoimmune disorders occur when the body erroneously perceives its own tissues as antigens and initiates an immune response.

## Review and Application Exercises

### Short Answer Exercises

1. What is the difference between innate and acquired immunity?
2. What are methods of producing active acquired immunity?
3. Which WBCs are phagocytes?
4. Describe phagocytosis.
5. Where are T lymphocytes formed, and what are their functions?
6. Where are B lymphocytes formed, and what are their functions?
7. What are antigens, and how do they elicit an immune response?
8. What are cytokines, and how do they function in the immune response?
9. What is complement, and how does it function in the immune response?
10. What are the main consequences of immunodeficiency states?

# Immunizing Agents

## KEY TERMS

- Active immunity
- Immunization
- Passive immunity
- Toxoids
- Vaccines

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss common characteristics of immunizations.
2. Discuss the importance of immunizations in promoting health and preventing disease.
3. Identify authoritative sources for immunization information.
4. Identify immunizations recommended for children.
5. Identify immunizations recommended for adults.
6. Discuss ways to promote immunization of all age groups.
7. Teach parents about recommended immunizations and record keeping.

## Applying Your Knowledge

Deborah Stein is a 29-year-old woman who is planning a trip abroad this year. She is visiting her health care provider to plan for the necessary immunizations for her trip. She is unsure about her immunization history and she is new to this medical practice.

.....

## Introduction

Immune responses and types of immunity are described in Chapter 38. Many antigens that activate the immune response are microorganisms that cause infectious diseases. Early scientists observed that people who had certain diseases were thereafter protected despite repeated exposure to the disease. It was later discovered that protection stemmed from body substances called antibodies and that antibodies could also be induced by deliberate exposure to the antigen. *Immunization* involves administration of an antigen to induce antibody formation (for active immunity) or administration of serum from immune people (for passive immunity). Preparations used for immunization are biologic products prepared by pharmaceutical companies and regulated by the U.S. Food and Drug Administration (FDA). Widespread use of these products has dramatically decreased the incidence of many infectious diseases. See Box 39-1 for recent changes in recommendations for immunizations.

## General Characteristics of Immunizing Agents

Some available agents are now infrequently used. These include the single vaccines for measles, mumps, and rubella, which have been largely replaced by the combination product containing all three vaccines (MMR). In addition, typhoid and yellow fever vaccines are used only in particular circumstances. These vaccines are not discussed further in this chapter.

## Box 39-1

## Recent Changes to Immunizations by Age Group

Newer immunization products and recent recommendations for various age groups include the following:

#### Children and Adolescents

- Rotavirus vaccine (Rotateq) to protect infants against rotavirus gastroenteritis, an infection that causes diarrhea, vomiting, and fever.
- A booster dose of tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap), recommended because protection against pertussis declines a few years after immunization with pertussis vaccine during infancy. Boostrix is used for persons aged 10 to 18 years, and Adacel is used for persons aged 11 to 64 years.
- Renewal of recommendations for four doses of pneumococcal vaccine (PCV7, Prevnar) for healthy young children. Two doses were recommended a few years ago because of a vaccine shortage.
- A second dose of chickenpox vaccine (e.g., Varivax) at 4 to 6 years old (first dose at 12–15 months). For adolescents, chickenpox vaccine for those who have never had chickenpox or been vaccinated previously; a second dose of chickenpox vaccine for adolescents who previously received a single dose
- A combined vaccine for measles, mumps, rubella, and chickenpox (Proquad) is available for use in children aged 12 months to 12 years. FDA approval has been requested for an additional combination vaccine (Pentacel) for diphtheria, tetanus, pertussis, polio, and *Haemophilus influenzae* type b (Hib). In clinical trials, Pentacel was administered at 2, 4, 6, and 15 to 18 months of age (4 doses) along with other recommended childhood vaccines.
- Hepatitis A vaccination for all children in the United States, with the first of two doses between 1 year and 2 years of age. It was formerly recommended for children in states with high rates of hepatitis A.
- Annual flu vaccination for children aged 6 months to 18 years and for household contacts, caregivers, and others who spend significant time with children from birth to 5 years.
- Human papilloma virus (HPV) vaccine (Gardasil) for all girls 11 or 12 years of age (can be given as early as 9 years) or up to 26 years of age if not received earlier, to help prevent HPV, a common sexually transmitted infection that can lead to genital warts and cervical cancer. Most effective if given before the person becomes sexually active.
- Meningococcal vaccine at 11 or 12 years of age. If not received earlier, recommended at entry to high school or college.

#### Adults

- Chickenpox vaccine for adults who never had the disease or vaccine; a second dose of vaccine for adults who previously received a single dose
- HPV vaccine if not previously received, up to age 26 years.
- Tdap booster vaccine (e.g., Adacel) is recommended for all adults under 65 years of age who have not already received Tdap, especially health professionals and those who have close contact with infants (under 1 year of age).
- Zoster vaccine (Zostavax) is available to prevent herpes zoster (shingles) in adults 60 years and older.

In general, immunizing agents are quite safe, and risks of the diseases they prevent are greater than the risks of the vaccines. However, risks and benefits for particular recipients should be considered because no vaccine is completely effective or completely safe. Some people may develop a disease after being immunized against it. However, if this happens, symptoms are usually less severe and complications are fewer than if the person had not been immunized. Adverse effects are usually mild and of short duration. Although the FDA evaluates vaccine safety before and after a vaccine is marketed, some adverse effects become apparent only after a vaccine is used in a large population.

### Agents for Active Immunity

The biologic products used for *active immunity* are vaccines and toxoids. *Vaccines* are suspensions of microorganisms or their antigenic products that have been killed or attenuated (weakened or reduced in virulence) so they can induce antibody formation while preventing or causing very mild forms of the disease. Many vaccines produce long-lasting immunity. Attenuated live vaccines produce immunity, usually lifelong, that is

similar to that produced by natural infection. However, there is a small risk of producing disease with live vaccines, especially in people with impaired immune function. Vaccines developed with recombinant DNA technology have a low risk for causing active disease.

*Toxoids* are bacterial toxins or products that have been modified to destroy toxicity while retaining antigenic properties (i.e., ability to induce antibody formation). Immunization with toxoids is not permanent; scheduled repeat doses (boosters) are required to maintain immunity.

Additional components of vaccines and toxoids may include aluminum phosphate, aluminum hydroxide, or calcium phosphate. Products containing aluminum should be given intramuscularly only, because they cannot be given intravenously and greater tissue irritation occurs with subcutaneous injections. These additives are used to delay absorption and increase antigenicity.

For maximum effectiveness, vaccines and toxoids must be given before exposure to the pathogenic microorganism. They should also be given by the recommended route to ensure the desired immunologic response.

## Indications for Use

Clinical uses of vaccines and toxoids include the following:

- Routine immunization of children against diphtheria, *H. influenzae* b infection, hepatitis A, hepatitis B, influenza A and B, measles (rubeola), mumps, pertussis, pneumococcal infection, poliomyelitis, rotavirus, rubella (German measles), tetanus, and varicella (chickenpox)
- Immunization of adolescents and adults against diphtheria, tetanus, and pertussis (Tdap rather than the previously used Td)
- Immunization of prepubertal girls or women of childbearing age against rubella. Rubella during the first trimester of pregnancy is associated with a high incidence of birth defects in the newborn.
- Immunization of people at high risk of serious morbidity or mortality from a particular disease. For example, pneumococcal vaccine is recommended for selected groups of people.
- Immunization of adults and children at high risk of exposure to a particular disease. For example, college freshmen who live in dormitories and military recruits may need immunization against meningococcal disease or mumps.

## Contraindications to Use

Vaccines and toxoids are usually contraindicated during febrile illnesses; immunosuppressive drug therapy (see Chap. 41); immunodeficiency states; leukemia, lymphoma, or generalized malignancy; and pregnancy.

### Applying Your Knowledge 39-1

What nursing assessments will the nurse perform to evaluate Ms. Stein for possible contraindications for immunization?

## Agents for Passive Immunity

Immune serums are the biologic products used for *passive immunity*. They act rapidly to provide temporary (for 1–3 months) immunity in people exposed to or experiencing a particular disease. The goal of therapy is to prevent or modify the disease process (i.e., decrease the incidence and severity of symptoms).

Immune globulin products are made from the serum of individuals with high concentrations of the specific antibody or immunoglobulin (Ig) required. These products may consist of whole serum or of the immunoglobulin portion of serum in which the specific antibodies are concentrated. Immunoglobulin fractions are preferred over whole serum because they are more likely to be effective. Plasma used to prepare these products is negative for hepatitis B surface antigen (HBsAg). Hyperimmune serums are available for cytomegalovirus, hepatitis B, rabies, rubella, tetanus, varicella zoster (shingles), and respiratory syncytial virus infections.

## Individual Immunizing Agents

Vaccines, toxoids, and immune serums are listed in Tables 39-1 and 39-2.

## Nursing Process

### Assessment

Assess the patient's immunization status by obtaining the following information:

- Determine the patient's previous history of diseases for which immunizing agents are available (e.g., measles, influenza).
- Ask if the patient has had previous immunizations.
  - For which diseases were immunizations received?
  - Which immunizing agent was received?
  - Were any adverse effects experienced? If so, what symptoms occurred, and how long did they last?
  - Was tetanus toxoid given for any cuts or wounds?
  - Did any foreign travel require immunizations?
- Determine whether the patient has any conditions that contraindicate administration of immunizing agents (e.g., malignancy, pregnancy, immunosuppressive drug therapy).
- For pregnant women not known to be immunized against rubella, serum antibody titer should be measured to determine resistance or susceptibility to the disease.
- For patients with wounds, assess the type of wound and determine how, when, and where it was sustained. Such information may reveal whether tetanus immunization is needed.
- For patients exposed to infectious diseases, try to determine the extent of exposure (e.g., household or brief, casual contact) and when it occurred.

### Nursing Diagnoses

- Deficient Knowledge: Importance of maintaining immunizations for both children and adults
- Risk for Fluid Volume Deficit related to inadequate intake and febrile reactions to immunizing agent
- Noncompliance in obtaining recommended immunizations related to fear of adverse effects
- Risk for Injury related to hypersensitivity, fever, and other adverse effects

### Planning/Goals

The patient will

- Avoid diseases for which immunizations are available and recommended
- Obtain recommended immunizations for children and self
- Keep appointments for immunizations

Nursing Process continues on page 628

## Interventions

Use measures to prevent infectious diseases, and provide information about the availability of immunizing agents. General measures include those to promote health and resistance to disease (e.g., nutrition, rest, exercise). Additional measures include the following:

- Education of the public, especially parents of young children, regarding the importance of immunizations to personal and public health. Include information about the diseases that can be prevented and where immunizations can be obtained.
- Assisting patients in developing a system to maintain immunization records for themselves and their children. This is important because immunizations are often obtained at different places and over a period of years. Written, accurate, up-to-date records help to prevent diseases and unnecessary immunizations.
- Prevention of disease transmission. The following are helpful measures:
  - Hand hygiene (probably the most effective method)
  - Avoiding contact with people who have known or suspected infectious diseases, when possible
  - Using isolation techniques when appropriate
  - Using medical and surgical aseptic techniques
  - For someone exposed to rubeola, administration of measles vaccine within 48 hours to prevent the disease
  - For someone with a puncture wound or a dirty wound, administration of tetanus immune globulin to prevent tetanus, a life-threatening disease
  - For someone with an animal bite, washing the wound immediately with large amounts of soap and water. Health care should then be sought. Administration of rabies vaccine may be needed to prevent rabies, a life-threatening disease.
  - Explaining to the patient that contracting rubella or undergoing rubella immunization during pregnancy, especially during the first trimester, may cause severe birth defects in the infant. The goal of immunization is to prevent congenital rubella syndrome. Current recommendations are to immunize children against rubella at 12 to 15 months of age. It is recommended that previously unimmunized girls 11 to 13 years of age be immunized against rubella. Furthermore, nonpregnant women of childbearing age should have rubella antibody tests. If antibody concentrations are low, the woman should be immunized. Pregnancy should be avoided for 3 months after immunization.

## Evaluation

- Interview and observe for symptoms.
- Interview and observe for adverse drug effects.
- Check immunization records when indicated.

## Principles of Therapy

### Keeping Up-to-Date With Immunization Recommendations

Recommendations regarding immunizations change periodically as additional information and new immunizing agents become available. Consequently, health care providers need to update their knowledge at least annually. The best source of information for current recommendations is the Centers for Disease Control and Prevention (CDC; [www.cdc.gov](http://www.cdc.gov)). The main source of CDC recommendations is the Advisory Committee on Immunization Practices (ACIP; [www.cdc.gov/nip/acip](http://www.cdc.gov/nip/acip)), which consists of experts appointed to advise the CDC on strategies to prevent vaccine-preventable diseases. Other sources of information include the American Academy of Pediatrics (AAP; [www.aap.org](http://www.aap.org)) and the American Academy of Family Physicians (AAFP; [www.aafp.org](http://www.aafp.org)). Local health departments can also be consulted about routine immunizations and those required for foreign travel. These sources can also provide information on new vaccine releases, vaccine availability, and usage of specific vaccines.

### Applying Your Knowledge 39-2

The nurse is unaccustomed to providing immunizations other than the usual childhood vaccines. How should you obtain current information for Ms. Stein and how often should the nurse update this information?

.....

### Storage of Vaccines

To maintain effectiveness of vaccines and other biologic preparations, the products must be stored properly. Most products require refrigeration at 2°C to 8°C (35.6°–46.4°F). Manufacturers' instructions for storage should be strictly followed.

### Applying Your Knowledge 39-3

#### How Can You Avoid This Medication Error?

The nurse looks in the supply area for vaccines to be administered to Ms. Stein at this visit. The MMR vaccine is on the shelf above the sink so the nurse prepares the injection and administers it to the patient.

.....

### Use in Special Populations

#### Use in Children

Routine immunization of children has reduced the prevalence of many common childhood diseases, and immunization rates have increased in recent years. By 4 to 6 years of age, children should have received vaccinations for chickenpox (varicella), diphtheria, hepatitis A and B, influenza, measles, mumps,

(text continues on page 637)

Table 39-1

Drugs at a Glance: Vaccines and Toxoids for Active Immunity

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Vaccines</b>			
<p><b>Haemophilus influenzae b (Hib)</b> (ActHIB, HibTITER, PedvaxHIB)</p> <p>Formed by conjugating a derivative of the organism with a protein. The protein increases antigenicity.</p>	<p>To prevent infection with Hib, a common cause of serious bacterial infections, including meningitis, in children younger than 5 y</p>		<p>ActHIB, HibTITER, IM, 2–6 mo, 0.5 mL every 2 mo for 3 doses; 15 mo, 0.5-mL booster dose</p> <p>7–11 mo, IM, 0.5 mL every 2 mo for 2 doses; 15 mo, 0.5-mL booster dose</p> <p>12–14 mo, IM 0.5 mL as single dose; 15 mo, 0.5-mL booster dose, at least 2 mo after the first dose</p> <p>15–71 mo, IM 0.5 mL as a single dose (no booster dose)</p> <p>Pedvax HIB, IM, 2–14 mo, 0.5 mL every 2 mo for 2 doses; 12–15 mo, 0.5-mL booster dose; 15–71 mo, IM 0.5 mL as a single dose (no booster dose)</p>
<p><b>Haemophilus influenzae b (Hib) with hepatitis B</b> (Comvax)</p> <p>May be given at the same time as DTaP; measles, mumps, rubella (MMR); injected polio vaccine (IPV), but with separate syringes and in separate sites</p>	<p>Routine immunization of children 6 wk–15 mo of age born to HBsAg-negative mothers</p>		<p>IM, 0.5 mL at 2, 4, and 12–15 months of age</p>
<p><b>Hepatitis A</b> (Havrix, Vaqta)</p> <p>More than 90% effective within 4 wk after first dose</p> <p>Contraindicated during febrile illness, immunosuppression</p> <p>Havrix adult form contains 1440 units in 1 mL; the pediatric form contains 360 or 720 units in 0.5 mL</p> <p>Vaqta adult form contains 50 units/mL; the pediatric form contains 25 units/0.5 mL</p> <p>The vaccines are interchangeable.</p>	<p>Workers in daycare centers, laboratories, food-handling establishments; men who have sex with men; IV drug users; military personnel; travelers to areas where hepatitis A is endemic; community residents during an outbreak; people with chronic liver disease (e.g., hepatitis B or C, cirrhosis)</p>	<p>Havrix, IM 1 mL initially and 6–12 mo later (total of 2 doses)</p> <p>Vaqta, IM in deltoid, 1 mL initially and 6–12 mo later (total of 2 doses)</p>	<p>Havrix, 1–18 y, IM, 360 units initially, 1 mo later, and 6–12 mo later (total of 3 doses) or 720 units initially and 6–12 mo later (total of 2 doses)</p> <p>Vaqta, IM, 25 units initially and 6–18 mo later (total of 2 doses)</p>

(continued on page 630)

Table 39-1

## Drugs at a Glance: Vaccines and Toxoids for Active Immunity (continued)

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<p><b>Hepatitis B</b> (Engerix-B, Recombivax HB, Engerix-B)</p> <p>Approximately 96% effective in children and young adults and 88% in adults older than 40 y</p> <p>Duration of protection unknown; can measure serum antibody levels periodically</p>	<p>Pre-exposure immunization of high-risk groups, such as health care providers (nurses, physicians, dentists, laboratory workers); patients with cancer, organ transplants, hemodialysis, immunosuppressant drug therapy, or multiple infusions of blood or blood products; men who have sex with men; IV drug abusers; household contacts of hepatitis B virus carriers; residents and staff of institutions for mentally challenged people</p> <p>Persons requiring postexposure vaccine include infants born to carrier mothers, people with accidental exposure of skin or mucous membrane to infected blood (e.g., needle-stick injuries), and household contacts or sexual partners of persons with acute hepatitis B infection</p>	<p>20 y and older: Engerix-B, IM, 1 mL initially and 1 mo and 6 mo later (3 doses)</p> <p>Predialysis and dialysis patients, IM, 2 mL initially and 1, 2, and 6 mo later (4 doses)</p> <p>Recombivax HB, IM, 1 mL initially and 1 mo and 6 mo later (3 doses)</p> <p>Predialysis and dialysis patients, IM, 1 mL initially and 1 mo and 6 mo later (3 doses)</p>	<p>Neonates to 19 y: Engerix-B IM 0.5 mL initially and 1 mo and 6 mo later (3 doses)</p> <p>Neonates to 19 y: Recombivax IM 0.5 mL initially and 1 mo and 6 mo later (3 doses)</p>
<p><b>Hepatitis A and hepatitis B</b> (Twinrix)</p> <p>Contains hepatitis A and hepatitis B antigens</p>	<p>Adults exposed to hepatitis A or B (e.g., medical personnel, staff in institutional settings such as daycare centers, prisons)</p> <p>Adults at risk of exposure, including travelers to areas of high incidence; people with chronic liver disease; laboratory workers, police, emergency medical personnel, sanitation workers</p>	<p>IM 1 mL initially and 1 mo and 6 mo later (total of 3 doses)</p>	
<p><b>Human papillomavirus (HPV)</b> (Gardasil)</p> <p>Because HPV is a common sexually transmitted infection, the vaccine is most effective when taken before becoming sexually active.</p>	<p>Prevention of diseases caused by HPV types 6, 11, 16, and 18 (cervical, vaginal and vulvar cancer; genital warts) in girls and women aged 9–26 y</p>	<p>IM 0.5 mL initially, 2 mo after first dose, and 6 mo after first dose (total of 3 doses)</p>	<p>9 y and older; same as adults</p>
<p><b>Influenza</b> (Fluzone, Fluvirin, FluMist)</p>	<p>Annual immunization of most people, especially:</p>	<p>All adults: IM 0.5 mL in a single dose</p>	<p>Injectable form</p>

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<p>Formulated annually to include current strains</p> <p>Provides protective antibody concentrations for about 6 mo</p> <p>Note: Fluvirin is indicated only in children 4 y and older. FluMist is indicated in healthy children and adolescents 5–17 y of age and in healthy adults 18–49 y of age (except during pregnancy).</p>	<p>Children between 6 months and 5 years old,</p> <p>Pregnant women,</p> <p>People older than 50 y,</p> <p>People who live in long-term health care facilities</p> <p>People with chronic medical conditions (e.g., diabetes, lung disease, HIV/AIDS)</p> <p>People living with or caring for young children, nursing-home residents, those with compromised immune systems, or those with chronic medical conditions</p>	<p>Healthy adults 18–49 y: Intranasal spray 0.5 mL per season</p>	<p>6–35 mo: IM, 0.25 mL, 1 dose if previously vaccinated; 2 doses at least 1 mo apart if first vaccination</p> <p>3–8 y: IM, 0.5 mL, 1 dose if previously vaccinated; 2 doses at least 1 mo apart if first vaccination</p> <p>9 y and older: IM, 0.5 mL in a single dose</p> <p>Intranasal spray</p> <p>5–8 y (not previously vaccinated with FluMist): 0.5 mL per dose, 60 d apart for a total of 2 doses</p> <p>5–8 y (previously vaccinated with FluMist): 0.5 mL in a single dose per season</p> <p>9 y and older: 0.6 mL in a single dose per season</p>
<p><b>Measles, mumps, and rubella (MMR)</b></p> <p>Preferred and more commonly used than single immunizing agents</p> <p>Contains live, attenuated viruses that cause measles, mumps, and rubella</p> <p>Protects more than 95% of recipients for many years</p>	<p>Immunization at 12–15 mo and a second dose at 4–6 y</p>	<p>IM 0.5 mL</p>	<p>Same as adults</p>
<p><b>Measles, mumps, rubella, and varicella vaccine (Proquad)</b></p>	<p>Routine immunization of children 12 mo to 12 y of age</p>		<p>Sub-Q 0.5 mL as a single dose</p>
<p><b>Meningitis/meningococcal disease (Menactra; menomune)</b></p> <p>Prevents invasive meningococcal infection caused by <i>Neisseria meningitidis</i></p> <p>Provides protective levels of antibody within 7–10 d</p> <p>Note: A few cases of Guillain-Barré syndrome have been reported after Menactra administration.</p>	<p>Immunization of people at risk in epidemic or endemic areas</p> <p>Recommended for college students living in dormitories</p>	<p>Menomune, Sub-Q 0.5 mL</p> <p>Menactra, IM, 0.5 mL</p>	<p>Menomune, same as adults for children older than 2 y</p> <p>Menactra, same as adults for children 11 y and older</p>

(continued on page 632)

Table 39-1

## Drugs at a Glance: Vaccines and Toxoids for Active Immunity (continued)

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<p><b>Pneumococcal polyvalent</b> (Pneumovax 23, Pnu-Immune 23)</p> <p>Contains 23 strains of pneumococci, which cause most of the serious pneumococcal infections in the United States</p> <p>Protection begins about 3 wk after vaccination and lasts years.</p> <p>Not recommended for children under 2 y</p>	<p>Adults with disorders associated with risk of pneumococcal infection (e.g., cardiovascular or pulmonary disease, diabetes mellitus, Hodgkin's disease, multiple myeloma, cirrhosis, alcohol dependence, renal failure, immunosuppression)</p> <p>Adults 65 y and older who are otherwise healthy</p> <p>Children 2 y and older with chronic disease associated with risk of pneumococcal infection (e.g., asplenia, nephrotic syndrome, immunosuppression)</p>	<p>Sub-Q, IM 0.5 mL as a single dose; may be repeated after 5 y</p>	<p>Same as adults; may be repeated after 3 y</p>
<p><b>Pneumococcal 7-valent</b> (Prennar)</p> <p>Contains 7 <i>Streptococcus pneumoniae</i> antigens conjugated to a protein to increase antigenicity</p>	<p>To prevent life-threatening pneumococcal infections (e.g., bacteremia, meningitis, pneumonia) in young children</p>		<p>Birth–6 mo: IM 0.5 mL at 2, 4, and 6 mo and at 12–15 mo (4 doses)</p> <p>7–11 mo: IM 0.5 mL initially, at least 4 wk later, and after 1 y birthday (3 doses)</p> <p>12–23 mo: IM 0.5 mL initially and at least 2 mo later (2 doses)</p> <p>24 mo–9 y: IM 0.5 mL in a single dose</p>
<p><b>Poliomyelitis , inactivated (IPV)</b> (IPOL)</p>	<p>Routine immunization of infants</p> <p>Immunization of adults not previously immunized and at risk of exposure (e.g., health care or laboratory workers)</p>	<p>Sub-Q, 0.5 mL monthly for 2 doses, than a third dose 6–12 mo later</p>	<p>Sub-Q, 0.5 mL at 2, 4, and 6–18 mo, and 4–6 y of age (4 doses) or at 2 and 4 mo (2 doses)</p>
<p><b>Rabies vaccine</b> (Imovax, RabAvert)</p> <p>Immunity develops in 7–10 d and lasts 1 y or longer</p>	<p>Pre-exposure immunization in people at high risk of exposure (e.g., veterinarians, animal handlers)</p> <p>Postexposure prophylaxis in people who have been bitten by potentially rabid animals or who have skin scratches or abrasions exposed to animal saliva (e.g., animal licking of wound), urine, or blood</p>	<p>Pre-exposure, IM, 1.0 mL for 3 doses. The second dose is given 1 wk after the first; the third dose is given 3–4 wk after the first. Then, booster doses (1 mL) every 2–5 y based on antibody titers.</p> <p>Postexposure, IM, 1 mL for 5 doses. After the initial dose, other doses are given 3, 7, 14, and 28 d later.</p>	<p>Same as adults</p>

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<p><b>Rotavirus</b> (Rotateq) Can be given with most other childhood vaccines Adverse effects are usually mild diarrhea and vomiting. However, an earlier rotavirus vaccine was withdrawn because of an association with intussusception and a few cases have been reported after administration of Rotateq.</p>	Prevention of rotavirus gastroenteritis in infants		PO 1 dose between 6 and 12 wk of age; a second and third dose at 4 to 10 wk intervals. The third dose should not be given after 32 wk of age.
<p><b>Tuberculosis (bacillus Calmette-Guérin)</b> (TICE BCG) Contains live, attenuated tuberculosis bacilli Converts negative tuberculin reactors to positive reactors; therefore, precludes use of the tuberculin skin test for screening or early diagnosis of tuberculosis Contraindicated in patients with impaired immune responses</p>	People at high risk of exposure, including newborns of women with tuberculosis	Percutaneous, by multiple puncture disk, 0.2–0.3 mL	<p><i>Newborns:</i> percutaneous by multiple puncture disk, 0.1 mL <i>Older than 1 mo:</i> same as adults</p>
<p><b>Varicella</b> (Varivax) Contains live, attenuated varicella virus Contraindicated in people with hematologic or lymphatic malignancy, immunosuppression, febrile illness, or pregnancy</p>	<p>Immunization of children 12 mo and older Immunization of adults</p>	Sub-Q 0.5 mL, followed by a second dose of 0.5 mL 4–8 wk after the first dose	12–15 mo: Sub-Q 0.5 mL followed by a second dose at 4–6 y of age
<p><b>Zoster vaccine</b> (Zostavax) Redness, edema, tenderness at injection site were most common adverse reactions during clinical trials. Duration of protection unknown</p>	Prevention of herpes zoster in adults 60 y and older	Sub-Q entire single-dose vial	
<b>Toxoids</b>			
<p><b>Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP, Tdap)</b> (Adacel, Boostrix, Daptacel, Infanrix, Tripedia) The acellular pertussis vaccine decreases the adverse effects associated with the earlier pertussis vaccine.</p>	<p>Immunization of children aged 6 wk–7 y  Booster dose for persons aged 10–18 y (Boostrix) or persons aged 11–64 y (Adacel)</p>	<p>IM 0.5 mL</p>	<p>IM 0.5 mL at approximately 2, 4, 6, and 18 mo of age and at 4–6 y  Adacel or Boostrix IM 0.5 mL</p>

(continued on page 634)

Table 39-1

## Drugs at a Glance: Vaccines and Toxoids for Active Immunity (continued)

Name/ Characteristics	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
DTaP and <i>Haemophilus influenzae</i> type B (DTaP-HiB) (TriHIBit)	Immunization of children 15–18 mo of age who have been previously immunized against diphtheria, tetanus, and pertussis		IM 0.5 mL
DTaP, hepatitis B, and polio (Pediarix)			IM 0.5 mL at 2, 4, and 6 mo of age (total of 3 doses)
<b>Diphtheria and tetanus toxoids (pediatric type) (DT)</b> Contains a larger amount of diphtheria antigen than “tetanus and diphtheria toxoids, adult type (Td)”	Routine immunization of infants and children 6 y and younger in whom pertussis vaccine is contraindicated (those who have adverse reactions to initial doses of DTaP vaccine)		<i>Infants and children 6 y and younger:</i> IM 0.5 mL for 2 doses at least 4 wk apart, followed by a booster dose 1 y later and when the child starts school
<b>Tetanus and diphtheria toxoids, (adult type) (Td)</b> Contains a smaller amount of diphtheria antigen than “diphtheria and tetanus toxoids, pediatric type (DT)”	Primary immunization or booster doses in adults and children older than 6 y	IM 0.5 mL for 2 doses, at least 4 wk apart, followed by a booster dose 6–12 mo later and every 10 y thereafter	<i>Older than 6 y:</i> same as adults
<b>Tetanus toxoid</b> Protects about 100% of recipients for 10 y or more Usually given in combination (e.g., DTaP or DT) for primary immunization of infants and children 6 y of age or older Usually given alone or combined with diphtheria toxoid (e.g., Td adult type) for primary immunization of adults	Routine immunization of infants and young children Primary immunization of adults Prevention of tetanus in previously immunized people who sustain a potentially contaminated wound	Primary immunization in adults not previously immunized, IM 0.5 mL for 3 doses: initially, 4–8 wk later, then at 6–12 mo. Then, 0.5-mL booster dose every 10 y. Prophylaxis, IM 0.5 mL if wound contaminated and no booster dose was received for 5 y; 0.5 mL if wound is clean and no booster dose was received for 10 y	Same as adults

*HBsAg*, hepatitis B surface antigen.

Table 39-2

## Drugs at a Glance: Immune Serums for Passive Immunity

NAME/ CHARACTERISTICS	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<p><b>Cytomegalovirus immune globulin, intravenous, human (CMV-IGIV)</b> (CytoGam)</p> <p>Contains antibodies against CMV</p>	Prevention of CMV infection in heart, kidney, liver, lung, and pancreas transplant recipients	Post-transplantation, IV infusion, 150 mg/kg within 72 h, then 100–150 mg/kg at 2, 4, 6, and 8 wk, then 50–100 mg/kg at 12 and 16 wk
<p><b>Hepatitis B immune globulin, human (HBIG)</b> (BayHep B, Nabi-HB)</p> <p>A solution of immunoglobulins that contains antibodies to HBsAg</p>	To prevent hepatitis after exposure. Neonates born to HBsAg-positive or unknown-status mothers are given HBIG and the first dose of hepatitis B vaccine within 12 h of birth.	<i>Adults and children:</i> IM, 0.06 mL/kg (usual adult dose, 3–5 mL) as soon as possible after exposure, preferably within 7 d. Repeat dose in 1 mo.
<p><b>Immune globulin (human) (IG; IGIM)</b> (BayGam)</p> <p>Given IM only</p> <p>Commonly called “gamma globulin”</p> <p>Obtained from pooled plasma of normal donors</p> <p>Consists primarily of IgG, which contains concentrated antibodies</p> <p>Produces adequate serum levels of IgG in 2–5 d</p>	<p>To decrease the severity of hepatitis A, measles, and varicella after exposure</p> <p>To treat immunoglobulin deficiency</p>	<p><i>Adults and children:</i> Exposure to hepatitis A, IM, 0.02 mL/kg</p> <p>Exposure to measles, IM, 0.25 mL/kg within 6 d of exposure</p> <p>Exposure to varicella, IM, 0.6–1.2 mL/kg</p> <p>Exposure to rubella (pregnant women only), IM, 0.55 mL/kg</p> <p>Immunoglobulin deficiency, IM, 1.3 mL/kg initially, then 0.6 mL/kg every 3–4 wk</p>
<p><b>Immune globulin intravenous (IGIV)</b> (Polygam S/D, Panglobulin, Venoglobulin-S)</p> <p>Given IV only</p> <p>Provides immediate antibodies</p> <p>Half-life about 3 wk</p> <p>Mechanism of action in ITP unknown</p> <p><b>BLACK BOX WARNING:</b> IGIV has been associated with renal dysfunction and failure and death. It should be used cautiously in patients with or at risk of developing renal impairment.</p>	<p>Immunodeficiency syndrome</p> <p>Idiopathic thrombocytopenic purpura (ITP)</p>	See manufacturers’ instructions
<p><b>Rabies immune globulin (human) RIG</b> (HyperRabS/D, Imogam)</p> <p>Gamma globulin obtained from plasma of people hyperimmunized with rabies vaccine</p> <p>Not useful in treatment of clinical rabies infection</p>	Postexposure prevention of rabies, in conjunction with rabies vaccine	<i>Adults and children:</i> IM, 20 units/kg (half the dose may be injected around the wound) as soon as possible after possible exposure (e.g., animal bite)

(continued on page 636)

Table 39-2

## Drugs at a Glance: Immune Serums for Passive Immunity (continued)

NAME/ CHARACTERISTICS	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<p><b>Respiratory syncytial virus immune globulin intravenous (human) (RSV-IGIV)</b> (RespiGam)</p> <p>Reduces severity of RSV illness and the incidence and duration of hospitalization in high-risk infants</p> <p>May cause fluid overload</p> <p>Not established as safe and effective in children with congenital heart disease</p>	<p>Prevention of serious RSV infections in high-risk children less than 2 y of age (i.e., those with bronchopulmonary dysplasia or history of premature birth [gestation of 35 wk or less])</p> <p>Treatment of RSV lower respiratory tract infections in hospitalized infants and young children</p>	<p><i>Children:</i> IV infusion via infusion pump, 1.5 mL/kg/h for 15 min, then 3 mL/kg/h for 15 min, then 6 mL/kg/h until the infusion is completed, then once monthly, if tolerated. Maximum monthly dose, 750 mg/kg</p>
<p><b>Rh<sub>0</sub>(D) immune globulin (human)</b> (RhoGAM)</p> <p>Prepared from fractionated human plasma</p> <p>A sterile concentrated solution of specific immunoglobulin (IgG) containing anti-Rh<sub>0</sub>(D)</p>	<p>To prevent sensitization in a subsequent pregnancy to the Rh<sub>0</sub>(D) factor in an Rh-negative mother who has given birth to an Rh-positive infant by an Rh-positive father</p>	<p><i>Obstetric use:</i> Inject contents of 1 vial IM for every 15 mL fetal packed red cell volume within 72 h after delivery, miscarriage, or abortion. Consult package instructions for blood typing and drug administration procedures.</p>
<p><b>Tetanus immune globulin (human)</b> (BayTet)</p> <p>Solution of globulins from plasma of people hyperimmunized with tetanus toxoid</p> <p>Tetanus toxoid (Td) should also be given to initiate active immunization if minor wound and more than 10 y since Td, if major wound and more than 5 y since Td, or if Td primary immunization series was incomplete.</p>	<p>To prevent tetanus in patients with wounds possibly contaminated with <i>Clostridium tetani</i> and whose immunization history is uncertain or incomplete</p> <p>Treatment of tetanus infection</p>	<p><i>Adults and children:</i> Prophylaxis, IM, 250 units as a single dose</p> <p>Treatment of clinical disease, IM 3000–6000 units in a single dose</p>
<p><b>Varicella-zoster immune globulin (human) (VZIG)</b></p> <p>The globulin fraction of human plasma</p> <p>Antibodies last 1 mo or longer.</p>	<p>Postexposure to chickenpox or shingles, to prevent or decrease severity of infections in children under 15 y of age who have not been immunized or who are immunodeficient because of illness or drug therapy</p> <p>Infants born to mothers who develop varicella 5 d before or 2 d after delivery and premature infants of less than 28 wk gestation</p>	<p>IM 125 units/10 kg up to a maximum of 625 units within 48 h after exposure if possible; may be given up to 96 h after exposure. Minimal dose, 125 units</p>

CMV, cytomegalovirus; IgG, immunoglobulin G; RSV, respiratory syncytial virus; HBsAg, hepatitis B surface antigen.

## Patient Teaching Guidelines Vaccinations

- Appropriate vaccinations should be maintained for adults as well as for children. Consult the Centers for Disease Control and Prevention (CDC) website ([www.cdc.gov](http://www.cdc.gov)) or a health care provider periodically because recommendations for particular groups change fairly often.
- Maintain immunization records for yourself and all members of your family. This is important because immunizations are often obtained at different places and over a period of years. Written, accurate, up-to-date records help to prevent diseases and unnecessary immunizations.
- If a health care provider recommends an immunization and you do not know whether you have had the immunization or the disease, it is probably safer to take the immunization than to risk having the disease. Immunization after a previous immunization or after having the disease usually is not harmful.
- Most vaccines cause fever and soreness at the site of injection. Acetaminophen (e.g., Tylenol) can be taken two to three times daily for 24 to 48 hours (by adults and children) to decrease fever and discomfort.
- Women of childbearing age who receive a rubella (German measles) or a varicella (chickenpox) immunization must avoid becoming pregnant (i.e., must use effective contraceptive methods) for 3 months.
- After receiving varicella vaccine (to prevent chickenpox), avoid close contact with newborns, pregnant women, and anyone whose immune system is impaired. Vaccinated people may transmit the vaccine virus to susceptible close contacts.
- After receiving a vaccine, stay in the area for approximately 30 minutes. If an allergic reaction is going to occur, it will usually do so within that time.

pertussis (whooping cough), polio, pneumococcal diseases, rubella (German measles), tetanus, and *Haemophilus influenzae* and rotavirus infections. Because some vaccines are administered more than once, a child may receive more than 20 injections by 2 years of age. Two strategies to increase immunizations are the development of combination vaccines and the administration of multiple vaccines (in separate syringes and at different sites) at one visit to a health care provider when feasible. The combination vaccines decrease the number of injections, and giving multiple vaccines decreases the number of visits to a health care provider. Several combination vaccines are now available and continue to be developed. Studies indicate that these strategies are effective. In general, children's health care providers should follow the "Recommended Childhood Immunization Schedule" issued in January of each year by the CDC. In addition, current guidelines should be consulted about immunizations for children with chronic illnesses (e.g., asthma, heart disease, diabetes) or immunosuppression (e.g., from cancer, organ transplantation, or HIV infection). Dosages and schedules of administration for children whose immunizations begin in early infancy are listed in Table 39-1; different schedules are recommended for children 1 to 5 years of age and for those older than 6 years of age who are being immunized for the first time or who have missed doses.

### Use in Healthy Adolescents, Young Adults, and Middle-Aged Adults

Adolescents who received all primary immunizations as infants and young children should have a second dose of varicella (chickenpox) vaccine, hepatitis A and hepatitis B vaccines (if not received earlier), a tetanus-diphtheria-pertussis booster (Tdap) between ages 11 and 18 years if 5 years since a tetanus-diphtheria (Td) booster, and meningococcal vaccine at 11 or 12 years of age. Adolescent girls should receive the human papilloma virus (HPV) vaccine if not received earlier. Young adults who are health care workers, are sexually active, or

belong to high-risk groups should receive varicella (chickenpox) vaccine or a second dose if they previously received a single dose; hepatitis A and hepatitis B vaccines if not previously received; a tetanus-diphtheria-pertussis booster (Tdap); MMR if not pregnant and rubella titer is inadequate or proof of immunization is unavailable; HPV vaccine (up to 26 years of age) if not previously received; and meningococcal vaccine if not previously received. In addition, young adults who are health care providers should have influenza vaccine annually. Middle-aged adults should maintain immunizations against tetanus-diphtheria-pertussis (Tdap); high-risk groups (e.g., those with chronic illness) and health care providers should receive hepatitis B vaccine once (if not previously taken) and influenza vaccine annually at 50 years of age and older. An additional vaccine to prevent zoster infections (shingles) is available for adults 60 years and older. Middle-aged adults (those born after 1956) should get at least one dose of measles-mumps-rubella (MMR) vaccine unless they have had either the vaccine or each of the three diseases.

### Use in Older Adults

Older adults become more susceptible to some diseases, and influenza, pneumococcal infections, tetanus, and shingles can be especially serious in this population. The varicella-zoster virus, the same virus that causes chickenpox, causes shingles.

Recommended immunizations for older adults usually consist of a tetanus-diphtheria (Td) booster every 10 years, annual influenza vaccine, and a one-time administration of pneumococcal vaccine at 65 years of age. A second dose of pneumococcal vaccine may be given at 65 years if the first dose was given 5 years previously.

A newer tetanus-diphtheria-pertussis vaccine is recommended to replace the Td booster dose in adults up to 64 years of age, and a vaccine to prevent shingles is available for adults 60 years and older. As with younger adults, immunization for most other diseases is recommended for older adults at high risk of exposure.

### Use in Patients With Immunosuppression

Compared with healthy, immunocompetent individuals, the antibody response to immunization is usually adequate but reduced in immunosuppressed people. Immunizations should be individualized. In general, those with diabetes mellitus or chronic pulmonary, renal, or hepatic disorders who are not receiving immunosuppressant drugs may be given both live attenuated and killed vaccines and toxoids to induce active immunity. However, they may need higher doses or more frequent administration to induce adequate immunity. With hepatitis B vaccine, for example, larger doses may be required initially and booster doses may be needed later if antibody concentrations fall.

Patients with active malignant disease may be given killed vaccines or toxoids but should not be given live vaccines (an exception is persons with leukemia who have not received chemotherapy for at least 3 months). When vaccines are used, they should be given at least 2 weeks before the start of chemotherapy or 3 months after chemotherapy is completed. Passive immunity with immunoglobulins may be used in place of active immunity.

Patients receiving a systemic corticosteroid in high doses (e.g., prednisone 20 mg or equivalent daily) or for longer than 2 weeks should wait at least 3 months before being given a live-virus vaccine. Immunizations are not contraindicated with short-term use (less than 2 weeks) or low to moderate doses (less than 20 mg of prednisone daily). In addition, long-term alternate-day therapy with short-acting agents; maintenance physiologic doses; and the use of topical, aerosol, or intra-articular injections are not contraindications to immunization.

Patients with HIV infection have less-than-optimal responses to immunizing agents because the disease produces major defects in cell-mediated and humoral immunity. Live bacterial (BCG, oral typhoid) or viral (MMR, varicella) vaccines should not be given because the bacteria or viruses may be able to reproduce and cause active infection. Persons with asymptomatic HIV infection should receive inactivated vaccines; those exposed to measles or varicella may be given immune globulin or varicella-zoster immune globulin for passive immunization.

For children with HIV infection, most routine immunizations (DTaP, IPV, MMR, Hib, influenza) are recommended. MMR is not recommended in children with severe immunosuppression, and varicella vaccine is recommended only for children with no evidence of immunosuppression. Pneumococcal vaccine is recommended for HIV-infected persons over 2 years of age.

### Use in Patients With Cancer

For patients with active malignant disease, live vaccines should not be given. Although killed vaccines and toxoids may be given, antibody production may be inadequate to provide immunity. When possible, patients should receive needed immunizations 2 weeks before or 3 months after immunosuppressive radiation or chemotherapy treatments. For example, patients with Hodgkin's lymphoma who are more than 2 years old should be immunized with pneumococcal and Hib vaccines 10 to 14 days before therapy is started. In addition, patients who have not received chemotherapy for 3 to 4 weeks may have an adequate antibody response to influenza vaccine.

## Nursing Actions Immunizing Agents

### NURSING ACTIONS

#### 1. Administer accurately

- a. Read the package insert and check the expiration date on all biologic products (e.g., vaccines, toxoids, human immune serums).
- b. Follow instructions for administering each vaccine.
- c. Check the patient's temperature before giving a vaccine.
- d. Give IM human immune serum globulin with an 18- to 20-gauge needle, preferably in gluteal muscles. If the dose is 5 mL or more, divide it and inject it into two or more IM sites. Follow manufacturer's instructions for preparation and administration of intravenous (IV) formulations.

### RATIONALE/EXPLANATION

Concentration, dosage, and administration of biologic products often vary with the products. Avoid administration of expired products and use reconstituted products within designated time limits because they are usually stable for only a few hours.

Most vaccines are given by injection. In general, the vastus lateralis is the largest skeletal muscle mass in infants and is preferred for IM injections. The deltoid or vastus lateralis muscle may be used for older children and adults. Injection into the gluteal muscles is not recommended because the vaccine may be injected into fatty tissue and be less effective in arousing an immune response.

Some immunizations are contraindicated during febrile illnesses.

To promote absorption and minimize tissue irritation and other adverse reactions

**NURSING ACTIONS**

- e. Aspirate carefully before IM or Sub-Q injection of any immunizing agent.
- f. Have aqueous epinephrine 1:1000 readily available before administering any vaccine.
- g. After administration of an immunizing agent in a clinic or office setting, have the patient stay in the area for at least 30 minutes. Provide patients with a Vaccine Information Statement (VIS).

**2. Observe for therapeutic effects**

- a. Absence of diseases for which immunized
- b. Decreased incidence and severity of symptoms when given to modify disease processes

**3. Observe for adverse effects**

## a. General reactions:

- (1) Pain, tenderness, redness at injection sites
- (2) Fever, malaise, muscle aches
- (3) Anaphylaxis—cardiovascular collapse, shock, laryngeal edema, urticaria, angioneurotic edema, severe respiratory distress
- (4) Serum sickness—urticaria, fever, arthralgia, enlarged lymph nodes

## b. With DTaP:

- (1) Soreness, erythema, edema at injection sites
- (2) Anorexia, nausea
- (3) Severe fever, encephalopathy, seizures

c. With *Haemophilus influenzae* b vaccine—pain and erythema at injection sites

## d. With hepatitis B vaccine:

- (1) Injection site soreness, erythema, induration
- (2) Fever
- (3) Anaphylaxis

## e. With influenza vaccine:

- (1) Via injection—pain, induration, and erythema at injection sites; flu-like symptoms such as chills, fever, malaise, muscle aches
- (2) Via intranasal spray—runny nose, headache, cough, sore throat, irritability in children

## f. With MMR vaccine:

- (1) Mild symptoms of measles—cough, fever up to 39.4°C (102°F), headache, malaise, photophobia, skin rash, sore throat
- (2) Febrile seizures
- (3) Arthralgia (joint pain)

**RATIONALE/EXPLANATION**

To avoid inadvertent IV administration and greatly increased risks of severe adverse effects  
For immediate treatment of allergic reactions

To observe for allergic reactions, which usually occur within 30 minutes

Most adverse effects are mild and transient. However, serious reactions occasionally occur. The risk of serious adverse effects from immunization is usually much smaller than the risk of the disease immunized against.

Adverse effects may be caused by the immunizing agent or by foreign protein incorporated with the immunizing agent (e.g., egg protein in viral vaccines grown in chick embryos).

Local tissue irritation may occur with injected immunizing agents.

These adverse effects commonly occur with vaccines and toxoids.

Anaphylaxis occasionally occurs with immunizing agents. It is a medical emergency that requires immediate treatment with Sub-Q epinephrine (0.5 mL for adults; 0.01 mL/kg for children). Anaphylaxis is most likely to occur within 30 minutes after immunizing agents are injected.

Serum sickness is a delayed hypersensitivity reaction that occurs several days or weeks after an injection of serum. Treatment is symptomatic. Symptoms are usually relieved by acetaminophen, antihistamines, and corticosteroids.

These effects are common.

These reactions are rare. If they occur, they are thought to be caused by the pertussis antigen, and further administration of pertussis vaccine or DTaP may be contraindicated. These effects occur in about 25% of recipients but are usually mild and resolve within 24 hours.

Soreness and fever commonly occur and can be relieved by acetaminophen or ibuprofen. Anaphylaxis and other severe reactions rarely occur.

Adverse effects can be minimized by giving acetaminophen at the time of immunization and at 4, 8, and 12 hours later. Injection site reactions and flu-like symptoms may start within 12 hours after vaccination.

These symptoms may occur 6–11 days after immunization.

These are rare but are more likely to occur in children less than 2 years of age.

Joint pain has been reported in as many as 25% of adult females 2–6 weeks after receiving rubella vaccine.

## Nursing Actions Immunizing Agents (continued)

### NURSING ACTIONS

(4) Anaphylaxis in recipients who are allergic to eggs

g. With pneumococcal vaccine:

(1) Local effects—soreness, induration, and erythema at injection sites

(2) Systemic effects—chills, fever, headache, muscle aches, nausea, photophobia, weakness

h. With polio vaccine:

(1) Soreness at injection sites

(2) Fever

(3) Anaphylaxis

i. With varicella vaccine:

(1) Early effects—transient soreness or erythema at injection sites

(2) Late effect—a mild, maculopapular skin rash with a few lesions

j. With immune globulin intravenous (IGIV):

(1) Chills; dizziness; dyspnea; fever; flushing; headache; nausea; urticaria; vomiting; tightness in chest; pain in chest, hip, or back

(2) Renal dysfunction, acute renal failure, death

### 4. Observe for drug interactions

a. Drugs that *decrease* effects of vaccines in general:

(1) Immunosuppressants (e.g., corticosteroids, antineoplastic drugs, phenytoin)

b. Drugs that *decrease* effects of measles and MMR vaccines:

(1) Immunosuppressants

(2) Immune globulins (e.g., RIG, RSV-IGIV, VZIG, IGIV)

(3) Interferon

c. Drug that *decreases* effects of meningococcal vaccine:

(1) Measles vaccine

d. With varicella vaccine, salicylates may *increase* risk of Reye's syndrome.

### RATIONALE/EXPLANATION

The measles and mumps viruses used in MMR vaccine are grown in chick-embryo cell cultures. Recipients who are allergic to eggs should be observed for 90 minutes after the vaccine is injected. MMR vaccine should be given only in a setting where personnel and equipment are available to treat anaphylaxis.

Local effects occur in 40%–90% of recipients; systemic effects occur less frequently.

Adverse effects are usually mild. Anaphylaxis rarely occurs. However, if it occurs within 24 hours after administration of polio vaccine, no additional doses of the vaccine should be given.

Injection site reactions occur in 20%–35% of recipients; a skin rash develops in a few (about 8%) recipients within a month. Those who develop a rash from the vaccine have milder symptoms of shorter duration than those who develop varicella naturally.

These effects are related to the rate of infusion. If they occur, the infusion should be stopped until the symptoms subside, then restarted at a slower rate. The symptoms can also be prevented or minimized by pre-infusion administration of acetaminophen and diphenhydramine or a corticosteroid. Acute renal failure is most likely to occur in patients older than 65 years of age; in those with pre-existing renal insufficiency, diabetes mellitus, volume depletion, or sepsis; or in those taking known nephrotoxic drugs.

Vaccines may be contraindicated in patients receiving immunosuppressive drugs. These patients cannot produce sufficient amounts of antibodies for immunity and may develop the illness produced by the particular organism contained in the vaccine. The disease is most likely to occur with the live-virus vaccines (measles, mumps, rubella). Similar effects occur when the patient is receiving radiation and phenytoin, an anticonvulsant drug that suppresses immune responses.

May decrease effectiveness of immunization; patients may remain susceptible to measles despite immunization.

To avoid inactivation of the attenuated virus, give measles or MMR vaccine at least 14–30 days before or 6–8 weeks after the immune globulin. Alternatively, may check antibody titers or repeat the measles vaccine dose 3 months after immune globulin administration

May inhibit antibody response to the vaccine

These vaccines should be given at least 1 month apart. Aspirin and other salicylates should be avoided for 6 weeks after vaccine administration because of potential for Reye's syndrome, which has been reported with salicylate use after natural varicella infection.

## Key Concepts

- Many infectious diseases can be prevented by immunizations.
- Immunizations are needed for all age groups.
- Children in the United States are much more likely to receive recommended immunizations than are adolescents and adults.
- Health care providers who provide or participate in immunizations need to keep their knowledge base current with annual updates regarding recommendations from the CDC.
- Health care providers need to assess and inform patients about recommended immunizations.
- New immunizing products continue to be developed.

## Review and Application Exercises

### Short Answer Exercises

1. What is the difference between active immunity and passive immunity?
2. How do vaccines act to produce active immunity?
3. What are the sources and functions of immune serums?
4. List common childhood diseases for which immunizing agents are available.
5. Which immunizations are recommended for adults?
6. What are advantages of administering a combination of immunizing agents rather than single agents?
7. What are common adverse reactions to immunizing agents, and how may they be prevented or minimized?
8. Why should live vaccines not be given to people whose immune system is suppressed by drugs or diseases?

### NCLEX-Style Questions

9. In explaining vaccines to a parent, the nurse knows that vaccines provide
  - a. active immunity
  - b. passive immunity
  - c. innate immunity
  - d. nonspecific immunity
10. The nurse caring for a patient with severe immunosuppression knows that this condition is a contraindication to
  - a. all injectable immunizations
  - b. the use of live bacterial or viral vaccines
  - c. the use of immune globulins for passive immunity
  - d. the use of most immunizing agents in children
11. To decrease fever and discomfort after an immunization, the nurse should advise that adults and children can take
  - a. an opioid analgesic every 6 to 8 hours for 48 hours
  - b. acetaminophen every 4 to 6 hours for at least 24 hours
  - c. an antihistamine for 2 days before and 2 days after vaccine administration
  - d. a sedative at bedtime to aid sleep
12. For a child receiving an immunization, the nurse should inform the parents that common after-effects may include
  - a. skin rash and swelling
  - b. redness and soreness at the injection site
  - c. muscle weakness and difficulty in walking
  - d. nausea, vomiting, and diarrhea
13. An adult patient has had an injury with skin penetration by a piece of dirty metal. He is seeking minor first aid care, but as the nurse you are concerned about prevention of tetanus. You know that adults should be given tetanus toxoid vaccine every
  - a. year
  - b. 2 years
  - c. 5 years
  - d. 10 years

# Hematopoietic and Immunostimulant Drugs

## KEY TERMS

- Colony-stimulating factors
- Erythropoietin
- Hematopoiesis
- Immunostimulant
- Myelosuppressive
- Neutropenia
- Pegylation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the goals and methods of enhancing hematopoietic and immune functions.
2. Discuss the use of hematopoietic agents in the treatment of anemia.
3. Discuss the use of filgrastim and sargramostim in neutropenia and bone marrow transplantation.
4. Describe the adverse effects and nursing process implications of administering filgrastim and sargramostim.
5. Discuss interferons in terms of clinical uses, adverse effects, and nursing process implications.

## Applying Your Knowledge

Alice Paul is a 76-year-old woman who is being treated with chemotherapy for inoperable liver cancer. She receives a combination chemotherapy regimen every 6 weeks. She is in the oncologist's office for her routine laboratory work 10 days after chemotherapy and complains of severe fatigue. The results of her blood work are:

.....

Hemoglobin 10.9 g  
 Hematocrit 32%  
 WBC 2000  
 ANC 800  
 Platelet count 120,000

## Introduction

Adequate blood cell production and development (*hematopoiesis*) and immune system function (immunocompetence) are vital processes in the human body's ability to fight harmful invaders. Inadequate or impaired hematopoiesis or immune function (immunodeficiency) leads to high risks for infection and cancer. Efforts to enhance a person's own body systems to fight disease include the development of drugs to stimulate hematopoiesis and immune function. Drugs that stimulate immune function are called immunostimulants, biologic response modifiers, and immunomodulators. These drugs are given to restore normal function or to increase the ability of the immune system to eliminate potentially harmful invaders. Drugs available for therapeutic use include hematopoietic *colony-stimulating factors* (CSFs; e.g., darbepoetin alfa, epoetin alfa, filgrastim, sargramostim), several interferons, and two interleukins. These drugs, which are the primary focus of this chapter, are described in the following sections and in Table 40-1.

Table 40-1

## Drugs at a Glance: Hematopoietic and Immunostimulant Agents

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Hematopoietic Agents</b>		
<b>Darbepoetin alfa</b> (Aranesp)	Anemia associated with chronic renal failure (CRF)	Sub-Q, IV 0.45 mcg/kg once weekly, adjusted to achieve and maintain hemoglobin level no greater than 12 g/dL
<b>Epoetin alfa</b> (Epoen, Procrit)	Prevention and treatment of anemia associated with CRF or anticancer chemotherapy Reduction of blood transfusions in anemic patients undergoing elective noncardiac, nonvascular surgery	CRF: IV, Sub-Q 50–100 units/kg 3 times weekly to achieve or maintain a hematocrit of 30%–36% <i>Cancer chemotherapy:</i> Sub-Q 150–300 units/kg 3 times weekly <i>Surgery:</i> Sub-Q 300 units/kg/d for 10 d before surgery, on the day of surgery, and for 4 d after surgery
<b>Colony-Stimulating Factors (CSFs)</b>		
<b>Filgrastim</b> (G-CSF) (Neupogen)	To prevent infection in patients with neutropenia induced by cancer chemotherapy or bone marrow transplantation To mobilize stem cells from bone marrow to peripheral blood, where they can be collected and reinfused after chemotherapy that depresses bone marrow function To treat severe chronic neutropenia	<i>Myelosuppressive chemotherapy:</i> Sub-Q injection, IV infusion over 15–30 min, or continuous Sub-Q or IV infusion 5 mg/kg/d, up to 2 wk until ANC reaches 10,000/mm <sup>3</sup> <i>Bone marrow transplantation:</i> IV or Sub-Q infusion, 10 mcg/kg/d initially, then titrated according to neutrophil count (5 mcg/kg/d if ANC over 1000/mm <sup>3</sup> for 3 consecutive days; stop drug if over 1000/mm <sup>3</sup> for 6 d. If ANC drops below 1000/mm <sup>3</sup> , restart filgrastim at 5 mcg/kg/d). <i>Collection of peripheral stem cells:</i> Sub-Q 10 mcg/kg/d for 6–7 d, with collection on the last 3 d of drug administration <i>Severe, chronic neutropenia:</i> Sub-Q 5 or 6 mcg/kg, once or twice daily, depending on clinical response and ANC
<b>Pegfilgrastim</b> (Neulasta)	To prevent infection in patients with neutropenia induced by cancer chemotherapy	Sub-Q 6 mg once per chemotherapy cycle. Do not give between 14 d before and 24 h after cytotoxic chemotherapy.
<b>Sargramostim</b> (GM-CSF) (Leukine)	After bone marrow transplantation to promote bone marrow function or to treat graft failure or delayed function Mobilization of stem cells in peripheral blood so they can be collected	<i>Bone marrow reconstitution:</i> IV infusion over 2 h, 250 mcg/m <sup>2</sup> /d, starting 2–4 h after bone marrow infusion, and continuing for 21 d <i>Graft failure or delay:</i> IV infusion over 2 h, 250 mcg/m <sup>2</sup> /d, for 14 d Course of treatment may be repeated after 7 d off therapy if engraftment has not occurred. <i>Mobilization of stem cells:</i> Sub-Q or IV over 24 h, 250 mcg/m <sup>2</sup> /d
<b>Interferons</b>		
<b>Interferon alfa-2a</b> (Roferon-A)	Chronic hepatitis C in adults* Hairy cell leukemia in adults* AIDS-related Kaposi's sarcoma in adults* Chronic myelogenous leukemia	<i>Hepatitis C:</i> Sub-Q, IM 3 million IU 3 times weekly for 12 mo <i>Hairy cell leukemia:</i> Sub-Q, IM Induction, 3 million IU daily for 16–24 wk Maintenance, 3 million IU 3 times weekly <i>Kaposi's sarcoma:</i> Sub-Q, IM

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
		Induction, 36 million IU daily for 10–12 wk Maintenance, 36 million IU 3 times weekly <i>Chronic myelogenous leukemia (CML)</i> : Sub-Q, IM 9 million IU daily
<b>Peginterferon alfa-2a</b> (Pegasys)	Chronic hepatitis B  Chronic hepatitis C, with ribavirin	Sub-Q, 180 mcg (1 mL) once weekly for 48 wk  Sub-Q, 180 mcg once weekly for 24 wk for viral genotypes 2 and 3; for 48 wk for viral strains 1 and 4
<b>Interferon alfa-2b</b> (Intron A)	Hairy cell leukemia in adults* AIDS-related Kaposi's sarcoma in adults* Condylomata (genital warts) Chronic hepatitis B Chronic hepatitis C, alone or with ribavirin Malignant melanoma, after surgical excision, to delay recurrence and prolong survival Non-Hodgkin's lymphoma	<i>Hairy cell leukemia</i> : Sub-Q, IM Induction and maintenance, 2 million IU/m <sup>2</sup> 3 times weekly up to 6 mo <i>Kaposi's sarcoma</i> : Sub-Q, IM Induction and maintenance, 30 million IU/m <sup>2</sup> 3 times weekly <i>Hepatitis B</i> : Sub-Q, IM 5 million IU daily or 10 million IU 3 times weekly (total of 30–35 million IU per wk) for 16 wk <i>Hepatitis C</i> : Sub-Q, IM 3 million IU 3 times weekly for 16 wk–24 mo <i>Malignant melanoma</i> : induction IV, 20 million IU/m <sup>2</sup> on 5 consecutive d per week for 4 wk; maintenance, Sub-Q 10 million IU/m <sup>2</sup> 3 times per week for 48 wk <i>Condylomata</i> : intralesionally 1 million IU/lesion (maximum of 5 lesions) 3 times weekly for 3 wk
<b>Peginterferon alfa-2b</b> (PEG-Intron)	Chronic hepatitis C, alone or with ribavirin	Sub-Q 1 mcg once weekly for 1 y
<b>Interferon alfacon-1</b> (Infergen)	Chronic hepatitis C in adults*	Sub-Q 9 mcg 3 times weekly for 24 wk, with at least 48 h between doses
<b>Interferon beta-1a</b> (Avonex, Rebif)	Multiple sclerosis, to reduce frequency of exacerbations	<i>Avonex</i> : IM 30 mcg once per week <i>Rebif</i> : Sub-Q 8.8 mcg for 2 wk, then 22 mcg for 2 wk, then 44 mcg. Give all doses three times weekly, with at least 48 h between doses.
<b>Interferon beta-1b</b> (Betaseron)	Same as interferon beta-1a	Sub-Q 0.25 mg every other day
<b>Interferon gamma-1b</b> (Actimmune)	Reducing frequency and severity of serious infections associated with granulomatous disease	Sub-Q 50 mcg/m <sup>2</sup> if body surface area (BSA) is over 0.5 m <sup>2</sup> ; 1.5 mcg/kg if BSA is under 0.5 m <sup>2</sup> , 3 times weekly
<b>Vaccine</b> Bacillus Calmette-Guérin (TICE BCG, TheraCys)	Bladder cancer	Intravesical instillation by urinary catheter, three vials, reconstituted according to manufacturer's instructions, then diluted further in 50 mL of sterile, preservative-free saline solution (total volume per dose, 53 mL). Repeat once weekly for 6 wk, then give one dose monthly for 6–12 mo (TICE BCG) or one dose at 3, 6, 12, 18, and 24 mo (TheraCys).

\*18 y of age and older.

AIDS, acquired immunodeficiency syndrome; ANC, absolute neutrophil count; IV, international units.

Bacillus Calmette-Guérin (BCG) vaccine, used in the treatment of bladder cancer, is also discussed. Other drugs with immunostimulant properties are discussed in other chapters. These include traditional immunizing agents (see Chap. 39); levamisole (Ergamisol), which restores functions of macrophages and T cells and is used with fluorouracil in the treatment of intestinal cancer (see Chap. 42); and antiviral drugs used in the treatment of acquired immunodeficiency syndrome (AIDS) (see Chap. 35). Levamisole and antiviral drugs are more accurately called immunorestoratives because they help a compromised immune system regain normal function rather than stimulating “supranormal” function. In AIDS, the human immunodeficiency virus (HIV) causes severe immune system dysfunction, so the antiviral drugs indirectly improve immunologic function.

## General Characteristics of Hematopoietic and Immunostimulant Drugs

- Most hematopoietic and *immunostimulant* drugs are synthetic versions of endogenous cytokines (see Chap. 38). Techniques of molecular biology are used to delineate the type and sequence of amino acids and to identify the genes responsible for producing the substances. These genes are then inserted into bacteria (usually *Escherichia coli*) or yeasts capable of producing the substances exogenously.
- Exogenous drug preparations have the same mechanisms of action as the endogenous products. Thus, CSFs bind to receptors on the cell surfaces of immature blood cells in the bone marrow and increase the number, maturity, and functional ability of the cells. Interferons, called alfa, beta, or gamma according to specific characteristics, also bind to specific cell-surface receptors and alter intracellular activities. In viral infections, they induce enzymes that inhibit protein synthesis and degrade viral ribonucleic acid. As a result, viruses are less able to enter uninfected cells, reproduce, and release new viruses.

In addition to their antiviral effects, interferons also have antiproliferative and immunoregulatory activities. They can increase expression of major histocompatibility complex (MHC) molecules, augment the activity of natural killer (NK) cells, increase the effectiveness of antigen-presenting cells in inducing the proliferation of cytotoxic T cells, aid the attachment of cytotoxic T cells to target cells, and inhibit angiogenesis (formation of blood vessels). Because of these characteristics, the interferons are used mainly to treat viral infections and cancers.

- In cancer, the exact mechanisms by which interferons and interleukins exert antineoplastic effects are unknown. However, their immunostimulant effects are thought to enhance activities of immune cells (i.e., NK cells, T cells, B cells, and macrophages), induce tumor-cell antigens (which make

tumor cells more easily recognized by immune cells), or alter the expression of oncogenes (genes that can cause a normal cell to change to a cancer cell). BCG vaccine is thought to act against cancer of the urinary bladder by stimulating the immune system and eliciting a local inflammatory response, but its exact mechanism of action is unknown.

- Exogenous cytokines are given by subcutaneous (Sub-Q) or intravenous (IV) injection because they are proteins that would be destroyed by digestive enzymes if given orally. Darbepoetin alfa (Aranesp), epoetin alfa (Epogen, Procrit), filgrastim (Neupogen, Neulasta), and the interferons are often self- or caregiver-administered to ambulatory patients.
- The drugs may produce adverse effects so that patients do not feel better when taking one of these drugs.
- The combination of injections and adverse effects may lead to noncompliance in taking the drugs as prescribed.
- All of the drugs are contraindicated for use in patients who have previously experienced hypersensitivity reactions to any component of the formulation.

## Classifications and Individual Drugs

### Hematopoietic Agents

**Darbepoetin alfa** (Aranesp) and **epoetin alfa** (Epogen, Procrit) are drug formulations of *erythropoietin*, a hormone from the kidney that stimulates bone marrow production of red blood cells. They are used to prevent or treat anemia associated with several conditions, including chronic renal failure and *myelosuppressive* anticancer chemotherapy (depresses bone marrow function). In chronic renal failure, epoetin has a serum half-life of 4 to 13 hours and produces detectable blood levels of erythropoietin within 24 hours with IV administration. With Sub-Q administration, peak serum levels occur within 5 to 24 hours and then decline slowly. Darbepoetin has a longer half-life (about 49 hours) in patients with chronic renal failure, and peak plasma levels occur in about 34 hours.

These erythropoiesis-stimulating drugs have been used to raise the hemoglobin and reduce the need for blood transfusions in many patients with anemia. However, studies indicated an increased risk of serious cardiovascular problems (e.g., hypertension, thromboembolic events) and death in patients with chronic renal failure and an increased risk of tumor progression and death in patients with cancer. These problems became evident when the drugs were used to achieve normal hemoglobin levels of 12 to 14 grams per deciliter. These results led the U.S. Food and Drug Administration (FDA) to issue a **BLACK BOX WARNING** advising prescribers to avoid using the drugs in patients with hemoglobin values of 12 grams per deciliter or above. In addition, when the drugs are used, they are prescribed at the lowest dose effective in raising hemoglobin levels just enough to avoid the need for blood transfusion, and hemoglobin levels are monitored regularly until they stabilize.

## Colony-Stimulating Factors

**Filgrastim** (Neupogen) and **sargramostim** (Leukine) are drug formulations of granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF), respectively. They are used to stimulate blood cell production by the bone marrow in patients with bone marrow transplantation or chemotherapy-induced *neutropenia*. The drugs can reduce the incidence and severity of infections in neutropenic patients. G-CSF is also used to collect stem cells for transplantation, and GM-CSF is also used to promote growth of blood vessels (angiogenesis) in patients with ischemic heart disease. The drug apparently promotes growth of arterioles around blocked areas in coronary arteries. It may be more effective than drugs that stimulate capillary growth, because arterioles are larger and can carry more blood. Filgrastim is conjugated with polyethylene glycol, in a process called *pegylation*, to produce **pegfilgrastim** (Neulasta), a formulation that stays in the body longer and can be given less often than filgrastim. *When used to stimulate blood cell production, the drugs should be stopped when blood cell counts normalize.*

## Interferons

**Interferons alfa-2a** and **alfa-2b**, structurally the same except for one amino acid, are used to treat hairy-cell leukemia (a type of B-cell leukemia in which the cells are covered with fine, hairlike structures), Kaposi's sarcoma associated with AIDS, and chronic hepatitis. Interferon alfa-2b is also approved for the treatment of genital warts (condylomata) associated with infection by human papillomavirus, non-Hodgkins lymphoma, and malignant melanoma. In chronic hepatitis, interferon alfa-2a or 2b may be combined with ribavirin, another antiviral drug, to increase effectiveness. In condylomata, interferon alfa-2b is injected directly into the lesions for several weeks.

The older preparations of interferon alfa have been largely replaced by peginterferon alfa for some clinical uses. These are interferons that have been conjugated with polyethylene glycol. Pegylation changes the pharmacokinetics of interferons so that they act longer and can be given less often. Peginterferons also provide constant blood levels, whereas unpegylated interferons provide fluctuating levels.

**Interferon alfa-n1** and **alfaon-1** are approved for treatment of chronic hepatitis C, a condition that can lead to liver failure and liver cancer. **Interferon gamma** is used to treat chronic granulomatous disease, which involves impaired phagocytosis of ingested microbes and frequent infections. Drug therapy reduces the incidence and severity of infections. **Interferon beta** is used for multiple sclerosis, an autoimmune neurologic disorder in which the drug slows progression of neurologic dysfunction, prolongs remissions, and reduces the severity of relapses.

Systemic interferons are usually well absorbed, widely distributed, and eliminated primarily by the kidneys. Although the main adverse effects are flu-like symptoms, alfa interferons may also cause or aggravate serious, life-threatening neuropsychiatric (including depression and some reports of suicide),

autoimmune, ischemic, and infectious disorders. Patients receiving the drugs should be closely monitored with clinical and laboratory examinations, and the drugs should be discontinued if persistently severe or worsening signs or symptoms of these disorders occur. In many cases, these disorders resolve after stopping interferon alfa.

## Interleukins

**Aldesleukin** (Proleukin) is a recombinant DNA version of interleukin-2 (IL-2). It activates cellular immunity; produces tumor necrosis factor, interleukin-1 (IL-1), and interferon gamma; and inhibits tumor growth. It is used to treat metastatic kidney cancer and metastatic melanoma skin cancer. The drug is highly toxic and is contraindicated in patients with pre-existing serious cardiovascular or pulmonary impairment. It is given only to hospitalized patients and should be prescribed and administered by health professionals (e.g., oncology nurses) who are experienced in its use. Because the drug is likely to be given by few nurses, details about administration and patient monitoring are omitted in this chapter.

**Oprelvekin** (Neumega) is recombinant IL-11, which stimulates platelet production. It is used to prevent thrombocytopenia and reduce the need for platelet transfusions in patients with cancer who are receiving myelosuppressive chemotherapy. However, its usefulness is limited because it is ineffective in severe thrombocytopenia and is highly toxic. Because of infrequent use, details about administration and patient monitoring are omitted in this chapter.

## Bacillus Calmette-Guérin

**Bacillus Calmette-Guérin vaccine** is a suspension of weakened *Mycobacterium bovis*, long used as an immunizing agent against tuberculosis. The drug's immunostimulant properties stem from its ability to stimulate cell-mediated immunity. It is used as a topical agent to treat superficial cancers of the urinary bladder, in which approximately 80% of patients achieve a therapeutic response. BCG is contraindicated in immunosuppressed patients because the live tubercular organisms may cause tuberculosis in this high-risk population.

## Nursing Process

### Assessment

- Assess the patient's status in relation to conditions for which hematopoietic and immunostimulant drugs are used (e.g., infection, neutropenia, cancer).
- Assess nutritional status, including appetite and weight.
- Assess functional abilities in relation to activities of daily living (ADLs).
- Assess adequacy of support systems for outpatients (e.g., transportation for clinic visits).
- Assess ability and attitude toward planned drug therapy and associated monitoring and follow-up.

*Nursing Process continues on page 648*

- Assess coping mechanisms of patient and significant others in stressful situations.
- Assess patient for factors predisposing to infection (e.g., skin lesions, invasive devices, cigarette smoking).
- Assess environment for factors predisposing to infection (e.g., family or health care providers with infections).
- Assess baseline values of laboratory and other diagnostic test reports to aid monitoring of responses to hematopoietic and immunostimulant drug therapy.

### Nursing Diagnoses

- Risk for Injury: Infection related to drug-induced neutropenia, immunosuppression, malnutrition, chronic disease; bleeding related to anemia or thrombocytopenia
- Risk for Injury: Adverse drug effects
- Activity Intolerance related to weakness, fatigue from debilitating disease, or drug therapy
- Anxiety related to the diagnosis of cancer, hepatitis, multiple sclerosis, or HIV infection
- Deficient Knowledge: Disease process; hematopoietic and immunostimulant drug therapy

### Planning/Goals

#### The patient will

- Participate in interventions to prevent or decrease infection
- Remain afebrile during immunostimulant therapy
- Experience increased immunocompetence as indicated by increased white blood cell (WBC) count (if initially leukopenic) or tumor regression
- Avoid preventable infections
- Experience relief or reduction of disease symptoms
- Maintain independence in ADLs when able; be assisted appropriately when unable
- Maintain adequate levels of nutrition and fluids, rest and sleep, and exercise
- Maintain or increase appetite and weight if initially anorexic and underweight
- Learn to self-administer medications accurately when indicated

### Interventions

- Practice and promote good hand hygiene techniques by patients and all others in contact with the patient.
- Use sterile technique for all injections, IV site care, wound dressing changes, and any other invasive diagnostic or therapeutic measures.
- Screen staff and visitors for signs and symptoms of infection; if infection is noted, do not allow contact with the patient.

- Allow patients to participate in self-care and decision making when feasible.
- Use isolation procedures when indicated, usually when the neutrophil count is less than 500/mm<sup>3</sup>.
- Promote adequate nutrition, with nutritious fluids, supplements, and snacks when indicated.
- Promote adequate rest, sleep, and exercise (e.g., schedule frequent rest periods, avoid interrupting sleep when possible, individualize exercise or activity according to the patient's condition).
- Inform patients about diagnostic test results, planned changes in therapeutic regimens, and evidence of progress.
- Allow family members or significant others to visit patients when feasible.
- Monitor complete blood count (CBC) and other diagnostic test reports for normal or abnormal values. **Note that darbepoetin and epoetin should be stopped when the hemoglobin level approaches 12 grams and filgrastim and sargramostim should be stopped when white blood cell counts normalize.** Report test results to prescribers when indicated.
- Schedule drug administration, diagnostic tests, and other elements of care to conserve patients' energy.
- Consult other health care providers (e.g., physician, dietitian, social worker) on the patient's behalf when indicated.
- Assist patients to learn ways to prevent or reduce the incidence of infections (e.g., meticulous personal hygiene, avoiding contact with infected people).
- Assist patients to learn ways to enhance immune mechanisms and other body defenses by healthy lifestyle habits, such as a nutritious diet, adequate rest and sleep, and avoidance of tobacco and alcohol.
- Assist patients or caregivers in learning how to prepare and inject darbepoetin alfa, epoetin alfa, filgrastim, or an interferon, when indicated.

### Evaluation

- Determine the number and type of infections that have occurred in neutropenic patients.
- Compare current CBC reports with baseline values for changes toward normal levels (e.g., WBC count 5000–10,000/mm<sup>3</sup>).
- Compare weight and nutritional status with baseline values for maintenance or improvement.
- Observe and interview for decreased numbers or severity of disease symptoms.
- Observe for increased energy and ability to participate in ADLs.
- Observe and interview outpatients regarding compliance with follow-up care.
- Observe and interview regarding the mental and emotional status of the patient and family members.

## Patient Teaching Guidelines

## Blood Cell and Immune System Stimulants

### General Considerations

- Help your body maintain immune mechanisms and other defenses by healthy lifestyle habits, such as a nutritious diet, adequate rest and sleep, and avoidance of tobacco and alcohol.
- Practice meticulous personal hygiene and avoid people and circumstances in which you are exposed to infection.
- Keep appointments with health care providers for follow-up care, blood tests, and so forth.
- Inform any other physician, dentist, or health care provider about your condition and the medications you are taking.
- Several of these medications can be taken at home, even though they are taken by injection. If you are going to self-inject a medication at home, allow sufficient time to learn and practice the techniques under the supervision of a health care provider. Correct preparation and injection are necessary to increase beneficial effects and decrease adverse effects.
- With interferons, report the occurrence of depression or thoughts of suicide, dizziness, hives, itching, chest tightness, cough, difficulty breathing or wheezing, or visual problems. These symptoms may require that the drug be

stopped or the dosage reduced. In addition, avoid pregnancy (use effective contraceptive methods), avoid prolonged exposure to sunlight, wear protective clothing, and use sunscreens.

### Self- or Caregiver Administration

- Take the drugs as prescribed. Although this is important with all medications, it is especially important with these. Obtaining beneficial effects and decreasing adverse effects depend to a great extent on how the drugs are taken.
- Use correct techniques to prepare and inject the medications. Instructions for mixing the drugs should be followed exactly.
  - With interferons:
    - Store in the refrigerator.
    - Do not freeze or shake the drug vial.
    - Do not change brands (changes in dosage may result).
    - Take at bedtime to reduce some common adverse effects (e.g., flu-like symptoms such as fever, headache, fatigue, anorexia, nausea, and vomiting).
    - Take acetaminophen (e.g., Tylenol, others), if desired, to prevent or decrease fever and headache.
    - Maintain a fluid intake of 2 to 3 quarts daily.

### Applying Your Knowledge 40-1

Mrs. Paul has a great risk for infection with her low WBC count and absolute neutrophil count. What should the nurse teach the patient about preventing infection?

.....

## Principles of Therapy

### Drug Dosage

With darbepoetin and epoetin, dosage is adjusted to achieve and maintain a hemoglobin value of no more than 12 grams per deciliter (serious adverse effects may occur with values higher than 12 g/dL). Dosage should be reduced when the hemoglobin level approaches 12 grams per deciliter or increases by more than 1 gram per deciliter in any 2-week period. With interferons, optimal dosages have not been established. For patients who experience severe adverse reactions with interferon alfa, dosage should be reduced by 50% or administration stopped until the reaction subsides.

### Laboratory Monitoring

With darbepoetin and epoetin, iron stores (transferrin saturation and serum ferritin) should be measured before and periodically during treatment. Hemoglobin should be measured twice weekly until stabilized and maintenance drug doses are established.

With most of the hematopoietic and immunostimulant drugs, a CBC with WBC differential and platelet count should be done before and during treatment to monitor response and prevent avoidable adverse reactions. With CSF, these tests are recommended twice weekly during drug administration. With interferons alfacon-1 and alfa-n1, tests of platelet and neutrophil counts, hemoglobin, serum creatinine, serum albumin, and thyroid-stimulating hormone are recommended for all patients before starting therapy, 2 weeks later, and periodically thereafter during the 24 weeks of therapy.

### Use in Special Populations

#### Use in Patients With Cancer

##### Hematopoietic Agents

Darbepoetin and epoetin are often used to prevent or treat anemia in patients with cancer. Studies indicate that patients with cancer-related anemia and a hemoglobin of 10 grams per deciliter or less feel better and require fewer blood transfusions with use of the drugs. An adequate intake of iron is required for drug effectiveness and an iron supplement is usually necessary.

Despite the benefits, evidence indicates that these agents may stimulate tumor growth, mainly when the drugs are used to achieve normal hemoglobin levels of 12 to 14 grams per deciliter. As a result, prescribers are warned to avoid dosages that increase hemoglobin to above 12 grams per deciliter. In addition, because cancer-related anemia may have numerous causes, some authorities recommend a return to the original indication for use of these drugs in cancer, that is, for anemia induced by chemotherapy that depresses bone marrow function.

### Colony-Stimulating Factors

Filgrastim, pegfilgrastim, and sargramostim are used to restore, promote, or accelerate bone marrow function in patients with cancer who are undergoing chemotherapy or bone marrow transplantation. With chemotherapy, many drugs cause bone marrow depression and result in anemia and neutropenia. Neutropenic patients are at high risk for bacterial, fungal and viral infections, which often stem from the normal microbial flora of the patient's body or environmental microorganisms. The patient is most vulnerable to infection when the neutrophil count falls below 500/mm<sup>3</sup>. Filgrastim and pegfilgrastim help to prevent infection by reducing the incidence, severity, and duration of neutropenia associated with several chemotherapy regimens. Most patients taking these drugs have fewer days of fever, infection, and antimicrobial drug therapy. In addition, by promoting bone marrow recovery after a course of cytotoxic antineoplastic drugs, the drugs also may allow higher doses or more timely administration of subsequent antitumor drugs.

When filgrastim is given to prevent infection in neutropenic patients with cancer, the drug should be started at least 24 hours after the last dose of the antineoplastic agent and continued during the period of bone marrow suppression and recovery. CBC and platelet counts should be performed twice weekly during therapy, and the drug should be stopped if the neutrophil count exceeds 10,000/mm<sup>3</sup>. Pegfilgrastim should not be given between 14 days before and 24 hours after cytotoxic chemotherapy.

When sargramostim is given to patients with cancer who have had bone marrow transplantation, the drug should be started 2 to 4 hours after the bone marrow infusion and at least 24 hours after the last dose of antineoplastic chemotherapy or 12 hours after the last radiotherapy treatment. CBC should be done twice weekly during therapy, and the neutrophil count should not exceed approximately 20,000/mm<sup>3</sup>.

### Applying Your Knowledge 40-2

#### How Can You Avoid This Medication Error?

Mrs. Paul is having her blood work done 10 days before chemotherapy. The nurse administers pegfilgrastim for the low WBC according to the standing orders for a WBC below 5000. What should the nurse have taken into account before giving the injection?

### Interferons

Interferon alfa has demonstrated antitumor effects in multiple myeloma, renal cell carcinoma, and others. In chronic myelogenous leukemia (CML), 70% response rates have been reported, and some patients undergo complete remission. Common solid tumors of the breast, lung, and colon are unresponsive.

In hairy-cell leukemia, interferons normalize WBC counts in 70% to 90% of patients. Drug therapy must be continued

indefinitely to avoid relapse, which usually develops rapidly after the drug is discontinued. In AIDS-related Kaposi's sarcoma, larger doses are required than in other clinical uses, with resultant increases in toxicity. Interferon alfa is recommended for patients with CD4 cell counts higher than 200 per milliliter (CD4 cells are the helper T cells attacked by the AIDS virus), who have no systemic symptoms, and who have had no opportunistic infections. Approximately 40% of these patients achieve a therapeutic response that lasts 1 to 2 years. In addition to antineoplastic effects, data indicate that viral replication is suppressed in responding patients.

### Bacillus Calmette-Guérin Vaccine

Bacillus Calmette-Guérin, when instilled into the urinary bladder of patients with superficial bladder cancer, causes remission in up to 82% of patients for an average of 4 years. Early, successful treatment of carcinoma in situ also prevents development of invasive bladder cancer. A specific protocol has been developed for administration of BCG solution, and it should be followed exactly.

### Applying Your Knowledge 40-3

Epoetin alfa is prescribed for Mrs. Paul's anemia. What dietary consideration should the nurse be aware of?

### Use in Patients Undergoing Bone Marrow and Stem Cell Transplantation

Filgrastim, pegfilgrastim, and sargramostim are used to treat patients who undergo bone marrow transplantation for Hodgkin's disease, non-Hodgkin's lymphoma, or acute lymphoblastic leukemia. Before receiving a bone marrow transplant, the patient's immune system is suppressed by anticancer drugs or irradiation. After transplantation, it takes 2 to 4 weeks for the engrafted bone marrow cells to mature and begin producing blood cells. During this time, the patient has virtually no functioning granulocytes and is at high risk for infection. Sargramostim promotes engraftment and function of the transplanted bone marrow, thereby decreasing risks of infection. If the graft is successful, the granulocyte count starts to rise in approximately 2 weeks. Sargramostim also is used to treat graft failure.

In stem cell transplantation, filgrastim or sargramostim is used to stimulate the movement of hematopoietic stem cells from the bone marrow to circulating blood, where they can be readily collected. Transplantation of large numbers of stem cells can lead to more rapid engraftment and recovery, with less risk of transplant failure and complications.

### Use in Patients With Chronic Viral Hepatitis

Chronic hepatitis B and hepatitis C (see Chap. 35) may lead to liver failure (and a need for liver transplantation) or liver cancer. Hepatitis B becomes chronic in 5% to 10% of patients. Interferon alfa and lamivudine or other antiviral drugs may be

used for treatment. Drug resistance may develop and active hepatitis may resume when the drugs are discontinued.

Hepatitis C most often affects young adults, 20 to 39 years old, although it may affect people of any age. It can remain asymptomatic for years, but 70% to 80% of infected people eventually develop chronic liver disease. Hepatitis C may be treated with a combination of an interferon (alfa-2b, pegylated alfa-2b, alfacon-1, or pegylated alfa-2a) and ribavirin; interferon monotherapy is used only when there are specific reasons not to use ribavirin. The current drug therapy of choice is peginterferon alfa-2a and ribavirin. Because peginterferon can be given once per week and maintains constant blood levels, it has largely replaced other interferons for both monotherapy and combination therapy for hepatitis C. The duration of drug therapy is determined by the particular strain of the causative virus. Genotypes 2 and 3 are more responsive and require 24 weeks of drug therapy, whereas genotypes 1 and 4 require 48 weeks.

### Use in Children

There has been limited experience with hematopoietic and immunostimulant drugs in children (younger than 18 years of age), and the drugs' safety and effectiveness have not been established. Filgrastim and sargramostim have been used in children with therapeutic and adverse effects similar to those in adults. In clinical trials, filgrastim produced a greater incidence of subclinical spleen enlargement in children than in adults, but whether this affects growth and development or has other long-term consequences is unknown.

Little information is available about the use of interferons in children. Interferon alfa-2b may be used to treat chronic hepatitis B in children. It is given Sub-Q in doses of 3 million units per/m<sup>2</sup> three times per week for the first week, then 6 million units/m<sup>2</sup> three times per week for 16 to 24 weeks. Dosage should be reduced by 50% or the drug discontinued if serious adverse effects or laboratory abnormalities develop.

### Use in Older Adults

In general, hematopoietic and immunostimulant agents have the same uses and responses in older adults as in younger adults. Older adults may be at greater risk of adverse effects, especially if large doses are used.

### Use in Patients With Renal Impairment

Except for darbepoetin and epoetin, which are used to treat anemia in patients with chronic renal failure, little information is available about the use of hematopoietic and immunostimulant drugs in patients with renal impairment. In some patients with pre-existing renal impairment, sargramostim increased serum creatinine. Values declined to baseline levels when the drug was stopped or its dosage reduced. Renal function tests are recommended every 2 weeks in patients with pre-existing impairment.

### Use in Patients With Hepatic Impairment

In some patients with pre-existing hepatic impairment, sargramostim increased serum bilirubin and liver enzymes. Values declined to baseline levels when the drug was stopped or its dosage reduced. Liver function tests are recommended every 2 weeks in patients with pre-existing impairment.

Interferons may aggravate hepatic impairment. Interferons alfa-2b, alfacon-1, and alfa-n1 are contraindicated in patients with signs and symptoms of liver disease (e.g., jaundice, ascites, bleeding disorders, or decreased serum albumin), autoimmune hepatitis, a history of autoimmune disease, or posttransplantation immunosuppression. Worsening of liver disease, with jaundice, hepatic encephalopathy, hepatic failure, and death, has occurred in these patients. The drugs should be discontinued in patients with signs and symptoms of liver failure.

### Use in Home Care

Darbepoetin, epoetin, filgrastim, pegfilgrastim, and the interferons are often self-administered or given by a caregiver to chronically ill patients. The home care nurse may need to teach patients or caregivers accurate drug preparation and injection techniques as well as proper disposal of needles and syringes. Assistance may also be needed in obtaining appropriate laboratory tests (e.g., CBC, platelet count, tests of renal or hepatic function) to monitor patients' responses to the medications. Other interventions depend on the drug being taken. For example, epoetin is not effective unless sufficient iron is present, and most patients need an iron supplement. When an iron preparation is prescribed, the home care nurse may need to emphasize the importance of taking it. With filgrastim, the nurse may need to help the patient and family with techniques to reduce exposure to infection.

## Nursing Actions

## Hematopoietic and Immunostimulant Agents

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give darbepoetin intravenously (IV) or subcutaneously (Sub-Q) once weekly; omit the dose if the hemoglobin level is above 12 g/dL.
- b. Give epoetin IV or Sub-Q; do not shake the vial; and discard any remainder of multidose vials 21 days after opening. Omit the dose if the hemoglobin level is above 12g/dL.

### RATIONALE/EXPLANATION

The drugs are preferably prepared in a pharmacy. When nurses or patients prepare the drugs, they should consult the manufacturer's instructions.

Outpatients may be taught self-administration.

## Nursing Actions Hematopoietic and Immunostimulant Agents (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

- c. Give filgrastim (Neupogen) according to indication for use:
- (1) With cancer chemotherapy, give by Sub-Q bolus injection, IV infusion over 15–30 minutes, or continuous Sub-Q or IV infusion.
  - (2) For bone marrow transplantation, give by IV infusion over 4 hours or by continuous IV or Sub-Q infusion.
  - (3) For collection of stem cells, give as a bolus or a continuous infusion.
  - (4) For chronic neutropenia, give Sub-Q.
- d. Give pegfilgrastim (Neulasta) Sub-Q only.
- e. Give sargramostim by IV infusion over 2 hours, after reconstitution with 1 mL sterile water for injection and addition to 0.9% sodium chloride.
- f. With interferons:
- (1) Read drug labels carefully to ensure having the correct drug preparation.
  - (2) Give most interferons Sub-Q, 3 times weekly, on a regular schedule (e.g., Mon., Wed., and Fri.), at about the same time of day, at least 48 hours apart.
  - (3) Inject interferon for condylomata intralesionally into the base of each wart with a small-gauge needle. For large warts, inject at several points.
- g. With intravesical bacillus Calmette-Guérin (BCG):
- (1) Reconstitute solution (see Table 40-1).
  - (2) Wear gown and gloves.
  - (3) Insert a sterile urethral catheter and drain bladder.
  - (4) Instill medication slowly by gravity.
  - (5) Remove catheter.
  - (6) Have the patient lie on abdomen, back, and alternate sides for 15 min in each position. Then, allow to ambulate but ask to retain solution for a total of 2 hours before urinating, if able.
  - (7) Dispose of all equipment in contact with BCG solution appropriately.
  - (8) Do not give if catheterization causes trauma (e.g., bleeding), and wait 1 week before a repeat attempt.

### 2. Observe for therapeutic effects

- a. With darbepoetin and epoetin, observe for increased red blood cells, hemoglobin, and hematocrit; increased energy and exercise capacity; improved quality of life.
- b. With parenteral interferons, observe for improvement in signs and symptoms.
- c. With intralesional interferon, observe for disappearance of genital warts.

### 3. Observe for adverse effects

- a. With darbepoetin and epoetin, observe for nausea, vomiting, diarrhea, arthralgias, hypertension, and other cardiovascular problems.

For patients with chronic renal failure on hemodialysis, epoetin can be given by bolus injection at the end of dialysis. For other patients with an IV line, the drug can be given IV. For patients without an IV line or who are ambulatory, the drug is injected Sub-Q. Shaking can inactivate the medication; the manufacturer does not ensure sterility or stability of multidose vials after 21 days. Manufacturer's recommendation

Manufacturer's recommendation

Available drugs have similar names but often differ in indications for use, dosages, and routes of administration. Manufacturer's recommendation

Manufacturer's recommendation

Reconstituted solution should be used immediately or refrigerated. Discard if not used within 2 hours.

BCG contains live mycobacterial organisms and is infectious.

Therapeutic effects depend on the dose and the patient's underlying condition. The goal is usually to achieve and maintain a hemoglobin of no more than 12 g/dL. With hairy-cell leukemia, hematologic tests may improve within 2 months, but optimal effects may require 6 months of drug therapy. With Kaposi's sarcoma, skin lesions may resolve or stabilize over several weeks. With chronic hepatitis, liver function tests may improve within a few weeks. Lesions usually disappear after several weeks of treatment.

Hypertension commonly occurs. The drugs also increase risks of myocardial infarction and stroke, especially if they are used to achieve hemoglobin levels greater than 12 g/dL.

**NURSING ACTIONS**

- b. With filgrastim, observe for nausea, vomiting, diarrhea, mucositis, bone pain, and erythema at Sub-Q injection sites.
- c. With pegfilgrastim, observe for bone pain, constipation, headache, muscle and joint pain, peripheral edema, and vomiting.
- d. With sargramostim, observe for bone pain, fever, headache, muscle aches, generalized maculopapular skin rash, and fluid retention (peripheral edema, pleural effusion, pericardial effusion).
- e. With interferons, observe for acute flu-like symptoms (e.g., fever, chills, fatigue, muscle aches, headache), nausea, vomiting, diarrhea, tissue damage at injection sites, chronic fatigue, depression, leukopenia, and increased liver enzymes.
- f. With intravesical BCG, assess for symptoms of bladder irritation (e.g., frequency, urgency, dysuria, hematuria) and systemic symptoms of fever, chills, and malaise.

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of sargramostim:
  - (1) Corticosteroids, lithium

**RATIONALE/EXPLANATION**

Bone pain occurs in approximately 25% of patients.

Bone pain occurs in approximately one-third to one-half of patients. Other effects occur in more than 10% of patients.

Pleural and pericardial effusions are more likely at doses greater than 20 mcg/kg/d. Adverse effects occur more often with sargramostim than filgrastim.

Acute effects occur in most patients, increasing with higher doses and decreasing with continued drug administration. Injection site damage occurs with all the interferons but more commonly with interferon beta-1b and pegylated interferon alfa-2b. Fatigue and depression occur with long-term use. These effects occur in more than 50% of patients, usually starting a few hours after administration and lasting 2 to 3 days.

Note: No significant interactions have been reported with darbepoetin or epoetin.

These drugs have myeloproliferative (bone-marrow stimulating) effects of their own, which may add to those of sargramostim.

## Key Concepts

---

- A drug formulation of erythropoietin is given to increase red blood cells in patients with anemia associated with chronic renal failure or bone marrow–damaging anticancer drug therapy.
- Adverse effects of epoetin and darbepoetin include increased risks of hypertension, myocardial infarction, and stroke, especially when used to increase hemoglobin above 12 grams per deciliter.
- Filgrastim is used to increase white blood cells and decrease risks of infection in patients with or at high risk of severe neutropenia.
- Interferons are used mainly for viral hepatitis and certain types of cancer.
- Filgrastim and some interferons are conjugated with polyethylene glycol, in a process called pegylation, to prolong drug actions.

## Review and Application Exercises

---

### Short Answer Exercises

1. What are the hematopoietic, colony-stimulating cytokines, and how do they function in the body?
2. What are adverse effects of filgrastim and sargramostim, and how may they be prevented or minimized?
3. What are the clinical uses of pharmaceutical interferons?
4. What are the adverse effects of interferons, and how can they be prevented or minimized?
5. Describe the clinical uses of hematopoietic and immunostimulant drugs in the treatment of anemia, neutropenia, cancer, bone marrow transplantation, and chronic viral hepatitis.

### NCLEX-Style Questions

6. The expected outcome of administering epoetin alfa (Epoen, Procrit) or darbepoetin alfa (Aranesp) to a patient with chronic renal failure is
  - a. decreased bleeding
  - b. increased WBC production
  - c. increased RBC production
  - d. improved renal function

7. The nurse who is administering epoetin alfa knows that most patients who take epoetin or darbepoetin also need to take
  - a. iron
  - b. potassium
  - c. antacids
  - d. analgesics
8. The nurse is caring for a patient who is undergoing chemotherapy for cancer. Filgrastim is ordered. The nurse explains to the patient that an expected outcome after the administration of filgrastim (Neupogen) is
  - a. fewer infections
  - b. decreased anemia
  - c. longer life expectancy
  - d. less nausea and vomiting
9. Interferon may be used to treat
  - a. most types of cancer
  - b. chronic hepatitis C
  - c. flu-like symptoms
  - d. mental depression
10. BCG for bladder cancer would be contraindicated for patients with a history of
  - a. heart disease
  - b. diabetes mellitus
  - c. pulmonary fibrosis
  - d. organ transplantation

# Immunosuppressants

## KEY TERMS

- Autoantigens
- Autoimmune disorders
- Cytotoxic
- Graft rejection reaction
- Graft-versus-host disease
- Immunosuppression
- Monoclonal antibody
- Murine antibodies
- Transplantation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe characteristics and consequences of immunosuppression.
2. Discuss characteristics and uses of major immunosuppressant drugs in autoimmune disorders and organ transplantation.
3. Identify adverse effects of immunosuppressant drugs.
4. Discuss nursing interventions to decrease adverse effects of immunosuppressant drugs.
5. Teach patients, family members, and caregivers about safe and effective immunosuppressant drug therapy.
6. Assist patients and family members to identify potential sources of infection in the home care environment.

## Applying Your Knowledge

Richard Kinney is a 58-year-old college administrator. He has had a long-standing history of hypertension that resulted in severe kidney damage. He required a kidney transplant 2 years ago. His current immunosuppressive drug regimen consists of prednisone, cyclosporine, sirolimus, and mycophenolate.

## Introduction

Immunosuppressant drugs interfere with the production or function of immune cells and cytokines. The drugs are used to decrease an undesirable immune response.

The immune response is normally a protective mechanism (see Chap. 38) that helps the body defend itself against potentially harmful agents. However, disease processes develop when the immune system perceives normally harmless substances (e.g., allergens) or the person's own body tissues as harmful invaders and tries to eliminate them. This inappropriate activation of the immune response is a major factor in allergic and autoimmune disorders (e.g., rheumatoid arthritis [RA], Crohn's disease, psoriasis).

An appropriate but undesirable immune response occurs when foreign tissue is transplanted into the body. If the immune response is not suppressed, the body reacts as with other antigens and attempts to destroy the foreign tissue (*graft rejection reaction*). Although numerous advances have been made in *transplantation* technology, the immune response remains a major factor in determining the success or failure of transplantation.

Drugs used therapeutically as immunosuppressants comprise a diverse group, several of which also are used for other purposes. These include corticosteroids (see Chap. 23) and certain *cytotoxic* antineoplastic drugs (see Chap. 42). These drugs are discussed here in relation to their effects on the immune response. The drugs used to treat inflammatory autoimmune disorders or to prevent or treat

transplant rejection reactions are the main focus of this chapter. These drugs are described in the following sections and in Table 41-1. To aid in the understanding of immunosuppressive drug therapy, selected inflammatory autoimmune disorders, tissue transplantation, and rejection reactions are described.

## Autoimmune Disorders

Autoimmune disorders occur when a person's immune system loses its ability to differentiate between antigens on its own cells (called self-antigens or *autoantigens*) and antigens on foreign cells. As a result, an immune response is aroused against

host tissues. Autoantigens for some disorders have been identified as specific proteins and are found in affected tissues; in other disorders, the autoantigen is unknown. Even when the autoantigen is known, the mechanism by which it is altered to elicit an immune response is unclear. Potential mechanisms include genetic susceptibility and possible "triggering" events (e.g., tissue damage by microorganisms or trauma, similarities between autoantigens and foreign antigens). After an autoantigen is changed so that it is perceived as foreign or "nonself," the immune response may involve T lymphocytes in direct destruction of tissue, production of proinflammatory cytokines that

Table 41-1

### Drugs at a Glance: Immunosuppressants

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Abatacept</b> (Orencia)	Rheumatoid arthritis	IV, according to body weight, initially, at 2 and 4 wk after initial dose, then every 4 wk. Weight below 60 kg, 500 mg; 60–100 kg, 750 mg; above 100 kg, 1000 mg
<b>Adalimumab</b> (Humira)	Rheumatoid arthritis Crohn's disease	Sub-Q 40 mg every other week
<b>Alefacept</b> (Amevive)	Psoriasis	IM 15 mg once weekly for 12 wk; IV 7.5 mg once weekly for 12 wk
<b>Anakinra</b> (Kineret)	Rheumatoid arthritis	Sub-Q 100 mg once daily
<b>Antithymocyte globulin</b> (Atgam, equine; Thymoglobulin, rabbit) dasd	Atgam, prevent or treat renal transplant rejection; treat aplastic anemia Thymoglobulin, treat renal transplant rejection	Atgam, IV 15 mg/kg/d for 14 d, then every other day for 14 d (total of 21 doses) Thymoglobulin, IV 1.5 mg/kg/d for 7–14 d
<b>Basiliximab</b> (Simulect)	Prevent renal transplant rejection	<i>Adults:</i> IV 20 mg within 2 h before transplantation and 20 mg 4 d after transplantation (total of two doses) <i>Children (2–15 y):</i> IV 12 mg/m <sup>2</sup> up to a maximum of 20 mg for two doses as for adults
<b>Cyclosporine</b> (Sandimmune, Neoral)	Prevent rejection of solid organ (e.g., heart, kidney, liver) transplant Prevent and treat graft-versus-host disease in bone marrow/stem cell transplantation Psoriasis Rheumatoid arthritis	<i>Sandimmune:</i> PO 15 mg/kg 4–12 h before transplantation, then 15 mg/kg once daily for 1–2 wk, then decrease by 5% per week to a maintenance dose of 5–10 mg/kg/d; IV 5–6 mg/kg infused over 2–6 h <i>Neoral:</i> PO, the first dose in patients with new transplants is the same as the first oral dose of Sandimmune; later doses are titrated according to cyclosporine blood levels.
<b>Daclizumab</b> (Zenapax)	Prevent renal transplant rejection	IV 1 mg/kg over 15 min. First dose within 24 h before transplantation, then a dose every 14 d for four doses (total of five doses)
<b>Efalizumab</b> (Raptiva)	Psoriasis	Sub-Q 0.7 mg/kg initially, then 1 mg/kg once weekly
<b>Etanercept</b> (Enbrel)	Rheumatoid arthritis Psoriatic arthritis Ankylosing spondylitis Juvenile chronic arthritis	<i>Adults:</i> Sub-Q 25 mg twice weekly, 72–96 h apart <i>Children (4–17 y):</i> Sub-Q 0.4 mg/kg up to a maximum of 25 mg per dose, twice weekly, 72–96 h apart

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Infliximab</b> (Remicade)	Crohn's disease Rheumatoid arthritis Psoriasis	IV infusion, 3–5 mg/kg initially, 2 and 6 wk later, then every 8 wk
<b>Leflunomide</b> (Arava)	Rheumatoid arthritis	PO 100 mg once daily for 3 d, then 20 mg once daily
<b>Methotrexate</b> (MTX) (Rheumatrex)	Severe rheumatoid arthritis unresponsive to other treatment Psoriasis	PO 7.5 mg/wk as single dose, or 2.5 mg q12h for 3 doses once weekly
<b>Muromonab-CD3</b> (Orthoclone OKT3)	Treatment of renal, cardiac, and hepatic transplant rejection	IV 5 mg bolus injection once daily for 10–14 d
<b>Mycophenolate mofetil</b> (CellCept, Myfortic)	Prevent renal, cardiac, and hepatic transplant rejection	Renal transplantation: PO, IV 1 g twice daily Cardiac and hepatic transplantation: PO, IV 1.5 g twice daily Extended-release tablets (Myfortic): PO 720 mg twice daily
<b>Omalizumab</b> (Xolair)	Allergic asthma	Sub-Q variable, according to weight and serum IgE levels. See manufacturer's instructions.
<b>Sirolimus</b> (Rapamune)	Prevent renal transplant rejection	Adults: PO 6 mg as soon after transplantation as possible, then 2 mg daily Children over 13 y: PO 3 mg/m <sup>2</sup> as loading dose, then 1 mg/m <sup>2</sup> daily
<b>Tacrolimus</b> (Prograf)	Prevent heart, kidney, and liver transplant rejection	Adults: IV infusion, 25–50 mcg/kg/d, starting 6 h after transplantation or later, until the patient can tolerate oral drug PO 150–200 mcg/kg/d, in two divided doses q12h, with the first dose 8–12 h after stopping the IV infusion Children: IV 50–100 mcg/kg/d; PO 200–300 mcg/kg/d

IgE, immunoglobulin E.

attract and activate phagocytes, and stimulation of B lymphocytes to produce antibodies that lead to inflammation and tissue damage.

Knowledge about the roles of inflammatory cells and cytokines in the immunologic response to tissue injury has increased in recent years. One example involves tumor necrosis factor (TNF)-alpha, a cytokine that plays a major role in the response to infection. Functions of TNF include activation of monocytes, macrophages, and cytotoxic T cells; enhancement of natural killer (NK) cell functions; increased leukocyte movement into areas of tissue injury; increased phagocytosis by neutrophils; and stimulation of B and T lymphocytes. Despite beneficial effects of a “normal” amount of TNF, however, an excessive TNF response has been associated with the pathogenesis of *autoimmune disorders* such as RA and Crohn's disease.

In addition to the factors that activate an immune response, there are also factors that prevent the immune system

from “turning off” the abnormal immune or inflammatory process. One of these factors may be an inadequate number of suppressor T cells, which are thought to be a subpopulation of helper or cytotoxic T cells. Another factor may be inadequate amounts of anti-inflammatory cytokines (e.g., interleukin [IL]-10).

In general, autoimmune disorders share inflammation as a major mechanism of tissue damage. Allergic asthma, Crohn's disease, psoriasis, psoriatic arthritis, and RA are inflammatory disorders that may be treated with immunosuppressant drugs.

## Tissue and Organ Transplantation

Tissue and organ transplantation involves replacing diseased host tissue with healthy donor tissue. The goal of such treatment is to save or enhance the quality of the host's life. Skin and renal grafts are commonly performed; heart, liver, lung, pancreas, and bone marrow/stem cell transplantations are

increasing. (Bone marrow cells from bone marrow aspiration can be used in transplants, but they have largely been replaced by hematopoietic stem cells mobilized from bone marrow into circulating blood, where they are easily retrieved.)

Although many factors affect graft survival, including the degree of matching between donor tissues and recipient tissues, drug-induced *immunosuppression* is a major part of transplantation protocols. The goal is to provide adequate immunosuppression. If immunosuppression is inadequate, graft rejection reactions occur with solid organ transplantation, and *graft-versus-host disease* (GVHD) occurs with bone marrow/stem cell transplantation. If immunosuppression is excessive, the patient develops serious infections and other adverse effects because the drug actions that slow the proliferation of activated lymphocytes also affect any rapidly dividing nonimmune cells. Serious complications can occur.

### Rejection Reactions With Solid Organ Transplantation

A rejection reaction occurs when the host's immune system is stimulated to destroy the transplanted organ. The immune cells of the transplant recipient attach to the donor cells of the transplanted organ and react against the antigens of the donor organ. The rejection process involves T and B lymphocytes, antibodies, multiple cytokines, and inflammatory mediators. In general, T-cell activation and proliferation are more important in the rejection reaction than B-cell activation and formation of antibodies. Cytotoxic and helper T cells are activated; activated helper T cells stimulate B cells to produce antibodies and lead to a delayed hypersensitivity reaction. The antibodies injure the transplanted organ by activating complement, producing antigen-antibody complexes, or causing antibody-mediated tissue breakdown. This reaction can destroy the solid organ graft within 2 weeks if the recipient's immune system is inadequately suppressed by immunosuppressant drugs.

Rejection reactions are acute or chronic. Acute reactions may occur from 10 days to a few months after transplantation and mainly involve cellular immunity and proliferation of T lymphocytes. Characteristics include signs of organ failure and vasculitis lesions that often lead to arterial narrowing or obliteration. Treatment with immunosuppressant drugs is usually effective in ensuring short-term survival of the transplant but does not prevent chronic rejection. Chronic reactions occur after months or years of normal function, are caused by both cellular and humoral immunity, and do not respond to increased immunosuppressive drug therapy. Characteristics include fibrosis of blood vessels and progressive failure of the transplanted organ.

Rejection reactions produce general manifestations of inflammation and specific manifestations depending on the organ involved. With renal transplantation, for example, acute rejection reactions produce fever, flank tenderness over the graft organ site, and symptoms of renal failure (e.g., increased serum creatinine, decreased urine output, edema, weight gain, hypertension). Chronic rejection reactions are characterized by a gradual increase in serum creatinine levels over 4 to 6 months.

### Bone Marrow/Stem Cell Transplantation and Graft-Versus-Host Disease

With bone marrow/stem cell transplantation, the donor cells mount an immune response (mainly by stimulating T lymphocytes) against antigens on the host's tissues, producing GVHD. Tissue damage is produced directly by the action of cytotoxic T cells or indirectly through the release of inflammatory mediators (e.g., complement) and cytokines (e.g., TNF-alpha and interleukins).

Acute GVHD occurs in 30% to 50% of patients, usually within 6 weeks. Signs and symptoms include delayed recovery of blood cell production in the bone marrow, skin rash, liver dysfunction (indicated by increased alkaline phosphatase, aminotransferases, and bilirubin), and diarrhea. The skin reaction is usually a pruritic maculopapular rash that begins on the palms and soles and may extend over the entire body. Liver involvement can lead to bleeding disorders and coma.

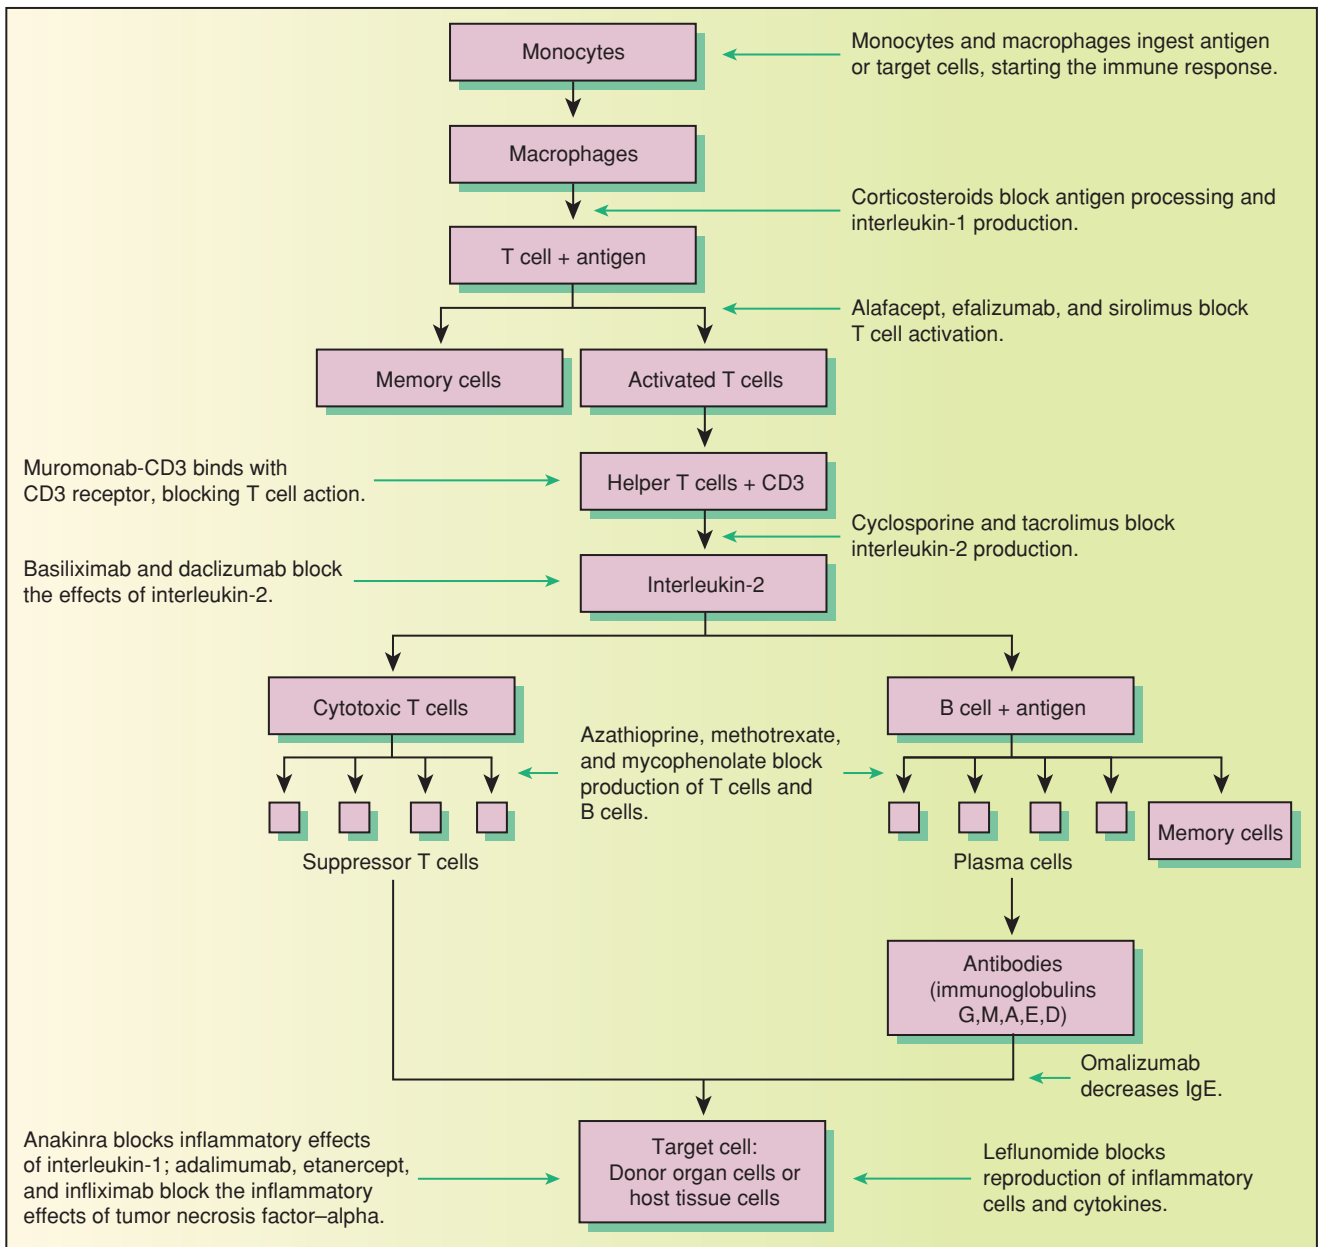

Chronic GVHD occurs when symptoms persist or occur 100 days or more after transplantation. It is characterized by abnormal humoral and cellular immunity, severe skin disorders, and liver disease. Chronic GVHD appears to be an autoimmune disorder in which activated T cells perceive self-antigens as foreign antigens.

## Classifications and Individual Drugs

Drugs used as immunosuppressants are diverse agents with often overlapping mechanisms and sites of action (Fig. 41-1). Older drugs generally depress the immune system (i.e., are non-specific and suppress the immune response to all antigens). This greatly increases risks of serious infections with bacteria, viruses, fungi, or protozoa during the immunosuppressed state. In addition, many immunosuppressant drugs slow the proliferation of activated lymphocytes and damage rapidly dividing nonimmune cells (e.g., mucosal cells, intestinal cells, bone marrow hematopoietic stem cells). As a result, serious, life-threatening complications can occur. For example, patients on long-term immunosuppressant drug therapy (e.g., with autoimmune disorders, organ transplantation) are at increased risk of serious infections, cancer (especially lymphoma), hypertension, and metabolic bone disease.

Extensive research has been done to develop drugs that modify the immune response (often called immunomodulators or biologic response modifiers). As a result, several drugs with more specific immunosuppressive actions are now available. Most are used in combination with older immunosuppressants for synergistic effects.

Immunosuppressants are discussed here as corticosteroids, cytotoxic antiproliferative agents, conventional antirejection agents, antibody preparations, cytokine inhibitors, and miscellaneous drugs. Indications for use and dosages of individual drugs are listed in Table 41-1; all of the drugs are contraindicated for people with hypersensitivity reactions to any component of the drug formulation.

**Figure 41-1** ■ Sites of action of immunosuppressant drugs. Available immunosuppressants inhibit the immune response by blocking that response at various sites.

## Corticosteroids

Corticosteroids are potent anti-inflammatory drugs that suppress the immune response at multiple levels. In many disorders, they relieve signs and symptoms by decreasing the accumulation of lymphocytes and macrophages and the production of cell-damaging cytokines at sites of inflammatory reactions. Because inflammation is a common response to chemical mediators or antigens that cause tissue injury, the anti-inflammatory and immunosuppressive actions of corticosteroids often overlap and are indistinguishable. However, corticosteroid effects on the immune response are emphasized here. In general, the drugs suppress growth of

all lymphoid tissue and therefore decrease formation and function of antibodies and T cells. For patients with autoimmune disorders, corticosteroids decrease inflammation but do not prevent tissue damage. For patients with transplanted tissues, a corticosteroid is usually given with other agents to prevent acute graft rejection. Specific effects include the following:

- Increased numbers of circulating neutrophils (more are released from bone marrow and fewer leave the circulation to enter inflammatory exudates). In terms of neutrophil functions, corticosteroids increase chemotaxis and release of lysosomal enzymes.

- Decreased numbers of circulating basophils, eosinophils, and monocytes. The reduced availability of monocytes is considered a major factor in the anti-inflammatory activity of corticosteroids. Functions of monocyte–macrophages are also impaired. Corticosteroids suppress phagocytosis and initial antigen processing (necessary to initiate an immune response), impair migration to areas of tissue injury, and block the differentiation of monocytes to macrophages.
- Decreased numbers of circulating lymphocytes (immune cells), resulting from impaired production (i.e., inhibition of deoxyribonucleic acid [DNA], ribonucleic acid [RNA], and protein synthesis), sequestration in lymphoid tissues, or lysis of the cells. T cells are markedly reduced; B cells are moderately reduced.
- Impaired function of cellular (T-cell) and humoral (B-cell) immunity. Corticosteroids inhibit the production of immunostimulant cytokines (e.g., IL-1, IL-2) required for activation and expansion of lymphocytes and cytotoxic cytokines (e.g., TNF and interferons). When administered for 2 to 3 weeks, the drugs also reduce serum concentrations of immunoglobulins [Ig] G and A.

## Cytotoxic, Antiproliferative Agents

Cytotoxic, antiproliferative drugs damage or kill cells that are able to reproduce, such as immunologically competent lymphocytes. These drugs are used primarily in cancer chemotherapy. However, in small doses, some also exhibit immunosuppressive activities and are used to treat autoimmune disorders and to prevent rejection reactions in organ transplantation. These drugs cause generalized suppression of the immune system and can kill lymphocytes and nonlymphoid proliferating cells (e.g., bone marrow blood cells, GI mucosal cells, germ cells in gonads).

**Azathioprine** is an antimetabolite that interferes with production of DNA and RNA and thus blocks cellular reproduction, growth, and development. Rapidly proliferating cells are most affected, including T and B lymphocytes, which normally reproduce rapidly in response to stimulation by an antigen. For many years, azathioprine was used to prevent rejection reactions to transplanted organs. However, it has largely been replaced by mycophenolate and is now rarely used for rheumatoid arthritis. Because of these declines in clinical uses, the drug is not discussed further in this chapter.

**Methotrexate** is a folate antagonist. It inhibits dihydrofolate reductase, the enzyme that converts dihydrofolate to the tetrahydrofolate required for biosynthesis of DNA and cell reproduction. The resultant DNA impairment inhibits production and function of immune cells, especially T cells. Methotrexate has long been used in the treatment of cancer. Other uses have evolved from its immunosuppressive effects, including treatment of autoimmune disorders (e.g., severe RA and psoriasis). It is also used (with cyclosporine) to prevent GVHD with bone marrow transplantation. Lower doses are given for these conditions than for cancers, and adverse drug

effects are fewer and less severe. CBC, platelet counts, and renal and liver function tests should be monitored.

**Mycophenolate** is used for prevention and treatment of rejection reactions with renal, cardiac, and hepatic transplantation. It inhibits proliferation and function of T and B lymphocytes. It has synergistic effects with corticosteroids and cyclosporine and is used in combination with these drugs.

After oral or intravenous administration, the drug is rapidly broken down to mycophenolic acid, the active component. Mycophenolic acid is further metabolized to inactive metabolites that are eliminated in bile and urine. Adverse effects include infection, neutropenia, and thrombocytopenia. For early detection of these effects, a CBC is recommended weekly during the first month, every 2 weeks during the second and third months, and monthly during the first year of drug administration.

## Applying Your Knowledge 41-1

Mr. Kinney is prescribed mycophenolate. Related to the administration of mycophenolate, you should assess Mr. Kinney for what adverse effects?

## Conventional Antirejection Agents

Cyclosporine, tacrolimus, and sirolimus are fungal metabolites with strong immunosuppressive effects. Cyclosporine and tacrolimus are chemically unrelated but have a similar action. They inhibit the synthesis of a cytokine, IL-2, which is required for activation of T cells and B cells. Sirolimus is structurally similar to tacrolimus. It inhibits T-cell activation and proliferation in response to several interleukins (e.g., IL-2, IL-4, IL-15). It also inhibits antibody production. Sirolimus and tacrolimus may have stronger immunosuppressant activity than cyclosporine.

By inhibiting helper–T-cell proliferation and cytokine expression, these three drugs reduce the activation of various cells involved in graft rejection, including cytotoxic T cells, NK cells, macrophages, and B cells. Consequently, they are widely used in heart, liver, kidney, and bone marrow transplantation.

**Cyclosporine** is used to prevent rejection reactions and prolong graft survival after solid organ transplantation (e.g., kidney, liver, heart, lung) or to treat chronic rejection in patients previously treated with other immunosuppressive agents. The drug inhibits both cellular and humoral immunity but affects T lymphocytes more than B lymphocytes. With T cells, cyclosporine reduces proliferation of helper and cytotoxic T cells and synthesis of several cytokines (e.g., IL-2, interferons). With B cells, cyclosporine reduces production and function to some extent, but considerable activity is retained.

Transplant rejection reactions mainly involve cellular immunity or T cells. With cyclosporine-induced deprivation of IL-2, T cells stimulated by the graft antigen do not undergo

clonal expansion and differentiation, and graft destruction is inhibited. In addition to its use in solid organ transplantation, cyclosporine is used to prevent and treat GVHD, a complication of bone marrow transplantation. In GVHD, T lymphocytes from the transplanted marrow of the donor mount an immune response against the tissues of the recipient.

Cyclosporine is not well absorbed with oral administration. The drug is highly bound to plasma proteins, and approximately 50% is distributed in erythrocytes, so drug levels in whole blood are higher than those in plasma. Peak plasma levels occur 4 to 5 hours after a dose, and the elimination half-life is 10 to 27 hours. Cyclosporine is metabolized in the liver and excreted in bile; less than 10% is excreted unchanged in urine.

Because the drug is insoluble in water, other solvents are used in commercial formulations. Thus, it is prepared in alcohol and olive oil for oral administration and in alcohol and castor oil for IV administration. Anaphylactic reactions, attributed to the castor oil, have occurred with the IV formulation. Neoral is an oral formulation that is better absorbed than oral Sandimmune. The two formulations are not equivalent and cannot be used interchangeably.

Serum drug levels are used to regulate dosage and should be monitored closely. Subtherapeutic levels may lead to organ transplant rejection; high levels increase adverse effects. Nephrotoxicity is a major adverse effect. Acute nephrotoxicity may occur and progress to chronic nephrotoxicity and kidney failure. Renal function tests (serum creatinine, blood urea nitrogen) should be monitored throughout cyclosporine therapy. Liver function tests (bilirubin, aminotransferase enzymes) should also be done regularly to monitor for hepatotoxicity. In addition, many drugs interact with cyclosporine to increase or decrease its effects, both therapeutic and toxic.

**Sirolimus** is used to prevent renal transplant rejection. It inhibits T-cell activation and is given concomitantly with a corticosteroid and cyclosporine. It may have synergistic effects with cyclosporine because it has a different mechanism of action. However, the two drugs are metabolized by the same cytochrome P450 3A4 enzymes and cyclosporine increases blood levels of sirolimus, possibly to toxic levels. Consequently, the drugs should not be given at the same time; sirolimus should be taken 4 hours after a dose of cyclosporine.

Sirolimus is well absorbed with oral administration. Its action has a rapid onset and peaks within 1 hour. It has a long half-life of 62 hours. It is metabolized in the liver and excreted mainly in feces. Serum drug levels are monitored in patients who are likely to have altered drug metabolism (e.g., those 13 years and older who weigh less than 40 kg, those with impaired hepatic function, and those who also are receiving enzyme-inducing or inhibiting drugs).

Adverse effects include anemia, edema, hepatotoxicity, hypercholesterolemia, hypertension, infection, leukopenia, nephrotoxicity, and thrombocytopenia. Because of the high risk of infection, antimicrobial prophylaxis is recommended for cytomegalovirus (CMV) infection for 3 months and *Pneumocystis pneumonia* for 1 year after transplantation.

## Applying Your Knowledge 41-2

### How Can You Avoid This Medication Error?

At 9:00 A.M., you prepare all of Mr. Kinney's medications and administer them.

**Tacrolimus** is similar to cyclosporine in its mechanisms of action, pharmacokinetic characteristics, and adverse effects. It prevents rejection of transplanted organs by inhibiting proliferation of T lymphocytes. Many transplant centers now use tacrolimus rather than cyclosporine, mainly because cyclosporine is given with corticosteroids. Using tacrolimus may allow corticosteroids to be reduced or stopped, thereby decreasing the adverse effects of long-term corticosteroid therapy.

Tacrolimus is not well absorbed orally, so higher oral doses than IV doses must be given to obtain similar blood levels. With IV administration, action onset is rapid and peak action occurs in 1 to 2 hours; with oral administration, onset varies and peak action occurs in 1.5 to 3.5 hours. The drug is metabolized in the liver and intestine to several metabolites, which are excreted in bile and urine. It has a half-life of 6 hours. Impaired liver function may slow its metabolism and elimination.

Dosage varies according to clinical response, adverse effects, and blood concentrations. Serum drug levels are monitored, with therapeutic ranges of 10 to 20 nanograms per milliliter for 6 months after transplantation, then 5 to 15 nanograms per milliliter. Children metabolize tacrolimus more rapidly than adults and require higher doses (per kg of body weight) to maintain similar blood levels.

There are numerous potential drug interactions that increase or decrease blood levels and effects. Because tacrolimus is metabolized mainly by the cytochrome P450 enzymes that metabolize cyclosporine, drug interactions known to alter cyclosporine effects are likely to alter tacrolimus effects. For example, antacids and enzyme inducers (e.g., carbamazepine, phenytoin, rifampin) may reduce therapeutic effects, nephrotoxic drugs (e.g., amphotericin B, aminoglycoside antibiotics) may increase nephrotoxic effects, and enzyme inhibitors (e.g., erythromycin, fluconazole and related antifungals) may increase blood levels and toxic effects. Plasma drug levels and measurements of serum creatinine, potassium, and glucose are recommended to monitor for the adverse effects of nephrotoxicity, hyperkalemia, and hyperglycemia.

## Antibody Preparations

Antibody (immunoglobulin) preparations are produced in the laboratory or derived from animals injected with human lymphoid tissue to stimulate an immune response. Such preparations are used in inflammatory autoimmune disorders, transplantation rejection reactions, and cancer.

The antibodies may be polyclonal or monoclonal. Polyclonal preparations are a mixture of antibodies (IgA, IgD, IgE,

IgG, IgM) produced by several clones of B lymphocytes. Each clone produces a structurally and functionally different antibody, even though the humoral immune response was induced by a single antigen. Monoclonal antibodies are produced in the laboratory by procedures that isolate and clone individual B lymphocytes, resulting in the production of identical antibody molecules. The antigen to which the desired antibody will respond is first injected into a mouse. The mouse mounts an immune response in which its B lymphocytes are stimulated to produce a specific antibody against that antigen. The B lymphocytes are then recovered from the spleen of the mouse and mixed with myeloma cells (a cell line that can live forever in culture) in polyethylene glycol. This treatment results in fusion of the cells and produces an antibody-secreting hybridoma, which can be cloned to produce large amounts of the desired antibody. The antibodies can be isolated from the culture and prepared for clinical use. Because the antibodies are proteins and would be destroyed if taken orally, they must be given by injection.

Older animal-derived antibodies (e.g., antithymocyte globulin, muromonab-CD3) are themselves antigenic; they usually elicit human antibodies against the animal cells within 2 weeks. Newer *murine* (mouse-derived) *antibodies* (e.g., basiliximab) have human antibodies added by recombinant DNA technology and are less likely to elicit an immune response. However, because the products are proteins, there is a risk of hypersensitivity reactions.

Because they are derived from one cell line or clone, monoclonal antibodies can be designed to suppress the specific components of the immune system that are causing tissue damage in particular disorders. They cause cell destruction by eliciting an antigen–antibody reaction, activating complement, targeting molecules on the cell surface that are necessary for growth or differentiation of that cell, or inhibiting proinflammatory cytokines.

Note that the generic names of monoclonal antibodies used as drugs end in “mab” and thus identify their origin.

### Polyclonal Antibodies

Antithymocyte globulin (ATG) is a nonspecific immune globulin. ATG (equine: Atgam) obtained from horse serum is used to treat renal transplant rejection reactions and aplastic anemia in patients who are not considered candidates for bone marrow transplantation. ATG (rabbit: Thymoglobulin) is used to treat renal transplant rejection reactions. Both preparations have been issued **BLACK BOX WARNINGS** by the U.S. Food and Drug Administration (FDA) to restrict use to experienced prescribers.

ATG contains antibodies that destroy lymphoid tissues and decrease the number of circulating T cells, thereby suppressing cellular and humoral immune responses. In addition to its high concentration of antibodies against T lymphocytes, the preparation contains low concentrations of antibodies against other blood cells. With Atgam, a skin test is recommended before administration to determine whether the patient is allergic to horse serum. Because there is a high risk of

anaphylactic reactions in recipients previously sensitized to horse serum, patients with positive skin tests should be desensitized before drug therapy is begun.

### Monoclonal Antibodies

**Alefacept** (Amevive) and **efalizumab** (Raptiva) are monoclonal antibodies used to treat moderate to severe psoriasis. Psoriasis involves activated T lymphocytes that secrete inflammatory mediators. The drugs bind to receptors on the surface of T lymphocytes, inhibit the receptors from interacting with particular antigens, and thereby inhibit activation of T lymphocytes.

Alefacept is given IM or IV, usually once weekly for 12 weeks. Its half-life after IV administration is about 10 days. Common adverse effects include lymphopenia and injection-site reactions (e.g., edema, inflammation, pain). Efalizumab is given subcutaneously (Sub-Q) once weekly for 12 weeks. It reaches steady-state concentration in 4 weeks and is excreted over 3 weeks. Common adverse effects include headache, infection, lymphocytosis, and a first-dose reaction characterized by chills, fever, muscle aches, and nausea.

**Basiliximab** (Simulect) and **daclizumab** (Zenapax) are humanized IgE (i.e., a combination of human and mouse-derived antibodies). They are called IL-2 receptor antagonists because they bind to IL-2 receptors on the surface of activated lymphocytes. This action inhibits the ability of IL-2 to stimulate proliferation and cytokine production of lymphocytes, a critical component of the cellular immune response involved in rejection reactions. The drugs are used to prevent organ rejection in patients receiving renal transplants and are given in combination with cyclosporine and a corticosteroid.

Basiliximab is given IV and its effects last an average of 36 days. Its elimination half-life is about 7 days in adults, 9 days in children. Daclizumab is also given IV and its elimination half-life is about 20 days in adults, 13 days in children. Common adverse effects include constipation, diarrhea, edema, fever, headache, hypertension, infection, nausea, and vomiting.

**Muromonab-CD3** (Orthoclone OKT3) is a *monoclonal antibody* that acts against an antigenic receptor called CD3, which is found on the surface membrane of most T cells in blood and body tissues. CD indicates clusters of differentiation or groups of cells with the same surface markers (antigenic receptors). The CD3 molecule is associated with the antigen recognition structure of T cells and is essential for T-cell activation. Muromonab-CD3 binds with its antigen (CD3) and therefore blocks all known functions of T cells containing the CD3 molecule. Because rejection reactions are mainly T-cell–mediated immune responses against antigenic (nonself) tissues, the drug’s ability to suppress such reactions accounts for its therapeutic effects in treating renal, cardiac, and hepatic transplant rejection. It is usually given for 10 to 14 days. After treatment, CD3-positive T cells reappear rapidly and reach pretreatment levels within 1 week. The drug’s name is

derived from its source (murine or mouse cells) and its action (monoclonal antibody against the CD3 antigen). Because the drug is a protein and induces antibodies in most patients, decreased effectiveness and serious allergic reactions may occur if it is readministered later. Second courses of treatment must be undertaken cautiously.

**Omalizumab** (Xolair) is a humanized monoclonal antibody used to treat allergic asthma that is not relieved by inhaled corticosteroids. Allergic asthma is thought to be caused mainly by IgE. When stimulated by an allergen, IgE combines with a receptor on mast cells and basophils and causes the release of allergic and proinflammatory mediators. Omalizumab binds with the IgE and reduces the amount of IgE free to bind to the receptors on mast cells and basophils. This action inhibits IgE-induced tissue injury.

Omalizumab is given Sub-Q and slowly absorbed. Peak concentration is reached in about 1 week, and it has a half-life of 3 to 4 weeks. It is metabolized in the liver. Dosage and frequency of administration are determined by body weight and serum IgE level, which should be measured before the start of treatment and periodically during treatment. Common adverse effects include injection-site reactions and infections (e.g., viral, upper respiratory tract, pharyngitis, sinusitis). However, a **BLACK BOX WARNING** about the risk of anaphylaxis was added to drug literature in 2007. Reportedly, patients may develop anaphylaxis after any dose of the drug and as long as 24 hours after a dose is given. Health care providers should have medications and other supplies available for treatment of anaphylaxis, should observe patients for at least 2 hours after an injection, and should teach patients how to self-administer emergency treatment.

## Cytokine Inhibitors

Two major cytokines in chronic, inflammatory autoimmune disorders are IL-1 and TNF-alpha. This knowledge led to the development of biologic agents directed against these cytokines. The cytokine inhibitors used as drugs (some of which are monoclonal antibodies, such as basiliximab and daclizumab) inhibit one of these cytokines to suppress inflammation and promote tissue repair in disorders such as RA, Crohn's disease, and psoriasis.

Cytokine inhibitors can greatly improve signs and symptoms of arthritis, Crohn's disease, and psoriasis. Despite their therapeutic effects, however, cytokine inhibitors also increase the risks of serious infections, especially the TNF-alpha inhibitors. A wide range of infections has occurred, including tuberculosis characterized by increased extrapulmonary and/or disseminated disease. Other serious infections include pneumococcal infections, necrotizing fasciitis, *Pneumocystis pneumonia*, and systemic fungal infections such as aspergillosis and cryptococcosis.

### Interleukin Blocking Agent

**Anakinra** (Kineret) is a recombinant interleukin-receptor antagonist. It binds to the IL-1 receptor and thereby blocks the inflammatory effects of IL-1. It is used to treat moderate to

severe RA in adults. It may be used alone or in combination with other disease-modifying antirheumatic drugs (except TNF blocking agents).

Anakinra is well absorbed with Sub-Q injection and reaches its peak concentration in 3 to 7 hours. Its elimination half-life is 4 to 6 hours. Common adverse effects include headache, injection-site reactions (redness, bruising, inflammation, pain), infection, nausea, diarrhea, decreased WBCs, sinusitis, and flulike symptoms.

### Tumor Necrosis Factor-Alpha Blocking Agents

**Adalimumab** (Humira) is a recombinant monoclonal antibody that binds to TNF-alpha receptor sites and prevents endogenous TNF-alpha from binding to the sites and exerting its injurious effects. The drug is used to treat moderate to severe RA. In RA, the drug reduces the elevated levels of TNF-alpha in synovial fluid that are thought responsible for pain and joint destruction.

Adalimumab is given Sub-Q, peak serum concentration occurs within 2 to 5 days, and its elimination half-life is about 2 weeks. Excretion is decreased in patients over 40 years of age. Common adverse effects include injection-site reactions, upper respiratory tract infections, headache, nausea, and skin rash.

**Etanercept** (Enbrel) is a synthetic TNF receptor that binds with TNF and prevents it from binding with its "normal" receptors on cell surfaces. This action inhibits TNF activity in inflammatory and immune responses. The drug is used to treat moderate to severe RA in adults and children. In this condition, TNF is increased in joint synovial fluid and considered important in joint inflammation and destruction. Etanercept can be used in combination with methotrexate in patients who do not respond adequately to methotrexate alone.

Etanercept is given Sub-Q and reaches its peak concentration in about 3 days. Onset of action occurs within 2 to 3 weeks, and its elimination half-life is about 5 days. Common adverse effects include headache, injection-site reactions, and infections.

**Infliximab** (Remicade) is a humanized IgG monoclonal antibody used to treat RA and Crohn's disease. It inhibits TNF-alpha from binding to its receptors and thus neutralizes its actions. Infliximab's ability to neutralize TNF-alpha accounts for its anti-inflammatory effects.

Infliximab is given IV. Its half-life elimination is about 8 days, and its onset of action in Crohn's disease is about 2 weeks. Adverse effects include formation of autoimmune antibodies and hypersensitivity reactions. Dyspnea, hypotension, and urticaria have occurred. The drug should be administered in settings in which personnel and supplies (e.g., epinephrine, antihistamines, corticosteroids) are available for treatment of hypersensitivity reactions and should be discontinued if severe reactions occur. In addition, infections developed in approximately 21% of patients in clinical trials, and the drug may aggravate congestive heart failure.

## Miscellaneous Immunosuppressants

**Abatacept** (Orencia) is used to treat RA. It inhibits activation of T lymphocytes in synovial membranes of joints affected by RA and thereby decreases inflammation and joint destruction. It may be used alone or with other anti-RA drugs except anakinra and TNF-alpha blocking agents. Common adverse effects include dizziness, headache, infections, and nausea.

**Leflunomide** (Arava) has antiproliferative and anti-inflammatory activities that are attributed to its effects on the immune system. The drug inhibits the synthesis of pyrimidines, which are components of DNA and RNA, and therefore blocks the expansion of T cells. Leflunomide is used to treat RA, in which it relieves signs and symptoms and slows the destruction of joint tissues.

After oral administration, leflunomide is metabolized to an active metabolite (called M1) that exerts most of the drug's effects. M1 has a half-life of about 2 weeks, and a loading dose of leflunomide is usually given for 3 days to achieve therapeutic blood levels more rapidly. The metabolite is highly bound to serum albumin and eliminated by further metabolism and renal or biliary excretion. Some of the M1 excreted in bile is reabsorbed, and this contributes to its long half-life. Most adverse effects in clinical trials were similar to those of placebos. With leflunomide, renal and liver function tests should be performed.

## Nursing Process

### Assessment

- Assess patients receiving or anticipating immunosuppressant drug therapy for signs and symptoms of current infection or factors predisposing them to potential infection (e.g., impaired skin integrity, invasive devices, cigarette smoking).
- Assess the environment for factors predisposing to infection (e.g., family or health care providers with infections, contact with young children, potential exposure to childhood infectious diseases).
- Assess nutritional status, including appetite and weight.
- Assess baseline values of laboratory and other diagnostic test results to aid monitoring of responses to immunosuppressant drug therapy. With pretransplantation patients, this includes assessing for impaired function of the diseased organ and for abnormalities that need treatment before surgery.
- Assess adequacy of support systems for transplant recipients.
- Assess posttransplantation patients for surgical wound healing, manifestations of organ rejection, and adverse effects of immunosuppressant drugs.

- Assess patients with autoimmune disorders (e.g., RA, Crohn's disease) for manifestations of the disease process and responses to drug therapy.

### Nursing Diagnoses

- Risk for Injury: Adverse drug effects
- Risk for Injury: Infection and cancer related to immunosuppression and increased susceptibility
- Deficient Knowledge: Disease process and immunosuppressant drug therapy
- Anxiety related to the diagnosis of serious disease or need for organ transplantation
- Social Isolation related to activities to reduce exposure to infection

### Planning/Goals

#### The patient will

- Participate in decision making about the treatment plan
- Receive or take immunosuppressant drugs correctly
- Verbalize or demonstrate essential drug information
- Participate in interventions to prevent infection (e.g., maintain good hygiene, avoid known sources of infection) while immunosuppressed
- Experience relief or reduction of disease symptoms
- Maintain adequate levels of nutrition and fluids, rest and sleep, and exercise
- Be assisted to cope with anxiety related to the disease process and drug therapy
- Keep appointments for follow-up care
- Have adverse drug effects prevented or recognized and treated promptly
- Maintain diagnostic test values within acceptable limits
- Maintain family and other emotional or social support systems
- Receive optimal instructions and information about the treatment plan, self-care in activities of daily living, reporting adverse drug effects, and other concerns
- Before and after tissue or organ transplantation, receive appropriate care, including prevention or early recognition and treatment of rejection reactions

### Interventions

- Practice and emphasize good personal and hand hygiene techniques by patients and all others in contact with patients.
- Use sterile technique for all injections, IV site care, wound dressing changes, and any other invasive diagnostic or therapeutic measures.
- Screen staff and visitors for signs and symptoms of infection; if infection is noted, do not allow contact with the patient.

- Report fever and other manifestations of infection immediately.
- Allow patients to participate in decision making when possible and appropriate.
- Use isolation techniques according to institutional policies, usually after transplantation or when the neutrophil count is less than 500/mm<sup>3</sup>.
- Assist patients to maintain adequate nutrition, rest and sleep, and exercise.
- Inform patients about diagnostic test results, planned changes in therapeutic regimens, and evidence of progress.
- Allow family members or significant others to visit patients when feasible.
- Monitor complete blood count (CBC) and other diagnostic test results related to blood, liver, and kidney function throughout drug therapy. Specific tests vary with the patient's health or illness status and the immunosuppressant drugs being taken.
- Schedule drug administration to maximize therapeutic effects and minimize adverse effects.
- Consult other health care providers (e.g., physician, dietitian, social worker) on the patient's behalf when indicated. Multidisciplinary consultation is essential for transplantation patients and desirable for patients with autoimmune disorders.
- Assist patients in learning strategies to manage day-to-day activities during long-term immunosuppression.

## Evaluation

- Interview and observe for accurate drug administration.
- Interview and observe for personal hygiene practices and infection-avoiding maneuvers.
- Interview and observe for therapeutic and adverse drug effects with each patient contact.
- Interview regarding knowledge and attitude toward the drug therapy regimen, including follow-up care and symptoms to report to health care providers.
- Determine the number and types of infections that have occurred in the neutropenic patient.
- Compare current CBC and other reports with baseline values for acceptable levels, according to the patient's condition.
- Observe and interview outpatients regarding compliance with follow-up care.
- Interview and observe for organ function and absence of rejection reactions in posttransplantation patients.

## Applying Your Knowledge 41-3

What are the specific teaching points to be covered with Mr. Kinney regarding proper self-administration of his medication?

## Patient Teaching Guidelines

## Immunosuppressant Drugs

### General Considerations

- People taking medications that suppress the immune system are at high risk for development of infections. As a result, patients, caregivers, and others in the patient's environment need to wash their hands often and thoroughly, practice meticulous personal hygiene, avoid contact with infected people, and practice other methods of preventing infection.
- Report adverse drug effects (e.g., signs or symptoms of infection such as sore throat or fever, decreased urine output if taking cyclosporine, easy bruising or bleeding if taking methotrexate) to a health care provider.
- Try to maintain healthy lifestyle habits, such as a nutritious diet, adequate rest and sleep, and avoiding tobacco and alcohol. These measures enhance immune mechanisms and other body defenses.
- Carry identification that lists the drugs being taken; the dosage; the prescriber's name, address, and telephone number; and instructions for emergency treatment. This information is needed if an accident or emergency situation occurs.
- Inform all health care providers that you are taking these drugs.
- Maintain regular supervision by a health care provider. This is extremely important for evaluating health status, evaluating drug responses and indications for dosage change, detecting adverse drug reactions, and having blood tests or other monitoring tests when indicated.
- Take no other drugs, prescription or nonprescription, without notifying the prescriber who is managing immunosuppressant therapy. Immunosuppressant drugs may influence reactions to other drugs, and other drugs may influence reactions to the immunosuppressants. Thus, taking other drugs may decrease therapeutic effects or increase adverse effects. In addition, some vaccinations should be avoided while taking immunosuppressant drugs.
- People of reproductive capability who are sexually active should practice effective contraceptive techniques during immunosuppressive drug therapy. With methotrexate, use contraception during and for at least 3 months (men) or one ovulatory cycle (women) after stopping the drug. With mycophenolate, effective contraception should be continued for 6 weeks after the drug is stopped. With sirolimus, effective contraception must be used before, during, and for 12 weeks after drug therapy.

(continued on page 666)

## Patient Teaching Guidelines

## Immunosuppressant Drugs (continued)

- Wear protective clothing and use sunscreens to decrease exposure of skin to sunlight and risks of skin cancers. Also, methotrexate and sirolimus increase sensitivity to sunlight and may increase sunburn.

### Self-Administration

- Follow instructions about taking the drugs. This is vital to achieving beneficial effects and decreasing adverse effects. If unable to take a medication, report to the prescriber or other health care provider; do not stop unless advised to do so. For transplant recipients, missed doses may lead to transplant rejection; for patients with autoimmune diseases, missed doses may lead to acute flare-ups of symptoms. In addition, take at approximately the same time each day to maintain consistent drug levels in the blood.
- With cyclosporine oral solution, use the same solution consistently. The two available solutions (Neoral and Sandimmune) are not equivalent and cannot be used interchangeably. If a change in formulation is necessary, it should be made cautiously and only under supervision of the prescriber.

Measure oral cyclosporine solution with the dosing syringe provided; add to orange or apple juice that is at room temperature (avoid grapefruit juice); stir well and drink at once (do not allow diluted solution to stand before drinking). Use a glass container, not plastic. Rinse the glass with more diluent to ensure the total dose is taken. Do not rinse the dosing syringe with water or other cleaning agents. Take on a consistent schedule with regard to time of day and meals.

These are the manufacturer's recommendations. Mixing with orange or apple juice improves taste; grapefruit

juice should not be used because it affects metabolism of cyclosporine. The amount of fluid should be large enough to increase palatability, especially for children, but small enough to be consumed quickly. Rinsing ensures the entire dose is taken.

- Take mycophenolate on an empty stomach; food decreases drug absorption by approximately 40%. Do not crush mycophenolate tablets and do not open or crush the capsules.
- Take sirolimus consistently with or without food; do not mix or take the drug with grapefruit juice. Grapefruit juice inhibits metabolism and increases adverse effects. If also taking cyclosporine, take the sirolimus 4 hours after a dose of cyclosporine.

If taking the oral solution, use the syringe that comes with the medication to measure and withdraw the dose from the bottle. Empty the dose into a glass or plastic container with at least 2 oz (1/4 cup or 60 mL) of water or orange juice. Do not use any other liquid to dilute the drug. Stir the mixture vigorously, and drink it immediately. Refill the container with at least 4 oz (1/2 cup or 120 mL) of water or orange juice, stir vigorously, and drink at once.

- Take tacrolimus with food to decrease stomach upset.
- If giving or taking an injected drug, be sure you understand how to mix and inject the medication correctly. With Enbrel, for example, rotate injection sites, give a new injection at least 1 inch from a previous injection site, and do not inject the medication into areas where the skin is tender, bruised, red, or hard. When possible, practice the required techniques and perform at least the first injection under supervision of a qualified health care professional.

## Principles of Therapy

### Risk–Benefit Factors

Immunosuppression is a serious, life-threatening condition that may result from disease or drug therapy. At the same time, immunosuppressant drugs are used to treat serious illnesses, and their use may be required. Rational use of the drugs requires thorough assessment of a patient's health status, clear-cut indications for use, a lack of more effective and safer alternative treatments, cautious administration, and vigilant monitoring of the patient's response. If a decision is then made that immunosuppressant drug therapy is indicated and benefits outweigh risks, the therapeutic plan must be discussed with the patient (i.e., reasons, expected benefits, consequences for the patient's health and lifestyle).

In addition to the specific risks of individual immunosuppressant drugs, general risks of immunosuppression include infection and cancer. Infection is a major cause of morbidity and mortality, especially in patients who are neutropenic (neutrophil count less than 1000/mm<sup>3</sup>) from cytotoxic immunosuppressant drugs, who take TNF inhibitors, or who have had bone marrow or solid organ transplantation. For those with solid organ transplantation, who must continue lifelong immuno-

suppression to avoid graft rejection, serious infection is a constant hazard. If efforts to prevent infections are unsuccessful, infections may be fatal unless recognized promptly and treated aggressively. Common infections are bacterial (gram-positive, such as *Staphylococcus aureus* or *S. epidermidis*; and gram-negative, such as *Escherichia coli*, *Klebsiella*, and *Pseudomonas* species), fungal (candidiasis, aspergillosis), or viral (CMV, herpes simplex, or herpes zoster). In addition, severe, disseminated tuberculosis is associated with the use of TNF inhibitors.

Cancer may result from immunosuppression. When T lymphocytes and NK cells are suppressed and unable to recognize and eliminate abnormal cells, the abnormal cells may undergo spontaneous malignant transformation and result in widespread and often aggressive malignancies. Most of the available information is related to posttransplant cancer development.

With early transplantations, major causes of death were graft rejection and infection. Now, improvements are leading to more transplants, older transplant recipients, and longer survival rates among recipients. One consequence of long-term survival and chronic immunosuppression is increased risk of developing a malignancy. The incidence is unknown but often estimated at 20% or more after 10 years of immunosuppression. As a result, cancer has become the second most common cause of mortality in transplant recipients.

The most common malignancies among transplant recipients are skin cancers and lymphomas. Other malignancies include solid organ tumors, some of which occur at similar rates in the general and posttransplant populations (e.g., brain, breast, lung, prostate) and some of which occur more often in the posttransplant population (e.g., renal cell cancer in renal transplant recipients; colon cancers; cervical, perineal/anal, and vulvar cancers in women). When breast cancer occurs posttransplantation, it often occurs at a younger age and grows more aggressively than in the general population. In addition, men with transplants are more likely to develop breast cancer than men in the general population.

When cancer develops, treatment includes reduced immunosuppressant drug therapy as well as treatment of the malignancy. Reducing dosages of immunosuppressant drugs increases risks of rejection reactions and the need for retransplantation.

## Use in Autoimmune Disorders

### Allergic Asthma

Allergic asthma is characterized by increased production of IgE in response to inhaled allergens. IgE molecules then interact with allergen molecules to form IgE–allergen complexes that damage tissues and produce signs and symptoms. Omalizumab (Xolair) combines with free IgE so that there is less IgE available to combine with allergens. It is second-line therapy for patients whose symptoms are not adequately controlled with inhaled corticosteroids.

### Crohn's Disease

Crohn's disease is a chronic, recurrent, inflammatory bowel disorder that can affect any area of the GI tract. The inflammation is attributed to a mixture of inflammatory mediators (e.g., IL-1 and -6, TNF-alpha) produced by activated macrophages. The goal of treatment is to decrease inflammation and promote healing of bowel lesions. Several medications are effective, including corticosteroids, cyclosporine, metronidazole, and sulfasalazine. Because elevated concentrations of TNF-alpha are found in patients' stools and correlate with episodes of increased disease activity, infliximab (Remicade) is also used. Infliximab reduces infiltration of inflammatory cells, production of TNF-alpha in inflamed areas of the intestine, and the number of cells that can produce TNF-alpha. It is indicated for patients with moderate to severe disease who do not respond adequately to other treatment measures.

### Psoriasis and Psoriatic Arthritis

Psoriasis is a skin disorder of unknown cause. It is thought that activated T lymphocytes produce cytokines that stimulate abnormal growth of affected skin cells and blood vessels. The accompanying inflammation results from infiltration of neutrophils and monocytes. Several medications (e.g., beta blockers, lithium) may precipitate or aggravate psoriasis. Corticosteroids and other immunosuppressants (e.g., cyclosporine, methotrexate) have long been used to treat psoriasis because they suppress inflammation and proliferation of T cells. Newer

biologic immunosuppressants (e.g., alefacept, efalizumab) also reduce the activity of T lymphocytes and the inflammation of skin lesions.

Psoriatic arthritis is a type of arthritis associated with psoriasis that is similar to RA. It may be characterized by extensive and disabling joint damage, especially in hand and finger joints. Etanercept (Enbrel) is a TNF-alpha inhibitor approved for treatment.

### Rheumatoid Arthritis

Rheumatoid arthritis is an abnormal immune response that leads to inflammation and damage of joint cartilage and bone. It is thought to involve the activation of T lymphocytes, release of inflammatory cytokines, and formation of antibodies. Research in recent years has delineated the roles of TNF-alpha and IL-1 in the pathophysiology of RA and led to the development of drugs directed against TNF-alpha (e.g., adalimumab, etanercept, infliximab) and IL-1 (e.g., anakinra).

These drugs are highly effective in relieving joint pain and inflammation and they also slow progression of RA, as measured by serial radiographs. Because of their ability to slow disease progression, they are called disease-modifying antirheumatic drugs (DMARDs). They act more rapidly than older DMARDs (e.g., methotrexate) and greatly improve the quality of life for patients with RA. However, their use is also associated with significant risks of serious infections, especially with the TNF-alpha blocking agents. To decrease the adverse effects of the TNF inhibitors, the following guidelines have been developed for patients receiving these drugs:

- Tuberculin testing before starting a TNF inhibitor and antitubercular prophylaxis for patients with positive skin-test results
- Administration of pneumococcal and perhaps meningococcal vaccine
- Administration of trimethoprim-sulfamethoxazole (TMP-SMX) to prevent infection
- Consideration of fluconazole administration to patients at high risk of developing coccidioidomycosis and cryptococcosis
- Education of patients and caregivers to avoid potential exposures to infection in the community
- Provision of antibiotics for immediate initiation at home with the onset of fever or upper respiratory infection, followed by seeking emergency care

### Use in Transplantation

Immunosuppressant drugs are used to prevent rejection of transplanted tissues, a reaction involving T and B lymphocytes and multiple inflammatory cytokines. Specific drug therapy protocols vary among transplantation centers and types of transplants; they continue to evolve in efforts to increase effectiveness and decrease complications of transplantation.

One strategy is to use combinations of immunosuppressant drugs. Combinations are rational because the drugs act on different components of the immune response and often have

overlapping and synergistic effects. They may also allow lower doses of individual drugs, which usually cause fewer or less severe adverse effects.

A second strategy is to reduce the number of drugs and drug dosages after transplanted tissue is functioning and rejection has been successfully prevented or treated. Vigilant monitoring is required, to catch rejection reactions early, when restarting immunosuppressant drugs or increasing their dosage can still save the transplant.

A third strategy involves interventions to decrease adverse effects of immunosuppressant drug therapy such as worsening of pre-existing conditions (e.g., diabetes mellitus, hypertension) and development of new diseases (e.g., nephrotoxicity, osteoporosis, and malignancies). Regular screening tests for breast, colon, and prostate cancer are recommended, along with annual skin examination.

### Drug Dosage

Immunosuppressant drugs are relatively toxic, and adverse effects occur more often and are more severe with higher doses. Thus, the general principle of using the smallest effective dose for the shortest period of time is especially important with immunosuppressant drug therapy. Dosage must be individualized according to the patient's serum drug levels and clinical response (i.e., improvement in signs and symptoms or occurrence of adverse effects). With corticosteroids, for example, high doses are usually given immediately after transplantation and during treatment of acute graft rejection reactions. Doses are usually tapered by 6 months after the transplantation, and long-term maintenance doses of prednisone are usually under 10 milligrams per day. For some patients, the drugs may be discontinued. With cyclosporine, higher doses are given for 3 months posttransplantation and may be given IV for a few days after surgery (at one third the oral dosage).

### Drug Selection and Type of Transplant

Cardiac transplant recipients are usually given cyclosporine, prednisone, and mycophenolate. Tacrolimus may be used instead of cyclosporine. Renal transplant recipients are usually given high doses of IV methylprednisolone for a few days, then switched to prednisone. If cyclosporine is used, despite its unpredictable absorption and nephrotoxicity, it is given in low doses. After approximately 3 months, maintenance drug therapy may consist of mycophenolate, prednisone, and cyclosporine or tacrolimus. Liver transplant recipients are usually given methylprednisolone initially, with cyclosporine or tacrolimus. Treatment of rejection reactions may include high-dose corticosteroids and muromonab-CD3 or anti-thymocyte globulin for 7 to 14 days. Bone marrow/stem cell transplant recipients are usually given cyclosporine and a corticosteroid.

## Use in Special Populations

### Use in Children

Most immunosuppressants are used in children for the same disorders and with similar effects as in adults. Corticosteroids impair growth in children. As a result, some transplantation centers avoid prednisone therapy until a rejection episode

occurs. When prednisone is used, administering it every other day may improve growth rates. Cyclosporine has been given to children as young as 6 months of age, and muromonab-CD3 has been used in children as young as 2 years of age. Mycophenolate has been used in a few children undergoing renal transplantation. In children with impaired renal function, recommended doses of mycophenolate cause a high incidence of adverse effects. Thus, dosage should be adjusted for the level of renal function. Tacrolimus has been used in children younger than 12 years of age who were undergoing liver transplantation. This usage indicates that children require relatively high doses because they metabolize the drug rapidly.

Little information is available about the use of newer immunosuppressants in children. Safety and effectiveness have not been established for basiliximab, daclizumab, infliximab, or leflunomide. Leflunomide is not recommended for children under 18 years of age. Etanercept is approved for children 4 to 17 years of age with juvenile RA. Most children in a 3-month study had an infection while receiving etanercept, but the infections were usually mild. Children reported abdominal pain, headache, nausea and vomiting with etanercept more often than adults. Other medications (e.g., a corticosteroid, methotrexate, a nonsteroidal anti-inflammatory drug, an analgesic) may be continued during treatment.

For children age 12 and older with allergic asthma, omalizumab is the only immunosuppressant drug approved for use. Dosages and frequency of administration are determined by body weight and serum levels of IgE. The drug is reportedly well tolerated in children.

### Use in Older Adults

Immunosuppressants are used for the same purposes and produce similar therapeutic and adverse effects in older adults as in younger adults. Because older adults often have multiple disorders and organ impairments, it is especially important that drug choices, dosages, and monitoring tests are individualized. In addition, infections occur more commonly in older adults, and this tendency is increased with immunosuppressant therapy.

### Use in Patients With Renal Impairment

Cyclosporine is nephrotoxic but commonly used in patients with renal and other transplants. Nephrotoxicity has been noted in 25% of renal, 38% of cardiac, and 37% of liver transplant recipients, especially with high doses. It usually subsides with decreased dosage or stopping the drug. In renal transplant recipients, when serum creatinine and blood urea nitrogen levels remain elevated, a complete evaluation of the patient must be done to differentiate cyclosporine-induced nephrotoxicity from a transplant rejection reaction. If renal function is deteriorating from cyclosporine, dosage reduction or a different immunosuppressant may be effective. If renal function is deteriorating from a rejection reaction, decreasing cyclosporine dosage would increase the severity of the reaction.

Methotrexate is mainly excreted in urine, so its half-life is prolonged in patients with renal impairment, with risks of accumulation to toxic levels and additional renal damage.

However, the risks are less with the small doses used for treatment of RA than for the high doses used in cancer chemotherapy. To decrease these risks, adequate renal function should be documented before the drug is given and patients should be well hydrated.

Mycophenolate produces higher plasma levels in renal transplant recipients with severe renal impairment than in patients with less severe renal impairment and healthy volunteers. Doses higher than 1 gram twice a day should be avoided in these patients.

Tacrolimus is associated with high rates of nephrotoxicity when given IV, so oral dosing is preferred.

Little information is available about the use of basiliximab, etanercept, infliximab, or leflunomide in patients with renal impairment. However, leflunomide metabolites are partly excreted renally and the drug should be used cautiously.

### Use in Patients With Hepatic Impairment

Cyclosporine reportedly causes hepatotoxicity (e.g., elevated serum aminotransferases and bilirubin) in approximately 4% of renal and liver transplant recipients and 7% of cardiac transplant recipients. This is most likely to occur during the first month of therapy, when high doses of cyclosporine are usually given, and usually subsides with reduced dosage.

Methotrexate may cause hepatotoxicity, even in the low doses used in RA and psoriasis. Many clinicians recommend serial liver biopsies for patients on long-term, low-dose methotrexate. In addition, in patients with or without initial liver impairment, liver function tests should be performed to monitor patients for hepatotoxicity and to guide drug dosage. In general, methotrexate dosage should be decreased if bilirubin is between 3 and 5 milligrams per deciliter or aspartate aminotransferase (AST) is above 180 international units per liter, and the drug should be omitted if bilirubin is above 5 milligrams per deciliter.

Mycophenolate is metabolized in the liver to an active metabolite that is further metabolized to inactive metabolites. Liver impairment may interfere with these processes and affect both action and elimination.

Sirolimus is extensively metabolized in the liver and may accumulate in the presence of hepatic impairment. The maintenance dose should be reduced by 35%; it is not necessary to reduce the loading dose.

Tacrolimus is metabolized in the liver by the cytochrome P450 enzyme system. Impaired liver function may decrease presystemic (first-pass) metabolism of oral tacrolimus and produce higher blood levels. Also, the elimination half-life is significantly longer. As a result, dosage must be decreased in patients with impaired liver function.

There is little or no information about the use of basiliximab, daclizumab, etanercept, or infliximab in patients with liver impairment. Leflunomide may be hepatotoxic in patients with normal liver function and is not recommended for use in patients with liver impairment or positive serology tests for hepatitis B or C. The manufacturer's recommendations for use should be consulted.

### Use in Home Care

With patients who are taking immunosuppressant drugs, a major role of the home care nurse is to assess the environment for potential sources of infection, assist patients and other members of the household to understand the patient's susceptibility to infection, and teach ways to decrease risks of infection. Although infections often develop from the patient's own body flora, other potential sources include people with infections, caregivers, water or soil around live plants, and raw fruits and vegetables. Meticulous environmental cleansing as well as personal and hand hygiene are required. In addition, the nurse may need to assist with clinic visits for monitoring and follow-up care.

### Applying Your Knowledge 41-4

Mr. Kinney has a depressed immune system secondary to the medications necessary to prevent organ rejection. What is Mr. Kinney at risk to develop?

## Nursing Actions Immunosuppressants

### NURSING ACTIONS

#### 1. Administer accurately

- For prepared IV solutions, check for appropriate dilution, discoloration, particulate matter, and expiration time. If okay, give by infusion pump, for the recommended time.
- Give antithymocyte globulin (diluted to a concentration of 1 mg/mL) IV, using an in-line filter and infusion pump, over at least 4 hours. After it is diluted, use within 24 hours.
- With basiliximab, infuse IV over 20–30 minutes. Use the reconstituted solution within 4 hours at room temperature or 24 hours if refrigerated.

### RATIONALE/EXPLANATION

IV drugs should be reconstituted and diluted in a pharmacy, and the manufacturers' instructions should be followed exactly. After they are mixed, most of these drugs are stable only for a few hours and some do not contain preservatives. Manufacturer's recommendations. Using a high-flow vein decreases phlebitis and thrombosis at the IV site. The filter is used to remove any insoluble particles.

The first dose is given within 2 hours before transplantation surgery and the second dose 4 days after transplantation.

(continued on page 670)

## Nursing Actions Immunosuppressants (continued)

### NURSING ACTIONS

- d. With IV cyclosporine, infuse over 2–6 hours.
- e. With oral cyclosporine solutions, measure doses with the provided syringe; add to room-temperature orange or apple juice (avoid grapefruit juice); stir well and have the patient drink at once (do not allow diluted solution to stand before drinking). Use a glass container, not plastic. Rinse the glass with more juice to ensure the total dose is taken. Do not rinse the dosing syringe with water or other cleaning agents. Give on a consistent schedule in relation to time of day and meals.
- f. Infuse reconstituted and diluted daclizumab IV over 15 minutes. After it is mixed, use within 4 hours or refrigerate up to 24 hours.
- g. With etanercept, inject 1 mL of the supplied Sterile Bacteriostatic Water for Injection into the vial, without shaking (to avoid excessive foaming). Give Sub-Q, rotating sites so that a new dose is injected at least 1 inch from an old site and never into areas where the skin is tender, bruised, red, or hard.
- h. Infuse reconstituted and diluted infliximab over approximately 2 hours, starting within 3 hours of preparation (contains no antibacterial preservatives).
- i. Give muromonab-CD3 in an IV bolus injection once daily. Do not give by IV infusion or mix with other drug solutions.
- j. Infuse IV mycophenolate over approximately 2 hours, within 4 hours of solution preparation (contains no antibacterial preservatives).
- k. Give oral mycophenolate on an empty stomach. Do not crush the tablets, do not open or crush the capsules, and ask patients to swallow the capsules whole, without biting or chewing.
- l. With sirolimus, give 4 hours after a dose of cyclosporine, give consistently with or without food, and do not give with grapefruit juice. With oral sirolimus solution, use the oral-dose syringe to withdraw a dose from the bottle, empty the dose into a glass or plastic container with at least 60 mL of water or orange juice (do not use any other diluent), stir the mixture vigorously and ask the patient to drink it immediately, refill the container with at least 120 mL of water or orange juice, stir vigorously, and ask the patient to drink all of the fluid.
- m. Give IV tacrolimus as a continuous infusion by infusion pump; give the first dose of oral tacrolimus 8–12 hours after stopping the IV infusion.

### 2. Observe for therapeutic effects

- a. When a drug is given to suppress the immune response to organ transplants, therapeutic effect is the absence of signs and symptoms indicating rejection of the transplanted tissue.
- b. When methotrexate is given for RA, observe for decreased pain.
- c. When adalimumab, etanercept, or infliximab is given for RA, observe for decreased symptoms and less joint destruction on x-ray examination reports.

### RATIONALE/EXPLANATION

IV drug is given to patients who are unable to take it orally; resume oral administration when feasible. Manufacturers' recommendations. Mixing with orange or apple juice improves taste; grapefruit juice should not be used because it affects metabolism of cyclosporine. The amount of fluid should be large enough to increase palatability, especially for children, but small enough to be consumed quickly. Rinsing ensures the entire dose is taken.

The first dose is given approximately 24 hours before transplantation, followed by a dose every 2 weeks for four doses (total of five doses).

This drug may be administered at home, by a patient or a caregiver, with appropriate instructions and supervised practice in mixing and injecting the drug.

Infliximab should be prepared in a pharmacy because special equipment is required for administration.

Manufacturer's recommendations

The IV drug must be reconstituted and diluted with 5% dextrose to a concentration of 6 mg/mL (1 g reconstituted drug in 140 mL or 1.5 g in 210 mL). Handle the drug cautiously to avoid contact with skin and mucous membranes. If such contact occurs, wash thoroughly with soap and water; rinse eyes with plain water.

Food decreases absorption. Avoid inhaling the powder from the capsules or getting on skin or mucous membranes. Such contacts produced teratogenic effects in animals.

Serum drug levels of sirolimus are increased if the two drugs are taken at the same time; consistent timing in relation to food provides more consistent absorption and blood levels; grapefruit juice inhibits the enzymes that metabolize sirolimus, thereby increasing blood levels of drug and increasing risks of toxicity.

Oral tacrolimus can usually be substituted for IV drug 2–3 days after transplantation.

Therapeutic effects usually occur within 3–6 weeks.

## NURSING ACTIONS

- d. When infliximab is given for Crohn's disease, observe for decreased symptoms.
- e. When alefacept or efalizumab is given for psoriasis, observe for improvement in skin lesions.

**3. Observe for adverse effects**

- a. Observe for infection (fever, sore throat, wound drainage, productive cough, dysuria, and so forth).
- b. With antithymocyte globulin, observe for:
  - (1) Anaphylaxis (chest pain, respiratory distress, hypotension, or shock)
  - (2) Chills and fever
- c. With basiliximab and daclizumab, observe for nausea, vomiting, diarrhea, heartburn, abdominal distention.
- d. With cyclosporine, observe for:
  - (1) Nephrotoxicity (increased serum creatinine and blood urea nitrogen [BUN], decreased urine output, edema, hyperkalemia)
  - (2) Hepatotoxicity (increased serum enzymes and bilirubin)
  - (3) Hypertension
  - (4) Anaphylaxis (with IV cyclosporine) (urticaria, hypotension or shock, respiratory distress)
  - (5) Central nervous system (CNS) toxicity (confusion, depression, hallucinations, seizures, tremor)
  - (6) Other (gingival hyperplasia, hirsutism)
- e. With infliximab, observe for:
  - (1) Infusion reactions (fever, chills, pruritus, urticaria, chest pain)
  - (2) GI upset (nausea, vomiting, abdominal pain)
  - (3) Respiratory symptoms (bronchitis, chest pain, coughing, dyspnea)
- f. With leflunomide, observe for:
  - (1) GI upset (nausea, diarrhea)
  - (2) Hepatotoxicity (elevation of transaminases)
  - (3) Skin disorders (alopecia, rash)
- g. With methotrexate, observe for:
  - (1) GI disorders (nausea, vomiting, diarrhea, ulcerations, bleeding)
  - (2) Bone marrow depression (anemia, neutropenia, thrombocytopenia)
  - (3) Hepatotoxicity

## RATIONALE/EXPLANATION

Risks are high in immunosuppressed patients, and frequency and severity increase with higher drug doses. Infections may be caused by almost any microorganism and may affect any part of the body, although respiratory and urinary tract infections may occur more often.

An uncommon but serious allergic reaction that may occur anytime during therapy. If it occurs, stop the drug infusion, inject 0.3 mL epinephrine 1:1000 Sub-Q or IM, and provide other emergency care as indicated.

Fever occurs in approximately 50% of patients; it may be decreased by premedicating with acetaminophen, an antihistamine, or a corticosteroid.

GI symptoms were often reported in clinical trials. Other adverse effects were similar for basiliximab, daclizumab, and placebo groups. All patients were also receiving cyclosporine and a corticosteroid.

This is a major adverse effect which often occurs 2–3 months after transplantation and results in a decreased level of renal function.

The reported incidence is less than 8% after kidney, heart, or liver transplantation. It usually occurs during the first month, when high doses are used, and decreases with dosage reduction.

This is especially likely to occur in patients with heart transplants and may require antihypertensive drug therapy. Do not give a potassium-sparing diuretic as part of the antihypertensive regimen because of increased risk of hyperkalemia. This rarely occurs. If it does, the allergen is thought to be the castor oil component because people who had allergic reactions with the IV drug have later taken oral doses without allergic reactions. During IV administration, observe the patient continuously for the first 30 minutes and often thereafter. Stop the infusion if a reaction occurs, and give emergency care (e.g., epinephrine 1:1000).

CNS effects are relatively uncommon and may be caused by factors other than cyclosporine (e.g., nephrotoxicity). Gingival hyperplasia can be minimized by thorough oral hygiene.

In clinical trials, adverse effects were similar to those occurring with placebo.

Monitor CBC regularly. Bone marrow depression is less likely to occur with the small doses used for inflammatory disorders than with doses used in cancer chemotherapy. Long-term, low-dose methotrexate may produce fatty changes, fibrosis, necrosis, and cirrhosis in the liver.

## Nursing Actions Immunosuppressants (continued)

### NURSING ACTIONS

- h. With muromonab-CD3, observe for:
- (1) An acute reaction called the cytokine release syndrome (high fever, chills, chest pain, dyspnea, hypertension, nausea, vomiting, diarrhea)
  - (2) Hypersensitivity (edema, difficulty in swallowing or breathing, skin rash, urticaria, rapid heart beat)
  - (3) Nausea, vomiting, diarrhea
- i. With mycophenolate, observe for:
- (1) GI effects (nausea, vomiting, diarrhea)
  - (2) Hematologic effects (anemia, neutropenia)
  - (3) CNS effects (dizziness, headache, insomnia)
- j. With sirolimus, observe for:
- (1) GI effects (abdominal pain, nausea, vomiting, constipation, diarrhea, hepatotoxicity)
  - (2) Hematologic effects (anemia, leukopenia, thrombocytopenia, hypercholesterolemia)
  - (3) Cardiovascular effects (edema, hypertension)
  - (4) CNS effects (insomnia, headache, tremor)
- k. With tacrolimus, observe for:
- (1) Nephrotoxicity (increased serum creatinine, decreased urine output)
  - (2) Neurotoxicity (minor effects include headaches, insomnia, nightmares, photophobia, tremors; major effects include expressive aphasia, confusion, coma, psychosis, encephalopathy, seizures)
  - (3) Infection (cytomegalovirus (CMV) infection and others)
  - (4) Hyperglycemia

### 4. Observe for drug interactions

- a. Drugs that *increase* effects of cyclosporine:
- (1) Aminoglycoside antibiotics (e.g., gentamicin), amphotericin B
  - (2) Enzyme inhibitors, including azole antifungals (e.g., itraconazole), calcium channel blockers (e.g., nifedipine), macrolide antibiotics (e.g., erythromycin, clarithromycin), cimetidine
- b. Drugs that *decrease* effects of cyclosporine:
- (1) Enzyme inducers, including anticonvulsants (e.g., carbamazepine, phenytoin), rifampin
- c. Drugs that *increase* effects of leflunomide:
- (1) Rifampin
  - (2) Hepatotoxic drugs (e.g., methotrexate)
- d. Drugs that *decrease* effects of leflunomide:
- (1) Charcoal
  - (2) Cholestyramine

### RATIONALE/EXPLANATION

This reaction is attributed to the release of cytokines by activated lymphocytes or monocytes. Symptoms may range from “flu-like” to serious cardiovascular and CNS disorders. Symptoms usually occur within 30–60 minutes after a dose and may last several hours. The reaction is most likely to occur with the first dose, with dosage increases, and when restarting after a period without the drug.

GI effects are more likely when mycophenolate is started and may subside if dosage is reduced. Monitor CBC reports regularly. Some renal and cardiac transplant recipients develop severe neutropenia, which may be related to mycophenolate, concomitant medications, viral infections, or a combination of these causes. If a patient has neutropenia, stop the drug or reduce the dose and start appropriate treatment as soon as possible.

Most adverse effects occurred in more than 10% of recipients. However, patients were also receiving cyclosporine and a corticosteroid.

Nephrotoxicity has occurred in one third or more of liver transplant recipients who received tacrolimus. The risk is greater with higher doses. Neurologic symptoms occur in approximately 10%–20% of patients receiving tacrolimus.

CMV infection commonly occurs.

Glucose intolerance may require insulin therapy.

Drug interactions have not been reported with the newer biologic immunosuppressants (adalimumab, alefacept, anakinra, basiliximab, daclizumab, etanercept, infliximab, omalizumab).

Increased risk of nephrotoxicity

Decreased hepatic metabolism, increased serum drug levels, and increased risk of toxicity

Drugs that induce CYP3A4 enzymes in the liver stimulate metabolism of cyclosporine and thereby reduce blood levels.

Rifampin induces liver enzymes and accelerates metabolism of leflunomide to its active metabolite. Additive hepatotoxicity

These drugs may be used to lower blood levels of leflunomide.

## NURSING ACTIONS

## RATIONALE/EXPLANATION

e. Drugs that <i>increase</i> effects of methotrexate:	Probenecid, salicylates, and sulfonamides may increase both therapeutic and toxic effects. The mechanism is unknown but may involve slowing of methotrexate elimination through the kidneys or displacement of methotrexate from plasma protein-binding sites.
(1) Probenecid	NSAIDs are often used concomitantly with methotrexate by patients with rheumatoid arthritis. There may be an increased risk of GI ulceration and bleeding.
(2) Salicylates	Procarbazine may increase nephrotoxicity.
(3) Sulfonamides	Hepatotoxic drugs increase hepatotoxicity.
(4) Nonsteroidal anti-inflammatory drugs (NSAIDs)	
(5) Procarbazine	
(6) Alcohol and other hepatotoxic drugs	
f. Drug that <i>decreases</i> effects of methotrexate:	Methotrexate acts by blocking folic acid. Its effectiveness is decreased by folic acid supplementation, alone or in multivitamin preparations.
(1) Folic acid	
g. Drugs that <i>increase</i> effects of mycophenolate:	Increase blood levels of mycophenolate, probably by decreasing renal excretion Increase blood levels
(1) Acyclovir, ganciclovir	
(2) Probenecid, salicylates	
h. Drug that <i>decreases</i> effects of mycophenolate:	Decreases absorption
(1) Cholestyramine	
i. Drugs that <i>increase</i> effects of sirolimus:	Increases blood levels of sirolimus and should not be given at same time (give sirolimus 4 hours after a dose of cyclosporine) These drugs inhibit metabolism of sirolimus, which increases blood levels and risks of toxicity.
(1) Cyclosporine	
(2) CYP3A4 enzyme inhibitors—azole antifungal drugs (e.g., itraconazole), calcium channel blockers (e.g., nifedipine, verapamil), macrolide antibiotics (e.g., erythromycin, clarithromycin), protease inhibitors (e.g., ritonavir, indinavir), cimetidine	
j. Drugs that <i>decrease</i> effects of sirolimus:	These drugs speed up the metabolism and elimination of sirolimus.
(1) Enzyme inducers—anticonvulsants (e.g., carbamazepine, phenytoin), rifamycins (e.g., rifampin, rifabutin), St. John's wort	
k. Drugs that <i>increase</i> effects of tacrolimus:	Increased nephrotoxicity
(1) Nephrotoxic drugs (e.g., aminoglycoside antibiotics, amphotericin B, cisplatin, NSAIDs)	These drugs may increase blood levels of tacrolimus, probably by inhibiting or competing for hepatic drug-metabolizing enzymes.
(2) Antifungals (e.g., clotrimazole, itraconazole), erythromycin and other macrolides, calcium channel blockers (e.g., diltiazem, verapamil), cimetidine, danazol, methylprednisolone, metoclopramide	
(3) Angiotensin-converting enzyme inhibitors, potassium supplements	Increased risk of hyperkalemia. Serum potassium levels should be monitored closely.
l. Drugs that <i>decrease</i> effects of tacrolimus:	With oral tacrolimus, antacids adsorb the drug or raise the pH of gastric fluids and increase its degradation. If ordered concomitantly, an antacid should be given at least 2 hours before or after tacrolimus.
(1) Antacids	Induction of drug-metabolizing enzymes in the liver may accelerate metabolism of tacrolimus and decrease its blood levels.
(2) Enzyme inducers—carbamazepine, phenytoin, rifampin, rifabutin	

## Key Concepts

- Immunosuppressants are used to decrease the immune response with allergic and autoimmune disorders and to avoid graft rejection after transplantation.
- With current treatments, most transplant patients must maintain immunosuppressive drug therapy the rest of their lives.
- Immunosuppressant drugs greatly increase risks of infection.
- Cyclosporine and tacrolimus are similar drugs that are effective immunosuppressants, widely used in organ transplantation, cause nephrotoxicity, and are subject to numerous drug interactions (enzyme-inhibiting drugs increase blood levels and enzyme-inducing drugs decrease blood levels).
- Many transplant centers now prefer tacrolimus over cyclosporine.
- Newer immunosuppressants have more specific effects on the immune system and may cause fewer or less severe adverse effects than older drugs.

## Review and Application Exercises

### Short Answer Exercises

1. List clinical indications for use of immunosuppressant drug therapy.
2. How do the different types of drugs exert their immunosuppressant effects?
3. What are major adverse effects of immunosuppressant drugs?
4. When assessing a patient receiving one or more immunosuppressant drugs, what specific signs and symptoms indicate adverse drug effects?
5. For a patient taking one or more immunosuppressant drugs, prepare a teaching plan related to safe and effective drug therapy.

### NCLEX-Style Questions

6. In addition to organ transplantation, immunosuppressant drugs are used to treat
  - a. serious infections
  - b. Crohn's disease and rheumatoid arthritis
  - c. gastroesophageal reflux disease (GERD)
  - d. seizure disorders

7. After organ transplantation, immunosuppressants are given to prevent
  - a. nephrotoxicity
  - b. hepatotoxicity
  - c. rejection reactions
  - d. bleeding disorders
8. The family of a middle-aged patient who has received a kidney transplant has questions about the increased risk of cancer as a result of the need for long-term (lifelong) immunosuppressant drugs. The nurse is correct in informing the family that the most common malignancies that occur with immunosuppression include
  - a. skin cancers and lymphomas
  - b. cancers of the GI tract
  - c. renal and liver cancers
  - d. brain and spinal cord cancers
9. Patients taking immunosuppressant drugs should be taught
  - a. ways to decrease infections
  - b. to avoid weight gain
  - c. to maintain a good fluid intake
  - d. to increase rest and decrease exercise

- Thrombocytopenia

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Contrast normal and malignant cells.
2. Describe major types of antineoplastic drugs in terms of mechanism of action, indications for use, administration, and nursing process implications.
3. Discuss the rationales for using antineoplastic drugs in combination with each other, with surgical treatment, and with radiation therapy.
4. Discuss adverse drug effects and their prevention or management.
5. Assist patients/caregivers in preventing or managing symptoms associated with chemotherapy regimens.
6. Teach, promote, and practice reduction of risk factors for development of cancer; early recognition of cancer signs and symptoms; and early implementation of effective treatment measures.

## Applying Your Knowledge

Julia Gardner is a 60-year-old retired teacher. She has been diagnosed with cancer in her right breast. Before her mastectomy, Ms. Gardner is receiving neoadjuvant chemotherapy. Ms. Gardner receives trastuzumab (Herceptin), doxorubicin, and paclitaxel (Taxol) IV every 3 weeks. She takes methotrexate PO 2 times a week.

## Introduction

Oncology is the study of malignant neoplasms and their treatment. Drugs used in oncologic disorders include those used to kill, damage, or slow the growth of cancer cells and those used to prevent or treat adverse drug effects. Antineoplastic drug therapy is a major treatment modality for cancer, along with surgery and radiation therapy.

Major groups of anticancer drugs are the traditional cytotoxic agents (e.g., alkylating agents, antimetabolites, antitumor antibiotics, plant alkaloids), newer cytotoxic “biologic targeted therapies” (e.g., monoclonal antibodies, growth-factor inhibitors), and hormone inhibitors, which are not cytotoxic. In addition, several drugs are used to ameliorate the adverse effects of cytotoxic drugs (e.g., cytoprotectants, including some immunostimulants discussed in Chap. 40). To aid understanding of the drugs used in oncologic disorders, selected characteristics of cancer and the drugs are described below.

## Cancer

The term *cancer* is used to describe many disease processes with the common characteristics of uncontrolled cell growth, invasiveness, and *metastasis*, as well as numerous etiologies, clinical manifestations, and treatments.

### Normal Versus Malignant Cells

Normal cells reproduce in response to a need for tissue growth or repair and stop reproduction when the need has been met. The normal *cell cycle* is the interval between the “birth” of a cell and its division into two daughter cells (Fig. 42-1). The daughter cells may then enter the resting phase ( $G_0$ ) or proceed through the reproductive cycle to form more new cells. Normal cells are also well differentiated in appearance and function and have a characteristic lifespan.

*Malignant* cells occupy space, take blood and nutrients away from normal tissues, and serve no useful purpose. They grow in an uncontrolled fashion and avoid the restraints (e.g., contact with other cells) that stop the growth of normal cells. They are undifferentiated, which means they have lost the structural and functional characteristics of the cells from which they originated. They are loosely connected, so that cells break off from the primary tumor and invade adjacent tissues. Loose cells also enter blood and lymph vessels, circulate through the body, and produce additional neoplasms at sites distant from the primary tumor.

A malignant cell develops from a transformed normal cell. The transformation may begin with a random *mutation* (abnormal structural change in the genetic material of a cell). A

mutated cell may be destroyed by body defenses (e.g., an immune response) or it may replicate. When the mutated cell eludes destruction by the immune system and begins to reproduce, additional changes that occur during succeeding cell divisions may produce cells with progressively fewer normal and more malignant characteristics. It usually takes years for malignant cells to produce a clinically detectable neoplasm.

### Development of Cancer

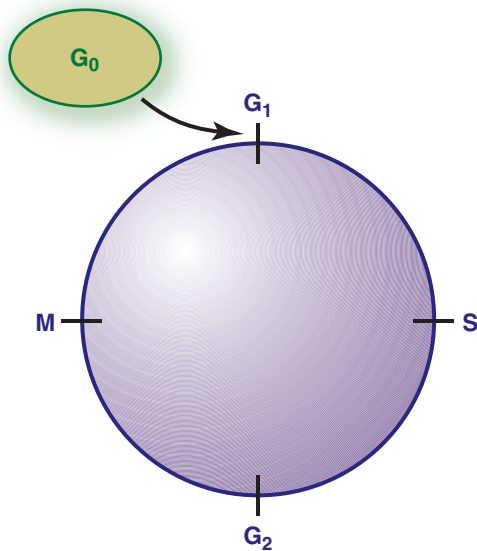

Cancer is a heterogeneous disease, and there are multiple causes, such as environmental factors (tobacco) and genetic factors. Genetic causes include mutation of genes, abnormal activation of genes that regulate cell growth and mitosis, or lack of tumor-suppressor genes. The abnormal genes, called *oncogenes*, are mutations of normal growth-regulating genes, called *proto-oncogenes*, which are present in all body cells. When proto-oncogenes are exposed to carcinogens and genetically altered to oncogenes, they may operate continuously and cause abnormal, disordered, and unregulated cell growth. Unregulated cell growth and proliferation increases the probability of neoplastic transformation of the cell. Tumors of the breast, colon, lung, and bone have been linked to activation of oncogenes.

Tumor-suppressor genes (*anti-oncogenes*) normally function to inhibit inappropriate cellular growth and proliferation. Abnormal tumor-suppressor genes (i.e., absent, damaged, mutated, or inactivated) may be inherited or result from exposure to carcinogens. When these genes are inactivated, a block to proliferation is removed and the cells begin unregulated growth. One tumor suppressor gene, p53, is present in virtually all normal tissues. When cellular deoxyribonucleic acid (DNA) is damaged, the p53 gene allows time for DNA repair and restricts proliferation of cells with abnormal DNA. Mutations of the p53 gene, a common genetic change in cancer, are associated with more than 90% of small cell lung cancers and more than 50% of breast and colon cancers. Mutant p53 proteins can also form complexes with normal p53 proteins and inactivate the function of the normal suppressor gene.

Thus, activation of oncogenes and inactivation of anti-oncogenes probably both play roles in cancer development. Multiple genetic abnormalities are characteristic of cancer cells and may occur concurrently or sequentially.

Overall, evidence indicates that neoplastic transformation is a progressive process involving several generations of cells, with each new generation becoming more like malignant cells. Thus, malignancy probably results from a combination of factors experienced over a person's lifetime, including random cell mutations, exposure to carcinogens, and host characteristics or lifestyle habits that increase susceptibility to cancer development. Some known carcinogens and risk factors are listed in Box 42-1.

After a cancer develops, factors influencing its growth include blood and nutrient supply, immune response, and hormonal stimulation (e.g., in tumors of the breast, uterus, ovary, and prostate). Malignant tumors are able to form new blood vessels (a process called *angiogenesis*) to support their growth.

**Figure 42-1** ■ Normal cell cycle. The normal cell cycle (the interval between the birth of a cell and its division into two daughter cells) involves several phases. During the resting phase ( $G_0$ ), cells perform all usual functions except replication; that is, they are not dividing but are capable of doing so when stimulated. Different types of cells spend different lengths of time in this phase, after which they either reenter the cell cycle and differentiate or die. During the first active phase ( $G_1$ ), ribonucleic acid (RNA) and enzymes required for production of deoxyribonucleic acid (DNA) are developed. During the next phase (S), DNA is synthesized for chromosomes. During  $G_2$ , RNA is synthesized, and the mitotic spindle is formed. Mitosis occurs in the final phase (M). The resulting two daughter cells may then enter the resting phase ( $G_0$ ) or proceed through the reproductive cycle.

## Box 42-1

## Carcinogens and Risk Factors

## Environmental Carcinogens

**Biologic carcinogens.** Viruses linked to cancer include Epstein-Barr (Burkitt's lymphoma, Hodgkin's disease), hepatitis B and C (liver), herpes simplex II (cervix and vulva), human papilloma (cervix, penis, oral cavity, esophagus, larynx), human immunodeficiency (Kaposi's sarcoma), and human T-cell lymphotropic (T-cell leukemia or lymphoma). In addition, *Helicobacter pylori* bacteria are associated with gastric cancer and gastric lymphoma.

**Radiation** (e.g., from sunlight) can damage DNA and cause cell mutations.

**Chemicals** include many substances that can damage cellular structures and interfere with cell regulation. Industrial carcinogens include benzene (bladder cancer), hydrocarbons (lung and skin cancer), polyvinyl chloride (liver cancer), and other substances used in the production of various products. Workers who manufacture the products and people who live in the plant vicinity are most likely to be affected. Tobacco products, including cigarettes and smokeless products, contain numerous carcinogens and are associated with cancers of the lungs, mouth, pharynx, larynx, esophagus, and bladder.

**Therapeutic drugs** are associated with both hematologic and solid neoplasms. The alkylating antineoplastic drugs are associated with leukemia, lymphoma, and other cancers. The drugs damage DNA and interfere with growth or replication of tumor cells. At the same time, they may damage the DNA of normal cells and transform some of them into malignant cells. Immunosuppressants (e.g., azathioprine, cyclosporine, tacrolimus, corticosteroids) are associated with an increased risk of non-Hodgkin's lymphoma and skin cancer in renal transplant patients. Other patients taking immunosuppressant drugs (e.g., for rheumatoid arthritis) are at risk for lymphomas, squamous cell carcinoma of skin, and soft tissue sarcomas, but at lower rates than transplant recipients.

Sex hormones are growth factors for certain cells. In women, estrogens are associated with breast and endometrial cancer. The antiestrogen tamoxifen is associated with endometrial cancer. In men, androgens are associated with prostate cancer; and anabolic steroids, especially in high doses and with prolonged use, are associated with hepatic neoplasms.

## Host Factors

**Age.** Except for a few early-childhood cancers, the risks of cancer increase with age.

**Alcohol use** is associated with cancers of the breast, head and neck, and liver.

**Diet.** A high-fat diet is associated with breast, colon, and prostate cancer; a low-fiber diet may increase risks of colon cancer.

**Gender.** Men are more likely to have leukemia and cancer of the urinary bladder, stomach, and pancreas; women are at risk of cancer of the breast, cervix, and endometrium. Lung and colon cancer occur equally in both sexes.

**Geography and ethnicity** are more environmental than hereditary or racial. Immigrants who adopt dietary and lifestyle habits of natives have similar risks and people who live in cities have greater risks because of greater exposure to air pollutants and other carcinogens. In the United States, African Americans have higher rates of multiple myeloma and cancers of the lung, prostate, esophagus, and pancreas than white people. In addition, African American women who develop breast cancer may have more aggressive, estrogen-receptor negative, high-grade tumors, and poorer survival rates than Hispanic and Caucasian women.

**Heredity.** In some families, there is a tendency toward development of cancer (e.g., close relatives of premenopausal women with breast cancer are at high risk for breast cancer).

**Immunosuppression**, whether caused by disease or drug therapy, is associated with an increased risk of lymphomas, skin cancers, and other malignancies.

**Obesity** is associated with increased risks of developing cancer of the breast, colon, endometrium, esophagus, liver, pancreas, and prostate gland.

**Previous cancer** is associated with a higher risk of other cancers in those who are treated with chemotherapy or radiation and survive. Secondary cancers are usually attributed to treatments that damage DNA and eventually transform normal cells into malignant cells.

**Tobacco use** is a major risk factor for cancers of the lung, esophagus, and head and neck. Chemicals in cigarette smoke cause most lung cancer, in smokers and other people exposed to cigarette smoke.

## Classification of Malignant Neoplasms

Malignant neoplasms are classified according to the type of tissue involved and other characteristics. With the exception of the acute leukemias, they are considered chronic diseases.

**Hematologic malignancies** involve the bone marrow and lymphoid tissues; they include leukemias, lymphomas, and multiple myeloma. *Leukemias* are cancers of the bone marrow characterized by overproduction of abnormal white blood cells. The four main types are acute lymphocytic, acute myelogenous, chronic lymphocytic, and chronic myelogenous. Lymphomas are tumors of lymphoid tissue characterized by abnormal proliferation of the white blood cells normally

found in lymphoid tissue. They usually develop within lymph nodes and may occur anywhere, because virtually all body tissues contain lymphoid structures. The two main types are Hodgkin's disease and non-Hodgkin's lymphoma. Multiple myeloma is a tumor of the bone marrow in which abnormal plasma cells proliferate. Because normal plasma cells produce antibodies and abnormal plasma cells cannot fulfill this function, the body's immune system is impaired. As the malignant cells expand, they crowd out normal cells, interfere with other bone marrow functions, infiltrate and destroy bone, and eventually metastasize to other tissues, such as the spleen, liver, and lymph nodes.

**Solid neoplasms** are composed of a mass of malignant cells (parenchyma) and a supporting structure of connective tissue, blood vessels, and lymphatics (stroma). The two major classifications are carcinomas and sarcomas. *Carcinomas* are derived from epithelial tissues (skin, mucous membrane, linings and coverings of viscera) and are the most common type of malignant tumors. They are further classified by cell type, such as adenocarcinoma or basal cell carcinoma. *Sarcomas* are derived from connective tissue (muscle, bone, cartilage, fibrous tissue, fat, blood vessels). They are subclassified by cell type (e.g., osteogenic sarcoma, angiosarcoma).

### Grading and Staging of Malignant Neoplasms

When a malignant neoplasm is identified, it is further “graded” according to the degree of malignancy and “staged” according to tissue involvement. Grades 1 and 2 are similar to the normal tissue of origin and show cellular differentiation; grades 3 and 4 are unlike the normal tissue of origin, less differentiated, and more malignant. Staging indicates whether the neoplasm is localized or metastasized and which organs are involved. These characteristics assist in treatment (e.g., localized tumors are usually amenable to surgery, radiation, or chemotherapy combined with radiation [concurrent] therapy; metastatic disease requires systemic chemotherapy alone).

### Effects of Cancer on the Host

Effects vary according to the location and extent of the disease process. There are few effects initially. As the neoplasm grows, effects occur when the tumor becomes large enough to cause pressure, distortion, or deficient blood supply in surrounding tissues; interfere with organ function; obstruct ducts and organs; and impair nutrition of normal tissues. More specific effects include anemia, malnutrition, pain, immunosuppression, infection, hemorrhagic tendencies, thromboembolism, hypercalcemia, cachexia, and various symptoms related to impaired function of affected organs and tissues.

### Overview of Antineoplastic Drug Therapy

One definition of *chemotherapy* is the use of medications to treat cancer (rather than surgical or radiation therapy). However, the term is most often used to indicate the use of traditional cytotoxic antineoplastic drugs (as differentiated from biologic or hormonal therapy). Actually, except for hormone inhibitors that slow the growth of cancer cells stimulated by hormones, the purpose of all antineoplastic drugs is to damage or kill cancer cells (i.e., be cytotoxic). Most chemotherapy regimens involve a combination of drugs with different actions at the cellular level, which destroys a greater number of cancer cells and reduces the risk of the cancer developing drug resistance. Because drug resistance is a major problem, many newer drugs are recommended for use after initial drug therapy becomes ineffective (i.e., allows tumor progression).

Chemotherapy is usually administered in cycles, depending on the type of cancer and which drugs are used. Cycles

involve taking the drugs daily, weekly, or monthly for a period of time, often with a recovery period following each treatment cycle. Recovery periods allow time for the patient’s body to rest and produce new, healthy cells. Chemotherapy is often continued as long as it is effective and does not produce unacceptable toxicity.

Because the consequences of inappropriate or erroneous drug therapy may be fatal for patients (from the disease or the treatment), chemotherapy regimens should be managed by medical oncologists experienced in use of the drugs. Because of the drugs’ toxicity, nurses who administer intravenous (IV) cytotoxic chemotherapy should be specially trained and certified in handling and administering the drugs safely and accurately.

## Traditional Cytotoxic Antineoplastic Drugs

These drugs comprise the largest, oldest, and most diverse group of antineoplastic drugs. General characteristics and subgroups are described below; names, indications for use, dosages, and selected adverse effects of individual drugs are listed in Table 42-1.

### General Characteristics

- Most drugs kill malignant cells by interfering with cell replication, with the supply and use of nutrients (e.g., amino acids, purines, pyrimidines), or with the genetic materials in the cell nucleus (DNA or RNA).
- The drugs act during the cell’s reproductive cycle (Fig. 42-2). Some, called cell cycle–specific, act mainly during specific phases such as DNA synthesis or formation of the mitotic spindle. Others act during any phase of the cell cycle and are called cell cycle–nonspecific.
- *Cytotoxic* drugs are most active against rapidly dividing cells, both normal and malignant. Commonly damaged normal cells are those of the bone marrow, the lining of the gastrointestinal (GI) tract, and the hair follicles. Healthy cells usually recover fairly soon.
- Each drug dose kills a specific percentage of cells. To achieve a cure, all malignant cells must be killed or reduced to a small number that can be killed by the person’s immune system.
- Antineoplastic drugs may induce drug-resistant malignant cells. Mechanisms may include inhibiting drug uptake or activation, increasing the rate of drug inactivation, pumping the drug out of the cell before it can act, increasing cellular repair of DNA damaged by the drugs, or altering metabolic pathways and target enzymes of the drugs. Mutant cells also may emerge.
- Most cytotoxic antineoplastic drugs are potential teratogens, and pregnancy should be avoided during and for several months after drug therapy is stopped.

Table 42-1

## Drugs at a Glance: Cytotoxic Antineoplastic Drugs

GENERIC/ TRADE NAME	ROUTES AND DOSAGE RANGES*	CLINICAL USES	ADVERSE EFFECTS
<b>Alkylating Drugs</b>			
<b>Nitrogen Mustard Derivatives</b>			
<b>Chlorambucil</b> (Leukeran)	PO 0.1–0.2 mg/kg/d for 3–6 wk. Maintenance therapy, 0.03–0.1 mg/kg/d	Chronic lymphocytic leukemia, Hodgkin's and non-Hodgkin's lymphomas	Bone marrow depression, hepatotoxicity, secondary leukemia
<b>Cyclophosphamide</b> (Cytoxan)	Induction therapy, PO 1–5 mg/kg/d; IV 20–40 mg/kg in divided doses over 2–5 days. Maintenance therapy, PO 1–5 mg/kg daily	Hodgkin's disease; non-Hodgkin's lymphomas; leukemias; cancer of breast, lung, or ovary; multiple myeloma; neuroblastoma	Bone marrow depression, nausea, vomiting, alopecia, hemorrhagic cystitis, hypersensitivity reactions, secondary leukemia or bladder cancer
<b>Ifosfamide</b> (Ifex)	IV 1.2 g/m <sup>2</sup> /d for 5 consecutive d. Repeat every 3 wk or after white blood cell and platelet counts return to normal after a dose.	Germ cell testicular cancer	Bone marrow depression, hemorrhagic cystitis, nausea and vomiting, alopecia, CNS depression, seizures
<b>Melphalan</b> (Alkeran)	PO 6 mg/d for 2–3 wk, then 28 drug-free days, then 2 mg daily IV 16 mg/m <sup>2</sup> every 2 wk for 4 doses, then every 4 wk	Multiple myeloma, ovarian cancer	Bone marrow depression, nausea and vomiting, hypersensitivity reactions
<b>Nitrosoureas</b>			
<b>Carmustine</b> (BiCNU, Gliadel)	IV 150–200 mg/m <sup>2</sup> every 6 wk Wafer, implanted in brain after tumor resection	Hodgkin's disease, non-Hodgkin's lymphomas, multiple myeloma, brain tumors	Bone marrow depression, nausea, vomiting
<b>Lomustine</b> (CCNU)	PO 130 mg/m <sup>2</sup> every 6 wk	Hodgkin's disease, brain tumors	Nausea and vomiting, bone marrow depression
<b>Platinum Compounds</b>			
<b>Carboplatin</b> (Paraplatin)	IV infusion 360 mg/m <sup>2</sup> on day 1 every 4 wk	Palliation of ovarian cancer	Bone marrow depression, nausea and vomiting, nephrotoxicity
<b>Cisplatin</b> (Platinol)	IV 100 mg/m <sup>2</sup> once every 4 wk	Advanced carcinomas of testes, bladder, ovary	Nausea, vomiting, anaphylaxis, nephrotoxicity, bone marrow depression, ototoxicity
<b>Oxaliplatin</b> (Eloxatin)	IV infusion 85 mg/m <sup>2</sup> every 2 wk	Advanced colon cancer	Anaphylaxis, anemia, increased risk of bleeding or infection, cold-induced acute neurotoxicities
<b>Antimetabolites</b>			
<b>Capecitabine</b> (Xeloda)	PO 1250 mg/m <sup>2</sup> q12h for 2 wk, then a rest period of 1 wk, then repeat cycle	Metastatic breast cancer, colorectal cancer	Bone marrow depression, nausea, vomiting, diarrhea, mucositis, hand & foot syndrome
<b>Cladribine</b> (Leustatin)	IV infusion 0.09 mg/kg/d for 7 consecutive d	Hairy cell leukemia	Bone marrow depression, nausea, vomiting
<b>Cytarabine</b> (Cytosar-U)	IV infusion 100 mg/m <sup>2</sup> /d for 7 d	Leukemias of adults and children	Bone marrow depression, nausea, vomiting, anaphylaxis, mucositis, diarrhea

(continued on page 680)

Table 42-1

## Drugs at a Glance: Cytotoxic Antineoplastic Drugs (continued)

GENERIC/ TRADE NAME	ROUTES AND DOSAGE RANGES*	CLINICAL USES	ADVERSE EFFECTS
<b>Fludarabine</b> (Fludara)	IV 25 mg/m <sup>2</sup> /d for 5 consecutive d; repeat every 28 d	Chronic lymphocytic leukemia	Bone marrow depression, nausea, vomiting, diarrhea
<b>Fluorouracil</b> (5-FU) (Adrucil, Efudex, Fluoroplex)	IV 12 mg/kg/d for 4 d, then 6 mg/kg every other day for 4 doses Topical, apply to skin cancer lesion twice daily for several weeks	Carcinomas of the breast, colon, stomach, and pancreas Solar keratoses, basal cell carcinoma	Bone marrow depression, nausea, vomiting, mucositis Pain, pruritus, burning at site of application
<b>Gemcitabine</b> (Gemzar)	IV 1000 mg/m <sup>2</sup> once weekly up to 7 wk or toxicity, withhold for 1 wk, then once weekly for 3 wk and withhold for 1 wk	Lung and pancreatic cancer	Bone marrow depression, nausea, vomiting, flu-like symptoms, skin rash
<b>Mercaptopurine</b> (Purinethol)	PO 2.5 mg/kg/d (100–200 mg for average adult)	Acute and chronic leukemias	Bone marrow depression, nausea, vomiting, mucositis
<b>P Methotrexate (MTX)</b> (Rheumatrex)	Acute leukemia in children, induction, PO, IV 3 mg/m <sup>2</sup> /d; maintenance, PO 30 mg/m <sup>2</sup> twice weekly Choriocarcinoma, PO, IM 15 mg/m <sup>2</sup> daily for 5 d	Leukemias; non-Hodgkin's lymphomas; osteosarcoma; choriocarcinoma of testes; cancers of breast, lung, head and neck	Bone marrow depression, nausea, vomiting, mucositis, diarrhea, fever, alopecia
<b>Pemetrexed</b> (Alimta)	IV infusion 500 mg/m <sup>2</sup> over 10 min, every 21 d	Non-small cell lung cancer	Mucositis, skin rash
<b>Antitumor Antibiotics</b>			
<b>Bleomycin</b> (Blenoxane)	IV, IM, Sub-Q 0.25–0.5 units/kg once or twice weekly	Squamous cell carcinoma, Hodgkin's and non-Hodgkin's lymphomas, testicular carcinoma	Pulmonary toxicity, mucositis, alopecia, nausea, vomiting, hypersensitivity reactions
<b>Dactinomycin</b> (Actinomycin D, Cosmegen)	IV 15 mcg/kg/d for 5 d and repeated every 2–4 wk	Rhabdomyosarcoma, Wilms' tumor, choriocarcinoma, testicular carcinoma, Ewing's sarcoma	Bone marrow depression, nausea, vomiting. Extravasation may lead to tissue necrosis.
<b>Daunorubicin conventional</b>	IV 25–45 mg/m <sup>2</sup> daily for 3 d every 3–4 wk	Acute leukemias, lymphomas	Same as doxorubicin, below
<b>Daunorubicin liposomal</b> (DaunoXome)	IV infusion, 40 mg/m <sup>2</sup> every 2 wk	AIDS-related Kaposi's sarcoma	Bone marrow depression, nausea, vomiting
<b>Doxorubicin conventional</b> (Adriamycin)	Adults, IV 60–75 mg/m <sup>2</sup> every 21 d Children, IV 30 mg/m <sup>2</sup> daily for 3 d, repeated every 4 wk	Acute leukemias; lymphomas; carcinomas of breast, lung, and ovary	Bone marrow depression, alopecia, mucositis, GI upset, cardiomyopathy. Extravasation may lead to tissue necrosis.
<b>Doxorubicin liposomal</b> (Doxil)	IV infusion, 20 mg/m <sup>2</sup> , once every 3 wk	AIDS-related Kaposi's sarcoma	Bone marrow depression, nausea, vomiting, fever, alopecia
<b>Epirubicin</b> (Ellence)	IV infusion 120 mg/m <sup>2</sup> every 3–4 wk	Breast cancer	Cardiotoxicity
<b>Idarubicin</b> (Idamycin)	IV injection 12 mg/m <sup>2</sup> /d for 3 d, with cytarabine	Acute myeloid leukemia	Same as doxorubicin, above

GENERIC/ TRADE NAME	ROUTES AND DOSAGE RANGES*	CLINICAL USES	ADVERSE EFFECTS
<b>Mitomycin</b> (Mutamycin)	IV 20 mg/m <sup>2</sup> every 6–8 wk	Metastatic carcinomas of stomach and pancreas	Bone marrow depression, nausea, vomiting. Extravasation may lead to tissue necrosis.
<b>Mitoxantrone</b> (Novantrone)	IV infusion 12 mg/m <sup>2</sup> on days 1–3, for induction of remission in leukemia	Acute nonlymphocytic leukemia, prostate cancer	Bone marrow depression, congestive heart failure, nausea
<b>Pentostatin</b> (Nipent)	IV 4 mg/m <sup>2</sup> every other week	Hairy cell leukemia unresponsive to interferon alfa	Bone marrow depression, hepatotoxicity, nausea, vomiting
<b>Valrubicin</b> (Valstar)	Intravesically, 800 mg once weekly for 6 wk	Bladder cancer	Dysuria, urgency, frequency, bladder spasms, hematuria
<b>Plant Alkaloids</b>			
<b>Camptothecins</b>			
<b>Irinotecan</b> (Camptosar)	IV infusion, 125 mg/m <sup>2</sup> once weekly for 4 wk, then a 2-wk rest period; repeat regimen	Metastatic cancer of colon or rectum	Bone marrow depression, diarrhea
<b>Topotecan</b> (Hycamtin)	IV infusion 1.5 mg/m <sup>2</sup> daily for 5 consecutive days every 21 d	Advanced ovarian cancer, small-cell lung cancer	Bone marrow depression, nausea, vomiting, diarrhea
<b>Podophyllotoxins</b>			
<b>Etoposide</b> (VePesid)	IV 50–100 mg/m <sup>2</sup> /d on days 1–5, or 100 mg/m <sup>2</sup> /d on days 1, 3, and 5, every 3–4 wk PO 2 times the IV dose	Testicular cancer, small-cell lung cancer	Bone marrow depression, allergic reactions, nausea, vomiting, alopecia
<b>Teniposide</b> (Vumon)	IV infusion 165 mg/m <sup>2</sup> twice weekly for 8–9 doses	Acute lymphocytic leukemia in children	Same as etoposide, above
<b>Taxanes</b>			
<b>Docetaxel</b> (Taxotere)	IV infusion 60–100 mg/m <sup>2</sup> , every 3 wk	Advanced breast cancer, non-small cell lung cancer	Bone marrow depression, nausea, vomiting, hypersensitivity reactions
<b>Paclitaxel</b> (Taxol)	IV infusion 135 mg/m <sup>2</sup> every 3 wk	Advanced ovarian cancer, advanced breast cancer, non-small cell lung cancer, AIDS-related Kaposi's sarcoma	Bone marrow depression, allergic reactions, hypotension, bradycardia, nausea, vomiting
<b>Vinca Alkaloids</b>			
<b>Vinblastine</b> (Velban)	Adults, IV 3.7–11.1 mg/m <sup>2</sup> (average 5.5–7.4 mg/m <sup>2</sup> ) weekly Children, IV 2.5–7.5 mg/m <sup>2</sup> weekly	Metastatic testicular carcinoma, Hodgkin's disease	Bone marrow depression, nausea, vomiting. Extravasation may lead to tissue necrosis.
<b>Vincristine</b> (Oncovin)	Adults, IV 1.4 mg/m <sup>2</sup> weekly Children, IV 2 mg/m <sup>2</sup> weekly	Hodgkin's and other lymphomas, acute leukemia, neuroblastoma, Wilms' tumor	Peripheral neuropathy. Extravasation may lead to tissue necrosis.
<b>Vinorelbine</b> (Navelbine)	IV injection 30 mg/m <sup>2</sup> once weekly	Non-small cell lung cancer	Bone marrow depression, peripheral neuropathy. Extravasation may lead to tissue necrosis.

(continued on page 682)

Table 42-1

## Drugs at a Glance: Cytotoxic Antineoplastic Drugs (continued)

GENERIC/ TRADE NAME	ROUTES AND DOSAGE RANGES*	CLINICAL USES	ADVERSE EFFECTS
<b>Miscellaneous Agents</b>			
<b>L-Asparaginase</b> (Elspar)	IV 1000 IU/kg/d for 10 d	Acute lymphocytic leukemia	Hypersensitivity reactions, including anaphylaxis
<b>Hydroxyurea</b> (Hydrea)	PO 80 mg/kg as a single dose every third day or 20–30 mg/kg as a single dose daily	Chronic myelocytic leukemia, melanoma, ovarian cancer, head and neck cancer	Bone marrow depression, nausea, vomiting, peripheral neuritis
<b>Ixabepilone</b> (Ixempra)	IV infusion 40 mg/m <sup>2</sup> over 3h, every 3 wk	Advanced breast cancer	Bone marrow suppression, peripheral neuropathy, nausea, vomiting, diarrhea, mucositis
<b>Levamisole</b> (Ergamisol)	PO 50 mg q8h for 3 d every 2 wk	Colon cancer, with fluorouracil	Nausea, vomiting, diarrhea
<b>Procarbazine</b> (Matulane)	PO 2–4 mg/kg/d for 1 wk, then 4–6 mg/kg/d	Hodgkin's disease	Bone marrow depression, mucositis, CNS depression

\*Dosages may vary significantly or change often, according to use in different types of cancer and in different combinations.

AIDS, acquired immunodeficiency syndrome.

- Most antineoplastic drugs are given orally or IV; some are given topically, intrathecally, or by instillation into a body cavity.
- Doxorubicin and daunorubicin are available in conventional and liposomal preparations. The liposomal preparations increase drug concentration in malignant tissues and decrease concentration in normal tissues, thereby increasing effectiveness while decreasing toxicity (e.g., cardiotoxicity).
- Common adverse effects include *alopecia* (hair loss), anemia, bleeding, fatigue, *mucositis* (inflammation and erosion of oral mucous membrane), nausea and vomiting, *neutropenia* (low white blood cell count), and *thrombocytopenia* (low platelet count). Other problems may include damage to the heart, liver, lungs, kidneys, or nerves. In general, adverse effects depend on the specific drugs used and the patient's health status.
- With treatment of leukemias and lymphomas, a serious, life-threatening adverse effect called tumor lysis syndrome may occur. This syndrome occurs when large numbers of cancer cells are killed or damaged and release their contents into the bloodstream. As a result, hyperkalemia, hyperphosphatemia, hyperuricemia, hypomagnesemia, hypocalcemia, and acidosis develop. Signs and symptoms depend on the severity of the metabolic imbalances but may include GI upset, fatigue, altered mental status, hypertension, muscle cramps, paresthesias (numbness and tingling), tetany,

seizures, electrocardiographic changes (e.g., dysrhythmias), cardiac arrest, reduced urine output, and acute renal failure. The condition can be prevented or minimized by aggressive hydration with IV normal saline, alkalization with IV sodium bicarbonate, and administration of allopurinol (e.g., 300 mg daily for adults and 10 mg/kg/d for children) to reduce uric acid levels. Maintaining a urine pH of 7 or more prevents renal failure from precipitation of uric acid crystals in the kidneys. Treatment of hyperkalemia may include IV dextrose and regular insulin (to drive potassium into cells) or Kayexalate to eliminate potassium in feces. Treatment of hyperphosphatemia may include administration of aluminum hydroxide or another phosphate-binding agent. Hemodialysis may be used if the other measures are ineffective.

- Many cytotoxic antineoplastic drugs have **BLACK BOX WARNINGS** about potentially serious adverse effects and special precautions for safe usage.

### Indications for Use

Cytotoxic antineoplastic drugs are used to cure the disease, relieve symptoms, or induce or maintain *remission* (symptom-free period). In hematologic neoplasms, drug therapy is the treatment of choice because the disease is systemic rather than localized. In solid tumors, drug therapy may be used before or after surgery or radiation therapy and when metastasis occurs.

**Figure 42-2** ■ Cell cycle effects of cytotoxic antineoplastic drugs.

Antineoplastic drugs are sometimes used in the treatment of nonmalignant conditions. For example, small doses of methotrexate (MTX) are used for rheumatoid arthritis and psoriasis.

## Classifications and Mechanisms of Action

Cytotoxic antineoplastic drugs are usually classified in terms of their mechanisms of action (alkylating agents and antimetabolites) or their sources (plant alkaloids, antibiotics).

### Alkylating Agents

Alkylating agents include nitrogen mustard derivatives, nitrosoureas, and platinum compounds. *Nitrogen mustard derivatives* (e.g., *cyclophosphamide*) interfere with cell division and the structure of DNA during all phases of the malignant cell cycle. As a result, they have a broad spectrum of activity. They are most effective in hematologic malignancies but also are used to treat breast, lung, and ovarian tumors. All of these drugs cause significant bone marrow depression (*myelosuppression*) and frequent complete blood counts (CBCs) are required.

*Nitrosoureas* also interfere with DNA replication and RNA synthesis and may inhibit essential enzymatic reactions of cancer cells. They are cell cycle–nonspecific and may be used in patients with GI, lung, and brain tumors. They are highly lipid soluble and therefore enter the brain and cerebrospinal fluid more readily than other antineoplastic drugs. They cause delayed bone marrow depression, with maximum *leukopenia* and thrombocytopenia occurring 5 to 6 weeks after drug administration. As a result, the drugs are given less often than other drugs, and CBCs are needed weekly for at least 6 weeks after a dose.

*Platinum compounds* are cell cycle–nonspecific agents that inhibit DNA, RNA, and protein synthesis. *Cisplatin* is used to treat advanced cancers of the bladder, ovary and testes. Adverse effects include severe nausea and vomiting and nephrotoxicity. Carboplatin is used to treat endometrial and ovarian carcinomas, and it produces bone marrow depression

as a major adverse effect. Oxaliplatin is used to treat colorectal cancer, with 5-fluorouracil and leucovorin. Adverse effects include anemia and peripheral neuropathy.

### Antimetabolites

Antimetabolites are diverse drugs that are allowed to enter cancer cells because they are similar to metabolites or nutrients needed by the cells for reproduction. Inside the cell, the drugs replace normal metabolites or inhibit essential enzymes. These actions deprive the cell of substances needed for formation of DNA or cause formation of abnormal DNA. The drugs are cell cycle–specific because they exert their cytotoxic effects only during the S phase of the cell's reproductive cycle, when DNA is being synthesized.

This group includes folic acid antagonists (e.g., **P** *methotrexate* (prototype), pemetrexed), purine antagonists (e.g., *mercaptopurine*), and pyrimidine antagonists (e.g., *fluorouracil*). These drugs are most effective against rapidly growing tumors, and individual drugs vary in their effectiveness with different kinds of cancer. Toxic effects include bone marrow depression, mucositis and ulceration of the GI tract, and hair loss. Pemetrexed blocks folate and enzymes essential for cancer cell reproduction and may increase blood levels of homocysteine. Homocysteine is produced when proteins are broken down in the blood and elevated blood levels are considered a risk factor for coronary artery disease and stroke. Treatment with folic acid and vitamin B<sub>12</sub> supplements, which can reduce homocysteine blood levels, is required for all patients taking the drug.

### Applying Your Knowledge 42-1

Because Ms. Gardner is being treated as an outpatient, it is extremely important that an appropriate plan of care be made to allow her to care for the adverse effects of these medications at home. What are the most common adverse effects of the methotrexate and what nursing interventions should be anticipated?

### Antitumor Antibiotics

These drugs (e.g., *doxorubicin*) bind to DNA so that DNA and RNA transcription is blocked. They are active in all phases of the cell cycle, and their cytotoxic effects are similar to those of the alkylating agents. Major toxicities are bone marrow depression and GI upset. Doxorubicin and related drugs also cause cardiotoxicity and tissue necrosis if *extravasation* (leaking of medication into soft tissues around the venipuncture site) occurs. Bleomycin may cause significant pulmonary toxicity.

### Plant Alkaloids

Plant alkaloids include derivatives of camptothecin (e.g., *topotecan*), podophyllotoxin (e.g., *etoposide*), taxanes (e.g., paclitaxel), and plants of the *Vinca* genus (e.g., *vincristine*). These drugs vary in their characteristics and clinical uses.

**Camptothecins** (also called DNA topoisomerase inhibitors) inhibit an enzyme required for DNA replication and repair. They have activity in several types of cancers; dose-limiting toxicity is myelosuppression.

**Podophyllotoxins** act mainly in the G<sub>2</sub> phase of the cell cycle and prevent mitosis. Etoposide is used mainly to treat testicular and small cell lung cancer; teniposide is used mainly for childhood acute lymphocytic leukemia. Dose-limiting toxicity is myelosuppression.

**Taxanes** inhibit cell division (antimitotic effects). They are used mainly for advanced breast and ovarian cancers. Dose-limiting toxicity is neutropenia.

**Vinca alkaloids** are cell cycle-specific agents that stop mitosis. These drugs have similar structures but different antineoplastic activities and adverse effects. Vincristine is used to treat Hodgkin's disease, acute lymphoblastic leukemia, and non-Hodgkin's lymphomas. Vinblastine is used to treat Hodgkin's disease and choriocarcinoma; vinorelbine is used to treat non-small cell lung cancer. The drugs can cause severe tissue damage with extravasation. In addition, vinblastine and vinorelbine cause bone marrow depression, and vincristine causes peripheral nerve toxicity.

### Miscellaneous Cytotoxic Agents

Miscellaneous agents vary in their sources, mechanisms of action, indications for use, and toxic effects. **L-Asparaginase** (Elspar) is an enzyme that inhibits protein synthesis and reproduction by depriving cells of required amino acids. It is used to treat acute lymphocytic leukemia and can cause allergic reactions, including anaphylaxis. **Pegaspargase** (Oncaspar) is a modified formulation for people who are hypersensitive to Elspar. **Hydroxyurea** acts in the S phase of the cell cycle to impair DNA synthesis. It is used to treat leukemia, melanoma, and advanced ovarian cancer. A major adverse effect is myelosuppression. **Ixabepilone** (Ixempra) is the first of a new class of antineoplastic drugs called epothilones. Epothilones, which are obtained from bacteria, stop growth of tumor cells by preventing cell division (antimitotic effects). Ixabepilone is a semisynthetic analog of epothilone approved for treatment of advanced breast cancer, alone or with capecitabine. Adverse effects include bone marrow suppression, hypersensitivity reactions, and peripheral neuropathy. **Procarbazine** inhibits DNA, RNA, and protein synthesis. It is used to treat Hodgkin's disease. It is a monoamine oxidase inhibitor and may cause hypertension if given with adrenergic drugs, tricyclic antidepressants, or foods with high tyramine content (see Chap. 10). Common adverse effects include leukopenia and thrombocytopenia.

## Biologic Targeted Antineoplastic Drugs

Two major mechanisms in cancer development are thought to be failure of the immune system to eliminate mutant, prema-

lignant, and malignant cells and failure of the growth-regulating mechanisms to control the proliferation of mutant, pre-malignant, and malignant cells. As increased understanding of cancer-cell biology has evolved in recent years, much research has focused on biologic agents to stimulate the immune system to fight cancer cells or to inhibit biologic processes that allow cancer cells to grow and proliferate.

Treatment of cancer with biologic agents is a growing modality as researchers try to increase anticancer effectiveness and decrease the adverse effects of traditional cytotoxic chemotherapy. Biologic antineoplastic drugs include immunotherapy drugs and drugs that “target” biologic processes of malignant cells. Some immunologic anticancer drugs are discussed in Chapter 40 (e.g., bacillus Calmette-Guérin vaccine for bladder cancer; interferon alfa for AIDS-related Kaposi's sarcoma, selected leukemias, malignant melanoma, and non-Hodgkin's lymphoma; and interleukin-2 for renal cell carcinoma). Other available drugs are monoclonal antibodies, tyrosine kinase inhibitors, and a proteasome inhibitor. These drugs are described below and in Table 42-2.

### Monoclonal Antibodies

Monoclonal antibodies (see Chap. 41) are produced from one cell line. Early murine (mouse-derived) antibodies produced problems as hosts' immune systems reacted against the foreign protein. Most newer drugs are humanized and target specific cellular components. In cancer, these drugs act by one of three main mechanisms: blocking a receptor and preventing the over-expressed growth factor receptors from signaling for cell division, attaching to a cell receptor so that the body's own immune system can kill the cell, or carrying chemotherapy or radioisotopes to the cancer cells and causing cell death.

**Alemtuzumab** (Campath) and **rituximab** (Rituxan) bind to an antigen on normal T and B lymphocytes and malignant lymphoid cells to activate antibody- and complement-mediated cytotoxicity. **Bevacizumab** (Avastin), **cetuximab** (Erbix), **panitumumab** (Vectibix), and **trastuzumab** (Herceptin) bind to growth factors or growth factor receptors found on blood vessels, colorectal cancer cells, and breast cancer cells, respectively, to prevent the growth factors from becoming activated and stimulating cell growth. For example, bevacizumab was developed to bind with vascular endothelial growth factor (VEGF) and inhibit the formation of the new blood vessels required for tumor growth (antiangiogenesis). In addition, trastuzumab was developed to bind with human epidermal growth factor receptor 2 (HER2), of which 25% to 30% of women with breast cancer have an excessive number.

**Gemtuzumab ozogamicin** (Mylotarg), **ibrutinomab tiuxetan** (Zevalin), and **tositumomab and iodine I-131 tositumomab** (Bexxar) are conjugated with a radioisotope or toxin to increase anticancer effectiveness.

Table 42-2

Drugs at a Glance: Biologic Antineoplastic Drugs

GENERIC/TRADE NAMES	ROUTES AND DOSAGE RANGES	CLINICAL USES	ADVERSE EFFECTS
<b>Monoclonal Antibodies</b>			
<b>Alemtuzumab</b> (Campath 1H)	IV infusion, initially, 3 mg/d as a 2-h infusion; increase to 10 mg/d, then to 30 mg/d as tolerated. Maintenance, 30 mg/d 3 times weekly on alternate days for up to 12 wk	Chronic lymphocytic leukemia in patients previously treated with alkylating agents and fludarabine	Allergic infusion reactions (dyspnea, fever, chills, skin rash), immunosuppression, hypotension, hypertension, peripheral edema, nausea, vomiting, diarrhea, mucositis
<b>Bevacizumab</b> (Avastin)	IV infusion, 5 mg/kg once every 14 d until disease progression is detected	Colorectal cancer	Heart failure, hemorrhage, hypertension, diarrhea, leukopenia, pain, dyspnea, dermatitis, stomatitis, vomiting
<b>Cetuximab</b> (Erbix)	IV infusion, initially, 400 mg/m <sup>2</sup> over 2 h; maintenance, 250 mg/m <sup>2</sup> over 1 h once weekly	Metastatic colorectal cancer	Anemia, leukopenia, infusion reaction, nausea, diarrhea, stomatitis, vomiting, dyspnea, fever
<b>Gemtuzumab ozogamicin</b> (Mylotarg)	IV infusion, 9 mg/m <sup>2</sup> , for 2 doses, 14 d apart	Acute myeloid leukemia	Chills, fever, nausea, vomiting, diarrhea
<b>Ibritumomab tiuxetan</b> (Zevalin)	See literature	Non-Hodgkin's lymphoma, with rituximab	Severe or fatal infusion reaction, severe bone marrow depression
<b>Panitumumab</b> (Vectibix)	IV infusion, 6 mg/kg over 60 min every 14 days. Doses over 1000 mg should be given over 90 min.	Metastatic colorectal cancer	Infusion reactions, skin rash, pulmonary fibrosis, nausea, vomiting, diarrhea
<b>Rituximab</b> (Rituxan)	IV infusion, 375 mg/m <sup>2</sup> once weekly for 4 doses	Non-Hodgkin's lymphoma	Hypersensitivity reactions, cardiac dysrhythmias
<b>Tositumomab and Iodine 131-Itositumomab</b> (Bexxar)	See literature	Non-Hodgkin's lymphoma	Fever, chills, nausea, vomiting, skin rash, headache, cough, infection, pain
<b>Trastuzumab</b> (Herceptin)	IV infusion, 4 mg/kg initially, then 2 mg/kg once weekly	Metastatic breast cancer	Cardiotoxicity (dyspnea, edema, heart failure)
<b>Growth Factor and Tyrosine Kinase Inhibitors</b>			
<b>Dasatinib</b> (Sprycel)	PO 70 mg twice daily	Chronic myelogenous leukemia Acute lymphoblastic leukemia	Anemia, diarrhea, dyspnea, edema, fever, infection, nausea, pain, skin rash
<b>Erlotinib</b> (Tarceva)	PO 150 mg daily	Non-small cell lung cancer, brain glioma	Nausea, vomiting, diarrhea, skin rash
<b>Imatinib</b> (Gleevec)	Adults, PO 400–800 mg/d Children, 3 y and older, PO 260–340 mg/m <sup>2</sup> /d	Chronic myeloid leukemia, gastrointestinal stromal tumors (GIST)	Dyspnea, edema, heart failure, hemorrhage, nausea, vomiting, diarrhea, neutropenia, thrombocytopenia
<b>Lapatinib</b> (Tykerb)	PO 1250 mg (5 tablets) once daily on days 1 to 21, with capecitabine PO 2000 mg/m <sup>2</sup> /d (in 2 doses, 12 h apart) on days 1 to 14 in a repeating 21-d cycle	Advanced breast cancer	Diarrhea, dyspnea, insomnia, nausea, vomiting, stomatitis

(continued on page 686)

Table 42-2

**Drugs at a Glance: Biologic Antineoplastic Drugs** (continued)

GENERIC/TRADE NAMES	ROUTES AND DOSAGE RANGES	CLINICAL USES	ADVERSE EFFECTS
<b>Sorafenib</b> (Nexavar)	PO 400 mg twice daily	Advanced renal cell cancer, advanced liver cell cancer	Hypertension, skin rash, alopecia, anemia, nausea, vomiting, diarrhea
<b>Sunitinib</b> (Sutent)	PO 50 mg daily for 4 wk, followed by 2 wk off drug	Advanced renal cell cancer, gastrointestinal stromal tumors (GIST)	Hypertension, skin rash, diarrhea, anemia, neutropenia, nausea and vomiting
<b>Temsirolimus</b> (Torisel)	IV infusion, 25 mg over 30–60 min once per week	Advanced renal cell cancer	Anorexia, diarrhea, edema, mucositis, nausea, skin rash
<b>Proteasome Inhibitor</b> <b>Bortezomib</b> (Velcade)	IV injection, 1.3 mg/m <sup>2</sup> , twice weekly for 2 wk, followed by a 10-d rest period	Multiple myeloma	Edema, nausea, vomiting, diarrhea, anemia, neutropenia, thrombocytopenia

Serious adverse effects of these drugs include a potentially fatal hypersensitivity-type infusion reaction (e.g., chills, fever, bronchospasm, dyspnea, skin rash or urticaria) and bone marrow depression (e.g., anemia, leukopenia, thrombocytopenia). To prevent or decrease infusion reactions, premedication with diphenhydramine (Benadryl) and acetaminophen is recommended. With alemtuzumab, a very high risk of infection results because the drug depletes normal B and T lymphocytes. As a result, prophylactic antimicrobial drugs are recommended during and for 3 months after alemtuzumab administration. Severe cardiotoxicity, including heart failure, has also been reported, more often with bevacizumab and trastuzumab. With trastuzumab, patients at higher risk of cardiotoxicity include those 60 years and older and those who have received doxorubicin (or a related drug) or cyclophosphamide. Left ventricular function should be evaluated in all patients before and during treatment and trastuzumab should be discontinued in those who develop significant decreases.

Monoclonal antibodies, which may be used alone or in combination with traditional cytotoxic antineoplastic drugs and other treatment modalities, have become an integral part of treatment plans for a variety of cancers. They and other biologic targeted therapies continue to be developed and tested for clinical use.

### Applying Your Knowledge 42-2

Ms. Gardner asks why she must take the Herceptin because there are such serious concerns about an allergic reaction to the monoclonal antibodies. How would you respond?

## Growth Factor and Tyrosine Kinase Inhibitors

Growth factors such as epidermal growth factor (EGF, which stimulates the growth of epithelial cells in the skin and other organs) and platelet-derived growth factor (PDGF, which stimulates the proliferation of vascular smooth muscle and endothelial cells) bind to receptors on cell membrane surfaces or within cells and initiate intracellular events that result in cell growth. EGF is normally produced in the kidneys and salivary glands and is found in almost all body fluids. When EGF binds to the external portion of the EGF receptor, it stimulates gene expression, cell proliferation, programmed cell death (apoptosis), and angiogenesis.

The EGF receptor (EGFR; also called the tyrosine kinase receptor), which is found in normal body cells and some malignant cells, has three distinctive areas (Fig. 42-3). One area is on the cell membrane surface and available to combine with EGF. A second area crosses the cell membrane. A third, an intracellular area, contains tyrosine kinase enzymes. Tyrosine kinase enzymes play an important role in the proliferation and differentiation of cells.

**Erlotinib** (Tarceva) inhibits the tyrosine kinase enzyme portion of the EGFR. This action inhibits cell proliferation and induces cell death. The drug is used to treat advanced non-small cell lung cancer, the most common type of lung cancer, which is known to over-express the EGFR. It is also used to treat malignant glioma, a type of brain tumor. Adverse effects include skin rash, diarrhea, nausea, and vomiting. In addition, interstitial lung disease has been reported in some patients, with a few deaths. Patients should be monitored for acute onset or worsening of dyspnea and pneumonitis. If interstitial lung disease is confirmed, erlotinib should be discontinued.

**Imatinib** (Gleevec) inhibits several tyrosine kinase enzymes that are essential to the growth of some cancer cells,

**Figure 42-3** ■ Actions of selected biologic targeted drugs. These drugs prevent epidermal growth factor (EGF) from combining with its receptors and thereby prevent or decrease cell growth. Cetuximab and trastuzumab bind with the extracellular portion of the EGF receptor; erlotinib blocks the intracellular (tyrosine kinase) portion of the EGF receptor.

including an abnormal type of tyrosine kinase thought to be the main cause of chronic myelogenous leukemia (CML) and the tyrosine kinases activated by PDGF and stem cell factor (SCF). This action inhibits cell proliferation and induces cell death. The drug is used to treat CML and a rare type of cancer called gastrointestinal stromal tumor (GIST). It is well absorbed with oral administration, and peak serum levels are reached in 2 to 4 hours. It is highly protein bound, its elimination half-life is 18 hours, it is metabolized in the liver, and it is excreted mainly in feces. Adverse effects include anemia, cardiotoxicity, edema, musculoskeletal pain, and nausea.

**Dasatinib** (Sprycel), **lapatinib** (Tykerb), **sorafenib** (Nexavar), **sunitinib** (Sutent), and **temsirolimus** (Torisel) are newer tyrosine kinase inhibitors with varying indications for use and adverse effects (see Table 42-2). Most are recommended for use after disease progression with imatinib or other treatment.

Most of these drugs are metabolized mainly by cytochrome P450 3A4 enzymes and interact with drugs that induce (e.g., rifampin, phenytoin) or inhibit (e.g., clarithromycin, itraconazole) these enzymes. Dosage may need to be increased with concurrent administration of inducers or decreased with concurrent use of inhibitors.

### Proteasome Inhibitor

Proteasomes are enzyme complexes in the cytoplasm and nucleus of all body cells, both normal and malignant. These enzymes regulate intracellular proteins. **Bortezomib** (Velcade) inhibits proteasomes, affects multiple proteins within cells, and

is thought to have multiple mechanisms of cytotoxicity (e.g., preventing formation of new blood vessels in tumors and accelerating death of malignant cells). In general, the drug leads to cell cycle arrest, delayed tumor growth, and cell death. It is indicated for treatment of multiple myeloma in patients whose disease progressed during previous treatment.

Bortezomib is moderately protein bound (83%) and metabolized by several cytochrome P450 enzymes in the liver. The drug should be used with caution in patients with impaired hepatic or renal function. Adverse effects include peripheral neuropathy, which may be increased with previous use of neurotoxic agents or pre-existing peripheral neuropathy. Dosage adjustment may be needed.

## Antineoplastic Hormone Inhibitor Drugs

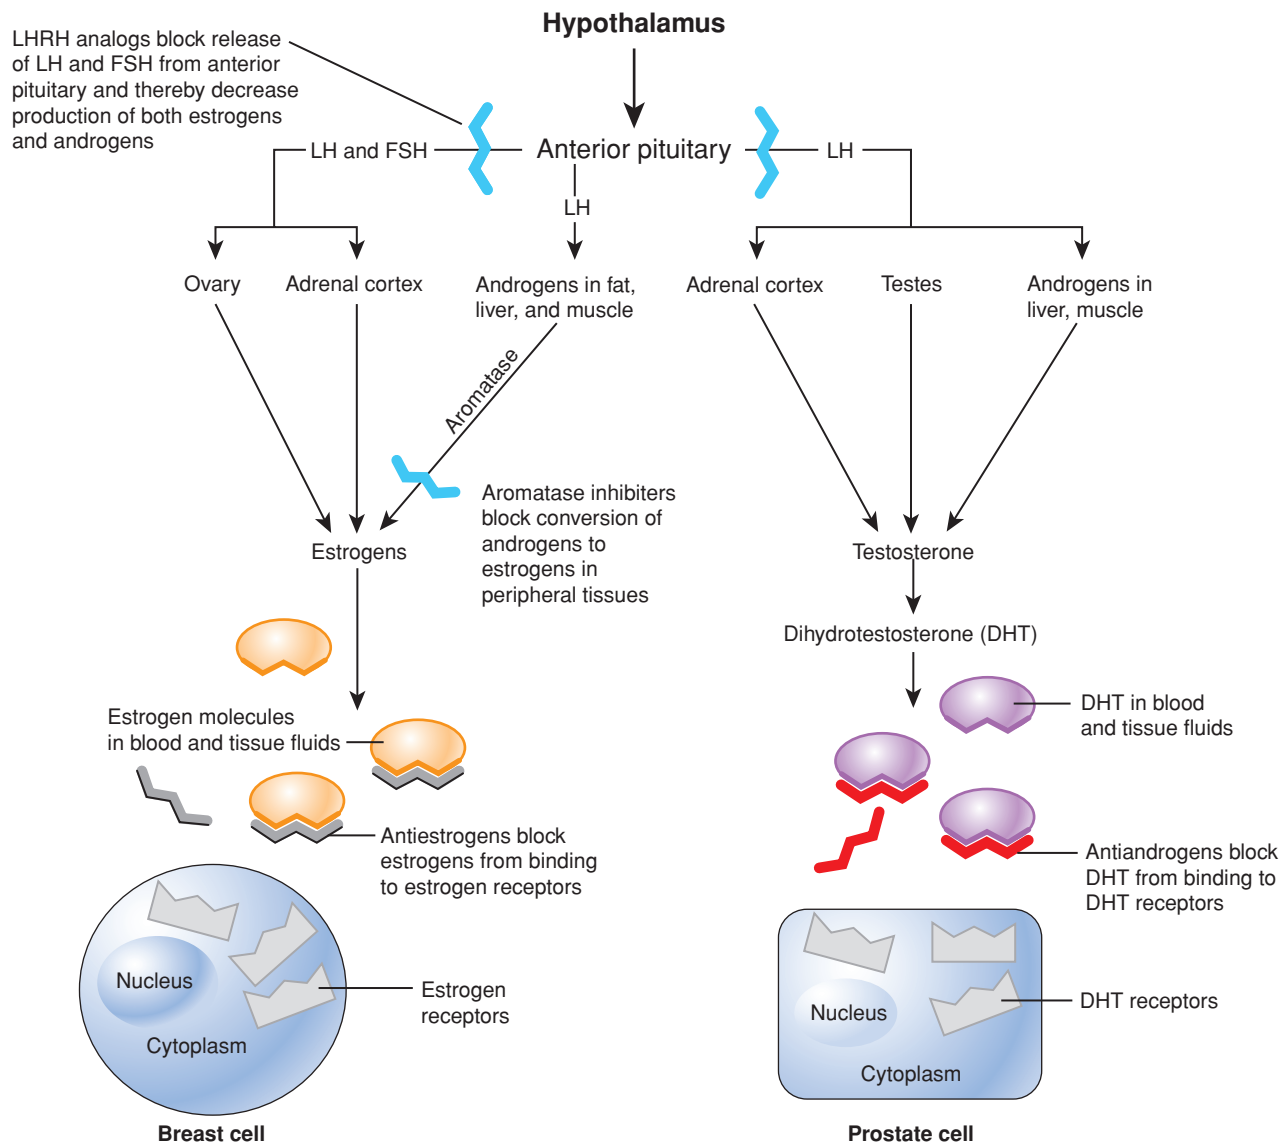

The main hormonal agents used in the treatment of cancer are the corticosteroids (see Chap. 23) and drugs that block the production or activity of estrogens and androgens. Corticosteroids suppress or kill malignant lymphocytes and are most useful in the treatment of leukemias, lymphomas, and multiple myeloma. They are also used to treat complications of cancer (e.g., brain metastases, hypercalcemia). Prednisone and dexamethasone are commonly used. Sex-hormone blocking drugs are used mainly to control tumor growth and relieve symptoms. They are not cytotoxic and adverse effects are usually mild.

Sex hormones are growth factors in some malignancies (e.g., estrogens in breast and uterine cancer, androgens in prostate cancer). The hormones may be normally produced within the body or administered as drugs. For example, oral contraceptives and long-term estrogen replacement therapy are associated with breast cancer.

Surgery or antihormonal drugs may be used to decrease hormonal stimulation of cancer growth. Estrogens and androgens are normally produced from cholesterol through a series of chemical conversions involving the hypothalamus, anterior pituitary, adrenal glands, and ovaries in females and testes in males. Preventing production anywhere along this path or blocking estrogens and androgens from combining with their

receptors in target tissues can decrease the growth of cells stimulated by the hormones. Excision of the ovaries or testes (surgical castration) and antihormonal drugs (medical or chemical castration) are commonly used. The ovaries are most likely to be removed in premenopausal women with breast cancer and the testes may be removed in men with prostate cancer. In general, currently used drugs interfere with hormone production or hormone action at the cellular level (Fig. 42-4).

The main hormone inhibitor drugs are the antiestrogens, aromatase inhibitors, antiandrogens, and luteinizing hormone-releasing hormone (LHRH; also known as gonadotropin-releasing hormone [GnRH]) analogs. These are described as follows and in Table 42-3.

**Figure 42-4** ■ Actions of hormone inhibitor drugs. Drugs used to treat breast cancer block the production of estrogens (e.g., LHRH analogs, aromatase inhibitors) or prevent estrogens from binding to receptors in breast cancer cells (antiestrogens). Drugs used to treat prostate cancer block the production of androgens (e.g., LHRH analogs) or prevent DHT, the active form of testosterone, from binding to receptors in prostate cancer cells (antiandrogens).

Table 42-3

## Drugs at a Glance: Antineoplastic Hormone Inhibitors

GENERIC/TRADE NAMES	ROUTES AND DOSAGE RANGES	CLINICAL USES	ADVERSE EFFECTS
<b>Antiestrogens</b>			
<b>Fulvestrant</b> (Faslodex)	IM 250 mg once monthly (one 5-mL or two 2.5-mL injections)	Advanced breast cancer in postmenopausal women	GI upset, hot flashes, injection site reactions
<b>Tamoxifen</b>	PO 20 mg once or twice daily	Breast cancer, after surgery or radiation; prophylaxis in high-risk women; and treatment of metastatic disease	Hot flashes, nausea, vomiting, vaginal discharge, risk of endometrial cancer in nonhysterectomized women
<b>Toremifene</b> (Fareston)	PO 60 mg once daily	Metastatic breast cancer in postmenopausal women	Hot flashes, nausea, hypercalcemia, tumor flare
<b>Aromatase Inhibitors</b>			
<b>Anastrozole</b> (Arimidex)	PO 1 mg once daily	Breast cancer in postmenopausal women	Nausea, hot flashes, edema
<b>Exemestane</b> (Aromasin)	PO 25 mg once daily	Breast cancer in postmenopausal women	Hot flashes, nausea, depression, insomnia, anxiety, dyspnea, pain
<b>Letrozole</b> (Femara)	PO 2.5 mg once daily	Breast cancer in postmenopausal women	Nausea, hot flashes
<b>Antiandrogens</b>			
<b>Bicalutamide</b> (Casodex)	PO 500 mg once daily (with goserelin or leuprolide)	Advanced prostatic cancer	Nausea, vomiting, diarrhea, hot flashes, pain, breast enlargement
<b>Flutamide</b> (Eulexin)	PO 250 mg every 8 h	Advanced prostatic cancer	Nausea, vomiting, diarrhea, hot flashes, hepatotoxicity
<b>LHRH Analogs</b>			
<b>Nilutamide</b> (Nilandron)	PO 300 mg daily for 30 d, then 150 mg daily	Advanced breast cancer in postmenopausal women	Diarrhea, GI bleeding, heart failure, hyperglycemia
<b>Goserelin</b> (Zoladex)	Sub-Q implant, 3.6 mg every 28 d or 10.8 mg every 12 wk	Advanced prostatic or breast cancer, endometriosis	Hot flashes, transient increase in bone pain
<b>Leuprolide</b> (Eligard, Lupron, Viadur)	Sub-Q 7.5 mg/mo IM 7.5 mg/mo, 22.5 mg/3 mo, or 30 mg/4 mo	Advanced prostatic cancer	Same as for goserelin, above
<b>Triptorelin</b> (Trelstar LA, Trelstar Depot)	IM implant 65 mg/12 mo IM 3.75 mg/28 d or 11.25 mg/3 mo	Advanced prostatic cancer	Same as for goserelin and leuprolide, above

GI, gastrointestinal.

## Antiestrogens

Antiestrogens (also called estrogen receptor modulators) used in the treatment of cancer include **fulvestrant** (Faslodex), **tamoxifen** (Nolvadex), and **toremifene** (Fareston). These drugs bind to estrogen receptors in normal and malignant cells. In breast cancer, the drugs compete with estrogen for receptor binding sites and thereby decrease the estrogen growth-stimulating action on malignant cells. Tamoxifen has been widely

used to prevent recurrence of breast cancer after surgical excision and to treat metastatic breast cancer in postmenopausal women with receptor-positive disease. For prevention, the drug is usually taken for 2 to 5 years.

Tamoxifen becomes ineffective after about 5 years, and several studies indicate greater effectiveness when an aromatase inhibitor is given instead of tamoxifen after 2 to 5 years. Although antiestrogens and aromatase inhibitors both block the growth of breast tumors that respond to

estrogen, their mechanisms of action are different. For example, tamoxifen inhibits the ability of breast cancer cells to use estrogen for growth, whereas an aromatase inhibitor inhibits the production of estrogen in fat, muscle, and other tissues. Adverse effects of antiestrogens include increased risk of blood clots or stroke, vaginal bleeding, and muscle cramps.

Sexually active premenopausal women who take tamoxifen should use effective nonhormonal contraception during and for 2 months after tamoxifen is discontinued. (Premenopausal women may also be treated with an LHRH analog, which may be as effective as antiestrogen therapy.)

## Aromatase Inhibitors

**Anastrozole** (Arimidex), **exemestane** (Aromasin), and **letrozole** (Femara) are aromatase inhibitors used to prevent or treat recurrence of estrogen-responsive breast cancer in postmenopausal women. Aromatase is an enzyme that catalyzes the production of estrogen in the ovaries of premenopausal women and in fat, liver, and muscle cells of postmenopausal or castrated women. Thus, inhibiting aromatase reduces estrogen levels in the blood and target tissues, including the breast.

Earlier, an aromatase inhibitor was used after 5 years of tamoxifen therapy. Later studies with letrozole or exemestane indicate that changing to an aromatase inhibitor after 2 or 3 years of tamoxifen therapy is more effective in decreasing recurrent breast cancer. Letrozole following tamoxifen is the current standard of care, and exemestane is being considered as first-line therapy (instead of tamoxifen) for metastatic breast cancer in postmenopausal women.

Adverse effects include nausea, diarrhea, headache, hot flashes, joint pain, bone loss and fractures, and vision disturbances. Because aromatase inhibitors promote bone loss, these drugs may not be appropriate for women at high risk of bone fractures.

## Antiandrogens

**Bicalutamide** (Casodex), **flutamide** (Eulexin), and **nilutamide** (Nilandron) are used to treat prostate cancer, usually with an LHRH analog (see below). The drugs bind to androgen receptors in cells of the prostate gland and thereby block dihydrotestosterone (DHT) stimulation of malignant cell growth.

In the prostate gland, normal cell growth and differentiation depends on the presence of androgens, specifically DHT, the active form of testosterone. These androgens are produced mainly by the testes and the adrenal glands through a series of chemical conversions also involving the hypothalamus and anterior pituitary. In prostate cancer, androgenic stimulation of tumor growth can be reduced by surgical excision of the organs involved in androgen production (usually the testes) or administering drugs that inhibit the production or action of androgens (e.g., antiandrogens, LHRH analogs). Adverse drug effects include hot flashes, breast enlargement and tenderness, nausea, vomiting, constipation, diarrhea, and pain.

## Luteinizing Hormone–Releasing Hormone (LHRH) Analogs

**Goserelin** (Zoladex), **leuprolide** (Eligard, Lupron, Viadur), and **triptorelin** (Trelstar) are synthetic versions of the hypothalamic LHRH that initiates production of both estrogens and androgens. Therapeutic doses of LHRH analogs initially increase the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary, then decrease their release by down-regulating receptors. Inhibiting the release of LH and FSH reduces the production of ovarian estrogen in women to postmenopausal levels and testicular testosterone in men to castration levels. These effects occur within 2 to 4 weeks after drug therapy is begun. In premenopausal women with estrogen receptor–positive breast cancer, medical castration with these drugs is increasingly being used instead of surgical excision of the ovaries. One of these drugs is usually combined with an antiestrogen. In men with prostate cancer, these drugs reduce androgens to the levels seen with surgical excision of the testes. In metastatic prostate cancer, an LHRH analog is often given with an antiandrogen to increase effectiveness. Goserelin is approved for treatment of both breast and prostate cancer; leuprolide and triptorelin are approved only for prostate cancer.

Adverse effects are basically those of estrogen or testosterone deficiency and may include nausea and hot flashes. The drugs may also cause or aggravate depression. Impotence occurs in men but may be reversible when the drug is discontinued. When given for prostate cancer, the drugs may cause increased bone pain and increased difficulty in urinating during the first few weeks of use.

## Cytoprotectant Drugs

Cytoprotectants reduce the adverse effects of cytotoxic drugs, which may be severe, debilitating, and life threatening (Box 42-2). Severe adverse effects may also limit drug dosage or frequency of administration, thereby limiting the effectiveness of chemotherapy. Several cytoprotectants are available to protect certain body tissues from one or more adverse effects and allow a more optimal dose and schedule of cytotoxic agents. To be effective, administration and scheduling must be precise in relation to administration of the cytotoxic agent. A cytoprotective agent does not prevent or treat all adverse effects of a particular cytotoxic agent and it may have adverse effects of its own.

**Amifostine** produces a metabolite that combines with cisplatin and decreases cisplatin-induced renal damage. **Dexrazoxane** decreases cardiac toxicity of doxorubicin. **Erythropoietin**, **filgrastim**, **oprelvekin**, and **sargramostim** (see Chap. 40) stimulate the bone marrow to produce blood cells. Erythropoietin stimulates production of red blood cells and is used for anemia; oprelvekin stimulates production of platelets and may be used to prevent thrombocytopenia; filgrastim and sargramostim stimulate production of white blood cells and are

## Box 42-2

## Management of Chemotherapy Complications

Complications of anticancer drug therapy range from minor to life threatening. Vigilant efforts toward prevention or early detection and treatment are needed.

- **Nausea and vomiting** commonly occur and are treated with antiemetics (see Chap. 62). With traditional cytotoxic chemotherapy, the drugs are most effective when started before drug administration and continued on a regular schedule for 24 to 48 hours afterward. An effective regimen is a serotonin receptor antagonist (e.g., ondansetron) and a corticosteroid (e.g., dexamethasone), given orally or IV. Other measures include a benzodiazepine (e.g., lorazepam) for anticipatory nausea and vomiting and limiting oral intake for a few hours. Guidelines have not been developed for managing nausea and vomiting with the biologic antineoplastic drugs.
- **Anorexia** interferes with nutrition. Well-balanced meals, with foods the patient is able and willing to eat, and nutritional supplements, to increase intake of protein and calories, are helpful.
- **Fatigue** is often caused or aggravated by anemia and can be treated with administration of erythropoietin. Alternating periods of activity and rest and an adequate diet may also be helpful.
- **Alopecia** occurs with cyclophosphamide, doxorubicin, MTX, and vincristine. Counsel patients taking these drugs that hair loss is temporary and that hair may grow back a different color and texture; suggest the purchase of wigs, hats, and scarves before hair loss is expected to occur; and instruct women to use a mild shampoo and avoid rollers, permanent waves, hair coloring, and other treatments that damage the hair.
- **Mucositis** (also called *stomatitis*) often occurs with the antimetabolites, antibiotics, plant alkaloids, and growth factor/tyrosine kinase inhibitors. It usually lasts 7 to 10 days and may interfere with nutrition; lead to oral ulcerations, infections, and bleeding; and cause pain. Nurse or patient interventions to minimize or treat mucositis include the following:
  - Brush the teeth after meals and at bedtime with a soft toothbrush and floss once daily. Stop brushing and flossing if the platelet count drops below 20,000/mm<sup>3</sup> because gingival bleeding is likely. Teeth may then be cleaned with soft, sponge-tipped or cotton-tipped applicators.
  - Rinse the mouth several times daily, especially before meals (to decrease unpleasant taste and increase appetite) and after meals (to remove food particles that promote growth of microorganisms). One suggested solution is 1 teaspoon of table salt and 1 teaspoon of baking soda in 1 quart of water. Commercial mouthwashes are not recommended, because their alcohol content causes drying of oral mucous membranes.
  - Encourage the patient to drink fluids. Systemic dehydration and local dryness of the oral mucosa contribute to the development and progression of mucositis. Pain and soreness contribute to dehydration. Fluids usually tolerated include tea, carbonated beverages, ices (e.g., popsicles), and plain gelatin desserts. Fruit juices may be diluted with water, ginger ale, Sprite, or 7-Up to decrease pain, burning, and further tissue irritation. Drinking fluids through a straw may be more comfortable, because this decreases contact of fluids with painful ulcerations.
- Encourage the patient to eat soft, bland, cold, nonacidic foods. Although individual tolerances vary, it is usually better to avoid highly spiced or rough foods.
- Remove dentures entirely or for at least 8 hours daily because they may irritate oral mucosa.
- Inspect the mouth daily for signs of inflammation and lesions.
- Give medications for pain. Local anesthetic solutions, such as viscous lidocaine, can be taken a few minutes before meals. Because the mouth and throat are anesthetized, swallowing and detecting the temperature of hot foods may be difficult, and aspiration or burns may occur. Doses should not exceed 15 mL every 3 hours or 120 mL in 24 hours. If systemic analgesics are used, they should be taken 30 to 60 minutes before eating.
- For oral infections resulting from mucositis, local or systemic antimicrobial drugs are used. Fungal infections with *Candida albicans* can be treated with antifungal tablets, suspensions, or lozenges. Severe infections may require systemic antibiotics, depending on the causative organism as identified by cultures of mouth lesions.
- **Infection** is common because the disease and its treatment lower host resistance to infection.
  - If fever occurs, especially in a neutropenic patient, possible sources of infection are usually cultured and antibiotics are started immediately.
  - Severe neutropenia can be prevented or its extent and duration minimized by administering filgrastim or sargramostim to stimulate the bone marrow to produce leukocytes. A protective environment may be needed to decrease exposure to pathogens.
  - Instruct the patient to avoid exposure to infection by avoiding crowds, anyone with a known infection, and contact with fresh flowers, soil, animals, or animal excrement.
  - Frequent and thorough hand hygiene by the patient and everyone involved in his or her care is necessary to reduce exposure to pathogenic microorganisms.
  - The patient should take a bath daily and put on clean clothes. In addition, the perineal area should be washed with soap and water after each urination or defecation.
  - When venous access devices are used, take care to prevent them from becoming sources of infection. For implanted catheters, inspect and cleanse around exit sites according to agency policies and procedures. Use strict sterile technique when changing dressings or flushing the catheters. For peripheral intravenous lines, the same principles of care apply, except that sites should be changed every 3 days or if signs of phlebitis occur.
  - Avoid indwelling urinary catheters when possible. When they are necessary, cleanse the perineal area

## Box 42-2

## Management of Chemotherapy Complications (continued)

with soap and water at least once daily and provide sufficient fluids to ensure an adequate urine output.

- Help the patient maintain a well-balanced diet. Oral hygiene and analgesics before meals may increase food intake. High-protein, high-calorie foods and fluids can be given between meals. Nutritional supplements can be taken with or between meals. Provide fluids with high nutritional value (e.g., milkshakes or nutritional supplements) if the patient can tolerate them and has an adequate intake of water and other fluids.
- **Bleeding** may be caused by thrombocytopenia and may occur spontaneously or with minor trauma. Precautions should be instituted if the platelet count drops to  $50,000/\text{mm}^3$  or below. Measures to avoid bleeding include giving oprelvekin to stimulate platelet production and prevent thrombocytopenia; avoiding trauma, including venipuncture and injections, when possible; using an electric razor for shaving; checking skin, urine, and stool for blood; and for platelet counts less than  $20,000/\text{mm}^3$ , stop brushing and flossing the teeth.
- **Extravasation.** Several drugs (called vesicants) cause severe inflammation, pain, ulceration, and tissue necrosis if they leak into soft tissues around veins. Thus, efforts are needed to prevent extravasation or to minimize tissue damage if it occurs.
  - Identify patients at risk for extravasation, including those who are unable to communicate (e.g., sedated patients, infants), have vascular impairment (e.g., from multiple attempts at venipuncture), or have obstructed venous drainage after axillary node surgery.
  - Be especially cautious with the anthracyclines (e.g., doxorubicin) and the vinca alkaloids (e.g., vincristine). Choose peripheral IV sites carefully, avoiding veins that are small or located in an edematous extremity or near a joint. Inject the drugs slowly (1–2 mL at a time) into the tubing of a rapidly flowing IV infusion, for rapid dilution and detection of extravasation. Observe the venipuncture site for swelling and ask the patient about pain or burning. After a drug has been injected, continue the rapid flow rate of the IV fluid for 2 to 5 minutes to flush the vein.
  - If using a central IV line, do not give the drug unless patency is indicated by a blood return. Using a central line does not eliminate the risk of extravasation.
  - When extravasation occurs, the drug should be stopped immediately. Techniques to decrease tissue damage include aspirating the drug (about 5 mL of blood, if able) through the IV catheter before it is removed, elevating the involved extremity, and applying warm (with dacarbazine, etoposide, vinblastine, and vincristine) or cold (with daunorubicin and doxorubicin) compresses. Nurses involved in cytotoxic chemotherapy must know the procedure to be followed if extravasation occurs so that it can be instituted immediately.
- **Hyperuricemia** from rapid breakdown of malignant cells can lead to kidney damage. Risks of *nephropathy* can be decreased by high fluid intake, high urine output, alkalinizing the urine with sodium bicarbonate, and giving allopurinol to inhibit uric acid formation.
- **Hand-foot syndrome** (also called palmar-plantar erythrodysesthesia or erythema) is a sunburn type of skin reaction with redness, tenderness, and possibly peeling, numbness, and tingling of palms and soles. It is associated with some traditional cytotoxic drugs (e.g., capecitabine, doxorubicin, fluorouracil) and some growth factor/tyrosine kinase inhibitors (e.g., lapatinib, sorafenib, sunitinib). It is attributed to leakage of drug from capillaries into the palms and soles; heat and friction increase leakage. Management efforts involve decreasing heat and friction (e.g., minimizing exposure of hands and feet to hot water), avoiding increased pressure (e.g., from long walks, squeezing small implements in cooking, gardening, etc.), or applying ice packs for 15 or 20 minutes at a time. Acetaminophen may be taken for discomfort.

used to reduce neutropenia and infection. **Leucovorin** is used with high-dose MTX. **Mesna** is used with ifosfamide, which produces a metabolite that causes hemorrhagic cystitis. Mesna combines with and inactivates the metabolite and thereby decreases cystitis. Dosages and routes of administration for these medications are listed in Table 42-4.

## Nursing Process

### Assessment

- Assess all patients for risk factors, screening behaviors, and/or manifestations of cancer, in order to prevent cancer, if possible, or recognize and seek treatment for cancer as early as possible. Risk factors include use of tobacco

products (including inhalation of secondhand cigarette smoke in home or work environments), drinking more than one drink a day (for women) or two drinks a day (for men), being overweight, damage to skin unprotected by sunscreen, and unsafe sexual behaviors. Screening behaviors include the use of breast self-examinations, regular mammograms, colonoscopy when indicated, measurement of prostate-specific antigen (PSA), and so forth.

- Assess the patient's condition before chemotherapy is started and often during treatment. Useful information includes the type, grade, and stage of the tumor as well as the signs and symptoms of cancer. General manifestations include anemia, malnutrition, weight loss, pain, and infection; specific manifestations depend on the organs affected.

Table 42-4

## Drugs at a Glance: Cytoprotective Agents

GENERIC/TRADE NAME	CLINICAL USE	ROUTES AND DOSAGE RANGES
<b>Amifostine</b> (Ethylol)	Reduction of cisplatin-induced renal toxicity	IV infusion 910 mg/m <sup>2</sup> once daily within 30 min of starting chemotherapy
<b>Dexrazoxane</b> (Zinecard)	Reduction of doxorubicin-induced cardiomyopathy in women with metastatic breast cancer who have received a cumulative dose of 300 mg/m <sup>2</sup> and need additional doxorubicin	IV 10 times the amount of doxorubicin (e.g., dexrazoxane 500 mg/m <sup>2</sup> per doxorubicin 50 mg/m <sup>2</sup> ), then give doxorubicin within 30 min of completing dexrazoxane dose
<b>Erythropoietin</b> (Epoen, Procrit)	Treatment of chemotherapy-induced anemia	Sub-Q 150–300 units/kg 3 times weekly, adjusted to maintain desired hematocrit
<b>Filgrastim</b> (Neupogen)	Treatment of chemotherapy-induced neutropenia	Sub-Q, IV 5 mcg/kg/d, at least 24 h after cytotoxic chemotherapy, up to 2 wk or an absolute neutrophil count of 10,000/mm <sup>3</sup>
<b>Leucovorin</b> (Wellcovorin)	“Rescue” after high-dose methotrexate for osteosarcoma Advanced colorectal cancer, with 5-fluorouracil	“Rescue,” PO, IV, IM 15 mg q6h for 10 doses, starting 24 h after methotrexate begun Colorectal cancer, IV 20 mg/m <sup>2</sup> or 200 mg/m <sup>2</sup> , followed by 5-fluorouracil, daily for 5 d, repeated every 28 d
<b>Mesna</b> (Mesnex)	Prevention of ifosfamide-induced hemorrhagic cystitis	IV, 20% of ifosfamide dose for 3 doses (at time of ifosfamide dose, then 4 h and 8 h after ifosfamide dose)
<b>Oprelvekin</b> (Neumega)	Prevention of thrombocytopenia	Sub-Q 50 mcg/kg once daily, usually for 10–21 d
<b>Sargramostim</b> (Leukine)	Myeloid reconstitution after bone marrow transplant; to decrease chemotherapy-induced neutropenia	IV infusion 250 mcg/m <sup>2</sup> /d until absolute neutrophil count is above 1500/mm <sup>3</sup> for 3 d, up to 42 d

- Assess for other diseases and organ dysfunctions (e.g., cardiac, renal, hepatic) that influence response to chemotherapy.
- Assess emotional status, coping mechanisms, family relationships, financial resources, and social support mechanisms. Anxiety and depression are common features during cancer diagnosis and treatment.
- Assess laboratory test results before chemotherapy to establish baseline data and during chemotherapy to monitor drug effects.
  - **Blood tests for tumor markers** (tumor-specific antigens on cell surfaces). Alpha-fetoprotein is a fetal antigen normally present during intrauterine and early postnatal life but absent in adulthood. Increased amounts may indicate hepatic or testicular cancer. Carcinoembryonic antigen (CEA) is secreted by several types of malignant cells (e.g., colorectal cancer). A rising level may indicate tumor progression and levels that are elevated before surgery and disappear after surgery indicate adequate tumor excision. If CEA levels rise later, it probably indicates tumor recurrence. With chemotherapy, falling CEA levels indicate effective-

ness. Other tumor markers are immunoglobulins (elevated levels may indicate multiple myeloma) and PSA (elevated levels may indicate prostatic cancer).

- **CBC** to check for anemia, leukopenia, and thrombocytopenia because most cytotoxic antineoplastic drugs cause bone marrow depression. A CBC and white blood cell differential are done before each cycle of chemotherapy to determine dosage and frequency of drug administration, to monitor bone marrow function so fatal bone marrow depression does not occur, and to assist the nurse in planning care. For example, the patient is very susceptible to infection when the leukocyte count is low, and bleeding is likely when the platelet count is low.
- **Other tests.** These include tests of kidney and liver function, serum calcium, uric acid, and others, depending on the organs affected by the cancer or its treatment.

### Nursing Diagnoses

- Pain, nausea and vomiting, weakness, and activity intolerance related to disease process or chemotherapy
- Imbalanced Nutrition: Less Than Body Requirements related to disease process or chemotherapy

*Nursing Process continues on page 694*

- Anxiety related to the disease, its possible progression, and its treatment
- Ineffective Family Coping related to illness and treatment of a family member
- Deficient Fluid Volume related to chemotherapy-induced nausea, vomiting, and diarrhea
- Risk for Injury: Infection related to drug-induced neutropenia; bleeding related to drug-induced thrombocytopenia; stomatitis related to damage of GI mucosal cells
- Deficient Knowledge about cancer chemotherapy and managing adverse drug effects

## Planning/Goals

### The patient will

- Receive assistance in coping with the diagnosis of cancer
- Experience reduced anxiety and fear
- Receive chemotherapy accurately and safely
- Experience reduction of tumor size, change of laboratory values toward normal, or other therapeutic effects of chemotherapy
- Experience minimal bleeding, infection, nausea and vomiting, and other consequences of chemotherapy
- Maintain adequate food and fluid intake and body weight
- Receive assistance in activities of daily living when needed
- Be informed about community resources for cancer care (e.g., Hospice, Reach to Recovery, other support groups)

## Interventions

- Participate in and promote efforts to prevent cancer.
  - Follow and promote the diet recommended by the American Cancer Society (i.e., decrease fat, eat at least five servings of fruits and vegetables daily, increase intake of dietary fiber, minimize intake of salt-cured or smoked foods).
  - Promote weight control. Obesity may contribute to the development of several cancers, including breast and endometrial cancer in women.
  - Identify cancer-causing agents in homes and workplaces and strategies to reduce exposure to them when possible.
  - Strengthen host defenses by promoting a healthful lifestyle (e.g., good nutrition, adequate rest and exercise, stress management techniques, avoiding or minimizing alcohol and tobacco use).
  - Avoid smoking cigarettes and being around smokers. Passive smoking increases risk of lung cancer in spouses of smokers and risks of brain cancer, lymphomas, and acute lymphogenous leukemia in children of smokers.
  - Minimize exposure to sunlight, use sunscreens liberally, and wear protective clothing to prevent skin cancer.

- Participate in and promote cancer screening tests in non-symptomatic people, especially those at high risk, to detect cancer before signs and symptoms occur. These tests include regular examination of breasts, cervix (Pap test), testicles, and skin and tests for colon cancer such as hemoccult tests on stool and colonoscopy. Early recognition of risk factors, premalignant tissue changes (dysplasia), biochemical tumor markers, and beginning malignancies may be life saving; early treatment can greatly reduce the suffering and problems associated with advanced cancer.
- For patients receiving cytotoxic anticancer drugs, try to prevent or minimize the incidence and severity of adverse reactions (see Box 42-2).
- Provide supportive care to patients and families. Physiologic care includes pain management, comfort measures, and assistance with nutrition, hygiene, ambulation, and other activities of daily living as needed. Psychological care includes allowing family members or significant others to be with the patient and participate in care when desired, and keeping patients and families informed.

## Evaluation

- Monitor drug administration for accuracy.
- Observe and interview for therapeutic effects of chemotherapy.
- Compare current laboratory reports with baseline values for changes toward normal values.
- Compare weight and nutritional status with baseline values for maintenance or improvement.
- Observe and interview for adverse drug effects and interventions to prevent or manage them.
- Observe and interview for effective pain management and other symptom control.

## Principles of Therapy

### Overview of Cancer Treatment

For many patients, cancer treatment involves surgery, radiation, and chemotherapy during the course of their disease. Surgery is used to excise localized tumors, which may be curative, and to treat complications of cancer, such as bowel obstruction. Radiation therapy is used to treat most types of cancer. It may be used alone for some malignancies, such as Hodgkin's disease or cervical cancer. It may be used with surgery to reduce the need for radical surgery, to eliminate malignant cells (e.g., positive lymph nodes) that remain after surgery, with chemotherapy to control growth of tumors, and to relieve symptoms in patients with metastatic bone or brain involvement.

Chemotherapy may be used to eliminate or control the growth of malignant cells or to relieve symptoms and improve the patient's quality of life. It is most effective when started

## Patient Teaching Guidelines

## Managing Chemotherapy

- There are many different chemotherapy drugs, and the ones used for a particular patient depend on the type of malignancy, its location, and other factors. Some are taken orally at home; many are given intravenously, in outpatient clinics, by nurses who are specially trained to administer the medications and monitor your condition. The medications are usually given in cycles such as every few weeks.
- The goal of chemotherapy is to be as effective as possible with tolerable side effects. Particular side effects vary with the medications used; some increase risks of infection, and some cause anemia, nausea, or hair loss. All of these can be managed effectively, and several medications can help prevent or minimize side effects. In addition, some helpful activities are listed below.
  - Keep all appointments for chemotherapy, blood tests, and check-ups. This is extremely important. Chemotherapy effectiveness depends on its being given on time; blood tests help to determine when the drugs should be given and how the drugs affect your body tissues.
  - Do everything you can to avoid infection, such as avoiding other people who have infections and washing your hands frequently and thoroughly. If you have a fever, chills, sore throat, or cough, notify your oncologist.
  - Try to maintain or improve your intake of nutritious food and fluids; this will help you feel better and maintain your weight at a more optimal level to promote healing. A dietitian can be helpful in designing a diet to meet your needs and preferences.
  - If your chemotherapy may cause bleeding, you can decrease the likelihood by shaving with an electric razor, avoiding aspirin and other nonsteroidal anti-inflammatory drugs (including over-the-counter Advil, Aleve, and others), and avoiding injections, cuts, and other injuries when possible. If you notice excessive bruising, bleeding gums when you brush your teeth, or blood in your urine or bowel movement, notify your oncologist immediately.
  - If hair loss is expected with the medications you take, you can use wigs, scarves, and hats. These should be purchased before starting chemotherapy, if possible. Hair loss is temporary; your hair will grow back!
- Inform any other physician, dentist, or health care provider that you are taking chemotherapy before any diagnostic test or treatment is begun. Some procedures may be contraindicated or require special precautions.
- If you are of childbearing age, effective contraceptive measures should be carried out during and a few months after chemotherapy.
- For medications taken at home, instructions for taking the drugs should be followed exactly for the most beneficial effects.
- Although specific instructions vary with the drugs you are taking, the following are a few precautions with some commonly used drugs:
  - With **cyclophosphamide**, take the tablets on an empty stomach. If severe stomach upset occurs, take with food. Also, drink 2 or 3 quarts of fluid daily, if possible, and urinate often, especially at bedtime. If blood is seen in the urine or signs of cystitis occur (e.g., burning with urination), report to a health care provider. The drug is irritating to the bladder lining and may cause cystitis. High fluid intake and frequent emptying of the bladder help to decrease bladder damage.
  - With **doxorubicin**, the urine may turn red for 1 to 2 days after drug administration. This discoloration is harmless; it does not indicate bleeding. Also, report to a health care provider if you have edema, shortness of breath, and excessive fatigue. Doxorubicin may need to be stopped if these symptoms occur.
  - With **fluorouracil**, drink plenty of liquids while taking.
  - With **methotrexate**, avoid alcohol, aspirin, and prolonged exposure to sunlight.
  - With **oxaliplatin**, avoid exposure to cold during, and for 3 to 5 days after, drug administration. This helps prevent or minimize nerve damage that may cause numbness, tingling, and pain in the throat or hands. Swallowing and daily activities that require hand grasping may be impaired.
  - With **vincristine**, eat high-fiber foods, such as whole cereal grains, if you are able, to prevent constipation. Also try to maintain a high fluid intake. A stool softener or bulk laxative may be prescribed for daily use.

before extensive tumor growth or when the tumor burden has been reduced by surgical excision or radiation therapy. When solid tumors metastasize, they become systemic diseases and are not accessible to surgical excision or radiation therapy. Neoadjuvant chemotherapy is used before surgery or radiation, to reduce the size of tumors; adjuvant chemotherapy is used after surgery or radiation to destroy or reduce microscopic metastases (e.g., in the treatment of patients with carcinomas of the breast, colon, lung, ovaries, or testes). Palliative chemotherapy is used in advanced cancer to relieve symptoms and treat or prevent complications.

### Drug Selection

Drug therapy for a particular patient depends on the type and stage of cancer, the effectiveness of particular drugs in that type

and stage of cancer, and the patient's age and health status, including liver and kidney function. Most regimens use combinations of drugs because they are more effective, less toxic, and less likely to cause drug resistance than single agents. Numerous combinations have been developed for use in specific types of cancer. Effective combinations include drugs that act by different mechanisms, act at different times in the reproductive cycle of malignant cells, and differ in their adverse effects. Bleomycin is often combined with myelosuppressive drugs because it rarely causes myelosuppression. However, it can cause severe allergic reactions with hypotension and pulmonary toxicity (e.g., interstitial pneumonitis, pulmonary fibrosis). Increasingly, biologic drugs such as monoclonal antibodies and tyrosine kinase inhibitors are being added to traditional cytotoxic drug regimens.

## Drug Dosage

Dosage must be calculated and regulated carefully to minimize toxicity. The patient's age, functional status, nutritional status, blood count, kidney and liver function, and previous chemotherapy or radiation therapy must be considered. Additional guidelines include the following:

- High doses, to the limits of tolerance of normal tissues (e.g., bone marrow), are usually most effective.
- Doses are usually calculated according to body surface area, which includes both weight and height, and are expressed as milligrams of drug per square meter of body surface area ( $\text{mg}/\text{m}^2$ ). Doses also can be expressed as milligrams per kilogram of body weight ( $\text{mg}/\text{kg}$ ). Because doses based on body surface area consider the patient's size, they are especially important for children. If the patient's weight changes more than a few pounds during treatment, doses should be recalculated.
- Dosage may be reduced for neutropenia, thrombocytopenia, stomatitis, diarrhea, and renal or hepatic impairment that reduces the patient's ability to eliminate the drugs.
- Total dose limits for doxorubicin ( $550 \text{ mg}/\text{m}^2$ ) and bleomycin (450 units) should not be exceeded.

## Drug Administration

- Dosage schedules are largely determined by clinical trials and should be followed as exactly as possible.
- Many antineoplastic drugs are given on an intermittent or cyclic schedule, according to pharmacokinetic principles of cancer chemotherapy. However, certain chemotherapeutic agents (e.g., 5-fluorouracil) are ideally administered continuously.
- Each antineoplastic drug should be used in the schedule, route, and dosage judged to be most effective for a particular type of cancer. With combinations of drugs, the recommended schedule should be followed precisely because safety and effectiveness may be schedule dependent. When chemotherapy is used as an adjuvant to surgery, it usually should be started as soon as possible after surgery, given in maximal tolerated doses just as if advanced disease were present, and continued for several months.
- IV drugs should be given by experienced personnel who ensure free flow of fluid to the vein and verify adequate blood return. Infusion should be through a large, upper-extremity vein. When possible, veins of the antecubital fossa, wrist, dorsum of the hand, and the arm where an axillary lymph node dissection has been done should be avoided. An indwelling central venous catheter is often inserted for patients who have poor peripheral venous access, who require many doses of chemotherapy, or who require continuous infusions.
- With bleomycin, a test dose of 1 to 2 milligrams should be given subcutaneously before starting full doses. Severe allergic reactions with hypotension may occur.

- With paclitaxel and docetaxel, premedication is needed to decrease severe hypersensitivity reactions with dyspnea, hypotension, angioedema, and urticaria. A few deaths have occurred despite premedication. With paclitaxel, one regimen is oral dexamethasone 20 milligrams at 12 and 6 hours before, with IV diphenhydramine (Benadryl) 50 milligrams and cimetidine 300 milligrams, famotidine 20 milligrams, or ranitidine 50 milligrams at 30 to 60 minutes before. Additional paclitaxel is contraindicated for patients who experience severe hypersensitivity reactions. With docetaxel, an oral corticosteroid (e.g., dexamethasone 8 mg twice daily) is recommended for 3 days, starting 1 day before docetaxel administration. This reduces risk and severity of hypersensitivity reactions and fluid retention.
- Premedication with diphenhydramine and acetaminophen is recommended before administration of several antineoplastic monoclonal antibodies to decrease potentially serious allergic reactions to drug infusions.

## Hormone Inhibitor Therapy

Sex hormone inhibitors (e.g., antiestrogens, aromatase inhibitors, antiandrogens, LHRH analogs) are often used to treat breast or prostate cancer. Decreasing the hormones that stimulate tumor growth in these tissues can decrease symptoms and prolong survival.

In some patients with breast cancer, the presence of receptors for estrogen indicates a likely response to drugs that decrease estrogen availability. After initial surgery and/or radiation therapy, tamoxifen or a related drug is often used to treat breast cancers in patients with estrogen receptors because it inhibits estrogen binding to estrogen receptors. However, tumors may become resistant to tamoxifen because of mutations in receptors that alter receptor functions. An aromatase inhibitor drug (e.g., letrozole, exemestane) is increasingly being used after 2 to 5 years of tamoxifen therapy and is being investigated for use as first-line therapy instead of tamoxifen. In patients with prostate cancer, antiandrogens (e.g., bicalutamide) and LHRH analogs decrease androgen availability.

When both hormone inhibitor and cytotoxic drug therapies are needed, they are not given concurrently because hormone antagonists decrease malignant cell growth and cytotoxic agents are most effective when the cells are actively dividing. In patients with breast cancer, a hormone-inhibiting drug is usually given before cytotoxic chemotherapy in metastatic disease and after chemotherapy when used for adjuvant treatment.

## Planning With Patient and Family

Patients with cancer and their families should be provided with information about their disease, their treatment options, and the preferred treatment. When cytotoxic chemotherapy is recommended, discussions should include expected benefits, adverse drug effects and their prevention or management, specific information about when and how the drugs will be admin-

istered, and the importance of regular blood tests to monitor drug effects. For those with Internet access, helpful information can be obtained at

CancerNet: [http://www.cancer.gov/cancer\\_information](http://www.cancer.gov/cancer_information)

OncoLink: <http://cancer.med.upenn.edu>

### Applying Your Knowledge 42-3

Ms. Gardner still appears concerned about a possible adverse reaction to the Herceptin. What should you tell her about the precautions taken when administering this drug?

## Safety Precautions With Cytotoxic Antineoplastic Drugs

Most cytotoxic antineoplastic drugs are carcinogenic, mutagenic, and teratogenic. Exposure during pregnancy increases risks of fetal abnormalities, ectopic pregnancy, and spontaneous abortion. In addition, parenteral solutions are irritating to the skin and mucous membranes and may cause contact dermatitis, cough, nausea, vomiting, and diarrhea. As a result, guidelines have been established for nurses who administer these drugs, to increase the safety of both patients and nurses. These guidelines include the following:

- Ensure appropriate orders (e.g., be sure the prescriber is qualified to write chemotherapy orders; do not accept verbal or telephone orders).
- Do not give injectable drugs unless certified to administer chemotherapy.
- Check all IV drug preparations for appropriate dilution, dosage that corresponds to the prescriber's order, absence of precipitates, expiration dates, and so forth.
- Avoid direct contact with solutions for injection by wearing gloves, face shields, and protective clothing (e.g., disposable, liquid-impermeable gowns).
- If handling a powder form of a drug, avoid inhaling the powder.
- Do not prepare the drugs in eating areas (to decrease risks of oral ingestion).
- Dispose of contaminated materials (e.g., needles, syringes, ampules, vials, IV tubing and bags) in puncture-proof containers labeled "Warning: Hazardous Material."
- Wear gloves when handling patients' clothing, bed linens, or excreta. Blood and body fluids are contaminated with drugs or metabolites for about 48 hours after a dose.
- Wash hands thoroughly after exposure or potential exposure.
- Wear a respiratory mask and follow recommended procedures for cleaning up spills.

## Use in Special Populations

### Use in Children

Children are at risk for a wide range of malignancies, including acute leukemias, lymphomas, brain tumors, Wilms' tumor, and sarcomas of muscle and bone. In recent years, however, there have been rapid advances in cancer care for children and high cure rates for many pediatric malignancies. Many of the advances have resulted from the systematic enrollment of children in well-designed clinical trials.

Chemotherapy should be designed, ordered, and supervised by pediatric oncologists. Dosage of cytotoxic drugs should be based on body surface area because this takes size into account. Special efforts are needed to maintain nutrition, organ function, psychological support, growth and development, and other aspects of health status during and after therapy. Long-term follow-up care is needed for survivors because of increased risk of health problems associated with the cancer or its treatment. For example, children who receive an anthracycline drug (e.g., doxorubicin) are at increased risk of developing cardiotoxic effects (e.g., heart failure) during treatment or after receiving the drug. Efforts to reduce cardiotoxicity include using alternative drugs when effective, giving smaller cumulative doses of anthracycline drug, and observing patients closely so that early manifestations can be recognized and treated before heart failure occurs. In addition, after successful chemotherapy, children are at increased risk for development of cancers in adulthood (e.g., leukemia). After radiation therapy, they are at increased risk of developing breast, thyroid, or brain cancer. Children treated for Hodgkin's disease seem to have the highest risk of developing a new cancer later.

Most of the newer anticancer drugs (e.g., targeted therapies such as monoclonal antibodies and tyrosine kinase inhibitors) are used to treat malignancies that do not commonly occur in children and little is known about their effects in children.

### Use in Older Adults

Aging is a risk factor for developing cancer, and the number of new cancer cases is about 10 times greater in people 65 years and older. Currently, 60% of all malignant tumors occur in persons aged 65 years and older. Although they are likely to have chronic cardiovascular, renal, and other disorders (comorbidities) that increase their risks of serious adverse effects, they should not be denied the potential benefits of traditional cytotoxic chemotherapy on the basis of age alone. In addition to comorbidities, issues that impact treatment include access to care, financial and transportation issues, functional status, need for independence, and social support. Physiologic changes of decreased renal function, impaired hepatic blood flow, and decreased cardiac reserve also add to the challenge of managing cancer in older adults. Vigilance is needed to maximize benefits and minimize hazards of antineoplastic drug administration. For example, older adults are more sensitive to the neurotoxic effects of vincristine and need reduced dosages of some drugs (e.g.,

cyclophosphamide, MTX) if renal function is impaired. Creatinine clearance (CrCl) should be monitored; serum creatinine level is not a reliable indicator of renal function in older adults because of their decreased muscle mass. Many antineoplastic drugs are metabolized by the liver; decreased liver blood flow and decreased liver size can lead to accumulation of drug due to decreased clearance, resulting in increased toxicity.

Estrogen- and androgen-inhibiting drugs are often used in older adults to treat breast or prostate cancer. The drugs may be used with or instead of other treatment modalities and are usually well tolerated. Newer biologic agents (targeted therapies) are commonly used to treat lung, colorectal, breast, and hematologic malignancies in older adults.

### Use in Patients With Renal Impairment

Some antineoplastic drugs are nephrotoxic (e.g., cisplatin, MTX), and many are excreted through the kidneys. In the presence of impaired renal function, risks of further impairment or accumulation of toxic drug levels are increased. Thus, renal function should be monitored carefully during therapy and drug dosages are often reduced according to CrCl levels. Renal effects of selected cytotoxic chemotherapy drugs and precautions to reduce nephrotoxicity are described in the following paragraphs.

*Carmustine* and *lomustine* are associated with azotemia and renal failure, usually with long-term IV administration and large cumulative doses. *Cisplatin* is nephrotoxic, and acute overdosage can cause renal failure. Because nephrotoxicity is increased with repeated doses, cisplatin is given at 3- or 4-week intervals and blood tests of renal function (e.g., creatinine, urea nitrogen, electrolytes) are measured before each course of therapy. Renal function is usually allowed to return to normal before another dose is given. Nephrotoxicity may be reduced by the use of amifostine or IV hydration and mannitol. *Cyclophosphamide* may cause hemorrhagic ureteritis and renal tubular necrosis with IV doses above 50 milligrams per kilogram. These effects usually subside when the drug is stopped. *Ifosfamide* may cause hemorrhagic cystitis, manifested by hematuria. Cystitis can be reduced by the use of mesna, vigorous hydration, and delaying drug administration if a predose urinalysis shows hematuria.

*Irinotecan* dosage should be reduced in patients with moderate renal impairment (CrCl 20–39 mL/minute). *Melphalan* should be reduced in dosage when given IV. *Mercaptopurine* should be reduced in dosage. MTX use in patients with impaired renal function may lead to accumulation of toxic amounts or additional renal damage. The patient's renal status should be evaluated before and during MTX therapy. If significant renal impairment occurs, the drug should be discontinued or reduced in dosage until renal function improves. In patients who receive high doses for treatment of osteosarcoma, MTX may cause renal damage leading to acute renal failure. Nephrotoxicity is attributed to precipitation of MTX and a metabolite in renal tubules. Renal

impairment may be reduced by monitoring renal function closely, ensuring adequate hydration, alkalinizing the urine, and measuring serum drug levels. *Procarbazine* may cause more severe adverse effects if given to patients with impaired renal function. Hospitalization is recommended for the first course of treatment.

Many other drugs should be used with caution in patients with renal impairment. *L-Asparaginase* often increases blood urea nitrogen; acute renal failure and fatal renal insufficiency have been reported. *Bleomycin* is rarely associated with nephrotoxicity, but its elimination half-life is prolonged in patients with a CrCl of less than 35 milliliters per minute. *Cytarabine* is detoxified mainly by the liver. However, patients with renal impairment may have more central nervous system (CNS)-related adverse effects, and dosage reduction may be needed. *Gemcitabine* was associated with mild proteinuria and hematuria during clinical trials, and hemolytic-uremic syndrome (HUS) was reported in a few patients. HUS may be manifested by anemia, elevated bilirubin and reticulocyte counts, and renal failure. The drug should be stopped immediately if HUS occurs; hemodialysis may be required.

*Bortezomib* should be used with caution; most other biologic drugs have not been studied in relation to renal impairment.

### Use in Patients With Hepatic Impairment

Some antineoplastic drugs are hepatotoxic and many are metabolized in the liver. With impaired hepatic function, risks of further impairment or accumulation of toxic drug levels are increased. Hepatic function should be monitored with most drugs and dosage reduction is needed with some. However, abnormal values for the usual liver function tests (e.g., serum aspartate aminotransferase [AST] and alanine aminotransferase [ALT], bilirubin, alkaline phosphatase) may indicate liver injury but do not indicate decreased ability to metabolize drugs. Patients with metastatic cancer often have impaired liver function.

Hepatotoxic drugs include the anthracyclines (e.g., doxorubicin), MTX, paclitaxel, and vincristine. Hepatic effects of selected drugs are described below.

*L-Asparaginase* is hepatotoxic in most patients; it may increase pre-existing hepatic impairment and hepatotoxicity of other medications. Signs of liver impairment, which usually subside when the drug is discontinued, include increased AST, ALT, alkaline phosphatase, and bilirubin and decreased serum albumin, cholesterol, and plasma fibrinogen. *Capecitabine* blood levels are significantly increased with hepatic impairment, and patients with liver metastases should be monitored closely. *Carmustine* may increase AST, ALT, alkaline phosphatase, and bilirubin when given IV. *Cisplatin* may cause a transient increase in liver enzymes and bilirubin. *Cytarabine* may cause CNS-related adverse effects in patients with impaired liver function. The drug should be used with caution and dosage may need to be

reduced. *Dacarbazine* is hepatotoxic, and a few cases of hepatic-vein thrombosis and fatal liver necrosis have been reported. *Daurorubicin*, liposomal formulation, should be reduced in dosage according to serum bilirubin (e.g., bilirubin 1.2–3 mg/dL, give three fourths the normal dose; bilirubin above 3 mg/dL, give one half the normal dose). Doxorubicin toxicity is increased with impaired hepatic function. Liver function tests should be done before drug administration, and dosage of both regular and liposomal formulations should be reduced according to the serum bilirubin (e.g., bilirubin 1.2 to 3 mg/dL, give one half the normal dose; bilirubin above 3 mg/dL, give one fourth the normal dose).

*Gemcitabine* increased serum aminotransferases in most patients during clinical trials. *Idarubicin* should not be given to patients with a serum bilirubin above 5 milligrams per deciliter. *Irinotecan* may cause abnormal liver function tests in patients with liver metastases. *Mercaptopurine* causes hepatotoxicity, especially with higher doses (above 2.5 mg/kg/day) and in combination with doxorubicin. Encephalopathy and fatal liver necrosis have occurred. The drug should be stopped if signs of hepatotoxicity (e.g., jaundice, hepatomegaly) occur. Serum aminotransferases, alkaline phosphatase, and bilirubin should be monitored weekly initially, then monthly. *MTX* may cause acute (increased serum aminotransferases, hepatitis) and chronic (fibrosis and cirrhosis) hepatotoxicity. Chronic toxicity is potentially fatal. It is more likely to occur after prolonged use (e.g., 2 years or longer) and after a total dose of at least 1.5 grams. Liver function tests should be closely monitored in patients with pre-existing liver damage or impaired hepatic function.

*Paclitaxel* may cause more toxicity in patients with impaired hepatic function. *Procarbazine* causes more toxic effects in patients with hepatic impairment. Hospitalization is recommended for the first course of therapy. *Topotecan* is cleared from plasma more slowly in patients with hepatic impairment. *Vinblastine* and *vincristine* may cause more toxicity with hepatic impairment, and dosage should be reduced 50% for patients with a direct serum bilirubin value above 3 milligrams per deciliter. *Bortezomib* should be used with caution in patients with impaired hepatic function. With *imatinib*, liver function tests should be monitored at baseline and at least monthly. The drug should be stopped for elevated bilirubin (3 times the upper limit of normal) or elevated transaminases (5 times the upper limit of normal) until values return to normal. The drug may then be resumed at a reduced dose, with continuous monitoring during treatment.

Other drugs that should be used with caution include the antineoplastic hormone inhibitors. The antiandrogens include bicalutamide, flutamide, and nilutamide. *Bicalutamide* is excreted slowly in patients with severe hepatic impairment and should be used with caution in patients with moderate to severe hepatic impairment, with periodic liver function tests during long-term therapy. *Flutamide* is associated with serum aminotransferase abnormalities, cholestatic jaundice,

hepatic encephalopathy, hepatic necrosis, and a few deaths. Liver function tests should be performed periodically and at the first sign or symptom of liver dysfunction (e.g., pruritus, dark urine, jaundice). Flutamide should be discontinued if jaundice develops in patients who do not have liver metastases or if serum aminotransferase levels increase more than two to three times the upper limit of normal. Liver damage usually subsides if flutamide is discontinued or if dosage is reduced. Nilutamide may cause hepatitis or increases in liver enzymes. Liver enzymes should be checked at baseline and every 3 months. If symptoms of liver injury occur or if aminotransferases increase over two to three times the upper limits of normal, nilutamide should be discontinued.

*Medroxyprogesterone* should be stopped if manifestations of impaired liver function develop. *Tamoxifen* is associated with changes in liver enzyme levels and occasionally more severe liver damage, including fatty liver, cholestasis, hepatitis, and hepatic necrosis. *Toremifene's* elimination half-life is prolonged in patients with hepatic cirrhosis or fibrosis.

*Bortezomib* should be used with caution in patients with impaired hepatic function; most other biologic agents have not been studied in relation to impaired hepatic function.

### Use in Home Care

Patients may receive parenteral cytotoxic drugs as outpatients and return home, or these and other antineoplastic drugs may be administered at home by the patient or a caregiver. The home care nurse may be involved in a wide range of activities associated with antineoplastic drug therapy, including administering the drugs, administering other drugs to prevent or manage adverse effects, and assessing patient and family responses to therapy. In addition, a major role involves teaching about the disease process, management of pain and other symptoms, the anticancer drugs, prevention or management of adverse drug effects, preventing infection, maintaining food and fluid intake, and other aspects of care. If a patient is receiving erythropoietin or oprelvekin subcutaneously, the patient or a caregiver may need to be taught injection technique.

The home care nurse also needs to teach patients and caregivers about safe handling of the traditional cytotoxic agents, including items contaminated with the drugs and patient body fluids or excreta. Precautions need to be similar to those used in health care agencies.

### Applying Your Knowledge 42-4

Ms. Gardner has a long drive to the clinic to receive her chemotherapy and has to arrange with a friend or relative to bring her. Ms. Gardner arrives at the clinic and you look for her orders. You are unable to locate any written orders so you call the physician, who gives you the orders over the telephone.

## Nursing Actions Antineoplastic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. With oral drugs, follow specific instructions for individual drugs.
- b. With **intravenous (IV) cytotoxic drugs**, general instructions include the following:
  - (1) Compare labels on prepared solutions to medication orders in terms of the drug, concentration, expiration date, and instructions for administration.
  - (2) Follow instructions for administering each drug. Common methods include injecting the drug into the tubing of a rapidly flowing IV or infusing the drug over a specified period of minutes to hours.
  - (3) For patients with a long-term venous access device (e.g., Hickman or Groshong catheter), follow agency protocols for drug administration and catheter care.
  - (4) Follow agency protocols for skin exposure or spills of cytotoxic drug solutions.
- c. With **monoclonal antibodies**, general instructions include the following:
  - (1) Compare labels on prepared solutions to medication orders in terms of the drug, concentration, expiration date, and instructions for administration.
  - (2) Administer by IV infusion; do not give as an IV push or bolus injection; do not mix with any other drugs.
  - (3) Follow instructions exactly re: rates of infusion.
  - (4) Pre-medicate with diphenhydramine and acetaminophen when ordered.
- d. With **growth factor/tyrosine kinase inhibitors**:
  - (1) Ask patients to swallow dasatinib tablets whole, without crushing or chewing.
  - (2) Give imatinib with a meal and large glass of water. Tablets may be dissolved in water or apple juice (50 mL for 100-mg tablet) for patients unable to swallow the tablets. Stir and have the patient drink the suspension immediately.
  - (3) Give lapatinib once daily, 1 h before or 1 h after a meal.
- e. With **bortezomib**, give the reconstituted solution as a bolus IV injection.
- f. With **hormonal drugs**:
  - (1) Give goserelin and leuprolide according to the manufacturers' instructions.
  - (2) Give letrozole, tamoxifen, and toremifene without regard to meals; give exemestane after a meal.
  - (3) Give fulvestrant intramuscularly, into buttock, as a single 5-mL injection or as two 2.5-mL injections.

#### 2. Observe for therapeutic effects

- a. Increased appetite
- b. Increased feelings of well-being
- c. Improved mobility
- d. Decreased pain
- e. Laboratory and diagnostic tests that indicate improvement

### RATIONALE/EXPLANATION

- These drugs are usually taken at home by patients or administered by a caregiver.
- These drugs should be given only by nurses who are certified to do so, who administer the drugs regularly, and who maintain their knowledge base about antineoplastic drug therapy. Drug solutions should be prepared in a pharmacy.
- Because the drugs are highly toxic, every precaution must be taken to ensure safe and accurate administration.
- Long-term devices decrease the number of venipunctures a patient must undergo but require special care to maintain patency and prevent infection.
- These solutions are hazardous materials that require special handling.
- These drugs should be prepared in a pharmacy. They may be given in an outpatient setting but recipients must be closely monitored.
- To ensure accurate administration of these diverse products.
- Manufacturer's recommendations
- Recommended rates vary according to the individual drugs and whether the first or later doses are being given.
- To prevent allergic-type infusion reactions, which are associated with alemtuzumab, cetuximab, gemtuzumab, panitumumab, and rituximab.
- Manufacturer's recommendations
- Manufacturer's recommendations
- Manufacturer's recommendations
- The drug is reconstituted with 3.5 mL of 0.9% sodium chloride injection, preferably in a pharmacy.
- These drugs require specific techniques.
- Manufacturer's recommendations
- Therapeutic effects depend to a large extent on the type of malignancy being treated. They may not become evident for several weeks after drug therapy is begun. With traditional cytotoxic drugs, some patients experience anorexia, nausea, and vomiting for 2 to 3 weeks after each cycle of drug therapy.

## NURSING ACTIONS

## RATIONALE/EXPLANATION

## 3. Observe for adverse effects

## a. With traditional cytotoxic drugs:

- (1) Hematologic effects: bone marrow depression with anemia, leukopenia, and thrombocytopenia; decreased antibodies and lymphocytes
- (2) Gastrointestinal (GI) effects—*anorexia, nausea, vomiting, diarrhea, constipation, oral and intestinal mucositis and mucosal ulcerations, oral candidiasis*
- (3) Dermatologic effects—*alopecia, dermatitis, hand-foot syndrome (redness, tenderness of palms and soles), phlebitis at injection sites*
- (4) Renal effects:
  - (a) Hyperuricemia and uric acid nephropathy
  - (b) With cisplatin, nephrotoxicity (increased blood urea nitrogen [BUN] and serum creatinine; decreased creatinine clearance)
  - (c) With cyclophosphamide or ifosfamide, hemorrhagic cystitis (blood in urine, dysuria, burning on urination)
- (5) Pulmonary effects—*cough, dyspnea, chest x-ray examination changes*
- (6) Cardiovascular effects—*heart failure (dyspnea, edema, fatigue), dysrhythmias, electrocardiographic changes*
- (7) Central nervous system effects—*peripheral neuropathy with vincristine, manifested by muscle weakness, numbness and tingling of extremities, foot drop, and decreased ability to walk*
- (8) Endocrine effects—*menstrual irregularities, sterility in men and women*

## b. With monoclonal antibodies:

- (1) Hypersensitivity-type infusion reactions—*chills, fever, bronchospasm, dyspnea, skin rash or urticaria*
- (2) Hematologic effects—*bone marrow depression (anemia, leukopenia, thrombocytopenia); high risk of infection, with chills, fever, respiratory, and other symptoms*
- (3) GI effects—*anorexia, nausea, vomiting, stomatitis, diarrhea*

Cytotoxic drugs may have adverse effects on any body tissue. These effects range from common to rare, from relatively mild to life threatening, and occur with usual dosage ranges. Myelosuppressive effects are used to guide drug therapy.

For most drugs, white blood cell (WBC) and platelet counts reach their lowest points (nadirs) 7 to 14 days after drug administration and return toward normal after 21 days. Normal leukocyte and platelet counts indicate recovery of bone marrow function. Anemia may occur later because the red blood cell lives longer than WBCs and platelets. Most of these drugs have immunosuppressant effects, which impair body defenses against infection.

Nausea and vomiting are common, usually occur within a few hours of drug administration, and often subside within 12 to 24 hours. Constipation is most likely to occur with vincristine. Mucositis may occur anywhere in the GI tract; may interfere with nutrition and cause significant discomfort; may lead to infection, hemorrhage, or perforation; and may require that drug therapy be stopped.

Hair loss may occur over several weeks. Hand-foot syndrome is associated with capecitabine, doxorubicin, and fluorouracil. Some drugs cause tissue necrosis if they leak into tissues around the injection site.

When malignant cells are destroyed, they release uric acid into the bloodstream. Uric acid crystals may precipitate in the kidneys and cause impaired function or failure.

Decreasing the dose or frequency of administration, vigorous hydration, and amifostine administration can reduce the incidence of nephrotoxicity.

Drug metabolites are thought to irritate bladder mucosa; the drug is stopped if this occurs. Cystitis can be decreased by an ample fluid intake. In addition, mesna is given with ifosfamide.

Adverse effects on the lungs are associated mainly with bleomycin and methotrexate. With bleomycin, pulmonary toxicity may be severe and progress to pulmonary fibrosis. Cardiomyopathy is associated mainly with doxorubicin and related drugs. This is a life-threatening adverse reaction.

This common effect of vincristine may worsen for several weeks after drug administration. There is usually some recovery of function eventually.

Although these drugs act more specifically than traditional cytotoxic drugs, they may still affect normal cells and produce serious adverse effects.

These products are proteins and may contain other components capable of arousing an allergic reaction. Premedication with diphenhydramine (Benadryl) and acetaminophen is recommended with most of the drugs (e.g., alemtuzumab, cetuximab, panitumumab, gemtuzumab, rituximab).

These effects occur with most of the drugs and leukopenia may be especially severe with alemtuzumab, for which prophylactic antimicrobial drugs are recommended during and for 2 to 3 months after drug administration.

These effects commonly occur.

## Nursing Actions Antineoplastic Drugs (continued)

### NURSING ACTIONS

- (4) Cardiovascular effects—hypertension, hypotension, peripheral edema, heart failure, especially with alemtuzumab, bevacizumab, gemtuzumab, and trastuzumab
- (5) Miscellaneous effects with most of the drugs—joint and muscle pain, weakness, dyspnea, headache, dizziness
- c. With growth factor and tyrosine kinase inhibitors
  - (1) GI effects—anorexia, nausea, vomiting, diarrhea, mucositis
  - (2) Dermatologic effects—skin rash, pruritus, hand-foot syndrome (redness, tenderness, tingling of palms and soles)
  - (3) Cardiovascular effects—bleeding, fluid retention, edema, heart failure, hypertension
  - (4) Miscellaneous effects—dyspnea, fatigue, fever, joint and muscle pain, neutropenia
- d. With bortezomib—dehydration, edema, fever, hypotension, nausea, vomiting, skin rash, peripheral neuropathy
- e. With hormone inhibitors:
  - (1) Aromatase inhibitors—hot flashes, fatigue, headache, nausea, musculoskeletal pain
  - (2) Antiestrogens—hot flashes, nausea, fluid retention, weight loss, musculoskeletal pain, vaginal discharge and menstrual irregularities in premenopausal women
  - (3) LHRH analogs—headache, depression, hot flashes, sexual dysfunction in males and females, infections in females
  - (4) Antiandrogens—hot flashes, breast tenderness and enlargement, chest pain, heart failure, weight gain, muscle pain, neuropathy

#### 4. Observe for drug interactions

- a. Drugs that increase effects of cytotoxic antineoplastic drugs:
  - (1) Anticoagulants, oral
  - (2) Bone marrow depressants
  - (3) Other antineoplastic drugs
- b. Drugs that increase effects of cyclophosphamide:
  - (1) Anesthetics, inhalation
  - (2) Carbamazepine, phenytoin, rifampin
  - (3) Other myelosuppressive antineoplastic drugs
- c. Drug that increases the effect of mercaptopurine: Allopurinol
- d. Drugs that increase effects of methotrexate (MTX):
  - (1) Alcohol
  - (2) Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), phenytoin, procarbazine, sulfonamides
  - (3) Other hepatotoxic drugs

### RATIONALE/EXPLANATION

Severe cardiotoxicity leading to heart failure may be more likely to occur with bevacizumab and trastuzumab. With trastuzumab, cardiotoxicity is most likely to develop in patients who are 60 years or older and those who have received doxorubicin or cyclophosphamide. Left ventricular function should be monitored and trastuzumab should be discontinued in those who develop significantly decreased ejection fractions.

These are common effects, especially diarrhea.

A variety of skin disorders may occur with all currently available drugs; hand-foot syndrome is associated with sorafenib, sunitinib, and temsirolimus.

Bleeding is associated with erlotinib and imatinib; fluid retention and edema with dasatanib, imatinib, and temsirolimus; heart failure with imatinib; hypertension with sorafenib.

Fatigue is associated with all of the drugs; dyspnea with dasatanib, erlotinib and temsirolimus; neutropenia with dasatanib and imatinib.

The risk of neuropathy may be increased with previous use of neurotoxic agents or pre-existing peripheral neuropathy.

Hot flashes and nausea are the most common adverse effect of drugs that decrease estrogen.

Hot flashes were the most commonly reported effect in both males and females; headache and depression were reported more often in females than in males.

Increased risk of bleeding

Increased bone marrow depression

Additive cytotoxic effects, both therapeutic and adverse

Lethal combination. Cyclophosphamide should be stopped at least 12 hours before general inhalation anesthesia is to be given.

These drugs induce liver enzymes, which accelerate transformation of the drug into its active metabolites

Increased bone marrow depression

Allopurinol increases formation of the active mercaptopurine metabolite; doses of mercaptopurine must be reduced to one third to one fourth the usual dose.

Additive liver toxicity. Avoid concomitant use.

Potentiate MTX by displacing it from protein-binding sites in plasma. Salicylates also block renal excretion of methotrexate. This may cause pancytopenia and liver toxicity.

Additive liver toxicity

**NURSING ACTIONS**

- (4) Other antineoplastic drugs
- (5) Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim)
- e. Drug that *decreases* effects of methotrexate (MTX): Leucovorin (folinic acid)
- f. Drugs that *increase* effects of vinca alkaloids:  
 (1) Erythromycin increases vinblastine toxicity; itraconazole increases vincristine toxicity.
- g. Drugs that *alter* effects of monoclonal antibodies:  
 (1) Paclitaxel may increase blood levels and effects of trastuzumab.
- h. Drugs that *alter* effects of growth factor and tyrosine kinase inhibitor drugs:  
 (1) Enzyme inhibitors (e.g., cimetidine, clarithromycin, itraconazole, others) *increase* effects; enzyme inducers (e.g., carbamazepine, phenytoin, rifampin, others) *decrease* effects.  
 (2) With imatinib, chronic use of acetaminophen may increase risks of hepatotoxicity.
- i. Drugs that *alter* effects of hormone inhibitors:  
 (1) With tamoxifen and toremifene, enzyme inhibitors increase effects and enzyme inducers decrease effects (see h. (1), above).  
 (2) With flutamide, amiodarone, fluoroquinolones, and fluvoxamine may increase effects; carbamazepine and rifampin may decrease effects.  
 (3) With nilutamide, fluconazole, fluvoxamine, gemfibrozil, isoniazid, and omeprazole may increase effects; carbamazepine and rifampin may decrease effects.

**RATIONALE/EXPLANATION**

- Additive cytotoxic effects, both therapeutic and adverse. Cisplatin may induce renal damage that impairs MTX excretion, increases blood levels, and increases toxicity.
- Increased MTX toxicity; avoid concurrent administration if possible.  
 Leucovorin antagonizes the toxic effects of MTX and is used as an antidote for high-dose MTX regimens or for overdose. It must be given exactly at the specified time, before affected cells become too damaged to respond.
- These drugs probably inhibit metabolism of vinblastine and vincristine.  
 Limited information is available about interactions with these drugs.
- Most interactions are thought to occur with drugs metabolized by CYP3A4 enzymes. If the biologic drugs are given concurrently with an enzyme inhibitor, dosage may be decreased; if given with an enzyme inducer, dosage may be increased.

**Key Concepts**

- Traditional cytotoxic antineoplastic drugs are nonselective in their effect on proliferating cells; therefore bone marrow toxicity is a common adverse effect of many cytotoxic drugs. These drugs kill the same fraction of cells with each cycle of chemotherapy treatment; repeated cycles of cytotoxic drugs potentially lower the number of cancer cells to a level where a person's immune responses are able to take over and destroy the remaining cancer cells.
- Biologic targeted antineoplastic agents are designed to specifically attack a target that is expressed exclusively, or disproportionately, in the cancer cell.
- Hormonal therapies that block the effects of estrogen (in an estrogen-responsive tumor) and androgen (in an androgen-responsive tumor), respectively, are essential in the treatment of breast and prostate cancers.
- Cancer in older adults presents a unique challenge, due in part to the presence of comorbidities and the physical, biologic, and physiologic changes that occur with normal aging. Until recently, older adults were excluded from participating in clinical trials.

## Review and Application Exercises

### Short Answer Exercises

- List major characteristics of malignant cells.
- Which common cancers are attributed mainly to environmental factors? Which are attributed to genetic factors?
- Which cytotoxic antineoplastic drugs are associated with serious adverse effects (e.g., bone marrow suppression, cardiotoxicity, hepatotoxicity, nephrotoxicity, neurotoxicity)?
- Which drugs are associated with second malignancies?
- How do the newer biologic agents differ from traditional cytotoxic drugs?
- What is the basis for the anticancer effects of hormone inhibiting drugs?
- For which cytotoxic drugs are cytoprotective drugs available?
- List at least one intervention to prevent or minimize each of the following adverse effects of traditional cytotoxic chemotherapy: anemia, bleeding, infection, nausea and vomiting, neutropenia, stomatitis.
- What measures are used to prevent or decrease the allergic infusion reactions associated with several antineoplastic monoclonal antibodies?

### NCLEX-Style Questions

- A priority nursing diagnosis to include in your care plan for a patient receiving cytotoxic chemotherapy is
  - Risk for Impaired Skin Integrity
  - Risk for Injury: Infection
  - Body Image Disturbance related to alopecia
  - Ineffective Family Coping

- For a patient receiving a drug that causes bone marrow depression, which of the following should be especially emphasized with the patient and family members or caregivers?
  - Wash hands often and avoid people with colds, flu, or other infections.
  - Fatigue and weakness are uncommon.
  - More nausea and vomiting may occur when the blood cell counts are low.
  - Take acetaminophen for fever.
- In explaining cytotoxic therapy to a family member of a patient who is to receive this treatment, the nurse explains that it
  - damages both malignant and nonmalignant cells
  - causes few adverse effects
  - stimulates growth of cancer cells
  - must be given daily
- Antineoplastic hormone inhibitor drugs used in the treatment of cancer
  - are highly cytotoxic to both cancer cells and normal cells
  - target specific antigens or vital processes of cancer cells
  - slow the growth of some cancer cells
  - protect normal cells from cytotoxic drugs
- The nurse who is giving a vesicant antineoplastic drug knows that the drug can
  - cause minor skin irritation
  - cause extensive tissue damage
  - only be given through a central IV line
  - be given by deep intramuscular injection if diluted with normal saline

## Drugs Affecting the Respiratory System

### Chapter Outline

- 43** ■ Physiology of the Respiratory System
- 44** ■ Drugs for Asthma and Other Bronchoconstrictive Disorders
- 45** ■ Antihistamines and Allergic Disorders
- 46** ■ Nasal Decongestants, Antitussives, and Cold Remedies

# Physiology of the Respiratory System

## KEY TERMS

- Alveolar–capillary membrane
- Alveoli
- Apneustic center
- Cilia
- Diffusion
- Perfusion
- Pneumotoxic center
- Surfactant
- Ventilation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review roles and functions of the main respiratory tract structures in oxygenation of body tissues.
2. Describe the role of carbon dioxide in respiration.
3. List common signs and symptoms affecting respiratory function.
4. Identify general categories of drugs used to treat respiratory disorders.

## Overview of the Respiratory System

The respiratory system helps meet the basic human need for oxygen ( $O_2$ ). Oxygen is necessary for energy for cellular metabolism. When the oxygen supply is inadequate, cell function is impaired; when oxygen is absent, cells die. Permanent brain damage occurs within 4 to 6 minutes of anoxia. In addition to providing oxygen to all body cells, the respiratory system also removes carbon dioxide ( $CO_2$ ), a major waste product of cell metabolism. Excessive accumulation of  $CO_2$  damages or kills body cells and produces respiratory acidosis.

The efficiency of the respiratory system depends on the quality and quantity of air inhaled, the patency of air passages, the ability of the lungs to expand and contract, and the ability of  $O_2$  and  $CO_2$  to cross the alveolar–capillary membrane. In addition to the respiratory system, the circulatory, nervous, and musculoskeletal systems have important functions in respiration. Additional characteristics of the respiratory system and the process of respiration are described in the following sections.

### Respiration

Respiration is the process of gas exchange by which  $O_2$  is obtained and  $CO_2$  is eliminated. This gas exchange occurs between the lung and the blood across the *alveolar–capillary membrane* and between the blood and body cells. More specifically, the four parts of respiration are:

- *Ventilation*—the movement of air between the atmosphere and the alveoli of the lungs
- *Perfusion*—blood flow through the lungs
- *Diffusion*—the process by which  $O_2$  and  $CO_2$  are transferred between alveoli and blood and between blood and body cells
- Regulation of breathing by the respiratory muscles and nervous system

### Respiratory Tract

The respiratory tract is a series of branching tubes with progressively smaller diameters. These tubes (nose, pharynx, larynx, trachea, bronchi, and bronchioles) function as air passageways and air “conditioners” that filter, warm, and humidify incoming air. Most of the conditioning is done by the ciliated mucous membrane that lines the entire respiratory tract, except the pharynx and alveoli. *Cilia* are tiny, hair-like projections that sweep mucus toward the pharynx to be expectorated

or swallowed. The mucous membrane secretes mucus, which forms a protective blanket and traps foreign particles, such as bacteria and dust.

When air is inhaled through the nose, it is conditioned by the nasal mucosa. When the nasal passages are blocked, the mouth serves as an alternate airway. The oral mucosa may warm and humidify air but cannot filter it.

## Pharynx, Larynx, and Trachea

Air passes from the nasal cavities to the pharynx (throat). Pharyngeal walls are composed of skeletal muscle, and their lining is composed of mucous membrane. The pharynx contains the palatine tonsils, which are large masses of lymphatic tissue. The pharynx is a passageway for food, fluids, and air. Food and fluids go from the pharynx to the esophagus, and air passes from the pharynx into the trachea.

The larynx is composed of nine cartilages joined by ligaments and controlled by skeletal muscles. It contains the vocal cords and forms the upper end of the trachea. It closes on swallowing to prevent aspiration of food and fluids into the lungs.

The trachea is the passageway between the larynx and the main stem bronchi. It is a cartilaginous tube lined with ciliated epithelium and mucus-secreting cells. Cilia and mucus help to protect and defend the lungs.

## Lungs

The lungs begin where the trachea divides into the right and left mainstem bronchi and contain the remaining respiratory structures. They are divided into five lobes, each with a secondary bronchus. The lobes are further subdivided into bronchopulmonary segments supplied by smaller bronchi. The bronchopulmonary segments contain lobules, which are the functional units of the lung (the site where gas exchange takes place). Each lobule is supplied by a bronchiole, an arteriole, a venule, and a lymphatic vessel. Blood enters the lobules through a pulmonary artery and exits through a pulmonary vein. Lymphatic structures surround the lobule and aid in the removal of plasma proteins and other particles from interstitial spaces.

The mainstem bronchi branch into smaller bronchi, then into bronchioles. Bronchioles are approximately the size of a pencil lead and do not contain cartilage or mucus-secreting glands. The walls of the bronchioles contain smooth muscle, which is controlled by the autonomic nervous system. Stimulation of parasympathetic nerves causes constriction; stimulation of sympathetic nerves causes relaxation or dilation.

The epithelial lining of the bronchioles becomes thinner with progressive branchings until only one cell layer is apparent. The bronchioles give rise to the *alveoli*, which are grape-like clusters of air sacs surrounded by capillaries.

The alveoli are composed of two types of cells. Type I cells are flat, thin epithelial cells that fuse with capillaries to form the alveolar–capillary membrane across which gas exchange occurs. Oxygen enters the bloodstream to be transported to body cells; CO<sub>2</sub> enters the alveoli to be exhaled from the lungs. Type II cells produce *surfactant*, a lipoprotein substance that

decreases the surface tension in the alveoli and aids lung inflation. The alveoli also contain macrophages that help to protect and defend the lungs.

The lungs are encased in a membrane called the pleura, which is composed of two layers. The inner layer, which adheres to the surface of the lung, is called the visceral pleura. The outer layer, which lines the thoracic cavity, is called the parietal pleura. The potential space between the layers is called the pleural cavity. It contains fluid that allows the layers to glide over each other and minimizes friction.

The lungs expand and relax in response to changes in pressure relationships (intrapulmonic and intrapleural pressures). Elastic tissue in the bronchioles and alveoli allows the lungs to stretch or expand to accommodate incoming air. This ability is called compliance. The lungs also recoil (like a stretched rubber band) to expel air. Some air remains in the lungs after expiration, which allows gas exchange to continue between respirations.

In addition to exchanging O<sub>2</sub> and CO<sub>2</sub>, the lungs synthesize, store, release, remove, metabolize, or inactivate a variety of biologically active substances. These substances, which may be locally released or carried in blood or tissue fluids, participate in both physiologic and pathologic processes. Specific substances that may be released from the lungs include biogenic amines (e.g., catecholamines, histamine, serotonin), arachidonic acid metabolites (e.g., prostaglandins, leukotrienes), angiotensin-converting enzyme, and heparin. The amines are important in regulating smooth muscle tone (i.e., constriction or dilation) in the airways and blood vessels. Prostaglandins and leukotrienes are important in inflammatory processes. Angiotensin-converting enzyme converts angiotensin I to angiotensin II, which is important in regulating blood pressure. Heparin helps to dissolve blood clots, especially in the capillaries, where small clots are trapped. The lungs also process peptides, lipids, hormones, and drugs and inactivate bradykinin.

## Lung Circulation

The pulmonary circulatory system transports O<sub>2</sub> and CO<sub>2</sub>. After oxygen enters the bloodstream across the alveolar–capillary membrane, it combines with hemoglobin in red blood cells for transport to body cells, where it is released. Carbon dioxide combines with hemoglobin in the cells for return to the lungs and elimination from the body.

The lungs receive the total cardiac output of blood and are supplied with blood from two sources, the pulmonary and bronchial circulations. The pulmonary circulation provides for gas exchange because the pulmonary arteries carry deoxygenated blood to the lungs and the pulmonary veins return oxygenated blood to the heart. The bronchial arteries arise from the thoracic aorta and supply the air passages and supporting structures. The bronchial circulation also warms and humidifies incoming air and can form new vessels and develop collateral circulation when normal vessels are blocked (e.g., in pulmonary embolism). The latter ability helps to keep lung tissue alive until circulation can be restored.

Capillaries in the lungs are lined by a single layer of epithelial cells called endothelium. Once thought to be a passive conduit for blood, it is now known that the endothelium performs several important functions. First, it forms a barrier that prevents leakage of water and other substances into lung tissue. Second, it participates in the transport of respiratory gases, water, and solutes. Third, it secretes vasodilating substances such as nitric oxide and prostacyclin. Nitric oxide also regulates smooth muscle tone in the bronchi, and prostacyclin also inhibits platelet aggregation. When pulmonary endothelium is injured (e.g., by endotoxins or drugs such as bleomycin, an anticancer drug), these functions are impaired.

## Nervous System's Role in Respiration

The nervous system regulates the rate and depth of respiration by the respiratory center in the medulla oblongata, the *pneumotaxic center* in the pons, and the *apneustic center* in the reticular formation. The respiratory center is stimulated primarily by increased  $\text{CO}_2$  in the fluids of the center. (However, excessive  $\text{CO}_2$  depresses the respiratory center.) When the center is stimulated, the rate and depth of breathing are increased, and excessive  $\text{CO}_2$  is exhaled. A lesser stimulus to the respiratory center is decreased oxygen in arterial blood.

The nervous system also operates several reflexes important to respiration. The cough reflex is especially important because it helps protect the lungs from foreign particles, air pollutants, bacteria, and other potentially harmful substances. A cough occurs when nerve endings in the respiratory tract mucosa are stimulated by dryness, pressure, cold, irritant fumes, or excessive secretions.

## Musculoskeletal System's Role in Respiration

The musculoskeletal system participates in chest expansion and contraction. Normally, the diaphragm and external intercostal muscles expand the chest cavity and are called muscles of inspiration. The abdominal and internal intercostal muscles are the muscles of expiration.

## Summary of Respiratory Function

Overall, normal respiration requires

1. Atmospheric air containing at least 21%  $\text{O}_2$ .
2. Adequate ventilation. Ventilation, in turn, requires patent airways, expansion and contraction of the chest, expansion and contraction of the lungs, and maintenance of a normal range of intrapulmonic and intrapleural pressures.
3. Adequate diffusion of  $\text{O}_2$  and  $\text{CO}_2$  through the alveolar-capillary membrane. Factors influencing diffusion include the thickness and surface area of the membrane and

pressure differences between gases on each side of the membrane.

4. Adequate perfusion or circulation of blood and sufficient hemoglobin to carry needed  $\text{O}_2$ .

In addition, normal breathing occurs 16 to 20 times per minute and is quiet, rhythmic, and effortless. Approximately 500 milliliters of air is inspired and expired with a normal breath (tidal volume); deep breaths or "sighs" occur 6 to 10 times per hour to ventilate more alveoli. Fever, exercise, pain, and emotions such as anger increase respirations. Sleep or rest and various medications, such as anti-anxiety drugs, sedatives, and opioid analgesics, slow respiration.

## Disorders of the Respiratory System

The respiratory system is subject to many disorders that interfere with respiration and other lung functions. These disorders may be caused by agents that reach the system through inhaled air or through the bloodstream and include respiratory tract infections, allergic disorders, inflammatory disorders, and conditions that obstruct airflow (e.g., excessive respiratory tract secretions, asthma, other chronic obstructive pulmonary diseases). Injury to the lungs by various disorders (e.g., anaphylaxis, asthma, mechanical stimulation such as hyperventilation, pulmonary thromboembolism, pulmonary edema, acute respiratory distress syndrome) is associated with the release of histamine and other biologically active chemical mediators from the lungs. These mediators often cause inflammation and constriction of the airways.

The ciliated epithelial cells of the larger airways, the type I epithelial cells of the alveoli, and the capillary endothelial cells of the alveolar area are especially susceptible to injury. When they are injured, cellular functions are impaired (e.g., decreased mucociliary clearance). Common signs and symptoms of respiratory disorders include cough, increased secretions, mucosal congestion, and bronchospasm. Severe disorders or inadequate treatment may lead to cell necrosis or respiratory failure.

## Drug Therapy

In general, drug therapy is more effective in relieving respiratory symptoms than in curing the underlying disorders that cause the symptoms. Major drug groups used to treat respiratory symptoms are bronchodilating and anti-inflammatory agents (see Chap. 44), antihistamines (see Chap. 45), and nasal decongestants, antitussives, and cold remedies (see Chap. 46).

## Key Concepts

- When the oxygen supply is inadequate, cell function is impaired; when oxygen is absent, cells die.
- The efficiency of the respiratory system depends on the quality and quantity of air inhaled, the patency of air passages, the ability of the lungs to expand and contract, and the ability of O<sub>2</sub> and CO<sub>2</sub> to cross the alveolar–capillary membrane.
- The nervous system regulates the rate and depth of respiration by the respiratory center in the medulla oblongata, the pneumotaxic center in the pons, and the apneustic center in the reticular formation.
- The respiratory system is subject to many disorders that interfere with respiration and other lung functions, including respiratory tract infections, allergic disorders, inflammatory disorders, and conditions that obstruct airflow.
- Major drug groups used to treat respiratory symptoms are bronchodilating and anti-inflammatory agents, antihistamines, and nasal decongestants, antitussives, and cold remedies.

## Review and Application Exercises

### Short Answer Exercises

1. What is the main function of the respiratory system?
2. Where does the exchange of oxygen and carbon dioxide occur?

3. List factors that stimulate rate and depth of respiration.
4. List factors that depress rate and depth of respiration.
5. What are common signs and symptoms of respiratory disorders for which drug therapy is often used?

# Drugs for Asthma and Other Bronchoconstrictive Disorders

## KEY TERMS

- Adrenergic drugs
- Anticholinergics
- Asthma
- Beta<sub>2</sub>-adrenergic agonists
- Bronchitis
- Bronchospasm
- Corticosteroids
- Emphysema
- Hyperreactivity
- Leukotrienes
- Mast cells
- Occupational asthma

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the main pathophysiologic characteristics of asthma and other bronchoconstrictive disorders.
2. Discuss the uses and effects of bronchodilating drugs, including adrenergics, anticholinergics, and xanthines.
3. Differentiate between short-acting and long-acting inhaled beta<sub>2</sub>-adrenergic agonists in terms of uses and nursing process implications.
4. Discuss the uses of anti-inflammatory drugs, including corticosteroids, leukotriene modifiers, and mast cell stabilizers.
5. Discuss reasons for using inhaled drugs when possible.
6. Differentiate between “quick relief” and long-term control of asthma symptoms.
7. Discuss the use of antiasthmatic drugs in special populations.
8. Teach patients self-care and long-term control measures.

## Applying Your Knowledge

Lynne Albright is a 48-year-old woman who has adult-onset asthma. Her medications include zafirlukast and salmeterol/fluticasone (Advair) daily. She uses an albuterol inhaler as needed. Ms. Albright is a professor in women’s studies for a large university. You are the on-site nurse for the campus.

## Introduction

The drugs described in this chapter are used to treat respiratory disorders characterized by bronchoconstriction, inflammation, mucosal edema, and excessive mucus production (asthma, bronchitis, and emphysema). Asthma is emphasized because of its widespread prevalence, especially in urban populations. Compared with Caucasians, African Americans and Hispanics have a higher prevalence and African Americans have a higher death rate from asthma. However, the differences are usually attributed to urban living and lesser access to health care rather than race or ethnic group. *Occupational asthma* (i.e., asthma resulting from repeated and prolonged exposure to industrial inhalants) is also a major health problem. Persons with occupational asthma often have symptoms while in the work environment, with improvement on days off and during vacations. Symptoms sometime persist after termination of exposure. Asthma may occur at any age but is especially common in children and older adults. Children who are exposed to allergens and airway

irritants such as tobacco smoke during infancy are at high risk for development of asthma.

## Asthma

### Symptoms

Asthma is an airway disorder characterized by bronchoconstriction, inflammation, and *hyperreactivity* to various stimuli. Resultant symptoms include dyspnea, wheezing, chest tightness, cough, and sputum production. Wheezing is a high-pitched, whistling sound caused by turbulent airflow through an obstructed airway. Thus, any condition that produces significant airway occlusion can cause wheezing. However, a chronic cough may be the only symptom for some people with asthma. Symptoms vary in incidence and severity from occasional episodes of mild respiratory distress, with normal functioning between “attacks,” to persistent, daily, or continual respiratory distress if not adequately controlled. Inflammation and damaged airway mucosa are chronically present, even when patients appear symptom free.

Acute symptoms of asthma may be precipitated by numerous stimuli, and hyperreactivity to such stimuli may initiate both inflammation and bronchoconstriction. Viral infections of the respiratory tract are often the causative agents, especially in infants and young children whose airways are small and easily obstructed. Asthma symptoms may persist for days or weeks after the viral infection resolves. In about 25% of patients with asthma, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can precipitate an attack. Some patients are allergic to sulfites and may experience life-threatening asthma attacks if they ingest foods processed with these preservatives (e.g., beer, wine, dried fruit). The U.S. Food and Drug Administration (FDA) has banned the use of sulfites on foods meant to be served raw, such as open salad bars. Patients with severe asthma should be cautioned against ingesting food and drug products containing sulfites or metabisulfites.

Gastroesophageal reflux disease (GERD), a common disorder characterized by heartburn and esophagitis, is also associated with asthma. Asthma that worsens at night may be associated with nighttime acid reflux. Although the precise mechanism of pulmonary symptoms of GERD in asthma is not known, there are suggestions that microaspirations or a vagally mediated, reflex type of bronchoconstriction may be involved. Asthma may also aggravate GERD, because antiasthma medications that dilate the airways also relax muscle tone in the gastroesophageal sphincter and may increase acid reflux. It has been suggested that in individuals with inadequate control of their asthma symptoms, a trial of an H<sub>2</sub>-blocker or proton-pump inhibitor therapy may be of benefit.

Additional precipitants may include allergens (e.g., pollens, molds), airway irritants and pollutants (e.g., chemical fumes, cigarette smoke, automobile exhaust), cold air, and exercise. Acute episodes of asthma may last minutes to hours.

### Pathophysiology

Bronchoconstriction (also called *bronchospasm*) involves strong muscle contractions that narrow the airways. Airway smooth

muscle extends from the trachea through the bronchioles. It is wrapped around the airways in a spiral pattern, and contraction causes a sphincter type of action that can completely occlude the airway lumen. Bronchoconstriction is aggravated by inflammation, mucosal edema, and excessive mucus and may be precipitated by the numerous stimuli described above.

When lung tissues are exposed to causative stimuli, *mast cells* release substances that cause bronchoconstriction and inflammation. Mast cells are found throughout the body in connective tissues and are abundant in tissues surrounding capillaries in the lungs. When sensitized mast cells in the lungs or eosinophils in the blood are exposed to allergens or irritants, multiple cytokines and other chemical mediators (e.g., acetylcholine, cyclic guanosine monophosphate [GMP], histamine, interleukins, leukotrienes, prostaglandins, serotonin) are synthesized and released. These chemicals act directly on target tissues of the airways, causing smooth muscle constriction, increased capillary permeability and fluid leakage, and changes in the mucus-secreting properties of the airway epithelium.

Bronchoconstrictive substances are antagonized by cyclic adenosine monophosphate (cyclic AMP). Cyclic AMP is an intracellular substance that initiates various intracellular activities, depending on the type of cell. In lung cells, cyclic AMP inhibits release of bronchoconstrictive substances and thus indirectly promotes bronchodilation. In mild to moderate asthma, bronchoconstriction is usually recurrent and reversible, either spontaneously or with drug therapy. In advanced or severe asthma, airway obstruction becomes less reversible and worsens because chronically inflamed airways undergo structural changes (e.g., fibrosis, enlarged smooth muscle cells, enlarged mucous glands), called “airway remodeling,” that inhibit their function.

### National Asthma Education and Prevention Program (NAEPP)

Because of asthma’s significance as a public health problem, the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH) established the NAEPP. The NAEPP assembled a group of experts who established “Guidelines for the Diagnosis and Management of Asthma.” After nearly a decade, these guidelines (Box 44-1) were updated in 2007, including an expanded portion on childhood asthma. Further distinction is placed on the importance of classifying asthma severity and assessing asthma control. The guidelines are the current “standard of care” for adults and children with asthma and center around four essential components of asthma care: assessment and monitoring, patient education, control of factors contributing to asthma severity, and pharmacologic treatment. Additional information can be obtained from <http://www.nhlbi.nih.gov>.

### Chronic Bronchitis and Emphysema

Chronic *bronchitis* and *emphysema*, commonly called chronic obstructive pulmonary disease (COPD), usually develop after long-standing exposure to airway irritants such as cigarette smoke. In these conditions, bronchoconstriction and

Expert Panel Guidelines\*

## Definition

*Asthma* is “a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning.”

## Goals of Therapy

1. Minimal or no chronic symptoms day or night
2. Minimal or no exacerbations
3. No limitations on activities; for children, no school/parent's work missed
4. Minimal use of short-acting inhaled beta<sub>2</sub> agonist (<1 time per day, <1 canister/month)
5. Minimal or no adverse effects from medications

## General Recommendations

- Establish and teach patients/parents/caregivers about quick relief measures and long-term control measures. Assist to identify and control environmental factors that aggravate asthma.
- For acute attacks, gain control as quickly as possible (a short course of systemic corticosteroids may be needed); then step down to the least medication necessary to maintain control.
- Review the treatment regimen every 1 to 6 months. If control is adequate and goals are being met, a gradual stepwise reduction in medication may be possible. If control is inadequate, the treatment regimen may need to be changed. For example, frequent or increasing use of a short-acting beta<sub>2</sub> agonist (>2 times a week with intermittent asthma; daily or increasing use with persistent asthma) may indicate the need to initiate or increase long-term control therapy. However, first reassess patients' medication techniques (e.g., correct use of inhalers), adherence, and environmental control measures.

## Quick Relief for Acute Exacerbations

- **Adults and children > 5 years:** Short-acting, inhaled, beta<sub>2</sub> agonist, 2–4 puffs as needed. If symptoms are severe, patients may need up to 3 treatments at 20-minute intervals or a nebulizer treatment. A short course of a systemic corticosteroid may also be needed.
- **Children 5 years and younger:** Short-acting beta<sub>2</sub> agonist by nebulizer or face mask and spacer or holding chamber. Alternative: oral beta<sub>2</sub> agonist. With viral respiratory infections, the beta<sub>2</sub> agonist may be needed q4–6h up to 24 hours or longer and a systemic corticosteroid may be needed.

## Long-Term Control

- **Step 1 Mild Intermittent** (symptoms 2 days/week or less or 2 nights/month or less): No daily medication needed; treat acute exacerbations with an inhaled beta<sub>2</sub> agonist and possibly a short course of a systemic corticosteroid.
- **Step 2 Mild Persistent** (symptoms >2/week but <1×/day or >2 nights/month):

- **Adults and children > 5 years:** Low-dose inhaled corticosteroid. Alternatives: cromolyn or nedocromil, a leukotriene modifier, or sustained-release theophylline to maintain a serum theophylline drug level of 5–15 mcg/mL.
- **Children 5 years and younger:** Administer the inhaled corticosteroid by a nebulizer or metered-dose inhaler (MDI) with a holding chamber. Alternatives: cromolyn (via nebulizer or MDI with holding chamber) or a leukotriene modifier.
- **Step 3 Moderate Persistent** (symptoms daily and >1 night/week):
  - **Adults and children > 5 years:** Low- to medium-dose inhaled corticosteroid and a long-acting beta<sub>2</sub> agonist. Alternatives: increase corticosteroid dose or continue low to medium dose of corticosteroid and add a leukotriene modifier or theophylline.
  - **Children < 5 years:** Low-dose inhaled corticosteroid and a long-acting beta<sub>2</sub> agonist or medium-dose inhaled corticosteroid.
- **Step 4 Severe Persistent** (symptoms continual during daytime hours and frequent at night):
  - **Adults and children > 5 years:** High-dose inhaled corticosteroid and long-acting beta<sub>2</sub> agonist and, if necessary, a systemic corticosteroid (2 mg/kg/d, not to exceed 60 mg/d). Reduce systemic corticosteroid when possible.
  - **Children < 5 years:** Same as for adults and older children.

Low (L), Medium (M), and High (H) Doses of Inhaled  
Corticosteroids:

	Adults (mcg)	Children (12 y and younger) (mcg)
Beclomethasone (42 or 84 mcg/puff)	L: 168–504 M: 504–840 H: >840	L: 84–336 M: 336–672 H: >672
Beclomethasone (40–80 mcg/puff)	L: 80–240 M: 240–480 H: >480	L: 80–160 M: 160–320 H: >320
Budesonide (200 mcg/inhalation)	L: 200–600 M: 600–1200 H: >1200	L: 200–400 M: 400–800 H: >800
Budesonide inhalation suspension for nebulization (child dose only)		L: 0.5 mg M: 1.0 mg H: 2.0 mg
Flunisolide (250 mcg/puff)	L: 500–1000 M: 1000–2000 H: >2000	L: 500–750 M: 1000–1250 H: >1250
Fluticasone aerosol (44, 110, or 220 mcg/puff)	L: 88–264 M: 264–660 H: >660	L: 88–176 M: 176–440 H: >440
Fluticasone powder (50, 100, or 250 mcg/puff)	L: 100–300 M: 300–600 H: >600	L: 100–200 M: 200–400 H: >400
Triamcinolone acetonide (100 mcg/puff)	L: 400–1000 M: 1000–2000 H: >2000	L: 400–800 M: 800–1200 H: >1200

\*Adapted from NAEPP Expert Panel Report 3 (NIH Publication No. 08-4051, 2007).

inflammation are more constant and less reversible than with asthma. Anatomic and physiologic changes occur over several years and lead to increasing dyspnea, activity intolerance, and reduced quality of life. These conditions usually affect middle-aged or older adults.

### Drug Therapy

Two general classifications of drugs are used for asthma management: long-term (prophylactic) control medications to achieve and maintain control of persistent asthma and quick relief (rescue) medications used during periods of acute symptoms and exacerbations. Specifically, two major groups of drugs used to treat asthma, acute and chronic bronchitis, and emphysema are bronchodilators and anti-inflammatory drugs. Bronchodilators are used to prevent and treat bronchoconstriction; anti-inflammatory drugs are used to prevent and treat inflammation of the airways. Reducing inflammation also reduces bronchoconstriction by decreasing mucosal edema and mucous secretions that narrow airways and by decreasing airway hyper-reactivity to various stimuli. The drugs are described in the following sections; pharmacokinetic characteristics of inhaled drugs are listed in Table 44-1.

### Bronchodilators

Table 44-2 lists routes and dosage ranges of the bronchodilators.

### Adrenergics

Adrenergic drugs (see Chap. 17) stimulate beta<sub>2</sub>-adrenergic receptors in the smooth muscle of bronchi and bronchioles. The receptors, in turn, stimulate the enzyme adenyl cyclase to increase production of cyclic AMP. The increased cyclic AMP

produces bronchodilation. Some beta-adrenergic drugs (e.g., epinephrine) also stimulate beta<sub>1</sub>-adrenergic receptors in the heart to increase the rate and force of contraction. Cardiac stimulation is an adverse effect when the drugs are given for bronchodilation. These drugs are contraindicated in patients with cardiac tachydysrhythmias and severe coronary artery disease; they should be used cautiously in patients with hypertension, hyperthyroidism, diabetes mellitus, and seizure disorders.

**Epinephrine** may be injected subcutaneously in an acute attack of bronchoconstriction, with therapeutic rescue effects in approximately 5 minutes and lasting for approximately 4 hours. However, an inhaled selective beta<sub>2</sub> agonist is the drug of choice in this situation. Epinephrine is also available without prescription in a pressurized aerosol form (e.g., Primatene). Almost all over-the-counter aerosol products promoted for use in asthma contain epinephrine. These products are often abused and may delay the patient from seeking medical attention. Patients should be cautioned that excessive use may produce hazardous cardiac stimulation and other adverse effects.

**Albuterol** and **levalbuterol** are short-acting beta<sub>2</sub>-adrenergic agonists used for prevention and treatment of bronchoconstriction. These drugs act more selectively on beta<sub>2</sub> receptors and cause less cardiac stimulation than epinephrine. Most often taken by inhalation, they are also the most effective bronchodilators and the treatment of first choice to relieve acute asthma. Because the drugs can be effectively delivered by aerosol or nebulization, even to young children and to patients on mechanical ventilation, there is seldom a need to give epinephrine or other nonselective adrenergic drugs by injection.

The beta<sub>2</sub> agonists are usually self-administered by metered-dose inhalers (MDIs). Although most drug references still list a regular dosing schedule (e.g., every 4 to 6 hours),

Table 44-1

Pharmacokinetics of Selected Inhaled Antiasthma Medications

Generic Name	ACTION			Metabolism/Excretion	Half-Life (Hours)
	Onset (min)	Peak (hours)	Duration (hours)		
<b>Adrenergics</b>					
Albuterol	5	0.5–2	4–6	Liver/urine	2–4
Levalbuterol	5–10	1	3–6	Liver/urine	3–4
Salmeterol	30–48 COPD 120	2–4	12	Liver/feces	5.5
<b>Anticholinergic</b>					
Ipratropium	1–3	1.5–2	≤ 4		1.6
<b>Corticosteroids</b>					
Beclomethasone	Rapid	1–2 wk		Liver/feces	2.3–6
Budesonide	Immediate	Rapid	8–12	Liver/urine (60%) & feces	2.8
Flunisolide	Slow	10–30	4–6	Liver/renal (50%), feces (40%)	1–2
Fluticasone	Slow		24	Liver/feces & urine	3.1

## Drugs at a Glance: Bronchodilating Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Bronchodilators</b>		
<b>Adrenergics</b>		
<b>Albuterol</b> (Proventil, Ventolin, AccuNeb)	Inhalation* aerosol (90 mcg/actuation): 1–2 oral inhalations q4–6h; prevention of exercise-induced bronchospasm, 2 inhalations 1 min before exercise Inhalation solution via nebulizer, 2.5 mg 3–4 times daily (in 2.5 mL sterile saline, over 5–15 min) Regular tablets: PO 2–4 mg 3–4 times daily Extended-release tablets: Proventil Repetabs PO 4–8 mg q12h, initially. Increase if necessary to a maximum of 32 mg/d, in divided doses, q12h.	<i>Inhalation aerosol</i> : 4 y and older (12 y and older for Proventil), same as adults <i>Nebulizer solution</i> , 12 y and older, same as adults; 2–12 y (AccuNeb), 1.25 mg 3–4 times daily, as needed, over 5–15 min <i>Regular tablets</i> : 12 y and older, same as adults; 6–12 y, 2 mg 3–4 times daily <i>Extended-release tablets</i> : 12 y and older, same as adults; 6–12 y: PO 4 mg q12h initially; increase if necessary to a maximum of 24 mg/d, in divided doses, q12h.
<b>Epinephrine</b> (Adrenalin, Bronkaid)	Aqueous solution (epinephrine 1:1000), Sub-Q 0.3–0.5 mg; dose may be repeated after 20 min if necessary for 3 doses Inhalation by inhaler, one or two inhalations 4–6 times per day Inhalation by nebulizer, 1–3 inhalations of 2.25% racemic epinephrine in 2.5 mL normal saline up to q3h	Aqueous solution (epinephrine 1:1000), Sub-Q 0.01 mL/kg q4h as needed. A single dose should not exceed 0.5 mL. Inhalation, same as adults for both inhaler and nebulizer
<b>Formoterol</b> (Foradil)	Oral inhalation by special inhaler (Aerolizer), 12 mcg (contents of 1 capsule) twice daily, q12h	5 y and older, same as adults
<b>Levalbuterol</b> (Xopenex, MDI; Xopenex HFA)	Nebulizer, 0.63–1.25 mg 3 times daily, q6–8h MDI: 1–2 puffs q4–6h	12 y and older, same as adults 6–11 y: Nebulizer, 0.31 mg 3 times daily, q6–8h MDI $\geq$ 4 y same as adults
<b>Metaproterenol</b> (Alupent)	Inhalation,* 2–3 puffs (0.65 mg/dose), q3–4h; maximum dose, 12 inhalations/d	Inhalation, not recommended for use in children <12 y
<b>Salmeterol</b> (Serevent)	Inhalation powder: 1 inhalation (50 mcg) q12h	<12 y, dosage not established Inhalation powder: 4 y and older, same as adults
<b>Terbutaline</b>	PO 2.5–5 mg q6–8h; maximum dose, 15 mg/d Sub-Q 0.25 mg, repeated in 15–30 min if necessary, q4–6h	PO 2.5 mg 3 times per day for children 12 y and older; maximum dose, 7.5 mg/d Sub-Q dosage not established
<b>Anticholinergics</b>		
<b>Ipratropium</b> bromide (Atrovent)	Two inhalations (36 mcg) from the metered-dose inhaler 4 times per day	Dosage not established
<b>Tiotropium</b> (Spiriva)	One tablet (18 mcg) in HandiHaler once daily	Dosage not established
<b>Xanthines</b>		
<b>Short-acting theophylline</b> (Aminophylline)	PO, 500 mg initially, then 200–300 mg q6–8h; IV infusion, 6 mg/kg over 30 min, then 0.1–1.2 mg/kg/h	PO, 7.5 mg/kg initially, then 5–6 mg/kg q6–8h; IV infusion, 6 mg/kg over 30 min, then 0.6–0.9 mg/kg/h

ROUTES AND DOSAGE RANGES		
Generic/Trade Name	Adults	Children
<b>Anticholinergics</b>		
<b>Xanthines</b>		
<b>Long-acting theophylline</b> (Theochron, others)	PO, 150–300 mg q8–12h; maximal dose 13 mg/kg or 900 mg daily, whichever is less	PO, 100–200 mg q8–12h; maximal dose, 24 mg/kg/d
<b>Combination Drugs</b>		
<b>Fluticasone/Salmeterol</b> (Advair)	Oral inhalation, one inhalation, twice daily	12 y and older: same as adults
<b>Ipratropium/Albuterol</b> (Combivent, DuoNeb)	Aerosol: two inhalations 4 times daily Nebulizing solution: 1 vial 4 times daily, increased to 6 times daily if necessary	Dosage not established

*\*Short-acting adrenergic bronchodilators are used mainly by inhalation, as needed, rather than on a regular schedule.  
MDI, multidose inhaler.*

asthma experts recommend that the drugs be used when needed (e.g., to treat acute dyspnea or prevent dyspnea during exercise). If these drugs are overused, they lose their bronchodilating effects because the beta<sub>2</sub>-adrenergic receptors become unresponsive to stimulation. This tolerance does not occur with the long-acting beta<sub>2</sub> agonists.

**Formoterol** and **salmeterol** are long-acting beta<sub>2</sub>-adrenergic agonists used only for prophylaxis of acute bronchoconstriction. They are not effective in acute attacks because they have a slower onset of action than the short-acting drugs (up to 20 minutes for salmeterol). Effects last 12 hours and the drugs should *not* be taken more frequently. If additional bronchodilating medication is needed, a short-acting agent (e.g., albuterol) should be used. The FDA has issued a **BLACK BOX WARNING** that initiating salmeterol in individuals with significantly worsening or acutely deteriorating asthma may be life-threatening.

**Metaproterenol** is a relatively selective, intermediate-acting beta<sub>2</sub>-adrenergic agonist that may be given orally or by MDI. It is used to treat acute bronchospasm and to prevent exercise-induced asthma. In high doses, metaproterenol loses some of its selectivity and may cause cardiac and central nervous system (CNS) stimulation.

**Terbutaline** is a relatively selective beta<sub>2</sub>-adrenergic agonist that is a long-acting bronchodilator. When given subcutaneously, terbutaline loses its selectivity and has little advantage over epinephrine. Muscle tremor is the most frequent side effect with this agent.

### Anticholinergics

*Anticholinergics* (see Chap. 20) block the action of acetylcholine in bronchial smooth muscle when given by inhalation. This action reduces intracellular GMP, a bronchoconstrictive substance.

**Ipratropium** was formulated to be taken by inhalation for maintenance therapy of bronchoconstriction associated with

chronic bronchitis and emphysema. Improved pulmonary function usually occurs in a few minutes. Ipratropium acts synergistically with adrenergic bronchodilators and may be used concomitantly. It improves lung function about 10% to 15% over an inhaled beta<sub>2</sub> agonist alone. Ipratropium may also be used to treat rhinorrhea associated with allergic rhinitis and the common cold. It is available as a nasal spray for such usage. Ipratropium is poorly absorbed and produces few systemic effects. However, cautious use is recommended in patients with narrow-angle glaucoma and prostatic hypertrophy. The most common adverse effects are cough, nervousness, nausea, gastrointestinal upset, headache, and dizziness.

**Tiotropium** (Spiriva) was approved to be taken once daily by inhalation for maintenance therapy of bronchoconstriction associated with chronic bronchitis and emphysema. Tiotropium has differences in its pharmacokinetic and pharmacologic properties that may make it superior to ipratropium as an anticholinergic agent. The primary adverse effect of tiotropium is dry mouth, though other effects include headache, dizziness, abdominal pain, constipation, diarrhea, flulike symptoms, and chest pain. Cautious use is recommended in patients with narrow-angle glaucoma.

### Xanthines

The main xanthine used clinically is **theophylline**. Despite many years of use, the drug's mechanism of action is unknown. Various mechanisms have been proposed, such as inhibiting phosphodiesterase enzymes that metabolize cyclic AMP, increasing endogenous catecholamines, inhibiting calcium ion movement into smooth muscle, inhibiting prostaglandin synthesis and release, or inhibiting the release of bronchoconstrictive substances from mast cells and leukocytes. In addition to bronchodilation, other effects that may be beneficial in asthma and COPD include inhibiting pulmonary edema by decreasing vascular permeability, increasing the ability of cilia to clear mucus from the airways, strengthening contractions of the

diaphragm, and decreasing inflammation. Theophylline also increases cardiac output, causes peripheral vasodilation, exerts a mild diuretic effect, and stimulates the CNS. The cardiovascular and CNS effects are adverse effects. Serum drug levels should be monitored to help regulate dosage and avoid adverse effects. Theophylline preparations are contraindicated in patients with acute gastritis and peptic ulcer disease; they should be used cautiously in those with cardiovascular disorders that could be aggravated by drug-induced cardiac stimulation.

Theophylline was formerly used extensively in the prevention and treatment of bronchoconstriction associated with asthma, bronchitis, and emphysema. Now it is considered a second-line agent that may be added in severe disease inadequately controlled by first-line drugs. Numerous dosage forms of theophylline are available. Theophylline ethylenediamine (aminophylline) contains approximately 85% theophylline and is the only formulation that can be given intravenously (IV). However, IV aminophylline is not recommended for emergency treatment of acute asthma because studies indicate little, if any, added benefit in adults or children. Oral theophylline preparations may be used for long-term treatment. Most formulations contain anhydrous theophylline (100% theophylline) as the active ingredient, and sustained-action tablets (e.g., Theochron) are more commonly used than other formulations. Theophylline is metabolized in the liver; metabolites and some unchanged drug are excreted through the kidneys.

### Applying Your Knowledge 44-1

#### How Can You Avoid This Medication Error?

Ms. Albright is having difficulty breathing and visits the on-site clinic. You assist her in the administration of her inhaled bronchodilator, the Advair.

## Anti-Inflammatory Agents

Table 44-3 provides routes and dosage ranges of anti-inflammatory antiasthmatic drugs.

### Corticosteroids

*Corticosteroids* (see Chap. 23) are used in the treatment of acute and chronic asthma and other bronchoconstrictive disorders. They suppress the release of inflammatory mediators, block the generations of cytokines, and decrease the recruitment of airway eosinophils. Beneficial effects of suppressing airway inflammation include decreased mucus secretion, decreased edema of airway mucosa, and repair of damaged epithelium, with subsequent reduction of airway reactivity. Corticosteroids increase the number and sensitivity of beta<sub>2</sub>-adrenergic receptors, which restores or increases the effectiveness of beta<sub>2</sub>-adrenergic bronchodilators. The number of beta<sub>2</sub> receptors increases within approximately 4 hours, and

improved responsiveness to beta<sub>2</sub> agonists occurs within approximately 2 hours.

In acute, severe asthma, a systemic corticosteroid in relatively high doses is indicated in patients whose respiratory distress is not relieved by multiple doses of an inhaled beta<sub>2</sub> agonist (e.g., every 20 minutes for 3 to 4 doses). The corticosteroid may be given IV or orally, and IV administration offers no therapeutic advantage over oral administration. After the drug is started, pulmonary function usually improves in 6 to 8 hours. Most patients achieve substantial benefit within 48 to 72 hours and the drug is usually continued for 7 to 10 days. Multiple doses are usually given because studies indicate that maintaining the drug concentration at steroid receptor sites in the lung is more effective than high single doses. High single or pulse doses do not increase therapeutic effects; they may increase risks of developing myopathy and other adverse effects, however. In some infants and young children with acute, severe asthma, oral prednisone for 3 to 10 days has relieved symptoms and prevented hospitalization.

Corticosteroids are the most consistently effective long-term control medications for asthma. In chronic asthma, a corticosteroid is usually taken by inhalation, on a daily schedule. It is often given concomitantly with one or more bronchodilators and may be given with another anti-inflammatory drug such as a leukotriene modifier or a mast cell stabilizer. In some instances, the other drugs allow smaller doses of the corticosteroid. For acute flare-ups of symptoms during treatment of chronic asthma, a systemic corticosteroid may be needed temporarily to regain control.

In early stages of the progressive disease, patients with COPD are unlikely to need corticosteroid therapy. In later stages, however, they usually need periodic short-course therapy for episodes of respiratory distress. When needed, the corticosteroid is given orally or parenterally because effectiveness of inhaled corticosteroids has not been established in COPD (see Evidence-Based Practice Box 23-1: Efficacy of Corticosteroids on the Outcome in Patients With Acute Exacerbations of COPD).

In end-stage COPD, patients often become “steroid-dependent” and require daily doses because any attempt to reduce dosage or stop the drug results in respiratory distress. Such patients experience numerous serious adverse effects of prolonged systemic corticosteroid therapy.

Corticosteroids should be used with caution in patients with peptic ulcer disease, inflammatory bowel disease, hypertension, congestive heart failure, and thromboembolic disorders. However, they cause fewer and less severe adverse effects when taken in short courses or by inhalation than when taken systemically for long periods of time.

**Beclomethasone, budesonide, flunisolide, fluticasone, mometasone, and triamcinolone** are topical corticosteroids for inhalation. Most inhaled drugs are being reformulated (indicated with “HFA” secondary to the propellant being used). Topical administration minimizes systemic absorption and adverse effects. These preparations may substitute for or allow reduced dosage of systemic corticosteroids. In people with

Table 44-3

Drugs at a Glance: Anti-Inflammatory Antiasthmatic Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Corticosteroids</b>		
<b>Beclomethasone</b> (QVAR)	Oral inhalation, two inhalations (0.84 mg/dose) three or four times daily; maximum, 20 inhalations/24 h	6–12 y: Oral inhalation, one or two inhalations three or four times per day; maximum dose, 10 inhalations/24 h
<b>Beclomethasone</b> (Beconase AQ)	1 spray in each nostril 2–4 times/day or 2 sprays in each nostril twice daily (total dose 168–336 mcg/day)	
<b>Budesonide</b> (Pulmocort Turbuhaler)	Oral inhalation, 200–400 mcg twice daily	6 y: Oral inhalation 200 mcg twice daily
<b>Flunisolide</b> (AeroBid, Aerospan-not interchangeable)	Aerobid: Oral inhalation, two inhalations (0.50 mg/dose) twice daily, morning and evening; maximum dose, four inhalations twice daily (2 mg) Aerospan: two inhalations twice daily; maximum eight inhalations daily	Aerobid: 6–15 y: Oral inhalation, two inhalations twice daily; maximum eight inhalation daily Aerospan: 6–11y: Oral inhalation: one inhalation twice daily; maximum four times daily
<b>Fluticasone</b> (Flonase)	4 sprays in each nostril once daily (265 mcg/day)	12 y and older: Same as adults 4–11 y: 1 spray in each nostril once daily; may increase to 2 sprays in each nostril for desired effect
<b>Fluticasone</b> aerosol (Flovent)	Aerosol, 88–440 mcg twice daily	Dosage not established
<b>Fluticasone</b> powder (Flovent Rotadisk)	Powder, 100–500 mcg twice daily	12 y and older: Same as adults 4–11 y: Powder, 50–100 mcg twice daily
<b>Hydrocortisone</b> sodium phosphate and sodium succinate	IV 100–200 mg q4–6h initially, then decreased or switched to an oral dosage form	IV 1–5 mg/kg q4–6h
<b>Methylprednisolone</b> sodium succinate	IV 10–40 mg q4–6h for 48–72 h	IV 0.5 mg/kg q4–6h
<b>Mometasone</b> (Asmanex Twisthaler, Nasonex)	Nasal inhalation two sprays (50 mcg/spray) in each nostril once daily	12 y and older: Same as adults 2–11 y: 1 spray (50 mcg) in each nostril once daily
<b>Prednisone</b>	PO 20–60 mg/d	PO 2 mg/kg/d initially
<b>Triamcinolone</b> (Azmacort)	Oral inhalation, two (100 mcg/puff) inhalations 3 or 4 times per day or four inhalations twice daily; maximum dose, 16 inhalations (1600 mcg)/24 h	6–12 y: one or two (100 mcg/puff) inhalations 3 or 4 times per day or two to four inhalations twice daily; maximum dose, 12 inhalations/24 h
<b>Leukotriene Modifiers</b>		
<b>Montelukast</b> (Singulair)	PO 10 mg once daily in the evening or at bedtime	15 y and older: Same as adults 6–14 y: PO 5 mg once daily in the evening 2–5 y: 4 mg once daily
<b>Zafirlukast</b> (Accolate)	PO 20 mg twice daily, 1 h before or 2 h after a meal	12 y and older: Same as adults 5–11 y: PO 10 mg twice daily
<b>Mast Cell Stabilizers</b>		
<b>Cromolyn</b> (Intal)	Nebulizer solution, oral inhalation, 20 mg 4 times daily Aerosol spray, oral inhalation, two sprays 4 times daily	2 y and older: Same as adults 5 y and older: Same as adults

asthma who are taking an oral corticosteroid, the oral dosage is reduced slowly (over weeks to months) when an inhaled corticosteroid is added. The goal is to give the lowest oral dose necessary to control symptoms. Beclomethasone, flunisolide, and fluticasone also are available in nasal solutions for treatment of allergic rhinitis, which may play a role in bronchoconstriction. Because systemic absorption occurs in patients using inhaled corticosteroids (about 20% of a dose), high doses should be reserved for those otherwise requiring oral corticosteroids.

**Hydrocortisone, prednisone, and methylprednisolone** are given to patients who require systemic corticosteroids. Prednisone is given orally; hydrocortisone and methylprednisolone may be given IV to patients who are unable to take an oral medication.

### Applying Your Knowledge 44-2

Ms. Albright has a friend who takes prednisone for his breathing problems. She asks why she isn't taking the same medication. How should you respond?

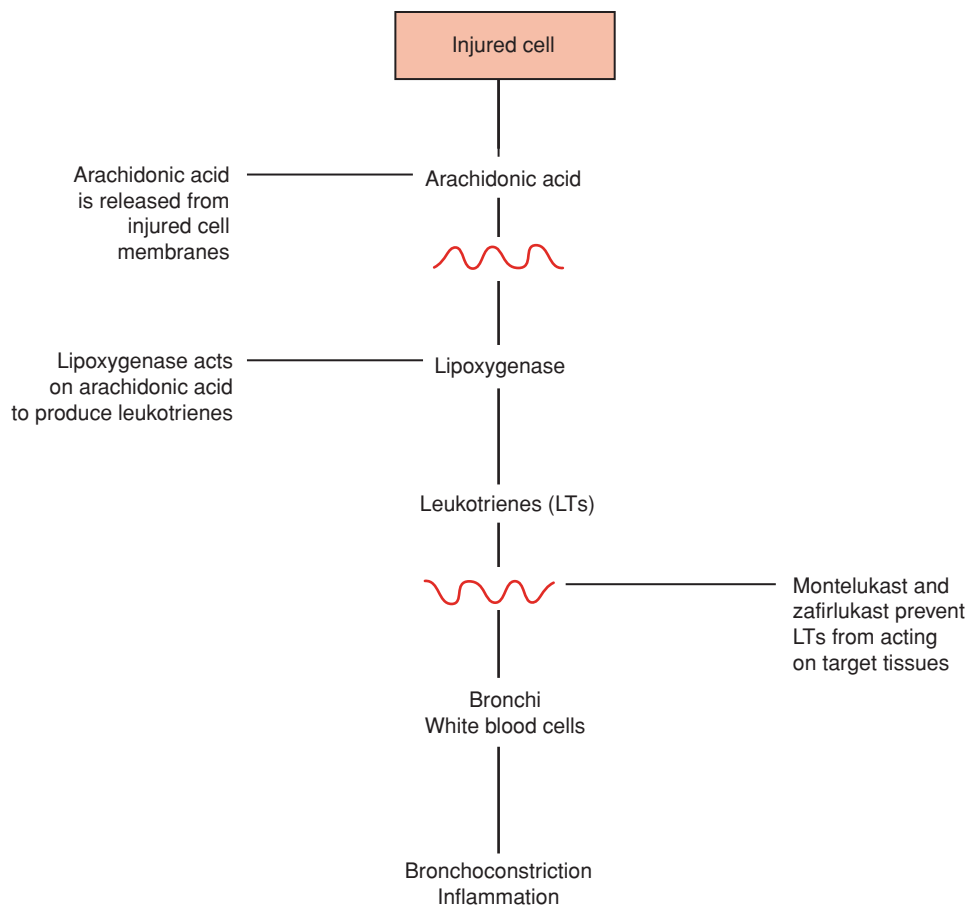

## Leukotriene Modifiers

*Leukotrienes* are strong chemical mediators of bronchoconstriction and inflammation, the major pathologic features of

asthma. They can cause sustained constriction of bronchioles and immediate hypersensitivity reactions. They also increase mucus secretion and mucosal edema in the respiratory tract. Leukotrienes are formed by the lipoxygenase pathway of arachidonic acid metabolism (Fig. 44-1) in response to cellular injury. They are designated by LT; the letter B, C, D, or E; and the number of chemical bonds in their structure (e.g., LTB<sub>4</sub>, LTC<sub>4</sub>, and LTE<sub>4</sub>, also called slow releasing substances of anaphylaxis, or SRS-A, because they are released more slowly than histamine).

Leukotriene modifier drugs were developed to counteract the effects of leukotrienes and are indicated for long-term treatment of asthma in adults and children. The drugs help to prevent acute asthma attacks induced by allergens, exercise, cold air, hyperventilation, irritants, and aspirin or NSAIDs. They are not effective in relieving acute attacks. However, they may be continued concurrently with other drugs during acute episodes.

The leukotriene modifiers include two agents, **montelukast** and **zafirlukast**, classed as leukotriene receptor antagonists. Zafirlukast and montelukast improve symptoms and pulmonary function tests (PFTs), decrease nighttime symptoms, and decrease the use of beta<sub>2</sub> agonist drugs. They are effective with oral administration, can be taken once or twice a day, can be used with bronchodilators and corticosteroids, and elicit a high degree of patient adherence and satisfaction.

**Figure 44-1** ■ Formation of leukotrienes and actions of leukotriene-modifying drugs.

However, they are less effective than low doses of inhaled corticosteroids.

Montelukast and zafirlukast are well absorbed with oral administration. They are metabolized in the liver by the cytochrome P450 enzyme system and may interact with other drugs metabolized by this system. Most metabolites are excreted in the feces. Zafirlukast is excreted in breast milk and should not be taken during lactation. The most common adverse effects reported in clinical trials were headache, nausea, diarrhea, and infection.

## Mast Cell Stabilizers

**Cromolyn** and **nedocromil** stabilize mast cells and prevent the release of bronchoconstrictive and inflammatory substances when mast cells are confronted with allergens and other stimuli. The drugs are utilized as an alternative, but not preferred, medication for prophylaxis of acute asthma attacks in patients with mild persistent asthma; they are not effective in acute bronchospasm or status asthmaticus and should not be used in these conditions. Use of one of these drugs may allow reduced dosage of bronchodilators and corticosteroids and can be used prior to exercise or exposure to known allergens.

The drugs are taken by inhalation. Cromolyn is available in a metered-dose aerosol and a solution for use with a power-operated nebulizer. A nasal solution is also available for prevention and treatment of allergic rhinitis.

Mast cell stabilizers are contraindicated in patients who are hypersensitive to the drugs. They should be used with caution in patients with impaired renal or hepatic function. Also, the propellants in the aerosols may aggravate coronary artery disease or dysrhythmias.

## Immunosuppressant Monoclonal Antibody

**Omalizumab** (Xolair) works by binding to immunoglobulin E (IgE), blocking receptors on the surfaces of mast cells and basophils. This prevents IgE from attaching to the cells, thus preventing the release of substances in the body that can trigger an allergic reaction and preventing the development of inflammation. As an immunomodifier, omalizumab is indicated as adjunctive therapy in patients with allergic asthma whose symptoms do not respond adequately to inhaled steroids. Due to the risk of anaphylaxis the FDA has issued a **BLACK BOX WARNING** for omalizumab. The drug should only be administered to patients in a health care setting under direct medical supervision by provider who can initiate treatment of life-threatening anaphylaxis. Further discussion of this drug is found in Chapter 41.

## Herbal and Dietary Supplements

Numerous preparations are promoted to relieve symptoms of asthma, and patients with asthma are increasingly using

alternative and complementary therapies. Many herbal preparations are used traditionally, and tradition varies by culture. As with most herbal treatments, few clinical studies support their use though some herbs used are similar to asthma preparations in their chemical properties. For example, caffeine is a xanthine and therefore has bronchodilating effects similar to, but weaker than, those of theophylline. In addition to herbal preparations for the long-term treatment of asthma, vitamins and minerals are used frequently (i.e., vitamins C, B<sub>6</sub>, E, and magnesium, selenium).

In general, herbal and dietary therapies in asthma, as in other disorders, have not been studied in controlled clinical trials and should be avoided. Because asthma can result in death in a matter of minutes, patients should be counseled *not* to use dietary or herbal supplements in place of prescribed bronchodilating and anti-inflammatory medications. Delays in appropriate treatment can have serious, even fatal, consequences.

## Applying Your Knowledge 44-3

Ms. Albright comes into the clinic and you suspect she is experiencing respiratory distress. You focus your assessment on what signs/symptoms?

.....

## Nursing Process

### Assessment

Assess the patient's pulmonary function.

- General assessment factors include rate and character of respiration, skin color, arterial blood gas analysis, and pulmonary function tests. Abnormal breathing patterns (e.g., rate below 12 or above 24 per minute, dyspnea, cough, orthopnea, wheezing, “noisy” respirations) may indicate respiratory distress. Severe respiratory distress is characterized by tachypnea, dyspnea, use of accessory muscles of respiration, and hypoxia. Early signs of hypoxia include mental confusion, restlessness, anxiety, and increased blood pressure and pulse rate. Late signs include cyanosis and decreased blood pressure and pulse. Hypoxemia is confirmed if arterial blood gas analysis shows decreased partial pressure of oxygen (PO<sub>2</sub>).
- In acute bronchospasm, a medical emergency, the patient is in obvious and severe respiratory distress. A characteristic feature of bronchospasm is forceful expiration or wheezing.
- If the patient has chronic asthma, try to determine the frequency and severity of acute attacks; factors that precipitate or relieve acute attacks; antiasthmatic medications taken occasionally or regularly; allergies; and condition between acute attacks, such as restrictions in activities of daily living due to asthma.

*Nursing Process continues on page 722*

- If the patient has chronic bronchitis or emphysema, assess for signs of respiratory distress, hypoxia, cough, amount and character of sputum, exercise tolerance (e.g., dyspnea on exertion, dyspnea at rest), medications, and nondrug treatment measures (e.g., breathing exercises, chest physiotherapy).

## Nursing Diagnoses

- Impaired Gas Exchange related to bronchoconstriction and excessive mucus production
- Activity Intolerance related to impaired gas exchange and fatigue
- Risk for Injury: Severe bronchospasm with asthma and adverse effects with antiasthmatic drugs
- Noncompliance: Overuse of adrenergic bronchodilators
- Deficient Knowledge: Factors precipitating bronchoconstriction and strategies to avoid precipitating factors
- Deficient Knowledge: Accurate self-administration of drugs, including use of inhalers

## Planning/Goals

### The patient will

- Self-administer bronchodilating and other drugs accurately
- Experience relief of symptoms
- Avoid preventable adverse drug effects
- Avoid overusing bronchodilating drugs
- Avoid exposure to stimuli that cause bronchospasm when possible
- Avoid respiratory infections when possible

## Interventions

Use measures to prevent or relieve bronchoconstriction when possible. General measures include those to prevent respiratory disease or promote an adequate airway. A specific monitoring plan should be in place, whether peak-flow or symptom monitoring. Some measures include the following:

- Use mechanical measures for removing excessive respiratory tract secretions and preventing their retention. Effective measures include coughing, deep breathing, percussion, and postural drainage.
- Help the patient identify and avoid exposure to conditions that precipitate bronchoconstriction. For example, allergens may be removed from the home, school, or work environment; cigarette smoke should be avoided when possible. When bronchospasm is precipitated by exercise, prophylaxis by prior inhalation of bronchodilating agents is better than avoiding exercise, especially in children.
- Assist patients with asthma to identify early signs of difficulty, including increased need for beta-adrenergic agonists, activity limitations, and waking at night with asthma symptoms.

- Monitor peak expiratory flow rate (PEFR) when indicated. Portable meters are available for use in clinics, physicians' offices, and patients' homes. This is an objective measure of airflow/airway obstruction and helps to evaluate the patient's treatment regimen.
- Assist patients with moderate to severe asthma in obtaining meters and learning to measure PEFR. Patients with a decreased PEFR may need treatment to prevent acute, severe respiratory distress.
- Assist patients and at least one family member in managing acute attacks of bronchoconstriction, including when to seek emergency care.
- Try to prevent or reduce anxiety, which may aggravate bronchospasm. Stay with the patient during an acute asthma attack if feasible. Patients experiencing severe and prolonged bronchospasm (status asthmaticus) should be admitted or transferred to a hospital intensive care unit.
- With any patients who smoke cigarettes, encourage cessation of smoking and provide information, resources, and assistance in doing so. Emphasize the health benefits of improved respiratory function.
- In addition, provide appropriate patient teaching related to drug therapy (see accompanying display).

## Evaluation

- Observe for relief of symptoms and improved arterial blood gas values.
- Interview and observe for correct drug administration, including use of inhalers.
- Interview and observe for tachydysrhythmias, nervousness, insomnia, and other adverse drug effects.
- Interview about and observe behaviors to avoid stimuli that cause bronchoconstriction and respiratory infections.

## Principles of Therapy

### Drug Selection and Administration

Choice of drug and route of administration are determined largely by the severity of the disease process and the patient's response to therapy. Some guidelines include the following:

- A selective, short-acting, inhaled beta<sub>2</sub>-adrenergic agonist (e.g., albuterol) is the initial drug of choice for acute bronchospasm.
- Because aerosol products act directly on the airways, drugs given by inhalation can usually be given in smaller doses and produce fewer adverse effects than oral or parenteral drugs.
- Ipratropium and tiotropium, the anticholinergic bronchodilators, are most useful in the long-term management of COPD. They are ineffective in relieving acute

## Patient Teaching Guidelines Antiasthmatic Drugs

### General Considerations

- Asthma and other chronic lung diseases are characterized by constant inflammation of the airways and periodic or persistent labored breathing from constriction or narrowing of the airways. Antiasthmatic drugs are often given in combination to combat these problems. Thus, it is extremely important to know the type and purpose of each drug.
- Except for the short-acting, inhaled bronchodilators (e.g., albuterol), antiasthmatic medications are used long term to control symptoms and prevent acute asthma attacks. This means they must be taken on a regular schedule and continued when symptom free.
- When an asthma attack (i.e., acute bronchospasm with shortness of breath, wheezing respirations, cough) occurs, the only fast-acting, commonly used medication to relieve these symptoms is an inhaled, short-acting bronchodilator (e.g., albuterol). Other inhaled and oral drugs are not effective and should not be used.
- Try to prevent symptoms. For example, respiratory infections can precipitate difficulty in breathing. Avoiding infections (e.g., by good hand hygiene, avoiding people with infections, annual influenza vaccinations, and other measures) can prevent acute asthma attacks. If you are allergic to tobacco smoke, perfume, or flowers, try to avoid or minimize exposure.
- A common cause of acute asthma attacks is not taking medications correctly. Some studies indicate that one third to two thirds of patients with asthma do not comply with instructions for using their medications. Factors that contribute to noncompliance with drug therapy include long-term use, expense, and adverse effects. If you have difficulty taking medications as prescribed, discuss the situation with a health care provider. Cheaper medications or lower doses may be effective alternatives. Just stopping the medications may precipitate acute breathing problems.
- If unable to prevent symptoms, early recognition and treatment may help prevent severe distress and hospitalizations. Signs of impending difficulty include increased needs for bronchodilator inhalers, activity limitations, waking at night because of asthma symptoms, and variability in the peak expiratory flow rate (PEFR), if you use a PEFR meter at home. The first treatment is to use a short-acting, inhaled bronchodilator. If this does not improve breathing, seek emergency care.
- Keep adequate supplies of medications on hand. Missing a few doses of long-term control or “preventive” medications may precipitate an acute asthma attack; not using an inhaled bronchodilator for early breathing difficulty may lead to more severe problems and the need for emergency treatment or hospitalization.
- Be sure you can use your metered-dose inhalers correctly. According to several research studies, many patients do not.
- Drinking 2 to 3 quarts of fluids daily helps thin secretions in the throat and lungs and makes them easier to remove.
- Avoid tobacco smoke and other substances that irritate breathing passages (e.g., aerosol hair spray, antiperspirants, cleaning products, and automobile exhaust) when possible.
- Avoid excessive intake of caffeine-containing fluids such as coffee, tea, and cola drinks. These beverages may increase bronchodilation but also may increase heart rate and cause palpitations, nervousness, and insomnia with bronchodilating drugs.
- Take influenza vaccine annually and pneumococcal vaccine at least once if you have chronic lung disease.
- Inform all health care providers about the medications you are taking and do not take over-the-counter drugs or herbal supplements without consulting a health care provider. Some drugs can decrease beneficial effects or increase adverse effects of antiasthmatic medications. For example, over-the-counter nasal decongestants, asthma remedies, cold remedies, and antisleep medications can increase the rapid heartbeat, palpitations, and nervousness often associated with bronchodilators. With herbal remedies, none are as effective as standard antiasthmatic medication, and they may cause serious or life-threatening adverse effects.

### Self-Administration

- Follow instructions carefully. Better breathing with minimal adverse effects depends on accurate use of prescribed medications. If help is needed with metered-dose inhalers, consult a health care provider.
- Use short-acting bronchodilator inhalers as needed, not on a regular schedule. If desired effects are not achieved or if symptoms worsen, inform the prescribing physician. Do not increase dosage or frequency of taking medication. Overuse increases adverse drug effects and decreases drug effectiveness.
- If taking formoterol or salmeterol, which are long-acting, inhaled bronchodilators, do not use more often than every 12 hours. If constricted breathing occurs, use a short-acting bronchodilator inhaler between doses of a long-acting drug. Salmeterol does not relieve acute shortness of breath because it takes approximately 20 minutes to start acting and 1 to 4 hours to achieve maximal bronchodilating effects.
- If taking an oral or inhaled corticosteroid, take on a regular schedule, at approximately the same time each day. The purpose of these drugs is to relieve inflammation in the airways and prevent acute respiratory distress. They are not effective unless taken regularly.
- If taking oral theophylline, take fast-acting preparations before meals with a full glass of water, at regular intervals around the clock. If gastrointestinal upset occurs, take with food. Take long-acting preparations every 8 to 12 hours; do not chew or crush.
- Take zafirlukast 1 hour before or 2 hours after a meal; montelukast and zileuton may be taken with or without food. Take montelukast in the evening or at bedtime. This schedule provides maximum beneficial effects during the night and early morning, when asthma symptoms often occur or worsen.
- Use inhalers correctly:
  1. Shake well immediately before each use.
  2. Remove the cap from the mouthpiece.
  3. Exhale to the end of a normal breath.
  4. With the inhaler in the upright position, place the mouthpiece just inside the mouth, and use the lips to

## Patient Teaching Guidelines

## Antiasthmatic Drugs (continued)

form a tight seal or hold the mouthpiece approximately two finger-widths from the open mouth.

5. While pressing down on the inhaler, take a slow, deep breath for 3 to 5 seconds, hold the breath for approximately 10 seconds, and exhale slowly.
6. Wait 3 to 5 minutes before taking a second inhalation of the drug.

7. Rinse the mouth with water after each use.
8. Rinse the mouthpiece and store the inhaler away from heat.
9. If you have difficulty using an inhaler, ask your provider about a spacer device (a tube attached to the inhaler that makes it easier to use).

bronchospasm by themselves, but they add to the bronchodilating effects of adrenergic drugs.

- Theophylline is used less often than formerly and is now considered a second-line drug. When used, it is usually given orally in an extended-release formulation for chronic disorders, such as COPD. IV aminophylline is no longer used to treat acute asthma attacks.
- Cromolyn is used prophylactically; it is ineffective in acute bronchospasm.
- Because inflammation has been established as a major component of asthma, an inhaled corticosteroid is being used early in the disease process, often with a bronchodilator or mast cell stabilizer. In acute episodes of bronchoconstriction, a corticosteroid is often given orally or IV for several days.
- In chronic disorders, inhaled corticosteroids should be taken on a regular schedule. These drugs may be effective when used alone or with relatively small doses of an oral corticosteroid. Optimal schedules of administration are not clearly established, but more frequent dosing (e.g., every 6 hours) may be more effective than less frequent dosing (e.g., every 12 hours), even if the total amount is the same. As with systemic glucocorticoid therapy, the recommended inhaled corticosteroid dose is the lowest amount required to control symptoms. High doses suppress adrenocortical function but much less so than systemic drugs. Small doses may impair bone metabolism and predispose adults to osteoporosis by decreasing calcium deposition and increasing calcium resorption from bone. In children, chronic administration of corticosteroids may retard growth. Local adverse effects (oropharyngeal candidiasis, hoarseness) can be decreased by reducing the dose, administering less often, rinsing the mouth after use, or using a spacer device. These measures decrease the amount of drug deposited in the oral cavity. The inhaled drugs are well tolerated with chronic use.
- A common regimen for treatment of moderate asthma is an inhaled corticosteroid on a regular schedule, two to four times daily, and a short-acting, inhaled beta<sub>2</sub>-adrenergic agonist as needed for prevention or treatment of bronchoconstriction. For more severe asthma, an inhaled corticosteroid is continued, and both a short-acting and a

long-acting beta<sub>2</sub> agonist may be given. A leukotriene modifier may also be added to the regimen to further control symptoms and reduce the need for corticosteroids and inhaled bronchodilators.

- Multidrug regimens are commonly used, and one advantage is that smaller doses of each agent can usually be given. This may decrease adverse effects and allow dosages to be increased when exacerbation of symptoms occurs. Available combination inhalation products include Combivent (albuterol and ipratropium) and Advair (salmeterol and fluticasone). Advair, which was developed to treat both inflammation and bronchoconstriction, was more effective than the individual components at the same doses and as effective as concurrent use of the same drugs at the same doses. In addition, the combination reduced the corticosteroid dose by 50% and was more effective than higher doses of fluticasone alone in reducing asthma exacerbations. The combination improved symptoms within 1 week. Additional combination products are likely to be marketed and may improve patient compliance with prescribed drug therapy.

## Drug Dosage

Dosage of antiasthmatic drugs must be individualized to attain the most therapeutic effects and the fewest adverse effects. Larger doses of bronchodilators and corticosteroids (inhaled, systemic, or both) are usually required to relieve the symptoms of acute, severe bronchoconstriction or status asthmaticus. Then, doses should be reduced to the smallest effective amounts for long-term control.

Dosage of theophylline preparations should be based mainly on serum theophylline levels (therapeutic range is 5–15 mcg/mL; toxic levels are 20 mcg/mL or above). Blood for serum levels should be drawn 1 to 2 hours after immediate-release dosage forms and about 4 hours after sustained-release forms are taken. In addition, children and cigarette smokers usually need higher doses to maintain therapeutic blood levels because they metabolize theophylline rapidly, and patients with liver disease, congestive heart failure, chronic pulmonary disease, or acute viral infections usually need smaller doses because these conditions impair theophylline metabolism. For obese patients, theophylline dosage should be calculated on the basis of lean or ideal body weight because theophylline is not highly distributed in fatty tissue.

## Toxicity: Recognition and Management

With antiasthmatic drugs, signs and symptoms of overdose and toxicity are probably most likely to occur when patients with acute or chronic bronchoconstrictive disorders overuse bronchodilators in their efforts to relieve dyspnea. General management of acute poisoning includes early recognition of signs and symptoms, stopping the causative drug, and instituting other treatment measures as indicated. Specific measures include the following:

- **Bronchodilator overdose.** With inhaled or systemic adrenergic bronchodilators, major adverse effects are excessive cardiac and CNS stimulation. Symptoms of cardiac stimulation include angina, tachycardia, and palpitations; serious dysrhythmias and cardiac arrest have also been reported. Symptoms of CNS stimulation include agitation, anxiety, insomnia, seizures, and tremors. Severe overdoses may cause delirium, collapse, and coma. In addition, hypokalemia, hyperglycemia, and hypotension or hypertension may occur. Management includes discontinuing the causative medications and using general supportive measures. Emesis, gastric lavage, or activated charcoal may be useful with oral drugs if benefit exceeds risk. For cardiac symptoms, monitor blood pressure, pulse, and electrocardiogram. Cautious use of a beta-adrenergic blocking drug (e.g., propranolol) may be indicated. However, a nonselective beta blocker may induce bronchoconstriction.
- **Theophylline overdose.** Signs and symptoms include anorexia, nausea, vomiting, agitation, nervousness, insomnia, tachycardia and other dysrhythmias, and tonic-clonic convulsions. Ventricular dysrhythmias or convulsions may be the first sign of toxicity. Serious adverse effects rarely occur at serum drug levels below 20 micrograms per milliliter. Overdoses with sustained-release preparations may cause a dramatic increase in serum drug concentrations much later (12 hours or longer) than the immediate-release preparations. Early treatment helps but does not prevent these delayed increases in serum drug levels.

In patients without seizures, induce vomiting unless the level of consciousness is impaired. In these patients, precautions to prevent aspiration are needed, especially in children. If overdose is identified within an hour of drug ingestion, gastric lavage may be helpful if unable to induce vomiting or vomiting is contraindicated. Administration of activated charcoal and a cathartic is also recommended, especially for overdoses of sustained-release formulations if benefit exceeds risk.

In patients with seizures, treatment includes securing the airway, giving oxygen, injecting IV diazepam (0.1–0.3 mg/kg, up to 10 mg), monitoring vital signs, maintaining blood pressure, providing adequate hydration, and monitoring serum theophylline levels until below 20 micrograms per milliliter. Also, symptomatic treatment of dysrhythmias may be needed.

- **Leukotriene modifiers and mast cell stabilizers.** These drugs seem relatively devoid of serious toxicity. There have been few reports of toxicity in humans and little clinical experience in managing it. If toxicity occurs, general supportive and symptomatic treatment is indicated.

## Use in Special Populations

### Use in Children

The American Academy of Pediatrics endorses the clinical practice guidelines established by the NAEP (see Box 44-1). In general, antiasthmatic medications are used in children and adolescents for the same indications as for adults. With adrenergic bronchodilators, recommendations for use vary according to route of administration, age of the child, and specific drug formulations. However, even infants and young children can be treated effectively with aerosolized or nebulized drugs. In addition, some oral drugs can be given to children as young as 2 years and most can be given to children 6 to 12 years of age.

With theophylline, use in children should be closely monitored because dosage needs and rates of metabolism vary widely. In children younger than 6 months, especially premature infants and neonates, drug elimination may be prolonged because of immature liver function. Except for preterm infants with apnea, theophylline preparations are not recommended for use in this age group. Children 6 months to 16 years of age, approximately, metabolize theophylline more rapidly than younger or older patients. Thus, they may need higher doses than adults in proportion to size and weight. If the child is obese, the dosage should be calculated on the basis of lean or ideal body weight because the drug is not highly distributed in fatty tissue. Long-acting dosage forms are not recommended for children younger than 6 years of age. Children may become hyperactive and disruptive from the CNS-stimulating effects of theophylline. Tolerance to these effects usually develops with continued use of the drug.

Corticosteroids are being used earlier in children as in adults and inhaled corticosteroids are first-line drugs for treatment of persistent bronchoconstrictive disorders. The effectiveness and safety of inhaled corticosteroids in children older than 3 years of age is well established; few data are available on the use of inhaled drugs in those younger than 3 years. Major concerns about long-term use in children include decreased adrenal function, growth, and bone mass. Most corticosteroids are given by inhalation, and dosage, type of inhaler device, and characteristics of individual drugs influence the extent and severity of these systemic effects.

Adrenal insufficiency is most likely to occur with systemic or high doses of inhaled corticosteroids. Dose-related inhibition of growth has been reported in short and intermediate studies, but long-term studies have found few, if any, decreases in expected adult height. Inhaled corticosteroids have not been associated with significant decreases in bone mass, but more studies of high doses and of drug therapy in adolescents are needed. Bone growth should be monitored closely in children taking corticosteroids. Although inhaled corticosteroids are the most effective anti-inflammatory medications available

for asthma, high doses in children are still of concern. The risk of high doses is especially great in children with other allergic conditions that require topical corticosteroid drugs. The risk can be decreased by using the lowest effective dose, administration techniques that minimize swallowed drug, and other antiasthmatic drugs to reduce corticosteroid dose.

Leukotriene modifiers have not been extensively studied in children and adolescents. With montelukast, the 10-milligram film-coated tablet is recommended for adolescents 15 years of age and older and a 4-milligram chewable tablet is recommended for children 2 to 5 years of age. Safety and effectiveness of zafirlukast in children younger than 12 years have not been established.

Cromolyn aerosol solution may be used in children 5 years of age and older, and nebulizer solution is used with children 2 years and older.

### Use in Older Adults

Older adults often have chronic pulmonary disorders for which bronchodilators and antiasthmatic medications are used. As with other populations, administering the medications by inhalation and giving the lowest effective dose decrease adverse effects. The main risks with adrenergic bronchodilators are excessive cardiac and CNS stimulation.

Theophylline use must be carefully monitored because drug effects are unpredictable. On the one hand, cigarette smoking and drugs that stimulate drug-metabolizing enzymes in the liver (e.g., phenobarbital, phenytoin) increase the rate of metabolism and therefore dosage requirements. On the other hand, impaired liver function, decreased blood flow to the liver, and some drugs (e.g., cimetidine, erythromycin) impair metabolism and therefore decrease dosage requirements. Adverse effects include cardiac and CNS stimulation. Safety can be increased by measuring serum drug levels and adjusting dosage to maintain therapeutic levels of 5 to 15 micrograms per milliliter. If the patient is obese, dosage should be based on lean or ideal body weight because theophylline is not highly distributed in fatty tissue.

Corticosteroids increase the risks of osteoporosis and cataracts in older adults. Leukotriene modifiers usually are well tolerated by older adults, with pharmacokinetics and effects similar to those in younger adults. With zafirlukast, however, blood levels are higher and elimination is slower than in younger adults.

### Use in Patients With Renal Impairment

Bronchodilating and anti-inflammatory drugs can usually be given without dosage adjustments in patients with impaired renal function. Beta agonists may be given by inhalation or parenteral routes. Theophylline can be given in usual doses, but serum drug levels should be monitored. Most corticosteroids are eliminated by hepatic metabolism, and dosage reductions are not needed in patients with renal impairment. No data are available about the use of montelukast, and no dosage adjustments are recommended for zafirlukast.

Cromolyn is eliminated by renal and biliary excretion; the drug should be given in reduced doses, if at all, in patients with renal impairment.

### Use in Patients With Hepatic Impairment

Montelukast and zafirlukast produce higher blood levels and are eliminated more slowly in patients with hepatic impairment. However, no dosage adjustment is recommended for patients with mild to moderate hepatic impairment.

Cromolyn is eliminated by renal and biliary excretion; the drug should be given in reduced doses, if at all, in patients with hepatic impairment.

### Use in Patients With Critical Illness

Acute, severe asthma (status asthmaticus) is characterized by severe respiratory distress and requires emergency treatment. Beta<sub>2</sub> agonists should be given in high doses and as often as every 20 minutes for 1 to 2 hours (by MDIs with spacer devices or by compressed-air nebulization). However, high doses of nebulized albuterol have been associated with tachycardia, hypokalemia, and hyperglycemia. After symptoms are controlled, dosage can usually be reduced and dosing intervals extended. High doses of systemic corticosteroids are also given for several days, IV or orally. If the patient is able to take an oral drug, there is no therapeutic advantage to IV administration.

When respiratory function improves, efforts to prevent future episodes are needed. These efforts may include identifying and avoiding suspected triggers, evaluation and possible adjustment of the patient's treatment regimen, and assessment of the patient's adherence to the prescribed regimen.

### Use in Home Care

Most of the drugs discussed in this chapter are used in the home setting; omalizumab should be administered only in the health care setting due to the risk of life-threatening anaphylaxis with administration. A major role of the home care nurse is to assist patients in using the drugs safely and effectively. Several studies have indicated that many people do not use MDIs and other inhalation devices correctly. The home care nurse needs to observe a patient using an inhalation device when possible. If errors in technique are assessed, further education may be needed. With inhaled medications, a spacer device may be useful, especially for children and older adults, because less muscle coordination is required to administer a dose. Adverse effects may be minimized as well.

For patients with asthma, especially children, assess the environment for potential triggers of acute bronchospasm, such as cigarette smoking. In addition, assist patients to recognize and treat (or get help for) exacerbations before respiratory distress becomes severe.

With theophylline, the home care nurse needs to assess the patient and the environment for substances that may affect metabolism of theophylline and decrease therapeutic effects or increase adverse effects. In addition, the nurse needs to reinforce the importance of not exceeding the prescribed dose, not crushing long-acting formulations, reporting adverse effects, and keeping appointments for follow-up care.

## Nursing Actions

## Drugs for Asthma and Other Bronchoconstrictive Disorders

## NURSING ACTIONS

## RATIONALE/EXPLANATION

**1. Administer accurately**

- a. Be sure patients have adequate supplies of inhaled bronchodilators and corticosteroids available for self-administration. Observe technique of self-administration for accuracy and assist if needed.
- b. Give immediate-release oral theophylline before meals with a full glass of water, at regular intervals around the clock. If gastrointestinal upset occurs, give with food.
- c. Give sustained-release theophylline q8–12h, with instructions not to chew or crush.
- d. Give zafirlukast 1 hour before or 2 hours after a meal; montelukast may be given with or without food.
- e. Give montelukast in the evening or at bedtime.

To promote dissolution and absorption. Taking with food may decrease nausea and vomiting.

Sustained-release drug formulations should never be chewed or crushed because doing so causes immediate release of potentially toxic doses.

The bioavailability of zafirlukast is reduced approximately 40% if taken with food. Food does not significantly affect the bioavailability of montelukast.

This schedule provides high drug concentrations during the night and early morning, when asthma symptoms tend to occur or worsen.

**2. Observe for therapeutic effects**

- a. Decreased dyspnea, wheezing, and respiratory secretions
- b. Reduced rate and improved quality of respirations
- c. Reduced anxiety and restlessness
- d. Therapeutic serum levels of theophylline (5–15 mcg/mL)
- e. Improved arterial blood gas levels (normal values:  $PO_2$ , 80 to 100 mm Hg;  $PCO_2$ , 35 to 45 mm Hg; pH, 7.35 to 7.45)
- f. Improved exercise tolerance
- g. Decreased incidence and severity of acute attacks of bronchospasm with chronic administration of drugs

Relief of bronchospasm and wheezing should be evident within a few minutes after giving subcutaneous epinephrine, or aerosolized adrenergic bronchodilators.

**3. Observe for adverse effects**

- a. With adrenergic bronchodilators, observe for tachycardia, dysrhythmias, palpitations, restlessness, agitation, insomnia.
- b. With ipratropium and tiotropium, observe for cough or exacerbation of symptoms.
- c. With xanthine bronchodilators, observe for tachycardia, dysrhythmias, palpitations, restlessness, agitation, insomnia, nausea, vomiting, convulsions.
- d. With inhaled corticosteroids, observe for hoarseness, cough, throat irritation, and fungal infection of mouth and throat.
- e. With cromolyn, observe for dysrhythmias, hypotension, chest pain, restlessness, dizziness, convulsions, CNS depression, anorexia, nausea and vomiting. Sedation and coma may occur with overdosage.

These signs and symptoms result from cardiac and central nervous system (CNS) stimulation.

Ipratropium and tiotropium produce few adverse effects because they are not absorbed systemically. Theophylline causes cardiac and CNS stimulation. Convulsions occur at toxic serum concentrations (>20 mcg/mL). They may occur without preceding symptoms of toxicity and may result in death. IV diazepam (Valium) may be used to control seizures. Theophylline also stimulates the chemoreceptor trigger zone in the medulla oblongata to cause nausea and vomiting.

Inhaled corticosteroids are unlikely to produce the serious adverse effects of long-term systemic therapy (see Chap. 23).

Some of the cardiovascular effects are thought to be caused by the propellants used in the aerosol preparation.

**4. Observe for drug interactions**

- a. Drugs that increase effects of bronchodilators:
  - (1) Monoamine oxidase inhibitors
  - (2) Erythromycin, clindamycin, cimetidine

These drugs inhibit the metabolism of catecholamines. The subsequent administration of bronchodilators may increase blood pressure.

These drugs may decrease theophylline clearance and thereby increase plasma levels.

(continued on page 728)

## Nursing Actions

Drugs for Asthma and Other  
Bronchoconstrictive Disorders (continued)

## NURSING ACTIONS

## RATIONALE/EXPLANATION

b. Drugs that decrease effects of bronchodilators:

- (1) Lithium
- (2) Phenobarbital
- (3) Propranolol, other nonselective beta blockers

Lithium may increase excretion of theophylline and therefore decrease therapeutic effectiveness.

This drug may increase the metabolism of theophylline by way of enzyme induction.

These drugs may cause bronchoconstriction and oppose effects of bronchodilators.

c. Drugs that alter effects of zafirlukast:

- (1) Aspirin
- (2) Erythromycin, theophylline

Increases blood levels

Decrease blood levels

## Key Concepts

- A specific monitoring plan for patients with asthma should be in place, whether through peak-flow or symptom monitoring.
- Two general classifications of drugs are used for asthma management: long-term control medications to achieve and maintain control of persistent asthma and quick relief medications used during periods of acute symptoms and exacerbations.
- Two major groups of drugs used to treat asthma, acute and chronic bronchitis, and emphysema are bronchodilators and anti-inflammatory drugs.
- A selective, short-acting, inhaled beta<sub>2</sub>-adrenergic agonist (e.g., albuterol) is the initial rescue drug of choice for acute bronchospasm; subcutaneous epinephrine may also be considered.
- Because aerosol products act directly on the airways, drugs given by inhalation can usually be given in smaller doses and produce fewer adverse effects than oral or parenteral drugs.
- Asthma may aggravate GERD, because antiasthma medications that dilate the airways also relax muscle tone in the gastroesophageal sphincter and may increase acid reflux.
- Almost all over-the-counter aerosol products promoted for use in asthma contain epinephrine, which may produce hazardous cardiac stimulation and other adverse effects.
- Cigarette smoking and drugs that stimulate drug-metabolizing enzymes in the liver (e.g., phenobarbital, phenytoin) increase the rate of metabolism and therefore dosage requirements of aminophylline.
- Due to the risk of anaphylaxis the FDA has issued a **BLACK BOX WARNING** for omalizumab.
- The FDA has issued a **BLACK BOX WARNING** that initiating salmeterol in individuals with significantly worsening or acutely deteriorating asthma may be life-threatening.

## Review and Application Exercises

## Short Answer Exercises

1. What are some causes of bronchoconstriction, and how can they be prevented or minimized?
2. How do beta-adrenergic agonists act as bronchodilators?
3. What adverse effects are associated with bronchodilators, and how can they be prevented or minimized?
4. For what effects are corticosteroids used in the treatment of bronchoconstrictive respiratory disorders?
5. How does cromolyn act to prevent acute asthma attacks?
6. What are the main elements of treating respiratory distress from acute bronchospasm?

### NCLEX-Style Questions

7. The nurse notes that a patient's serum theophylline level is 25 mcg/mL and that a scheduled dose of the medication is due. The nurse should
  - a. Hold the scheduled dose, contact the health care provider, and assess the patient for signs of theophylline toxicity.
  - b. Administer the dose as scheduled.
  - c. Administer only half of the dose and repeat the theophylline level in 4 hours.
  - d. Hold the dose until the next meal and administer at that time.
8. A patient, taking a short-acting inhaled bronchodilator and a steroid inhaler at the same scheduled time, asks the nurse if the order of administration of the inhalers matters. The best response by the nurse is
  - a. "You should not take both inhalers at the same time."
  - b. "The short-acting inhaled bronchodilator should be used first, followed by the steroid inhaler."
  - c. "Either medication can effectively be used first."
  - d. "The steroid inhaler should be used first, followed by the short-acting inhaled bronchodilator."
9. A patient on a steroid inhaler complains of anorexia and discomfort when he eats. The nurse reports this to the care provider, and the patient is diagnosed with oropharyngeal candidiasis. This is an adverse effect that can be decreased by all of the following except
  - a. reducing the dose
  - b. administering the drug more frequently
  - c. rinsing the mouth after use
  - d. using a spacer device
10. Montelukast is effective in relieving the inflammation and bronchoconstriction associated with acute asthmatic attacks through which principal action?
  - a. stabilizing mast cells
  - b. blocking leukotriene receptors
  - c. binding to immunoglobulin E (IgE)
  - d. decreasing prostaglandin synthesis

# Antihistamines and Allergic Disorders

## KEY TERMS

- Anaphylactic reactions
- Anaphylactoid reactions
- Anticholinergic effects
- Antihistamines
- Histamine
- Hypersensitivity
- Serum sickness

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Delineate effects of histamine on selected body tissues.
2. Describe the types of hypersensitivity or allergic reactions.
3. Discuss allergic rhinitis, allergic contact dermatitis, and drug allergies as conditions for which antihistamines are commonly used.
4. Identify the effects of histamine that are blocked by histamine<sub>1</sub> (H<sub>1</sub>) receptor antagonist drugs.
5. Differentiate first- and second-generation antihistamines.
6. Describe antihistamines in terms of indications for use, adverse effects, and nursing process implications.
7. Discuss the use of antihistamines in special populations.

## Applying Your Knowledge

Lakisha Whitehead, age 32, suffers from seasonal allergies. You work at a community health clinic. Ms. Whitehead comes to the clinic seeking your advice about what medication might provide relief of her symptoms of runny nose and eyes, nasal congestion, and productive cough.

## Introduction

*Antihistamines* are drugs that antagonize the action of histamine. Thus, to understand the use of these drugs, it is necessary to understand histamine and its effects on body tissues, characteristics of allergic reactions, and selected conditions for which antihistamines are used.

### Histamine and Its Receptors

*Histamine* is the first chemical mediator to be released in immune and inflammatory responses. It is synthesized and stored in most body tissues, with high concentrations in tissues exposed to environmental substances (e.g., the skin and mucosal surfaces of the eye, nose, lungs, and gastrointestinal [GI] tract). It is also found in the central nervous system (CNS). In these tissues, histamine is located mainly in secretory granules of mast cells (tissue cells surrounding capillaries) and basophils (circulating blood cells).

Histamine is discharged from mast cells and basophils in response to certain stimuli (e.g., allergic reactions, cellular injury, extreme cold). After it is released, it diffuses rapidly into other tissues, where it interacts with histamine receptors on target organs, called H<sub>1</sub> and H<sub>2</sub>. H<sub>1</sub> receptors are located mainly on smooth muscle cells in blood vessels and the respiratory and GI tracts. When histamine binds with these receptors and stimulates them, effects include

- Contraction of smooth muscle in the bronchi and bronchioles (producing bronchoconstriction and respiratory distress)
- Stimulation of vagus nerve endings to produce reflex bronchoconstriction and cough
- Increased permeability of veins and capillaries, which allows fluid to flow into subcutaneous tissues and form edema
- Increased secretion of mucous glands. Mucosal edema and increased nasal mucus produce the nasal congestion characteristic of allergic rhinitis and the common cold.
- Stimulation of sensory peripheral nerve endings to cause pain and pruritus. Pruritus is especially prominent with allergic skin disorders.
- Dilation of capillaries in the skin, to cause flushing

When  $H_2$  receptors are stimulated, the main effects are increased secretion of gastric acid and pepsin, increased rate and force of myocardial contraction, and decreased immunologic and proinflammatory reactions (e.g., decreased release of histamine from basophils, decreased movement of neutrophils and basophils into areas of injury, inhibited T- and B-lymphocyte function). Stimulation of both  $H_1$  and  $H_2$  receptors causes peripheral vasodilation (with hypotension, headache, and skin flushing) and increases bronchial, intestinal, and salivary secretion of mucus.

## Hypersensitivity (Allergic) Reactions

In predisposed individuals, harmless environmental antigens that do not cause a reaction in most people may trigger an adaptive immune response, immunologic memory, and, on subsequent exposure to the environmental antigen, inflammation responses (see Chap. 38). *Hypersensitivity*, or allergic, reactions are exaggerated responses by the immune system that produce tissue injury and may cause serious disease. The mechanisms that eliminate pathogens in adaptive immune responses are essentially identical to those of natural immunity. Allergic reactions may result from specific antibodies, sensitized T lymphocytes, or both, formed during exposure to an antigen. Treatments and interventions are covered in other chapters.

### Types of Responses to Cell-Mediated Invasion

Hypersensitivity reactions are grouped into four types according to the mechanisms by which they are produced. The substances that produce the effect for types I, II, and III hypersensitivity reactions are antibody molecules. The substances responsible for type IV reactions are antigen-specific T cells.

Type I (also called immediate hypersensitivity because it occurs within minutes of exposure to the antigen) is an immunoglobulin E (IgE)-induced response triggered by the interaction of antigen with antigen-specific IgE bound on mast cells, causing mast cell activation. Histamine and other mediators are released immediately, and cytokines, chemokines, and leukotrienes are synthesized after activation. Anaphylaxis is a type I response that may be mild (characterized mainly by

urticaria, other dermatologic manifestations, or rhinitis) or severe and life threatening (characterized by respiratory distress and cardiovascular collapse). It is uncommon and does not occur on first exposure to an antigen; it occurs with a second or later exposure, after antibody formation was induced by an earlier exposure. Severe anaphylaxis (sometimes called anaphylactic shock; see Chap. 51) is characterized by cardiovascular collapse from profound vasodilation and pooling of blood in the splanchnic system so that the patient has severe hypotension and functional hypovolemia. Respiratory distress often occurs from laryngeal edema and bronchoconstriction. Urticaria often occurs because the skin has many mast cells that release histamine. Anaphylaxis is a systemic reaction that usually involves the respiratory, cardiovascular, and dermatologic systems. Severe anaphylaxis may be fatal if not treated promptly and effectively.

Type II responses are mediated by IgG or IgM generating direct damage to the cell surface. These cytotoxic reactions include blood transfusion reactions, hemolytic disease of newborns, autoimmune hemolytic anemia, and some drug reactions. Hemolytic anemia (caused by destruction of erythrocytes) and thrombocytopenia (caused by destruction of platelets), both type II hypersensitivity responses, are adverse effects of certain drugs (e.g., penicillin, methyl dopa, heparin).

Type III is an IgG- or IgM-mediated reaction characterized by formation of antigen-antibody complexes that induce an acute inflammatory reaction in the tissues. *Serum sickness*, the prototype of these reactions, occurs when excess antigen combines with antibodies to form immune complexes. The complexes then diffuse into affected tissues, where they cause tissue damage by activating the complement system and initiating the immune response. If small amounts of immune complexes are deposited locally, the antigenic material can be phagocytized and digested by white blood cells and macrophages without tissue destruction. If large amounts are deposited locally or reach the bloodstream and become deposited in blood vessel walls, the lysosomal enzymes released during phagocytosis may cause permanent tissue destruction.

Type IV hypersensitivity (also called delayed hypersensitivity because of the lag time from exposure to antigen until the response is evident) is a cell-mediated response in which sensitized T lymphocytes react with an antigen to cause inflammation mediated by release of lymphokines, direct cytotoxicity, or both. The classic type IV hypersensitivity reaction is the tuberculin test, but similar reactions occur with contact dermatitis and some graft rejection.

### Allergic Rhinitis

Allergic rhinitis is inflammation of nasal mucosa caused by a type I hypersensitivity reaction to inhaled allergens. It is a very common disorder characterized by nasal congestion, itching, sneezing, and watery drainage. Itching of the throat, eyes, and ears often occurs as well.

There are two types of allergic rhinitis. Seasonal disease (often called hay fever) produces acute symptoms in response to the protein components of airborne pollens from trees, grasses, and weeds, mainly in spring or fall. Perennial disease

produces chronic symptoms in response to nonseasonal allergens such as dust mites, animal dander, and molds. Actually, mold spores can cause both seasonal and perennial allergies because they are present year round, with seasonal increases. Some people have both types, with chronic symptoms plus acute seasonal symptoms.

People with a personal or family history of other allergic disorders are likely to have allergic rhinitis. When nasal mucosa is inflamed, symptoms can be worsened by nonallergenic irritants such as tobacco smoke, strong odors, air pollution, and climatic changes.

Allergic rhinitis is an immune response in which normal nasal breathing and filtering of air brings inhaled antigens into contact with mast cells and basophils in nasal mucosa, blood vessels, and submucosal tissues. With initial exposure, the inhaled antigens are processed by lymphocytes that produce IgE, an antigen-specific antibody that binds to mast cells. With later exposures, the IgE interacts with inhaled antigens and triggers the breakdown of the mast cell. This breakdown causes the release of histamine and other inflammatory mediators such as prostaglandins and leukotrienes (Fig. 45-1). These

mediators, of which histamine may be the most important, dilate and engorge blood vessels to produce nasal congestion, stimulate secretion of mucus, and attract inflammatory cells (e.g., eosinophils, lymphocytes, monocytes, macrophages). In people with allergies, mast cells and basophils are increased in both number and reactivity. Thus, these cells may be capable of releasing large amounts of histamine and other mediators.

Allergic rhinitis that is not effectively treated may lead to chronic fatigue, impaired ability to perform usual activities of daily living, difficulty sleeping, sinus infections, postnasal drip, cough, and headache. In addition, this condition is a strong risk factor for asthma.

### Allergic Contact Dermatitis

Allergic contact dermatitis is a type IV hypersensitivity reaction resulting from direct contact with antigens to which a person has previously become sensitized (e.g., poison ivy or poison oak, cosmetics, hair dyes, metals, drugs applied topically to the skin). This reaction, which may be acute or chronic, usually occurs more than 24 hours after re-exposure to an antigen and may last from days to weeks.

**Figure 45-1** ■ Type I hypersensitivity reaction: allergic rhinitis. (A) The first exposure of mast cells in nasal mucosa to inhaled antigens (e.g., pollens from weeds, grasses, trees) leads to the formation of immunoglobulin E (IgE) antibody molecules. These molecules then bind to the surface membranes of mast cells. This process sensitizes mast cells to the effects of inhaled antigens (allergens). (B) When sensitized mast cells are re-exposed to inhaled pollens or other antigens, they release histamine and other chemical mediators, which then act on nasal mucosa to produce characteristic symptoms of allergic rhinitis.

Affected areas of the skin are usually inflamed, warm, edematous, intensely pruritic, and tender to touch. Skin lesions are usually erythematous macules, papules, and vesicles (blisters) that may drain, develop crusts, and become infected. Lesion location may indicate the causative antigen.

### Allergic Food Reactions

Typically, food allergies are an immune response to the ingestion of a protein. Some food allergens such as shellfish, fish, corn, seeds, bananas, egg, milk, soy, peanut, and tree nuts have a higher inherent risk for triggering anaphylaxis than others. However, many other foods have been identified as allergens, including certain fruits and vegetables. Commonly, children allergic to milk, eggs, wheat, or soy outgrow their allergy. Exclusive breast-feeding has been found to be protective against the development of food allergies in early life but to increase the risk of food allergies as the individual ages. There is no known preventive strategy to prevent food allergies except to delay introducing allergy-prone foods to infants until the gastrointestinal tract has had time to mature. The timing for this varies from food to food and from infant to infant. The most common food allergy among adults is shellfish, often first presenting later in life.

### Allergic Drug Reactions

Virtually any drug may induce an immunologic response in susceptible people, and any body tissues may be affected. Allergic drug reactions are complex and diverse and may include any of the types of hypersensitivity described previously. A single drug may induce one or more of these states and multiple symptoms. There are no specific characteristics that identify drug-related reactions, although some reactions commonly attributed to drugs (e.g., skin rashes, drug fever, hematologic reactions, hepatic reactions) rarely occur with plant pollens and other naturally occurring antigens. Usually, however, the body responds to a drug as it does to other foreign materials (antigens). In addition, some reactions may be caused by coloring agents, preservatives, and other additives rather than the drug itself. It may be difficult to recognize in an individual with atypical, resolving, or partially treated symptoms, as when skin signs such as urticaria are absent or masked by medications.

Allergic drug reactions should be considered when new signs and symptoms develop or when they differ from the usual manifestations of the illness being treated, especially if a reaction

- Follows ingestion of a drug, especially one known to produce allergic reactions
- Is unpredictable and occurs in only a few patients when many patients receive the suspected drug
- Occurs approximately 7 to 10 days after initial exposure to the suspected drug (to allow antibody production)
- Follows a previous exposure to the same or similar drug (sensitizing exposure)
- Occurs minutes or hours after a second or subsequent exposure

- Occurs after small doses (reduces the likelihood that the reaction is due to dose-related drug toxicity)
- Occurs with other drugs that are chemically or immunologically similar to the suspected drug
- Produces signs and symptoms that differ from the usual pharmacologic actions of the suspected drug
- Produces signs and symptoms usually considered allergic in nature (e.g., anaphylaxis, urticaria, serum sickness)
- Produces similar signs and symptoms to previous allergic reactions to the same or a similar drug
- Increases eosinophils in blood or tissue
- Resolves within a few days of discontinuing the suspected drug

Virtually all drugs have been implicated in *anaphylactic reactions*. Penicillins and other antimicrobials, radiocontrast media, aspirin and other nonsteroidal anti-inflammatory drugs, and antineoplastics such as L-asparaginase and cisplatin are more common offenders. Less common causes include anesthetics (local and general), opioid analgesics, skeletal muscle relaxants used with general anesthetics, and vaccines. Approximately 10% of severe anaphylactic reactions are fatal. In many cases, it is unknown whether clinical manifestations are immunologic or nonimmunologic in origin.

Serum sickness is a delayed hypersensitivity reaction most often caused by drugs, such as antimicrobials. In addition, many drugs that produce anaphylaxis also produce serum sickness. With initial exposure to the antigen, symptoms usually develop within 7 to 10 days and include urticaria, lymphadenopathy, myalgia, arthralgia, and fever. The reaction usually resolves within a few days but may be severe or even fatal. With repeated exposure to the antigen, after prior sensitization of the host, accelerated serum sickness may develop within 2 to 4 days, with similar but often more severe signs and symptoms.

Systemic lupus erythematosus (SLE) is an autoimmune disorder that may be idiopathic from nondrug causes or induced by hydralazine, procainamide, isoniazid, and other drugs. Clinical manifestations vary greatly, depending on the location and severity of the inflammatory and immune processes, and may include skin lesions, fever, pneumonia, anemia, arthralgia, arthritis, nephritis, and others. Drug-induced lupus produces less renal and CNS involvement than idiopathic SLE.

Fever often occurs with allergic drug reactions. It may occur alone, with a skin rash and eosinophilia, or with other drug-induced allergic reactions such as serum sickness, SLE, vasculitis, and hepatitis. Dermatologic conditions (e.g., skin rash, urticaria, inflammation) commonly occur with allergic drug reactions and may be the first and most visible manifestations.

### Pseudoallergic Drug Reactions

Pseudoallergic drug reactions resemble immune responses (because histamine and other chemical mediators are released), but they do not produce antibodies or sensitized T lymphocytes. *Anaphylactoid reactions* are like anaphylaxis in

terms of immediate occurrence, symptoms, and life-threatening severity. The main difference is that they are not antigen–antibody reactions and therefore may occur on first exposure to the causative agent. The drugs bind directly to mast cells, activate the cells, and cause the release of histamine and other vasoactive chemical mediators. Contrast media for radiologic diagnostic tests are often implicated.

## General Characteristics of Antihistamines

There are several classes of antihistamines: alkylamines (brompheniramine, chlorpheniramine, etc.), ethanolamines (carbinoxamine, clemastine, etc.), ethylenediamines (tripelenamine, pyrillamine), phenothiazines (methdilazine, promethazine, etc.), piperazines (cyclizine, hydroxyzine, etc.), piperidines (azatadine, cyproheptadine), and the miscellaneous

group. The term *antihistamine* generally indicates classic or traditional drugs. With increased knowledge about histamine receptors, these drugs are often called H<sub>1</sub> receptor antagonists. These drugs prevent or reduce most of the physiologic effects that histamine normally induces at H<sub>1</sub> receptor sites. Thus, they

- Inhibit smooth muscle constriction in blood vessels and the respiratory and GI tracts
- Decrease capillary permeability
- Decrease salivation and tear formation

The drugs are similar in effectiveness as histamine antagonists but differ in adverse effects. These are the antihistamines discussed in this chapter. Cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid) are H<sub>2</sub> receptor antagonists or blocking agents used to prevent or treat peptic ulcer disease. These are discussed in Chapter 59. Selected H<sub>1</sub> antagonists are described in the following sections and in Table 45-1.

Table 45-1

Drugs at a Glance: Commonly Used Antihistamines

GeneriC/Trade Name	Indications for use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>First Generation</b>			
<b>Brompheniramine</b> (LoHist)	Allergic rhinitis	1–2 tablets (6–12 mg) q12h	12 y and older: Same as adults. 6–12 y: 1 tablet (6 mg) q12h
<b>Chlorpheniramine</b> (Chlor-Trimeton)	Allergic rhinitis	PO 4 mg q4–6h; maximal dose, 24 mg in 24 h Timed-release forms, PO 8 mg q8–12h or 12 mg q12h; maximal dose, 24 mg in 24 h	12 y and older: Same as adults 6–12 y: PO 2 mg q4–6h; maximal dose, 12 mg in 24 h 2–6 y: PO 1 mg q4–6h Timed-release forms, ≥12 y: PO 8 mg q8–12h or 12 mg q12h; maximal dose, 24 mg in 24 h
<b>Clemastine</b> (Tavist)	Allergic rhinitis Urticaria/angioedema	Allergic rhinitis, PO 1.34 mg twice daily, increased up to a maximum of 8.04 mg daily, if necessary Urticaria/angioedema, PO 2.68 mg one to three times daily	Allergic rhinitis, 6–12 y (syrup only): PO 0.67 mg twice daily, increased up to a maximum of 4.02 mg daily, if necessary Urticaria/angioedema, 6–12 y (syrup only): PO 1.34 mg twice daily
<b>Cyproheptadine</b>	Hypersensitivity reactions (allergic rhinitis, conjunctivitis, dermatitis)	PO 4 mg q8h initially, increase if necessary. Maximal dose 0.5 mg/kg/d	(Calculate total daily dosage as 0.25 mg/kg or 8 mg/m <sup>2</sup> ) 7–14 y: PO 4 mg q8–12h; maximal dose, 16 mg/d 2–6 y: 2 mg q8–12h; maximal dose, 12 mg/d
<b>Dexchlorpheniramine</b>	Hypersensitivity reactions (allergic rhinitis, conjunctivitis, dermatitis)	Regular tablets and syrup, PO 2 mg q4–6h Timed-release tablets, PO 4–6 mg at bedtime or q8–12h	12 y and older: Same as adults 6–11 y: PO 1 mg q4–6h 2–5 y: PO 0.5 mg q4–6h Timed-release tablets, 12 y and older: Same as adults; 6–12 y: 4 mg once daily, at bedtime

(continued on page 736)

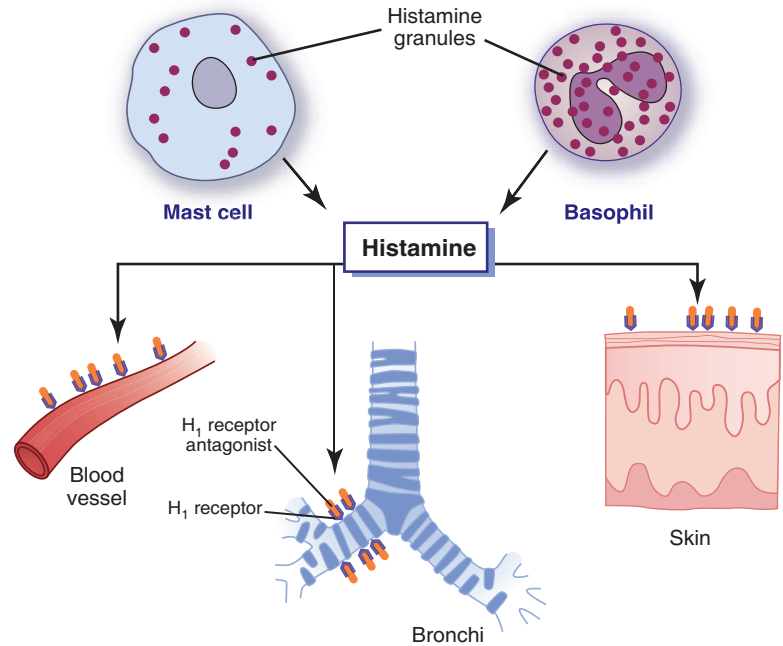

Table 45-1

**Drugs at a Glance: Commonly Used Antihistamines** (continued)

Generic/Trade Name	Indications for use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>P Diphenhydramine</b> (Benadryl)	Hypersensitivity reactions (allergic rhinitis, conjunctivitis, dermatitis) Motion sickness Parkinsonism Insomnia Antitussive (syrup only)	Hypersensitivity reaction, motion sickness, parkinsonism, PO 25–50 mg q4–8h; IV or deep IM 10–50 mg, increased if necessary to a maximal daily dose of 400 mg Insomnia, PO 50 mg at bedtime Syrup for cough, PO 25 mg (10 mL) q4h, not to exceed 100 mg (40 mL) in 24 h	Weight greater than 10 kg (22 lbs): PO 12.5–25 mg q6–8h, 5 mg/kg/d, or 150 mg/m <sup>2</sup> /d; IV 5 mg/kg/d, or 150 mg/m <sup>2</sup> /d. Maximum oral or parenteral dosage, 300 mg daily Insomnia, ≥12 y: Same as adults Syrup for cough, 6–12 y: PO 12.5 mg (5 mL) q4h, not to exceed 50 mg (20 mL) in 24 h; 2–6 y: PO 6.25 mg (2.5 mL) q4h, not to exceed 25 mg (10 mL) in 24 h
<b>Hydroxyzine</b> (Vistaril)	Pruritus Sedation Antiemetic	PO 25 mg q6–8h; IM 25–100 mg as needed	older than 6 y: PO 50–100 mg daily in divided doses under 6 y: PO 50 mg daily in divided doses
<b>Phenindamine</b> (Nolahist)	Allergic rhinitis	PO 25 mg q4–6h; maximal dose 150 mg in 24 h	12 y or older: Same as adults 6–11 y: PO 12.5 mg q4–6h; maximal dose 75 mg in 24 h
<b>Promethazine</b> (Phenergan)	Hypersensitivity reactions (allergic rhinitis, conjunctivitis, dermatitis) Sedation Antiemetic Motion sickness	PO, IM, rectally, 25 mg q4–6h as needed	2 y or older: 12.5 mg q4–6h as needed
<b>Tripolidine</b> (Zymine)	Allergic rhinitis	PO 10 mL (1.2 mg/5 mL) q4–6h, not to exceed 40 mL/24 h	12 y or older: Same as adults 6–12 y: 5 mL q4–6h, not to exceed 20 mL/24h 4–6 y: 3.75 mL q4–6h, not to exceed 15 mL/24h 2–4 y: 2.5 mL q4–6h, not to exceed 10 mL/24h 4 m–2 y: 1.25 mL q4–6h, not to exceed 5 mL/24h
<b>Second Generation</b>			
<b>Azelastine</b> (Astelin)	Allergic rhinitis	Nasal inhalation, two sprays per nostrils q12h	12 y or older: Same as adults
<b>Cetirizine</b> (Zyrtec)	Allergic rhinitis Chronic idiopathic urticaria	PO 5–10 mg once daily Renal or hepatic impairment, PO 5 mg once daily	6 y or older: Same as adults 6 mo–5y: PO 2.5 mg (one-half tsp) once daily
<b>Desloratadine</b> (Clarinex)	Allergic rhinitis Chronic idiopathic urticaria	5 mg once daily	12 y or older: Same as adults 12 y or younger: Dosage not established
<b>Fexofenadine</b> (Allegra)	Allergic rhinitis	PO 60 mg twice daily Renal impairment, PO 60 mg once daily	12 y or older: Same as adults 6–11 y: PO 30 mg twice daily
<b>Loratadine</b> (Claritin)	Allergic rhinitis Chronic idiopathic urticaria	PO 10 mg once daily Renal or hepatic impairment, PO 10 mg every other day	6 y or older: Same as adults 2–5 y: PO 5 mg daily

**Figure 45-2** ■ Action of antihistamine drugs. Histamine<sub>1</sub> (H<sub>1</sub>) receptor antagonists bind to H<sub>1</sub> receptors. This prevents histamine from binding to its receptors and acting on target tissues.

### Mechanism of Action

Antihistamines are structurally related to histamine and occupy the same receptor sites as histamine, which prevents histamine from acting on target tissues (Fig. 45-2). Thus, the drugs are effective in inhibiting vascular permeability, edema formation, bronchoconstriction, and pruritus associated with histamine release. They do not prevent histamine release or reduce the amount released.

### Indications for Use

Antihistamines are used for a variety of allergic and nonallergic disorders to prevent or reverse target organ inflammation and its effects on organ function. The drugs can relieve symptoms but do not relieve the hypersensitivity.

- Allergic rhinitis. Of people with seasonal allergic rhinitis, 75% to 95% experience some relief of sneezing, rhinorrhea, nasal congestion, and conjunctivitis with the use of antihistamines. People with perennial allergic rhinitis usually experience decreased nasal congestion and drying of nasal mucosa. However, many people require an additional drug to relieve symptoms. Cromolyn, ipratropium, and several corticosteroids are available in intranasal preparations for this purpose. These drugs, with dosage ranges for adults and children, are listed in Table 45-2.
- Anaphylaxis. Antihistamines are helpful in treating urticaria and pruritus but are not effective in treating bronchoconstriction and hypotension. Epinephrine, rather than an antihistamine, is the drug of choice for treating severe anaphylaxis.
- Allergic conjunctivitis. This condition, which is characterized by redness, itching, and tearing of the eyes, is often associated with allergic rhinitis. Antihistamine eye medications may be given (see Chap. 63).

- Drug allergies and pseudoallergies. Antihistamines may be given to prevent or treat reactions to drugs. When used for prevention, they should be given before exposure (e.g., before a diagnostic test that uses an iodine preparation as a contrast medium, before an intravenous infusion of amphotericin B). When antihistamines are used for treatment, giving the antihistamine and stopping the causative drug usually relieve signs and symptoms within a few days.
- Transfusions of blood and blood products. Premedication with an antihistamine is often used to prevent allergic reactions.
- Dermatologic conditions. Antihistamines are the drugs of choice for treatment of allergic contact dermatitis and acute urticaria (a vascular reaction of the skin characterized by papules or wheals and severe itching, often called hives). Urticaria often occurs because the skin has many mast cells to release histamine. Other indications for use include drug-induced skin reactions, pruritus ani, and pruritus vulvae. Systemic drugs are used; topical preparations are not recommended because they often induce skin rashes themselves. With pruritus, oral cyproheptadine and hydroxyzine (Vistaril) are especially effective.
- Miscellaneous. Some antihistamines are commonly used for nonallergic disorders, such as motion sickness, nausea and vomiting (e.g., promethazine, hydroxyzine; see Chap. 62), and sleep (e.g., diphenhydramine). The active ingredient in over-the-counter (OTC) sleep aids (e.g., Compoz, Sominex) is a sedating antihistamine. Antihistamines are also common ingredients in OTC cold remedies (see Chap. 46).

### Contraindications to Use

Antihistamines are contraindicated or must be used with caution in pregnant women and patients with hypersensitivity to

Table 45-2

## Drugs at a Glance: Intranasal Drugs for Allergic Rhinitis

GeneriC/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Anticholinergic</b>		
<b>Ipratropium</b> (Atrovent nasal spray)	2 sprays (42 mcg or 84 mcg) per nostril 2–4 times daily	12 y and older: Same as adults
<b>Corticosteroids</b>		
<b>Beclomethasone</b> (Beconase)	1 inhalation (42 mcg) in each nostril 2–4 times daily	12 y and older: Same as adults 6–12 y: 1 inhalation in each nostril 3 times daily
<b>Budesonide</b> (Rhinocort)	256 mcg daily as 2 sprays per nostril twice daily or 4 sprays per nostril once daily	6 y and older: Same as adults
<b>Flunisolide</b> (Nasalide, Nasarel)	2 sprays (50 mcg) in each nostril 2 times daily, increase to 3 times daily if necessary	6–14 y: 1 spray (25 mcg) in each nostril 3 times daily or 2 sprays per nostril (50 mcg) 2 times daily
<b>Fluticasone</b> (Flonase)	2 sprays (50 mcg each) per nostril once daily (200 mcg daily)	4 y and older: 1 spray per nostril per day (100 mcg daily)
<b>Mometasone</b> (Nasonex)	2 sprays (50 mcg each) per nostril once daily (200 mcg daily)	12 y and older: Same as adults 3–11 y: 1 spray per nostril once daily (100 mcg daily)
<b>Triamcinolone</b> (Nasacort, Nasacort AQ)	2 sprays (55 mcg/spray) in each nostril once daily	6 y and older: Same as adults initially, then reduce to 1 spray per nostril per day
<b>Mast Cell Stabilizer</b>		
<b>Cromolyn</b> (Nasal crom)	1 spray in each nostril 3–6 times daily, q4–6h	6 y and older: Same as adults

the drugs, narrow-angle glaucoma, prostatic hypertrophy, stenosing peptic ulcer, and bladder neck obstruction.

## Classifications and Individual Drugs

### First-Generation H<sub>1</sub> Receptor Antagonists

These chemically diverse antihistamines (also called nonselective or sedating agents) bind to both central and peripheral H<sub>1</sub> receptors and can cause CNS depression or stimulation. They usually cause CNS depression (drowsiness, sedation) with therapeutic doses and may cause CNS stimulation (anxiety, agitation) with excessive doses, especially in children. They also have substantial *anticholinergic effects* (e.g., cause dry mouth, urinary retention, constipation, blurred vision).

**Brompheniramine**, **chlorpheniramine** (Chlor-Trimeton), and **dexchlorpheniramine** cause minimal drowsiness. **P Diphenhydramine** (Benadryl), the prototype of first-generation antihistamines, causes a high incidence of drowsiness and anticholinergic effects. **Hydroxyzine** (Vistaril) and **promethazine** (Phenergan) are strong CNS depressants and cause extensive drowsiness.

First-generation antihistamines are usually well absorbed after oral administration. Immediate-release oral forms act within 15 to 60 minutes and last 4 to 6 hours. Enteric-coated or sustained-release preparations last 8 to 12 hours. Most drugs are given orally; a few may be given parenterally. These drugs are primarily metabolized by the liver, with metabolites and small amounts of unchanged drug excreted in urine within 24 hours. Several of these drugs are available without prescription. Brompheniramine, chlorpheniramine, and diphenhydramine are available alone and in combination with adrenergic nasal decongestants, analgesics, and allergy, cold, and sinus remedies.

### Second-Generation H<sub>1</sub> Receptor Antagonists

Second-generation H<sub>1</sub> antagonists (also called selective or non-sedating agents) were developed mainly to produce less sedation than the first-generation drugs. They cause less CNS depression because they are selective for peripheral H<sub>1</sub> receptors and do not cross the blood–brain barrier. Loratadine (Claritin) and cetirizine (Zyrtec) are available for OTC sales. Proponents of OTC availability usually argue that the drugs are safer than the first-generation drugs that have been available OTC for many years.

**Azelastine** (Astelin) is the only antihistamine formulated as a nasal spray for topical use. When applied to nasal mucosa,

it produces peak levels in 2 to 3 hours and lasts 12 to 24 hours. It is metabolized in the liver to an active metabolite and is excreted mainly in feces. The other drugs are well absorbed with oral administration and have a rapid onset of action. **Cetirizine** (Zyrtec) is an active metabolite of hydroxyzine that causes less drowsiness than hydroxyzine. It reaches maximal serum concentration in 1 hour and is about 93% protein bound. About half of a dose is metabolized in the liver; the other half is excreted unchanged in the urine. **Fexofenadine** (Allegra) reaches peak serum concentrations in about 2.5 hours, is 60% to 70% protein bound, and 95% is excreted unchanged in bile and urine. **Loratadine** (Claritin) effects occur within 1 to 3 hours, reach a maximum in 8 to 12 hours, and last 24 hours or longer. Loratadine is metabolized in the liver and its long duration of action is due, in part, to an active metabolite. The patent for loratadine expired in December 2002, clearing the way for generic formulations. **Desloratadine** (Clarinex), an active metabolite of loratadine and marketed by the manufacturer of Claritin, seems to offer no advantage over loratadine or other second-generation drugs.

## Nursing Process

### Assessment

- Assess the patient's condition in relation to disorders for which antihistamines are used. For the patient with known allergies, try to determine the factors that precipitate or relieve allergic reactions and specific signs and symptoms experienced during a reaction.
- Assess every patient for a potential hypersensitivity reaction. For example, it is standard practice on first contact to ask a patient if he or she has any food, drug, or other allergies. The health care provider is likely to get more complete information by asking patients about allergic reactions to specific drugs (e.g., antibiotics such as penicillin, local anesthetics) rather than asking if they are allergic to or cannot take any drugs.

If a drug allergy is identified, ask about specific signs and symptoms as well as any drugs currently being taken. With previous exposure and sensitization to the same or a similar drug, immediate allergic reactions may occur. With a new drug, antibody formation and allergic reactions usually require a week or longer. Most reactions appear within a month of starting a drug.

When a suspected allergic reaction occurs (e.g., skin rash, fever, edema, dyspnea), interview the patient or consult medical records about the drug, dose, route, and time of administration. In addition, evaluate all the drugs a patient is taking as a potential cause of the reaction. This assessment may involve searching drug literature to see if the suspected drug is associated with allergic reactions, and discussion with physicians and pharmacists.

## Nursing Diagnoses

- Risk for Injury related to drowsiness with first-generation antihistamines
- Deficient Knowledge: Safe and accurate drug use
- Deficient Knowledge: Strategies for minimizing exposure to allergens and irritants

## Planning/Goals

### The patient will

- Experience relief of symptoms
- Take antihistamines accurately
- Avoid hazardous activities if sedated from antihistamines
- Avoid preventable adverse drug effects
- Avoid taking sedative-type antihistamines with alcohol or other sedative drugs

## Interventions

- For patient's with known allergies, assist in identifying and avoiding precipitating factors when possible. If it is a drug allergy, encourage the patient to carry a medical alert device that identifies the drug.
- Monitor the patient closely for excessive drowsiness during the first few days of therapy with antihistamines known to cause sedation.
- Encourage a fluid intake of 2000 to 3000 mL daily, if not contraindicated.
- Because antihistamines are most effective before exposure to the stimulus that causes histamine release, assist patient's in learning when to take the drugs (e.g., during seasons of high pollen and mold counts).
- When indicated, obtain an order and administer an antihistamine before situations known to elicit allergic reactions (e.g., blood transfusions, diagnostic tests that involve contrast media).
- For patients who have experienced an allergic or pseudoallergic drug reaction, assist them in learning about the drug thought responsible (including the generic and commonly used trade names), suitable alternatives for future drug therapy, and potential sources of the drug.
- For children with allergies, provide all family members, daycare, and school with an emergency plan.
- Provide appropriate patient teaching regarding any drug therapy (see accompanying display).

## Evaluation

- Observe for relief of symptoms.
- Interview and observe for correct drug usage.
- Interview and observe for excessive drowsiness.

## Applying Your Knowledge 45-1

Ms. Whitehead starts taking OTC loratadine. What patient teaching points are appropriate?

## Principles of Therapy

### Prevention of Histamine-Releasing Reactions

When possible, avoiding exposure to known allergens can prevent allergic reactions. If antihistamine therapy is required, it is more effective if started before exposure to allergens because the drugs can then occupy receptor sites before histamine is released.

### Drug Selection

- Choosing an antihistamine is based on the desired effect, duration of action, adverse effects, and other characteristics

of available drugs. For most people, a second-generation drug is the first drug of choice. However, they are quite expensive. If costs are prohibitive for a patient, a first-generation drug may be used with minimal daytime sedation if taken at bedtime or in low initial doses, with gradual increases over a week or two. Azelastine nasal spray also causes little sedation, but it leaves an unpleasant taste. Overall, safety should be the determining factor. Some studies have shown cognitive and performance impairment with the first-generation drugs even when the person does not feel drowsy or impaired.

- For treatment of acute allergic reactions, a rapid-acting agent of short duration is preferred.
- For chronic allergic symptoms (e.g., allergic rhinitis), long-acting preparations provide more consistent relief. A patient may respond better to one antihistamine than to another. Thus, if one does not relieve symptoms or produces excessive sedation, another may be effective.
- For treatment of the common cold, studies have demonstrated that antihistamines do not relieve symptoms and are

## Patient Teaching Guidelines

## Antihistamines

### General Considerations

- Some antihistamines should not be taken by people with glaucoma, peptic ulcer, urinary retention, or pregnancy. Inform your physician if you have any of these conditions or, for over-the-counter (OTC) antihistamines, read the label to see if you should avoid a particular drug.
- Antihistamines may dry and thicken respiratory tract secretions and make them more difficult to remove. Thus, do not take diphenhydramine (Benadryl), which is available OTC, if you have active asthma, bronchitis, or pneumonia.
- Some antihistamines cause drowsiness or dizziness and impair mental alertness, judgment, and physical coordination, especially during the first few days. Do not smoke, drive a car, operate machinery, or perform other tasks requiring alertness and physical dexterity until drowsiness has worn off, to avoid injury.
- Avoid using sedating antihistamines with other sedative-type drugs (e.g., alcohol, medications to relieve nervousness or produce sleep), to avoid adverse effects and dangerous drug interactions. Alcohol and other drugs that depress brain function may cause excessive sedation, respiratory depression, and death.
- Do not take more than one antihistamine at a time (e.g., two prescription drugs, two OTC drugs, or a combination of prescription and OTC drugs) because adverse effects are likely. If you do not know whether a particular medication is an antihistamine, consult a health care provider. For example, many OTC cold remedies and “nighttime” or “PM” allergy or sinus preparations contain an antihistamine. In addition, the active ingredient in OTC sleep aids is a sedating antihistamine, usually diphenhydramine (Benadryl).

- Avoid prolonged exposure to sunlight and use sunscreens and protective clothing; some antihistamines may increase sensitivity to sunlight and risks of skin damage from sunburn.
- Report adverse effects, such as excessive drowsiness. The physician may be able to change drugs or dosages to decrease adverse effects.
- Store antihistamines out of reach of children to avoid accidental ingestion.
- If you experience an allergic reaction to a medication, obtain information about the drug thought responsible (including its various names), acceptable alternatives for future drug therapy, and potential sources of the drug. In addition, read the list of ingredients on labels of OTC drug preparations, inform all health care providers about the drug reaction before taking any newly prescribed drug, and wear a medical alert device that lists drugs to be avoided. Note that people may be allergic to additives (e.g., dyes, binders, others) rather than the active drug.

### Self-Administration

- Take antihistamines only as prescribed or as instructed on packages of OTC preparations to increase beneficial effects and decrease adverse effects. If you miss a dose, do not take a double dose.
- Take most antihistamines with meals to decrease stomach upset. Take loratadine (Claritin) on an empty stomach for better absorption; cetirizine (Zyrtec) and desloratadine (Clarinex) may be taken with or without food.
- Do not chew or crush sustained-release tablets and do not open sustained-release capsules. Such actions can cause rapid drug absorption, high blood levels, and serious adverse effects, rather than the slow absorption and prolonged action intended with these products.

not recommended. However, an antihistamine is often included in prescription and OTC combination products for the common cold.

### Applying Your Knowledge 45-2

Ms. Whitehead returns to the clinic. She states, “The medication makes me feel better, but it is so expensive. I have a hard time affording it.” What advice can you offer?

## Use in Special Populations

### Use in Children

First-generation antihistamines (e.g., diphenhydramine) may cause drowsiness and decreased mental alertness in children as in adults. Young children may experience paradoxical excitement. These reactions may occur with therapeutic dosages. In overdosage, hallucinations, convulsions, and death may occur. Close supervision and appropriate dosages are required for safe drug usage in children.

Diphenhydramine is not recommended for use in newborn infants (premature or full-term) or children with chickenpox or a flu-like infection. When used in young children, doses should be small because of drug effects on the brain and nervous system. Promethazine should not be used in children with hepatic disease, Reye’s syndrome, a history of sleep apnea, or a family history of sudden infant death syndrome.

The second-generation drugs vary in recommendations for use according to age groups. Cetirizine and loratadine may be used in children 2 years and older. Syrup formulations are available for use in younger children. Azelastine may be used in children 5 years and older, fexofenadine may be used in children 6 years of age and older, and desloratadine may be used in children 12 years and older.

### Applying Your Knowledge 45-3

#### How Can You Avoid This Medication Error?

During her visit, Ms. Whitehead tells you that her 18-month-old daughter has a cold. Last night, she gave her daughter a dose of the loratadine to relieve her symptoms and help the child get some rest.

### Use in Older Adults

First-generation antihistamines (e.g., diphenhydramine) may cause confusion (with impaired thinking, judgment, and memory), dizziness, hypotension, sedation, syncope, unsteady gait, and paradoxical CNS stimulation in older adults. These effects, especially sedation, may be misinterpreted as senility or mental depression. Older men with prostatic hypertrophy may have difficulty voiding while taking these drugs. Some of these adverse reactions derive from anticholinergic effects of the drugs and are likely to be more severe if the patient is also tak-

ing other drugs with anticholinergic effects (e.g., tricyclic antidepressants, older antipsychotic drugs, some antiparkinson drugs). Despite the increased risk of adverse effects, however, diphenhydramine is sometimes prescribed as a sleep aid for occasional use in older adults. As with many other drugs, smaller-than-usual dosages are indicated.

In general, second-generation antihistamines should be used for older adults. They are much safer because they do not impair consciousness, thinking, or ability to perform activities of daily living (e.g., driving a car or operating various machines).

### Use in Patients With Renal Impairment

Little information is available about using antihistamines in patients with impaired renal function. With diphenhydramine, the dosing interval should be extended to 12 to 18 hours in patients with severe kidney failure. With cetirizine (5 mg once daily), desloratadine (5 mg every other day), fexofenadine (60 mg once daily), and loratadine (10 mg every other day), recommended doses for initial use are approximately one half of those used for young and middle-aged adults. No data are available regarding use of azelastine. However, because the drug is metabolized in the liver and excreted mainly in feces, it is unlikely that a dosage reduction is needed in patients with renal impairment.

### Use in Patients With Hepatic Impairment

Little information is available about using antihistamines in patients with impaired hepatic function. With diphenhydramine, single doses are probably safe, but the effects of multiple doses have not been studied in this population. With promethazine, cholestatic jaundice has been reported, and the drug should be used with caution. With cetirizine (5 mg once daily) and loratadine (10 mg every other day), smaller-than-usual doses are recommended. No data are available regarding use of azelastine. However, because the drug is metabolized in the liver and excreted mainly in feces, cautious use and a possible dosage reduction may be needed in patients with hepatic impairment.

### Use in Patients With Critical Illness

Antihistamines are not often used in the treatment of patients with critical illness. Most are given orally, and many critically ill patients are unable to take oral drugs. Diphenhydramine may be given by injection, usually as a single dose, to a patient who is having a blood transfusion or a diagnostic test to prevent allergic reactions. Hydroxyzine or promethazine may be given by injection for nausea and vomiting or to provide sedation but are not usually the first drugs of choice for these indications.

### Use in Home Care

Antihistamines are often taken in the home setting, especially for allergic rhinitis and other allergic disorders. Most people are familiar with the uses and side effects of antihistamines. The home care nurse is unlikely to be involved in antihistamine drug therapy unless visiting a patient for other care and purposes. If a first-generation drug is being used, the home care nurse needs to assess for drowsiness and safety hazards in the

environment (e.g., operating a car or other potentially hazardous machinery). In most people, tolerance develops to the sedative effects within a few days if they are not taking other sedative-type drugs or alcoholic beverages.

If a patient has an allergic disorder, the home care nurse may need to assist in identifying and alleviating environmental allergens (e.g., cigarette smoke, animal dander, dust mites).

## Nursing Actions Antihistamines

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give most oral antihistamines with food; give loratadine on an empty stomach; give cetirizine or desloratadine with or without food.
- b. Give intramuscular antihistamines deeply into a large muscle mass.
- c. Inject intravenous (IV) antihistamines slowly, over a few minutes.
- d. When a drug is used to prevent motion sickness, give it 30–60 minutes before travel.

#### 2. Observe for therapeutic effects

- a. A verbal statement of therapeutic effect (relief of symptoms)
- b. Decreased nausea and vomiting when given for antiemetic effects
- c. Decreased dizziness and nausea when taken for motion sickness
- d. Drowsiness or sleep when given for sedation

#### 3. Observe for adverse effects

- a. First-generation drugs
  - (1) Sedation
  - (2) Paradoxical excitation—restlessness, insomnia, tremors, nervousness, palpitations
  - (3) Convulsive seizures
  - (4) Dryness of mouth, nose, and throat; blurred vision; urinary retention; constipation
  - (5) GI distress—anorexia, nausea, vomiting
- b. Second-generation drugs
  - (1) Drowsiness
  - (2) Dry mouth
  - (3) Fatigue
  - (4) Headache
  - (5) GI upset

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of first-generation antihistamines:
  - (1) Alcohol and other CNS depressants (e.g., antianxiety and antipsychotic agents, opioid analgesics, sedative-hypnotics)
  - (2) Monoamine oxidase inhibitors
  - (3) Tricyclic antidepressants
- b. Drugs that *increase* effects of loratadine:
  - (1) Macrolide antibacterials (azithromycin, clarithromycin, erythromycin)
  - (2) Azole antifungals (fluconazole, itraconazole, ketoconazole, miconazole)
  - (3) Cimetidine
- c. Drugs that may *decrease* effects of fexofenadine:
  - (1) Rifampin

### RATIONALE/EXPLANATION

To decrease gastrointestinal (GI) effects of the drugs

To decrease tissue irritation

Severe hypotension may result from rapid IV injection.

Therapeutic effects depend on the reason for use.

Drowsiness due to central nervous system (CNS) depression is the most common adverse effect.

This reaction is more likely to occur in children. It may result from the anticholinergic effects of antihistamines.

Antihistamines, particularly the phenothiazines, may lower the seizure threshold.

Due to anticholinergic effects

Adverse effects are few and mild.

Drowsiness and dry mouth are more likely to occur with cetirizine; headache is more likely to occur with loratadine; desloratadine and fexofenadine reportedly produce minimal adverse effects.

Note: No documented drug interactions have been reported with intranasal azelastine or oral cetirizine or desloratadine.

Additive CNS depression. Concomitant use may lead to drowsiness, lethargy, stupor, respiratory depression, coma, and death.

Inhibit metabolism of antihistamines, leading to an increased duration of action; increased incidence and severity of sedative and anticholinergic adverse effects.

Additive anticholinergic side effects

All of these drugs increase plasma levels of loratadine by decreasing its metabolism.

Rifampin may induce enzymes that accelerate metabolism of fexofenadine.

## Key Concepts

- Virtually any drug may induce an immunologic response in susceptible people, and any body tissues may be affected
- Allergic rhinitis is inflammation of nasal mucosa caused by a type I hypersensitivity reaction to inhaled allergens.
- Some food allergens such as shellfish, egg, milk, peanuts, and tree nuts have a higher inherent risk for triggering anaphylaxis than others.
- First-generation antihistamines (e.g., diphenhydramine) may cause drowsiness and decreased mental alertness in children as in adults.
- First-generation antihistamines have substantial anticholinergic effects (e.g., cause dry mouth, urinary retention, constipation, blurred vision).
- Second-generation H<sub>1</sub> antagonists cause less CNS depression because they are selective for peripheral H<sub>1</sub> receptors and do not cross the blood–brain barrier.
- Azelastine (Astelin) is the only antihistamine formulated as a nasal spray for topical use.
- Patients with drug allergies should wear a medical alert bracelet identifying the drug.
- For children with allergies, provide all family members, daycare, and school with an emergency plan.

## Review and Application Exercises

### Short Answer Exercises

1. Describe several factors that cause histamine release from cells.
2. What signs and symptoms are produced by the release of histamine?
3. How do antihistamines act to block the effects of histamine?
4. Differentiate between H<sub>1</sub> and H<sub>2</sub> receptor antagonists in terms of pharmacologic effects and clinical indications for use.
5. In general, when should an antihistamine be taken to prevent or treat allergic disorders?
6. Compare and contrast the first- and second-generation antihistamines.

### NCLEX-Style Questions

7. In explaining options for antihistamine medications to a patient, the nurse knows that second-generation H<sub>1</sub> antagonists differ from first-generation antagonists in that they
  - a. cause greater CNS sedation
  - b. are available only by prescription
  - c. are less expensive
  - d. do not cross the blood–brain barrier
8. Your patient has asked for an antihistamine to relieve his symptoms of an upper respiratory infection. You explain to him that studies have demonstrated that for treatment of the common cold, antihistamines
  - a. are effective in relieving cold symptoms
  - b. do not relieve symptoms and are not recommended
  - c. should be compounded with other products to be effective
  - d. relieve nonallergenic symptoms only
9. The nurse in the emergency room anticipates an order of a severe allergic reaction with anaphylaxis, knowing that the drug of choice for severe allergic reactions with anaphylaxis is
  - a. atropine
  - b. cimetidine (Tagamet)
  - c. epinephrine
  - d. loratadine (Claritin)
10. The nurse who receives an order to administer diphenhydramine (Benadryl) knows that this medication is recommended for use in
  - a. premature or full-term infants
  - b. adults to prevent allergic reactions
  - c. children with chickenpox
  - d. children with a flu-like infection
11. Due to the action of antihistamines on target tissues, these drugs are effective in producing all of the following actions except
  - a. inhibiting vascular permeability
  - b. reducing pruritus
  - c. minimizing edema formation
  - d. preventing histamine release

# Nasal Decongestants, Antitussives, and Cold Remedies

## KEY TERMS

- Antitussive
- Decongestants
- Expectorants
- Mucolytics
- Rhinitis
- Rhinorrhea
- Sinusitis

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe characteristics of selected upper respiratory disorders and symptoms.
2. Review decongestant and adverse effects of adrenergic drugs.
3. Describe general characteristics and effects of antitussive agents.
4. Discuss the advantages and disadvantages of using combination products to treat the common cold.
5. Evaluate over-the-counter allergy, cold, cough, and sinus remedies for personal or patients' use.
6. Use the nursing process in the care of individuals with the common cold.

## Applying Your Knowledge

Archie Hobbs is a 45-year-old welder at an industrial plant. As the occupational nurse for the facility, you observe a high rate of people with colds. Archie comes to the health office complaining about his nasal congestion and cough.

## Introduction

The drugs discussed in this chapter are used to treat upper respiratory disorders and symptoms such as the common cold, sinusitis, nasal congestion, cough, and excessive secretions. Some of these diverse drugs are discussed more extensively in other chapters; they are discussed here in relation to their use in upper respiratory conditions.

## Common Respiratory Disorders

### The Common Cold

The common cold, a viral infection of the upper respiratory tract, is the most common respiratory tract infection. Adults usually have two to four colds per year; schoolchildren may have as many as 10 annually. Colds can be caused by many types of virus, most often the rhinovirus. Shedding of these viruses by infected people, mainly from nasal mucosa, can result in rapid spread to other people.

The viruses can enter the body through mucous membranes. Cold viruses can survive for several hours on the skin and hard surfaces, such as wood and plastic. There may also be airborne

spread from sneezing and coughing, but this source is considered secondary. After the viruses gain entry, the incubation period is generally 5 days, the most contagious period is about 3 days after symptoms begin, and the cold usually lasts near 7 days. Because of the way cold viruses are spread, frequent and thorough hand hygiene (by both infected and uninfected people) is the most important protective and preventive measure. The tendency for overmedication and inappropriate use of antibiotics with the common cold are widespread and pose significant risk for complications and drug resistance.

### Sinusitis

*Sinusitis* is inflammation of the paranasal sinuses, air cells that connect with the nasal cavity and are lined by similar mucosa. As in other parts of the respiratory tract, ciliated mucous membranes help move fluid and microorganisms out of the sinuses and into the nasal cavity. This movement becomes impaired when sinus openings are blocked by nasal swelling, and the impairment is considered a major cause of sinus infections. Another contributing factor is a lower oxygen content in the sinuses, which aids the growth of microorganisms and impairs local defense mechanisms. *Rhinitis* (inflammation and congestion of nasal mucosa) and upper respiratory tract infections are the most common causes of sinusitis. Symptoms may include moderate to severe headache, tenderness or pain in the affected sinus area, and fever.

### Applying Your Knowledge 46-1

Mr. Hobbs works in an area with many other people. What should you emphasize to help prevent the further spread of infection throughout the plant?

.....

## Common Signs and Symptoms of Respiratory Disorders

### Nasal Congestion

Nasal congestion is manifested by obstructed nasal passages (“stuffy nose”) and nasal drainage (“runny nose”). It is a prominent symptom of the common cold and rhinitis (including allergic rhinitis; see Chap. 45). Nasal congestion results from dilation of the blood vessels in the nasal mucosa and engorgement of the mucous membranes with blood. At the same time, nasal membranes are stimulated to increase mucus secretion. Related symptomatic terms are *rhinorrhea* (secretions discharged from the nose) and rhinitis (inflammation of nasal mucosa, usually accompanied by nasal congestion, rhinorrhea, and sneezing).

### Cough

Cough is a forceful expulsion of air from the lungs. It is normally a protective reflex for removing foreign bodies, environmental irritants, or accumulated secretions from the respiratory tract. The cough reflex involves central and peripheral mechanisms. Centrally, the cough center in the medulla oblongata

receives stimuli and initiates the reflex response (deep inspiration, closed glottis, buildup of pressure within the lungs, and forceful exhalation). Peripherally, cough receptors in the pharynx, larynx, trachea, or lungs may be stimulated by air, dryness of mucous membranes, or excessive secretions. A cough is productive when secretions are expectorated; it is nonproductive when it is dry and no sputum is expectorated.

Cough is a prominent symptom of respiratory tract infections (e.g., the common cold, influenza, bronchitis, pharyngitis) and chronic obstructive pulmonary diseases (e.g., emphysema, chronic bronchitis).

### Increased Secretions

Increased secretions may result from excessive production or decreased ability to cough or otherwise remove secretions from the respiratory tract. Secretions may seriously impair respiration by obstructing airways and preventing air flow to and from alveoli, where gas exchange occurs. Secretions also may cause atelectasis (a condition in which part of the lung is airless and collapses) by blocking airflow, and they may cause or aggravate infections by supporting bacterial growth.

Respiratory disorders characterized by retention of secretions include influenza, pneumonia, upper respiratory infections, acute and chronic bronchitis, emphysema, and acute attacks of asthma. Nonrespiratory conditions that predispose to secretion retention include immobility, debilitation, cigarette smoking, and postoperative status. Surgical procedures involving the chest or abdomen are most likely to be associated with retention of secretions because pain may decrease the patient's ability to cough, breathe deeply, and ambulate.

## General Characteristics Of Drugs Used In/For Respiratory Disorders

Numerous drugs are available and widely used to treat the symptoms of respiratory disorders. Many are nonprescription drugs and can be obtained alone or in combination products. Available products include nasal decongestants, antitussives, and expectorants.

### Nasal Decongestants

Nasal *decongestants* are used to relieve nasal obstruction and discharge. Adrenergic (sympathomimetic) drugs are most often used for this purpose (see Chap. 17). These agents relieve nasal congestion and swelling by constricting arterioles and reducing blood flow to nasal mucosa. Oxymetazoline (Afrin) is a commonly used nasal spray; pseudoephedrine (Sudafed) is taken orally. Rebound nasal swelling can occur with excessive or extended use of nasal sprays.

Nasal decongestants are most often used to relieve rhinitis associated with respiratory infections or allergies. They also may be used to reduce local blood flow before nasal surgery and to aid visualization of the nasal mucosa during diagnostic examinations.

These drugs are contraindicated in patients with severe hypertension or coronary artery disease because of their cardiac stimulating and vasoconstricting effects. They also are contraindicated for patients with narrow-angle glaucoma and those taking tricyclic or monoamine oxidase inhibitor antidepressants. They must be used with caution in the presence of cardiac dysrhythmias, hyperthyroidism, diabetes mellitus, glaucoma, and prostatic hypertrophy.

### Applying Your Knowledge 46-2

#### How Can You Avoid This Medication Error?

Mr. Hobbs has been sick for more than 7 days. He feels that he is getting worse. When you ask him what medication he is taking, he reports that he is using a nasal spray that you had recommended the last time he was congested.

## Antitussives

*Antitussive* agents suppress cough by depressing the cough center in the medulla oblongata or the cough receptors in the throat, trachea, or lungs. Centrally acting antitussives include narcotics (e.g., codeine, hydrocodone) and non-narcotics (e.g., dextromethorphan). Locally acting agents (e.g., throat lozenges, cough drops) may suppress cough by increasing the flow of saliva and by containing demulcents or local anesthetics to decrease irritation of pharyngeal mucosa. Flavored syrups are often used as vehicles for other drugs.

The major clinical indication for use of antitussives is a dry, hacking, nonproductive cough that interferes with rest and sleep. It is not desirable to suppress a productive cough because the secretions need to be removed. Although antitussives continue to be used and adults report beneficial effects in reducing cough, antitussives, particularly dextromethorphan, has not been demonstrated to be effective in children and adolescents. The American Academy of Pediatrics and several other groups advise against the use of antitussives in children and adolescents.

## Expectorants

*Expectorants* are agents given orally to liquefy respiratory secretions and allow for their easier removal. Guaifenesin is the most commonly used expectorant, because the drug reduces the viscosity of tenacious secretions by increasing respiratory tract fluid. It is available alone and as an ingredient in many combination cough and cold remedies, although research studies do not support its effectiveness and many authorities do not recommend its use.

## Mucolytics

*Mucolytics* are administered by inhalation to liquefy mucus in the respiratory tract. Solutions of mucolytic drugs may be nebulized into a face mask or mouthpiece or instilled directly into the respiratory tract through a tracheostomy. Sodium chloride solution and acetylcysteine (Mucomyst) are the only agents

recommended for use as mucolytics. Acetylcysteine is effective within 1 minute after inhalation, and maximal effects occur within 5 to 10 minutes. It is effective immediately after direct instillation. Oral acetylcysteine is widely used in the treatment of acetaminophen overdose (see Chap. 7).

## Cold Remedies

Many combination products are available for treating symptoms of the common cold. Many of the products contain an antihistamine, a nasal decongestant, and an analgesic. Some contain antitussives, expectorants, and other agents as well. Many cold remedies are over-the-counter (OTC) formulations. Commonly used ingredients include chlorpheniramine (antihistamine), pseudoephedrine (adrenergic nasal decongestant), acetaminophen (analgesic and antipyretic), dextromethorphan (antitussive), and guaifenesin (expectorant). Although antihistamines are popular OTC drugs because they dry nasal secretions, they are not recommended because they can also dry lower respiratory secretions and worsen secretion retention and cough. The use of OTC products containing pseudoephedrine to manufacture methamphetamine has increased at an alarming rate. Most states have passed laws placing these products behind pharmacy counters to restrict and control sales.

Many products come in several formulations, with different ingredients, and are advertised for different purposes (e.g., allergy, sinus disorders, multisymptom cold and flu remedies). For example, allergy remedies contain an antihistamine; “nondrowsy” or “daytime” formulas contain a nasal decongestant, but do not contain an antihistamine; “PM” or “night” formulas contain a sedating antihistamine to promote sleep; pain, fever, and multisymptom formulas usually contain acetaminophen; and “maximum strength” preparations usually refer only to the amount of acetaminophen per dose, usually 1000 milligrams for adults. In addition, labels on OTC combination products list ingredients by generic name, without identifying the type of drug. As a result of these bewildering products, consumers, including nurses and other health care providers, may not know what medications they are taking or whether some drugs increase or block the effects of other drugs.

The use of antivirals for cold treatment has also increased in popularity. **Oseltamivir** (Tamiflu) limits spread of virus within the respiratory tract and may also prevent virus penetration of respiratory secretions to initiate replication. Oseltamivir has activity against influenza A and B. Although the drug was effective in community-acquired colds caused by rhinoviruses in two placebo-controlled trials, there is not sufficient evidence to support its use in viral upper respiratory tract infections.

### Applying Your Knowledge 46-3

Mr. Hobbs also complains of a productive cough. He has been taking chlorpheniramine to treat it. What advice should you give to Mr. Hobbs with regard to the appropriate treatment of a productive cough?

## Individual Drugs

Individual decongestants, antitussives, expectorants, and mucolytics are listed in Table 46-1; selected combination products are listed in Table 46-2.

## Herbal and Dietary Supplements

Several supplements are commonly used to prevent or treat symptoms of the common cold. While labeled as “natural,” these supplements have effects with or on prescription medications. In general, there is limited or no support for such use.

**Echinacea** preparations differ in chemical composition depending on which of the nine species or parts of the plant (e.g., leaves, roots, whole plant) are used as well as the season of harvesting. Also, which constituents of the plants are phar-

macologically active is unclear. A Cochrane review concluded that there is no conclusive evidence that echinacea products effectively treat or prevent the common cold.

**Vitamin C** is used to reduce the incidence and severity of colds and influenza. No unequivocal evidence suggests that vitamin C shortens the duration of colds and alleviates its symptoms in adults, although clinical trials with adults have been partially positive. The therapeutic benefit of vitamin C in reducing cold incidence and severity in children has not been demonstrated.

**Zinc gluconate** lozenges are marketed as a cold remedy. However, some studies indicate beneficial effects and others do not. Most of the studies suggesting benefit are considered flawed in methodology. For example, although some studies were supposed to be blind, the lozenges’ distinctive taste likely allowed the drug to be distinguished from a placebo. More recently, nasal zinc preparations (Cold-Eeze, Zycam) have been developed, and the possible risk of loss of smell posed by nasal zinc likely outweighs any benefit.

Table 46-1

### Drugs at a Glance: Nasal Decongestants, Antitussives, Expectorants and Mucolytics

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Nasal Decongestants</b>		
<b>Naphazoline</b> (Privine) 0.05% spray or drops	Topically, 1–2 sprays or drops no more often than q6h. Maximum, 4 doses/24 h; not to exceed 3 continuous d	12 y and older: Same as adults under 12 y: Not recommended
<b>Oxymetazoline</b> (Afrin) 0.05% spray	Topically, 2–3 sprays in each nostril, q10–12h. Maximum, 2 doses/24 h	6 y and older: Same as adults under 6 y: Not recommended
<b>Phenylephrine</b> (Neo-Synephrine)	PO 10–20 mg q4h. Maximum, 120 mg/24 h Topically, 1–2 sprays or drops of 0.25%, 0.5%, or 1% solution in each nostril no more often than q4h. Maximum, 6 doses/24 h. not to exceed 3 continuous d	12 y and older: Same as adults 6–11 y: PO 10 mg q4h. Maximum, 60 mg/24 h Topically, 1–2 sprays or drops of 0.25% solution in each nostril no more often than q4h. Maximum, 6 doses/24 h. Not to exceed 3 continuous d 2–5 y: Topically, 1–2 sprays or drops of 0.125% solution no more often than q4h. Maximum 6 doses/24 h. Not to exceed 3 continuous d
<b>Pseudoephedrine</b> (Sudafed, Dimetapp)	Regular tablets, PO 30 mg q4–6 h Extended-release tablets, PO 120 mg q12h or 240 mg q24h. Maximum, 240 mg in 24 h	12 y and older: Same as adults for regular and extended-release tablets 6–12 y: 30 mg q4–6h. Maximum, 120 mg/24 h 2–5 y: PO 15 mg q4–6h. Maximum, 60 mg/24 h under 2 y: PO: 4 mg/kg /day in divided doses q6 h
<b>Narcotic Antitussive</b>		
<b>Codeine</b>	PO 10–20 mg q4–6h. Maximum, 120 mg/24 h	6–12 y: PO 5–10 mg q4–6h. Maximum, 60 mg/24 h 2–6 y: PO 2.5–5 mg q4–6h. Maximum, 30 mg/24 h

**ROUTES AND DOSAGE RANGES**

Generic/Trade Name	Adults	Children
<b>Hydrocodone</b> bitartrate (Hycodan)	PO 1 (5 mg) tablet q4–6h up to 6 daily	Not recommended
<b>Non-Narcotic Antitussive</b> <b>Dextromethorphan</b> (Benlyn DM, others)	Liquid, lozenges, and syrup, 10–30 mg q4–8h. Maximum, 120 mg/24 h Sustained-action liquid (Delsym), PO 60 mg q12h	12 y and older: Same as adults 6–12 y: 5–10 mg q4h or 15 mg q6–8h; Maximum, 60 mg/24 h 2–6 y: 2.5–7.5 mg q4–8h. Maximum, 30 mg/24 h Sustained-action liquid, 6–12 y: 30 mg q12h 2–5 y: 15 mg q12h
<b>Expectorant</b> <b>Guaifenesin</b> (glyceryl guaiacolate) (Robitussin, others)	PO 100–400 mg q4h. Maximum, 2400 mg/24 h	12 y and older: Same as adults 6–12 y: PO 100–200 mg q4h. Maximum, 1200 mg/24 h 2–6 y: PO 50–100 mg q4h. Maximum, 600 mg/24 h
<b>Mucolytic</b> <b>Acetylcysteine</b> (Mucomyst)	Nebulization, 1–10 mL of a 20% solution or 2–20 mL of a 10% solution q2–6h Instillation, 1–2 mL of a 10% or 20% solution q1–4h Acetaminophen overdose, PO 140 mg/kg initially, then 70 mg/kg q4h for 17 doses; dilute a 10% or 20% solution to a 5% solution with cola, fruit juice, or water	Acetaminophen overdose, see literature

**Table 46-2**

**Drugs at a Glance: Representative Multi-Ingredient Nonprescription Cold, Cough, and Sinus Remedies**

Trade Name	INGREDIENTS				
	Antihistamine	Nasal Decongestant	Analgesic	Antitussive	Expoectorant
Actifed Cold & Allergy	Triprolidine 2.5 mg/tablet	Pseudoephedrine 60 mg/tablet			
Advil Cold and Sinus Tablets		Pseudoephedrine 30 mg/tablet	Ibuprofen 200 mg/tablet		
Cheracol D Cough Liquid				Dextromethorphan 10 mg/5 mL	Guaifenesin 100 mg/5 mL
Comtrex Cold & Sinus Tablets	Brompheniramine 2 mg/tablet	Pseudoephedrine 30 mg/tablet	Acetaminophen 500 mg/tablet		
Contact Day & Night Cold & Flu Tablets	(Night) Diphenhydramine 50 mg/tablet	Pseudoephedrine 60 mg/tablet	Acetaminophen 650 mg/tablet	(Day) Dextromethorphan 30 mg/tablet	
Coricidin D Cold, Flu & Sinus Tablets	Chlorpheniramine 2 mg/tablet	Pseudoephedrine 30 mg/tablet	Acetaminophen 325 mg/tablet

## Drugs at a Glance: Representative Multi-Ingredient Nonprescription Cold, Cough, and Sinus Remedies (continued)

Trade Name	INGREDIENTS				
	Antihistamine	Nasal Decongestant	Analgesic	Antitussive	Expectorant
Dimetapp Cold and Allergy Elixir	Brompheniramine 1 mg/5 mL	Pseudoephedrine 15 mg/5 mL			
Dristan Cold Formula	Chlorpheniramine 2 mg/tablet	Phenylephrine 5 mg/tablet	Acetaminophen 325 mg/tablet		
Motrin Sinus Tablets		Pseudoephedrine 30 mg/tablet	Ibuprofen 200 mg/tablet		
Robitussin Cold and Flu Tablets		Pseudoephedrine 10 mg/tablet	Acetaminophen 325 mg/tablet	Dextromethorphan 30 mg/tablet	Guaifenesin 200 mg/tablet
Sinutab Sinus Allergy Maximum Strength Tablets	Chlorpheniramine 2 mg/tablet	Pseudoephedrine 30 mg/tablet	Acetaminophen 500 mg/tablet	Dextromethorphan 10 mg/tablet	
TheraFlu Flu, Cold, and Cough Powder	Chlorpheniramine 4 mg/pack	Pseudoephedrine 60 mg/pack	Acetaminophen 650 mg/pack	Dextromethorphan 20 mg/pack	
Vicks NyQuil Cold & Flu Capsules	Doxylamine 6.25 mg/capsule	Pseudoephedrine 30 mg/capsule	Acetaminophen 250 mg/capsule	Dextromethorphan 10 mg/capsule	

## Nursing Process

### Assessment

Assess the patient's condition in relation to disorders for which the drugs are used.

- With nasal congestion, observe for decreased ability to breathe through the nose. If nasal discharge is present, note the amount, color, and thickness. Question the patient about the duration and extent of nasal congestion and factors that precipitate or relieve the symptom.
- With coughing, a major assessment factor is whether the cough is productive of sputum or dry and hacking. If the cough is productive, note the color, odor, viscosity, and amount of sputum. In addition, assess factors that stimulate or relieve cough and the patient's ability and willingness to cough effectively.
- Assess fluid intake and hydration status.

### Nursing Diagnoses

- Risk for Injury related to cardiac dysrhythmias, hypertension, and other adverse effects of nasal decongestants
- Noncompliance: Overuse of nasal decongestants
- Deficient Knowledge: Appropriate use of single- and multi-ingredient drug formulations

## Planning/Goals

### The patient will

- Experience relief of symptoms
- Take drugs accurately and safely
- Avoid overuse of decongestants
- Avoid preventable adverse drug effects
- Act to avoid recurrence of symptoms

### Interventions

Encourage patients to use measures to prevent or minimize the incidence and severity of symptoms:

- Avoid smoking cigarettes or breathing secondhand smoke, when possible. Cigarette smoke irritates respiratory tract mucosa, and this irritation causes cough, increased secretions, and decreased effectiveness of cilia in cleaning the respiratory tract.
- Avoid or limit exposure to crowds, especially during winter when the incidence of colds and influenza is high.
- Avoid contact with people who have colds or other respiratory infections. This is especially important for patients with chronic lung disease, because upper respiratory infections may precipitate acute attacks of asthma or bronchitis.
- Maintain a fluid intake of 2000 to 3000 mL daily unless contraindicated by cardiovascular or renal disease.

- Maintain nutrition, rest, activity, and other general health measures.
- Practice good hand hygiene techniques.
- Annual vaccination for influenza is recommended for patients who are elderly or have chronic respiratory, cardiovascular, or renal disorders.
- Provide appropriate teaching related to drug therapy (see accompanying display).

### Evaluation

- Interview and observe for relief of symptoms.
- Interview and observe for tachycardia, hypertension, drowsiness, and other adverse drug effects.
- Interview and observe for compliance with instructions about drug use.

## Principles Of Therapy

### Drug Selection and Administration

Choice of drugs and routes of administration are influenced by several patient- and drug-related variables. Some guidelines include the following:

- Single-drug formulations allow flexibility and individualization of dosage, whereas combination products may contain unneeded ingredients and are more expensive. However, many people find combination products more convenient to use.
- With nasal decongestants, topical preparations (i.e., nasal solutions or sprays) are often preferred for short-term use. They are rapidly effective because they come into direct contact with nasal mucosa. If used longer than the recommended 3 days or in excessive amounts, however, these products may produce rebound nasal congestion. Oral drugs

## Patient Teaching Guidelines

## Nasal Decongestants, Anticough Medications, and Multi-Ingredient Cold Remedies

### General Considerations

- These drugs may relieve symptoms but do not cure the disorder causing the symptoms.
- An adequate fluid intake, humidification of the environment, and sucking on hard candy or throat lozenges can help relieve mouth dryness and cough.
- Over-the-counter (OTC) cold remedies should not be used longer than 1 week. Do not use nose drops or sprays more often or longer than recommended. Excessive or prolonged use may damage nasal mucosa and produce chronic nasal congestion.
- Do not increase dosage if symptoms are not relieved by recommended amounts.
- See a health care provider if symptoms persist longer than 1 week.
- Inform health care providers about any herbal supplements that are being taken.
- Read the labels of OTC allergy, cold, and sinus remedies for information about ingredients, dosages, conditions or other medications with which the drugs should not be taken, and adverse effects.
- Do not combine two drug preparations containing the same or similar active ingredients. For example, pseudoephedrine is the nasal decongestant component of most prescription and OTC sinus and multi-ingredient cold remedies. The recommended dose for immediate-release preparations is usually 30 to 60 mg of pseudoephedrine; doses in extended-release preparations are usually 120 mg. Taking more than one preparation containing pseudoephedrine (or phenylephrine, a similar drug) may increase dosage to toxic levels and cause irregular heartbeats and extreme nervousness.
- Note that many combination products contain acetaminophen or ibuprofen as pain relievers. If you are taking

another form of one of these drugs (e.g., Tylenol or Advil), there is a risk of overdosage and adverse effects. Acetaminophen can cause liver damage; ibuprofen is a relative of aspirin that can cause gastrointestinal upset and bleeding. Thus, you need to be sure your total daily dosage is not excessive (with Tylenol, above four doses of 1000 mg each; with ibuprofen, above 2400 mg).

- Individuals with diabetes mellitus should read OTC labels for sugar content because many decongestants and cough medicines may contain sucrose, glucose, or corn syrup as a base.

### Self-Administration

- Take medications as prescribed or as directed on the labels of OTC preparations. Taking excessive amounts or taking recommended amounts too often can lead to serious adverse effects.
- Do not chew or crush long-acting tablets or capsules (e.g., those taken once or twice daily). Such actions can cause rapid drug absorption, high blood levels, and serious adverse effects, rather than the slow absorption and prolonged action intended with these products.
- For OTC drugs available in different dosage strengths, start with lower recommended doses rather than “maximum strength” formulations or the highest recommended doses. It is safer to see how the drugs affect you, then increase doses if necessary and not contraindicated.
- With topical nasal decongestants:
  1. Use only preparations labeled for intranasal use. For example, phenylephrine (Neo-Synephrine) is available in both nasal and eye formulations. The two types of solutions cannot be used interchangeably. In addition, phenylephrine preparations may contain 0.125%, 0.25%, 0.5%, or 1% of drug. Be sure the

## Patient Teaching Guidelines

(continued)

## Nasal Decongestants, Anticough Medications, and Multi-Ingredient Cold Remedies

- concentration is appropriate for the person to receive it (e.g., an infant, young child, or older adult).
- Blow the nose gently before instilling nasal solutions or sprays. This clears nasal passages and increases effectiveness of medications.
  - To instill nose drops, lie down or sit with the neck hyperextended and instill medication without touching the dropper to the nostrils (to avoid contamination of the dropper and medication). Rinse the medication dropper after each use.
  - For nasal sprays, sit or stand, squeeze the container once to instill medication, and rinse the spray tip after each use. Most nasal sprays are designed to deliver one dose when used correctly.
- If decongestant nose drops are ordered for nursing infants, give a dose 20 to 30 minutes before feeding. Nasal congestion interferes with an infant's ability to suck.
    - Take or give cough syrups undiluted and avoid eating and drinking for approximately 30 minutes. Part of the beneficial effect of cough syrups stems from soothing effects on pharyngeal mucosa. Food or fluid removes the medication from the throat.
    - Report palpitations, dizziness, drowsiness, or rapid pulse. These effects may occur with nasal decongestants and cold remedies and may indicate excessive dosage.

are preferred for long-term use (>7 days). For patients with cardiovascular disease, topical nasal decongestants are usually preferred. Oral agents are usually contraindicated because of cardiovascular effects (e.g., increased force of myocardial contraction, increased heart rate, increased blood pressure).

- Antihistamines are clearly useful in allergic conditions (e.g., allergic rhinitis; see Chap. 45), but their use to relieve cold symptoms is controversial. First-generation antihistamines (e.g., chlorpheniramine, diphenhydramine) have anticholinergic effects that may reduce sneezing, rhinorrhea, and cough. Also, their sedative effects may aid sleep. Many multi-ingredient cold remedies contain an antihistamine.
- Cough associated with the common cold usually stems from postnasal drainage and throat irritation. Most antitussives are given orally as tablets or cough syrups. Syrups serve as vehicles for antitussive drugs and may exert antitussive effects of their own by soothing irritated pharyngeal mucosa. Dextromethorphan is the antitussive drug of choice in most circumstances and is the antitussive ingredient in almost all OTC cough remedies (often designated by “DM” on the product label). However, as discussed previously, some authorities question the effectiveness of antitussives and do not recommend them for use in children or adults.
- Ipratropium (Atrovent), an anticholinergic drug, in a 0.06% nasal spray, is U.S. Food and Drug Administration (FDA) approved for treatment of rhinorrhea associated with the common cold.
- Cromolyn, a mast cell stabilizer, used by oral or intranasal inhalation, seems effective in reducing the symptoms and duration of the common cold but it is not FDA approved for this purpose. In one study, it was used every 2 hours for the first 2 days, then 4 times daily. The nasal solution (Nasal-crom) is available OTC.
- For treatment of excessive respiratory tract secretions, mechanical measures (e.g., coughing, deep breathing, ambu-

lation, chest physiotherapy, forcing fluids) are more likely to be effective than expectorant drug therapy.

## Use in Special Populations

### Use in Children

Upper respiratory infections with nasal congestion, sore throat, cough, and increased secretions are common in children, and the drugs described in this chapter are often used. Several OTC cough and cold medicines for use in infants have been recalled voluntarily by U.S. manufacturers due to concerns about possible misuse that could result in overdoses. Recommendations from consumer groups advising against the use of OTC cough and cold medicines in children less than 2 years of age have been submitted to the FDA. More research is needed regarding dosage, safety, and effectiveness of cough and cold mixtures in children. Some considerations include the following:

## Evidence-Based Practice

### 46-1 Cough and the Common Cold

The American College of Chest Physicians (ACCP) published evidence-based clinical practice guidelines regarding cough and the common cold. Pharmacologic recommendations include the following:

- Treatment of individuals with the common cold experiencing acute cough, postnasal drip, and throat clearing with a first-generation antihistamine/decongestant preparation (sustained-release pseudoephedrine and brompheniramine) is recommended. Naproxen can also be taken to help decrease cough in this group.
- Newer generation, nonsedating antihistamines are ineffective for reducing cough and should not be used in individuals with the common cold (ACCP, 2006).

- Most-upper respiratory infections are viral in origin, and antibiotics are not generally recommended. For sore throat, a throat culture for streptococcus organisms should be performed and the results obtained before an antibiotic is prescribed. For bronchitis, which is almost always viral, antibiotics are not usually indicated unless pneumonia is suspected or the cough lasts 10 to 14 days without improvement.
- Cough medicines are not considered effective by some authorities.
- With nasal decongestants, pseudoephedrine is considered effective in children older than 5 years of age, but research studies are inconclusive about its effectiveness in younger children. One consideration is that the low doses found in children's preparations may be insufficient to produce therapeutic effects. As a result, some pediatricians do not recommend usage, whereas others say the drug may be useful in some children.
- Nasal congestion may interfere with an infant's ability to nurse. Phenylephrine nasal solution, applied just before feeding time, is usually effective. However, excessive amounts or too-frequent administration of topical agents may result in rebound nasal congestion and systemic effects of cardiac and central nervous system stimulation. Therefore, the drug should be given to infants only when recommended by a pediatric specialist.
- Parents often administer a medication (e.g., acetaminophen, ibuprofen) for pain and fever when a child has cold symptoms, whether the child has pain and fever or not.

Some pediatricians suggest treating fevers above 101 degrees if the child seems uncomfortable but not to treat them otherwise. Parents may need to be counseled that fever is part of the body's defense mechanism and may help the child recover from an infection.

### Use in Older Adults

A major consideration is that older adults are at high risk of adverse effects from oral nasal decongestants (e.g., hypertension, cardiac dysrhythmias, nervousness, insomnia). Adverse effects from topical agents are less likely, but rebound nasal congestion and systemic effects may occur with overuse. Older adults with significant cardiovascular disease should avoid the drugs. Also, as in other populations, antitussives and expectorants have questionable effectiveness.

### Use in Home Care

These drugs are used primarily in home settings, and household members may ask the home care nurse for advice about OTC remedies for conditions such as allergies, colds, coughs, and sinus headaches. Before recommending a particular product, the nurse needs to assess the intended recipient for conditions or other medications that contraindicate the product's use. For example, the nasal decongestant component may cause or aggravate cardiovascular disorders (e.g., hypertension). In addition, other medications the patient is taking need to be evaluated in terms of potential drug interactions with the remedy. The home care nurse also must emphasize the need to read the label of any OTC medication for ingredients, precautions, contraindications, drug interactions, administration instructions, and so forth.

## Nursing Actions

## Nasal Decongestants, Antitussives, and Cold Remedies

### NURSING ACTIONS

#### 1. Administer accurately

- a. With topical nasal decongestants:
  - (1) Use only preparations labeled for intranasal use.
  - (2) Use the drug concentration ordered.
  - (3) For instillation of nose drops, have the patient lie down or sit with the neck hyperextended. Instill medication without touching the dropper to the nares. Rinse the medication dropper after each use.
  - (4) For nasal sprays, have the patient sit, squeeze the container once to instill medication, avoid touching the spray tip to the nares, and rinse the spray tip after each use.
  - (5) Give nasal decongestants to infants 20–30 minutes before feeding.
- b. Administer cough syrups undiluted and instruct the patient to avoid eating and drinking for approximately 30 minutes.

### RATIONALE/EXPLANATION

Intranasal preparations are usually dilute, aqueous solutions prepared specifically for intranasal use. Some agents (e.g., phenylephrine) are available in ophthalmic solutions as well. The two types of solutions cannot be used interchangeably. Some drug preparations are available in several concentrations. For example, phenylephrine preparations may contain 0.125%, 0.25%, 0.5%, or 1% of drug. To avoid contamination of the dropper and medication

Most nasal sprays are designed to deliver one dose when used correctly. If necessary, secretions may be cleared and a second spray used. Correct usage and cleansing prevents contamination and infection.

Nasal congestion interferes with an infant's ability to suck.

Part of the therapeutic benefit of cough syrups stems from soothing effects on pharyngeal mucosa. Food or fluid removes the medication from the pharynx.

## Nursing Actions

Nasal Decongestants, Antitussives,  
and Cold Remedies (continued)

## NURSING ACTIONS

**2. Observe for therapeutic effects**

- a. When nasal decongestants are given, observe for decreased nasal obstruction and drainage.
- b. With antitussives, observe for decreased coughing.
- c. With cold and allergy remedies, observe for decreased nasal congestion, rhinitis, muscle aches, and other symptoms.

**3. Observe for adverse effects**

- a. With nasal decongestants, observe for:
  - (1) Tachycardia, cardiac dysrhythmias, hypertension
  - (2) Rebound nasal congestion, chronic rhinitis, and possible ulceration of nasal mucosa
- b. With antitussives, observe for:
  - (1) Excessive suppression of the cough reflex (inability to cough effectively when secretions are present)
  - (2) Nausea, vomiting, constipation, dizziness, drowsiness, pruritus, and drug dependence
  - (3) Nausea, drowsiness, and dizziness with non-narcotic antitussives
- c. With combination products (e.g., cold remedies), observe for adverse effects of individual ingredients (i.e., antihistamines, adrenergics, analgesics, and others).

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of nasal decongestants:
  - (1) Cocaine, digoxin, general anesthetics, monoamine oxidase (MAO) inhibitors, other adrenergic drugs, thyroid preparations, and xanthines
  - (2) Antihistamines, epinephrine, ergot alkaloids, MAO inhibitors, methylphenidate
- b. Drugs that *increase* antitussive effects of codeine:
  - (1) CNS depressants (alcohol, antianxiety agents, barbiturates, and other sedative-hypnotics)
- c. Drugs that *alter* effects of dextromethorphan:
  - (1) MAO inhibitors
- d. Drugs that may *alter* effects of combination products for coughs, colds, and allergies:
  - (1) Adrenergic (sympathomimetic) agents (see Chap. 17)
  - (2) Antihistamines (see Chap. 45)
  - (3) CNS depressants (see Chaps. 6, 8, and 13)
  - (4) CNS stimulants (see Chap. 15)

## RATIONALE/EXPLANATION

Therapeutic effects depend on the reason for use.

The goal of antitussive therapy is to suppress nonpurposeful coughing, not productive coughing.

These effects may occur with any of the adrenergic drugs (see Chap. 17). When adrenergic drugs are used as nasal decongestants, cardiovascular effects are more likely to occur with oral agents. However, topically applied drugs also may be systemically absorbed through the nasal mucosa or by being swallowed and absorbed through the gastrointestinal tract. Adverse effects on nasal mucosa are more likely to occur with excessive or long-term (>10 d) use.

This is a potentially serious adverse effect because retained secretions may lead to atelectasis, pneumonia, hypoxia, hypercarbia, and respiratory failure.

These are adverse effects associated with narcotic agents (see Chap. 6). When narcotics are given for antitussive effects, however, they are given in relatively small doses and are unlikely to cause adverse reactions.

Adverse effects are infrequent and mild with these agents.

Adverse effects are rarely significant when the products are used as prescribed. There may be subtherapeutic doses of one or more component drugs, especially in over-the-counter formulations. Also, the drowsiness associated with antihistamines may be offset by stimulating effects of adrenergics. Ephedrine, for example, has central nervous system (CNS)-stimulating effects.

These interactions are more likely to occur with oral decongestants than topically applied drugs. Increased risks of cardiac dysrhythmias

Increased risks of hypertension due to vasoconstriction

Additive CNS depression. Codeine is given in small doses for antitussive effects, and risks of significant interactions are minimal.

This combination is contraindicated. Apnea, muscular rigidity, hyperpyrexia, laryngospasm, and death may occur. Interactions depend on the individual drug components of each formulation. Risks of clinically significant drug interactions are increased with use of combination products.

## Key Concepts

- Most upper respiratory infections are viral in origin, and antibiotics are not generally recommended.
- Retention of secretions commonly occurs with influenza, pneumonia, upper respiratory infections, acute and chronic bronchitis, emphysema, and acute attacks of asthma.
- Nonrespiratory conditions that predispose to secretion retention include immobility, debilitation, cigarette smoking, and postoperative status.
- An adequate fluid intake, humidification of the environment, and sucking on hard candy or throat lozenges can help relieve mouth dryness and cough.
- Rebound nasal swelling can occur with excessive or extended use of nasal sprays.
- First-generation antihistamines (e.g., chlorpheniramine, diphenhydramine) have anticholinergic effects that may reduce sneezing, rhinorrhea, and cough.
- There is limited or no support for the use of dietary or herbal supplements to prevent or treat symptoms of the common cold.
- Several OTC cough and cold medicines for use in infants have been recalled voluntarily due to concerns about possible misuse that could result in overdoses.

## Review and Application Exercises

### Short Answer Exercises

1. How do adrenergic drugs relieve nasal congestion?
2. Who should usually avoid OTC nasal decongestants and cold remedies?
3. What are advantages and disadvantages of multi-ingredient cold remedies?
4. In a patient with a productive cough, what are nondrug interventions to promote removal of secretions?
5. A patient who uses echinacea, vitamin C, or zinc lozenges asks you what you think about the products as cold remedies. How would you reply?

### NCLEX-Style Questions

6. A common mucolytic used to liquefy mucus in the respiratory tract is
  - a. acetylcysteine (Mucomyst)
  - b. ipratropium (Atrovent)
  - c. dextromethorphan
  - d. pseudoephedrine (Sudafed)
7. In caring for a patient with nasal congestion, the nurse knows that adrenergic drugs are used as nasal decongestants to relieve symptoms by
  - a. constricting arterioles and reducing blood flow to nasal mucosa
  - b. stimulating air movement in the lungs
  - c. stabilizing mast cells
  - d. initiating the cough reflex
8. As the nurse caring for a patient with nasal congestion who is using the over-the-counter decongestant oxymetazoline (Afrin), you counsel the patient that this medication should only be used for the time recommended on the package and not for longer use because excessive use may produce
  - a. copious lower respiratory tract secretions
  - b. ringing in the ears
  - c. rebound nasal congestion
  - d. a suppressed cough reflex
9. Cold remedies listed as “nondrowsy” or labeled as being “daytime” formulas do not contain
  - a. a nasal decongestant
  - b. a first-generation antihistamine
  - c. a pain reliever
  - d. any of the above

## KEY TERMS

- Atria
- Collateral circulation
- Diastole
- Endocardium
- Epicardium
- Myocardium
- Pericardium
- Septum
- Ventricles

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Recognize the functions of the heart, blood vessels, and blood in supplying oxygen and nutrients to body tissues.
2. Describe the role of vascular endothelium in maintaining homeostasis.
3. Discuss atherosclerosis as the basic disorder causing many cardiovascular disorders for which drug therapy is required.
4. Manage the care of individuals with cardiovascular disorders for which drug therapy is a major treatment modality.

## Introduction

The cardiovascular or circulatory system is composed of the heart, blood vessels, and blood. The general functions of the system are to carry oxygen, nutrients, hormones, antibodies, and other substances to all body cells and to remove waste products of cell metabolism (carbon dioxide and others). The efficiency of the system depends on the heart's ability to pump blood, the patency and functions of blood vessels, and the quality and quantity of blood.

## Heart

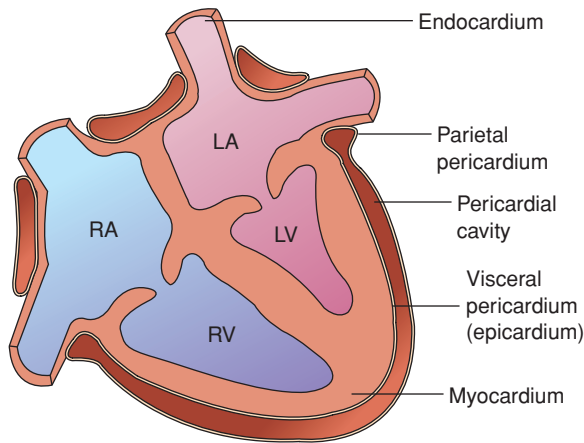

The heart is a hollow, muscular organ that functions as a two-sided pump to circulate 5 to 6 liters of blood through the body every minute. Major components and characteristics are identified in Figure 47-1 and described in the following sections.

### Chambers of the Heart

The heart has four chambers: two atria and two ventricles. The *atria* are receiving chambers. The right atrium receives deoxygenated blood from the upper part of the body by way of the superior vena cava, from the lower part of the body by way of the inferior vena cava, and from veins and sinuses within the heart itself. The left atrium receives oxygenated blood from the lungs through the pulmonary veins. The *ventricles* are distributing chambers. The right ventricle sends deoxygenated blood through the pulmonary circulation. It is small and thin walled because it contracts against minimal pressure. The left ventricle pumps oxygenated blood through the systemic circuit. It is much more muscular and thick walled because it contracts against relatively high pressure. The right atrium and right ventricle form one pump, and the left atrium and left ventricle form another. A muscular wall called the *septum* separates the right and left sides of the heart.

### Layers of the Heart

The layers of the heart are the endocardium, myocardium, and epicardium. The *endocardium* is the membrane lining the heart chambers. It is continuous with the endothelial lining of blood vessels

**Figure 47-1** ■ Layers of the heart, showing the visceral pericardium, the pericardial cavity, and the parietal pericardium. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

entering and leaving the heart, and it covers the heart valves. The *myocardium* is the strong muscular layer of the heart that provides the pumping power for circulation of blood. The *epicardium* is the outer, serous layer of the heart. The heart is enclosed in a fibroserous sac called the *pericardium*.

## Heart Valves

Heart valves function to maintain the one-way flow of blood and prevent backflow. The mitral valve separates the left atrium and left ventricle. The tricuspid valve separates the right atrium and right ventricle. The pulmonic valve separates the right ventricle and pulmonary artery. The aortic valve separates the left ventricle and aorta.

## Conduction System

The heart contains special cells that can carry electrical impulses much more rapidly than ordinary muscle fibers. This special conduction system consists of the sinoatrial (SA) node, the atrioventricular node, bundle of His, right and left bundle branches, and Purkinje fibers. The SA node, the normal pacemaker of the heart, generates a burst of electrical energy approximately 60 to 100 times each minute under normal circumstances. The electrical current flows over the heart in an orderly way to produce contraction of both atria, then both ventricles. An expanded discussion of cardiac conduction is found in Chapter 49.

A unique characteristic of the heart is that any cell in any chamber can generate its own electrical impulse to contract. For example, the ventricles can beat independently, but at a rate of less than 40 beats per minute. This provides a backup mechanism should the SA node fail to fire, with an inherent rate that does not compete with SA node firing. In addition, the heart does not require nervous stimulation to contract. However, the autonomic nervous system does influence heart rate. Sympathetic nerves increase heart rate (through the release of epinephrine and norepinephrine); parasympathetic nerves (by way of the vagus nerve) decrease heart rate.

## Blood Supply

The heart receives its blood supply from the coronary arteries. Coronary arteries originate at the base of the aorta in the aortic cusps and fill during *diastole*, the resting or filling phase of the cardiac cycle. Coronary arteries branch into smaller arteries that supply specific parts of the myocardium, without an overlapping supply from other arterial branches. However, artery-to-artery anastomoses occur between many adjacent vessels. These anastomotic arteries may not supply sufficient blood to the heart if a major artery is suddenly occluded, but they may dilate to considerable size when disease (usually coronary atherosclerosis) develops slowly. The resultant *collateral circulation* may provide a sufficient blood supply for myocardial function, at least during rest.

## Blood Vessels

There are three types of blood vessels: arteries, veins, and capillaries. Arteries and veins are similar in that they have three layers. The intima, the inner lining, is composed of a layer of endothelial cells next to the blood (to provide a smooth surface for blood circulation) and an elastic layer that joins the media. The media is the middle layer of muscle and elastic tissue. The adventitia is the outer layer of connective tissue.

Blood vessel walls are composed of two types of cells, smooth muscle cells and endothelial cells. Vascular smooth muscle functions to maintain blood pressure and blood flow. It contracts and relaxes in response to numerous stimuli, including local and circulating mediators. Contractile properties also vary among blood vessels, with some being more responsive to stimuli than others. Overall, regulation of tone in vascular smooth muscle depends on the intracellular concentration of calcium ions. Increased intracellular calcium leads to increased vascular tone. There are several mechanisms by which calcium ions can enter the cell.

Endothelial cells, once thought to be passive conduits for blood flow, are now known to perform two extremely important functions in maintaining homeostatic processes. One function is structural, in which the cells act as a permeability barrier and regulate passage of molecules and cells across the blood vessel wall. The second function is metabolic, in which the cells secrete opposing mediators that maintain a balance between bleeding and clotting of blood (including activation and inhibition of platelet functions and fibrinolysis), constriction and dilation of blood vessels, and promotion and inhibition of vascular cell growth and inflammation. Selected mediators are listed in Table 47-1; some are discussed in more detail in later chapters.

## Arteries

Arteries and arterioles contain a well-developed layer of smooth muscle (the media) and are sometimes called resistance vessels. Their efficiency depends on their patency and

Table 47-1

## Endothelial Mediators That Regulate Cardiovascular Function

PROMOTING FACTORS	INHIBITING FACTORS
<p><b>Vasomotor Tone</b></p> <p><b>Vasodilators</b>            Endothelial-derived hyperpolarizing factor (EDHF)            Nitric oxide (also called endothelial-derived relaxing factor, or EDRF)            Prostacyclin (prostaglandin I<sub>2</sub>)</p>	<p><b>Vasoconstrictors</b>            Angiotensin II            Endothelin            Endothelium-derived constricting factor            Platelet-derived growth factor            Thromboxane A<sub>2</sub></p>
<p><b>Blood Coagulation</b></p> <p><b>Procoagulants</b>            Tissue factor            Von Willebrand factor</p> <p><b>Platelet activators</b>            Platelet-activating factor            Von Willebrand factor</p> <p><b>Profibrinolytic factors</b>            Tissue plasminogen activator (t-PA)            Urokinase-type plasminogen activator</p>	<p><b>Anticoagulants</b>            Heparin sulfate            Thrombomodulin</p> <p><b>Platelet inhibitors</b>            Nitric oxide            Prostacyclin</p> <p><b>Antifibrinolytic factor</b>            Plasminogen activator inhibitor-1</p>
<p><b>Cell Growth</b>            Angiotensin II            Endothelin            Platelet-derived growth factor</p>	<p>Heparin            Nitric oxide            Prostacyclin</p>
<p><b>Inflammation</b></p> <p><b>Proinflammatory factors</b>            Cellular and intercellular adhesion molecules            Monocyte chemoattractant protein-1            Interleukin-8</p>	<p><b>Anti-inflammatory factors</b>            Nitric oxide</p>

ability to constrict or dilate in response to various stimuli. The degree of constriction or dilation (vasomotor tone) determines peripheral vascular resistance, which is a major determinant of blood pressure.

## Veins

Veins and venules have a thin media and valves that assist blood flow against gravity. They are sometimes called capacitance vessels, because blood may accumulate in various parts of the venous system. Their efficiency depends on patency, competency of valves, and the contraction and relaxation action of muscles around veins.

## Capillaries

Capillaries, the smallest blood vessels, connect the arterial and venous segments of the circulation. They consist of a single layer of connected endothelial cells and a few smooth muscle cells. Gases, nutrients, cells, and waste products are exchanged between blood and extracellular fluid across capillary walls. The endothelial lining acts as a semipermeable membrane to

regulate the exchange of plasma solutes with extracellular fluid. Lipid-soluble materials diffuse directly through the capillary cell membrane; water and water-soluble materials enter and leave the capillary through the junctions or gaps between endothelial cells.

## Lymphatics

Lymphatic vessels, which are composed mainly of endothelium, parallel the veins and empty into the venous system. They drain tissue fluid that has filtered through the endothelium of capillaries and venules from the plasma. They then carry lymphocytes, large molecules of protein and fat, microorganisms, and other materials to regional lymph nodes.

## Blood

Blood functions to nourish and oxygenate body cells, protect the body from invading microorganisms, and initiate hemostasis when a blood vessel is injured. Specific functions and components are listed in the following sections.

## Functions

- Transports oxygen to cells and carbon dioxide from cells to lungs for removal from the body
- Transports absorbed food products from the gastrointestinal tract to tissues; at the same time, carries metabolic wastes from tissues to the kidneys, skin, and lungs for excretion
- Transports hormones from endocrine glands to other parts of the body
- Transports leukocytes and antibodies to sites of injury, infection, and inflammation
- Assists in regulation of body temperature by transferring heat produced by cell metabolism to the skin, where it can be released
- Transports platelets to injured areas for hemostasis

## Components

- Plasma comprises approximately 55% of the total blood volume, and it is more than 90% water. Other components are
  - Serum albumin, which helps maintain blood volume by exerting colloid osmotic pressure
  - Fibrinogen, which is necessary for hemostasis
  - Gamma globulin, which is necessary for defense against microorganisms
  - Less than 1% antibodies, nutrients, metabolic wastes, respiratory gases, enzymes, and inorganic salts
- Solid particles or cells comprise approximately 45% of total blood volume. Cells include erythrocytes (red blood cells or RBCs), leukocytes (white blood cells or WBCs), and thrombocytes (platelets). The bone marrow produces all RBCs, 60% to 70% of WBCs, and all platelets. Lymphatic tissues (spleen and lymph nodes) produce 20% to 30% of WBCs, and reticuloendothelial tissues (spleen, liver, lymph nodes) produce 4% to 8% of WBCs. Cell characteristics include the following:
  - Erythrocytes function primarily to transport oxygen. Almost all oxygen (95%–97%) is transported in combination with hemoglobin; very little is dissolved in blood. The lifespan of a normal RBC is approximately 120 days.
  - Leukocytes function primarily as a defense mechanism against microorganisms. They leave the bloodstream to enter injured tissues and phagocytize the injurious agent. They also produce antibodies. The lifespan of a normal WBC is a few hours.
  - Platelets are fragments of large cells, called megakaryocytes, found in the bone marrow. Platelets are essential for blood coagulation. For example, when a blood vessel is injured, platelets adhere to each other and the edges of the injury to form a cluster of activated platelets (i.e., a platelet thrombus or “plug”) that adheres to the vessel wall and prevents leakage of blood. In addition, the clus-

tered platelets release substances (e.g., adenosine diphosphate, thromboxane  $A_2$ , von Willebrand factor) that promote recruitment and aggregation of new platelets.

Platelets have no nucleus and cannot replicate. If not used, they circulate for approximately a week before being removed by phagocytic cells of the spleen.

## Cardiovascular Disorders

Cardiovascular disorders, which are common causes of morbidity and mortality, often stem from blood vessel abnormalities. In turn, most vascular diseases result from the malfunction of endothelial cells or smooth muscle cells. Dysfunctional endothelium is considered a major factor in atherosclerosis, acute coronary syndromes (symptomatic myocardial ischemia, asymptomatic myocardial infarction [MI], and MI with or without ST-segment elevation), hypertension, and thromboembolic disorders. The main cause of endothelial dysfunction is injury to the blood vessel wall from trauma or disease processes. The injury alters the normal regulatory forces and leads to vasospasm, thrombosis, growth of the intimal layer of the blood vessel, rupture of atherosclerotic plaque, tissue ischemia and infarction, and dysrhythmias. Pathologic changes in the structure of the capillary and venular endothelium also result in the accumulation of excess fluid in interstitial space (edema), a common symptom of cardiovascular and other disorders.

Overall, cardiovascular disorders may involve any structure or function of the cardiovascular system. Because the circulatory system is a closed system, a disorder in one part of the system eventually disturbs the function of all other parts.

## Drug Therapy Used for Cardiovascular Disorders

Cardiovascular disorders usually managed with drug therapy include atherosclerosis, heart failure, cardiac dysrhythmias, ischemia, myocardial infarction, hypertension, hypotension, and shock. Peripheral vascular disease and valvular disease are usually managed surgically. Blood disorders that respond to drug therapy include certain types of anemia and coagulation disorders.

The goal of drug therapy in cardiovascular disorders is to restore homeostasis or physiologic balance between opposing factors (e.g., coagulant vs. anticoagulant, vasoconstriction vs. vasodilation). Cardiovascular drugs may be given to increase or decrease cardiac output, blood pressure, and heart rate; to alter heart rhythm; to increase or decrease blood clotting; to alter the quality of blood; and to decrease chest pain of cardiac origin. In addition, these drugs may be given for palliation of symptoms without alteration of the underlying disease process.

## Key Concepts

- The efficiency of the cardiovascular system depends on the heart's ability to pump blood, the patency and functions of blood vessels, and the quality and quantity of blood.
- Heart valves function to maintain the one-way flow of blood and prevent backflow.
- A unique characteristic of the heart is that any cell in any chamber can generate its own electrical impulse to contract at an inherent rate that does not compete with SA node firing; this provides a backup mechanism should the SA node fail to fire.
- Coronary arteries originate at the base of the aorta in the aortic cusps and fill during diastole, the resting or filling phase of the cardiac cycle.
- Blood functions to nourish and oxygenate body cells, protect the body from invading microorganisms, and initiate hemostasis when a blood vessel is injured.
- Dysfunctional endothelium is considered a major factor in atherosclerosis, acute coronary syndromes, hypertension, and thromboembolic disorders.
- The goal of drug therapy in cardiovascular disorders is to restore homeostasis or physiologic balance between opposing factors (e.g., coagulant vs. anticoagulant, vasoconstriction vs. vasodilation).
- Cardiovascular drugs may be given to increase or decrease cardiac output, blood pressure, and heart rate; to alter heart rhythm; to increase or decrease blood clotting; to alter the quality of blood; and to decrease chest pain of cardiac origin.

## Review and Application Exercises

### Short Answer Exercises

1. How does the heart muscle differ from skeletal muscle?
2. What is the normal pacemaker of the heart?
3. In what circumstances do other parts of the heart take over as pacemaker?
4. What is the effect of parasympathetic (vagal) stimulation on the heart?
5. What is the effect of sympathetic stimulation on the heart and blood vessels?
6. List five chemical mediators produced by endothelial cells and their roles in maintaining cardiovascular function.
7. How does endothelial cell dysfunction contribute to cardiovascular disorders?

# Drug Therapy for Heart Failure

## KEY TERMS

- Catecholamines
- Decompensation
- Diastolic dysfunction
- Digitalis toxicity
- Digitalization
- Endothelin
- Inotropic
- Loading dose
- Maintenance dose
- Renin
- Systolic dysfunction
- Therapeutic index
- Ventricular remodeling

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Recognize major manifestations of heart failure (HF).
2. Discuss the role of endothelial dysfunction in HF.
3. Differentiate the types of drugs used to treat HF.
4. Identify the role of digoxin in the management of HF and atrial fibrillation.
5. List characteristics of digoxin in terms of effects on myocardial contractility and cardiac conduction, indications for use, principles of therapy, and nursing process implications.
6. Differentiate digitalizing and maintenance doses of digoxin.
7. Explain the roles of potassium chloride, lidocaine, atropine, and digoxin immune fab in the management of digoxin toxicity.

## Applying Your Knowledge

Clara Motsinger is a 70-year-old woman who has HF. She has been treated with an ACE inhibitor and a diuretic for several years, but this drug regimen has now failed to control her HF. Her cardiologist has added digoxin 0.125 mg daily (tablets) to her treatment regimen.

## Introduction

Heart failure (HF) is a complex clinical condition that occurs when the heart cannot pump enough blood to meet tissue needs for oxygen and nutrients. It may result from impaired myocardial contraction during systole (*systolic dysfunction*), impaired relaxation and filling of ventricles during diastole (*diastolic dysfunction*), or a combination of systolic and diastolic dysfunction. HF has also been referred to as congestive heart failure (CHF) because frequently there is congestion (fluid accumulation) in the lungs and peripheral tissues. Many patients, however, do not have congestive symptoms; therefore, *heart failure* is the preferred term.

## Causes of Heart Failure

At the cellular level, HF stems from dysfunction of contractile myocardial cells and the endothelial cells that line the heart and blood vessels (see Chap. 47). Vital functions of the endothelium include maintaining equilibrium between vasodilation and vasoconstriction, coagulation and anticoagulation, and cellular growth promotion and inhibition. Endothelial dysfunction allows processes that narrow the blood vessel lumen (e.g., buildup of atherosclerotic plaque, growth of cells, inflammation, activation of platelets) and lead to blood-clot formation and vasoconstriction

that further narrow the blood vessel lumen. These are major factors in coronary artery disease and hypertension, the most common conditions leading to HF.

Other causative factors include hyperthyroidism, excessive intravenous (IV) fluids or blood transfusions, and drugs that decrease the force of myocardial contraction (e.g., anti-dysrhythmic drugs) or cause retention of sodium and water (e.g., corticosteroids, estrogens, nonsteroidal anti-inflammatory agents). These factors impair the pumping ability or increase the workload of the heart so an adequate cardiac output cannot be maintained.

## Compensatory Mechanisms of Heart Failure

As the heart fails, the low cardiac output and inadequately filled arteries activate the neurohormonal system by several feedback mechanisms. One mechanism is increased sympathetic activity and circulating *catecholamines* (neurohormones), which increases the force of myocardial contraction, increases heart rate, and causes vasoconstriction. The effects of the baroreceptors in the aortic arch and carotid sinus that normally inhibit undue sympathetic stimulation are blunted in patients with HF, and the effects of the high levels of circulating catecholamines are intensified. Endothelin, a neurohormone secreted primarily by endothelial cells, is the most potent endogenous vasoconstrictor and may exert direct toxic effects on the heart and result in myocardial cell proliferation.

Another mechanism is activation of the renin-angiotensin-aldosterone system. *Renin* is an enzyme produced in the kidneys in response to impaired blood flow and tissue perfusion. When released into the bloodstream, renin stimulates the production of angiotensin II, a powerful vasoconstrictor. Arterial vasoconstriction impairs cardiac function by increasing the resistance (afterload) against which the ventricle ejects blood. This raises filling pressures inside the heart, increases stretch and stress on the myocardial wall, and predisposes to subendocardial ischemia. In addition, patients with severe HF have constricted arterioles in cerebral, myocardial, renal, hepatic, and mesenteric vascular beds. This results in increased organ hypoperfusion and dysfunction. Venous vaso-

constriction limits venous capacitance, resulting in venous congestion and increased diastolic ventricular filling pressures (preload). Angiotensin II also promotes sodium and water retention by stimulating aldosterone release from the adrenal cortex and the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland.

All of these mechanisms combine to increase blood volume and pressure in the heart chambers, stretch muscle fibers, and produce dilation, hypertrophy, and changes in the shape of the heart (a process called *cardiac or ventricular remodeling*) that make it contract less efficiently. Overall, the compensatory mechanisms increase preload (amount of venous blood returning to the heart), workload of the heart, afterload (amount of resistance in the aorta and peripheral blood vessels that the heart must overcome to pump effectively), and blood pressure. These compensatory mechanisms that initially preserve cardiac function result in progressive deterioration of myocardial function over time.

## Signs and Symptoms of Heart Failure

Cardinal manifestations of HF are dyspnea and fatigue, which can lead to exercise intolerance and fluid retention, resulting in pulmonary congestion and peripheral edema. Patients with compensated (asymptomatic) HF usually have no symptoms at rest and no edema; dyspnea and fatigue occur only with activities involving moderate or higher levels of exertion. Symptoms that occur with minimal exertion or at rest and are accompanied by ankle edema and distention of the jugular vein (from congestion of veins and leakage of fluid into tissues) reflect *decompensation* (symptomatic HF). Acute, severe cardiac decompensation is manifested by pulmonary edema, a medical emergency that requires immediate treatment. Two models currently exist for classification of HF. The New York Heart Association (NYHA) classifies HF based on functional limitations. A newer system of staging HF, proposed by the American College of Cardiology (ACC) and the American Heart Association (AHA), is based on the progression of HF. These classifications complement each other and are often used together to determine and evaluate therapy (Table 48-1).

**Table 48-1**

### Classifying Signs and Symptoms of Heart Failure to Determine Treatment

NEW YORK HEART ASSOCIATION (NYHA) CLASSIFICATION	AMERICAN COLLEGE OF CARDIOLOGY (ACC)/AMERICAN HEART ASSOCIATION (AHA) GUIDELINES	RECOMMENDATIONS
	Stage A. Patient at high risk for developing heart failure (HF) but without structural heart disease or signs and symptoms of HF.	<ul style="list-style-type: none"> <li>■ Treat hypertension, lipid disorders, diabetes.</li> <li>■ Encourage patient to stop smoking and to exercise regularly.</li> <li>■ Discourage use of alcohol, illicit drugs.</li> </ul>

**NEW YORK HEART  
ASSOCIATION (NYHA)  
CLASSIFICATION****AMERICAN COLLEGE OF  
CARDIOLOGY (ACC)/AMERICAN  
HEART ASSOCIATION (AHA)  
GUIDELINES****RECOMMENDATIONS**

**Class I.** Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or angina.

**Stage B.** Structural heart disease, but without signs and symptoms of HF.

- ACE inhibitor or angiotensin receptor blocker if indicated

**Class II.** Slight limitation of physical activity but asymptomatic at rest. Ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.

**Stage C.** Structural heart disease with prior or current signs and symptoms of HF.

- All stage A therapies
- Beta-blocker unless contraindicated
- Implantable defibrillator, if indicated

**Class III.** Marked limitation of physical activity, but typically asymptomatic at rest. Less-than-ordinary physical activity causes fatigue, palpitations, dyspnea, or angina.

**Stage D.** End-stage disease requiring specialized treatment strategies, such as mechanical circulatory support, continuous inotropic infusion, or heart transplant.

- All stage A and B therapies
- Sodium-restricted diet
- Diuretics for fluid retention
- Digoxin
- Avoid or withdraw antiarrhythmic agents, most calcium channel blockers, and nonsteroidal anti-inflammatory drugs.
- Consider aldosterone antagonists, angiotensin receptor blockers, hydralazine, and nitrates.
- Biventricular pacing

**Class IV.** Unable to perform any physical activity without discomfort; symptoms may be present at rest. Discomfort increases with physical activity.

- All therapies for stages A, B, and C
- Permanent mechanical support
- Continuous inotropic therapy
- Heart transplant
- Hospice care

Hunt, S. A., Abraham, W. T., Chin, M. H., Feldman, F. A., Francis, G. S., Ganiats, T. G., Jessup, M., et al. (2005). ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult- summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 2001 Guidelines for the Evaluation and Management of Heart Failure). Retrieved September 30, 2007, from [http://www.acc.org/quality\\_and\\_science/clinical\\_guidelines/failure/date/-wkt.pdf](http://www.acc.org/quality_and_science/clinical_guidelines/failure/date/-wkt.pdf)

## Drug Therapy for Heart Failure

Several drugs are used to treat acute HF. A diuretic, in combination with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB), is first-line therapy for chronic failure. Digoxin, a beta-adrenergic blocking agent, or an aldosterone inhibitor may be added to the ACE inhibitor or ARB and diuretic regimen.

Drug therapy for HF continues to evolve as the pathophysiologic mechanisms are better understood and research studies indicate more effective regimens. Combinations of drugs are commonly used in efforts to improve circulation, alter the compensatory mechanisms, and reverse heart damage. Most of the drugs used to treat HF are also used in other disorders and are discussed in other chapters; their effects in HF are described in Box 48-1. The primary focus of this chapter is inotropic agents, which include digoxin (a cardiac glycoside) and the phosphodiesterase inhibitor milrinone. An additional classification of drugs, human B-type natriuretic peptides, is also presented. These drugs are discussed in the following sections and in Table 48-2.

## Inotropes

### Cardiac Glycosides (Digoxin)

**Digoxin** (Lanoxin) is the only commonly used digitalis glycoside. In the following discussion, the terms *digitalization* and *digitalis toxicity* refer to digoxin.

#### General Characteristics

When digoxin is given orally, absorption varies among available preparations. Lanoxicaps, which are liquid-filled capsules, and the elixir used for children are better absorbed than tablets. With tablets, the most frequently used formulation, differences in bioavailability are important because a person who is stabilized on one formulation may be underdosed or overdosed if another formulation is taken. Differences are attributed to the rate and extent of tablet dissolution rather than amounts of digoxin. In addition to drug dosage forms, other factors that may decrease digoxin absorption include the presence of food in the GI tract, delayed gastric emptying, malabsorption syndromes, and concurrent administration of some drugs (e.g., antacids, cholestyramine).

## Box 48-1

## Additional Drugs Used to Treat Heart Failure

**Adrenergics**

Dopamine or dobutamine (see Chaps. 17 and 51) may be used in acute, severe heart failure (HF) when circulatory support is required, usually in a critical care unit. Given by intravenous (IV) infusion, these drugs strengthen myocardial contraction (inotropic or cardiotoxic effects) and increase cardiac output. Dosage or flow rate is titrated to hemodynamic effects; minimal effective doses are recommended because of vasoconstrictive effects. The drugs also cause tachycardia and hypertension and increase cardiac workload and oxygen consumption.

**Angiotensin-Converting Enzyme (ACE) Inhibitors**

Captopril and other ACE inhibitors (see Chap. 52) are drugs of first choice in treating patients with chronic HF. ACE inhibitors are usually given in combination with a diuretic. All of the drugs have similar effects, but captopril, enalapril, lisinopril, quinapril, and ramipril are Food and Drug Administration (FDA)-approved for treatment of HF. Some clinicians use captopril initially because it has a short half-life and is rapidly eliminated when stopped, then switch to a long-acting drug if captopril is tolerated by the patient. Digoxin, a beta-adrenergic blocking agent, or an aldosterone inhibitor may be added to the ACE-inhibitor/diuretic regimen.

These drugs improve cardiac function and decrease mortality. They also relieve symptoms, increase exercise tolerance, and delay further impairment of myocardial function and progression of HF (i.e., ventricular dilatation and enlargement [ventricular remodeling]). They act mainly to decrease activation of the renin–angiotensin–aldosterone system, a major pathophysiologic mechanism in HF. More specifically, the drugs prevent inactive angiotensin I from being converted to angiotensin II. Angiotensin II produces vasoconstriction and retention of sodium and water; inhibition of angiotensin II decreases vasoconstriction and retention of sodium and water. Thus, major effects of the drugs are dilation of both veins and arteries, decreased preload and afterload, decreased workload of the heart, and increased perfusion of body organs and tissues.

During ACE-inhibitor therapy, patients usually need to see a health care provider frequently for dosage titration and monitoring of serum creatinine and potassium levels for increases. Elevated creatinine levels may indicate impaired renal function, in which case dosage needs to be reduced; elevated potassium levels indicate hyperkalemia, an adverse effect of the drugs.

**Angiotensin II Receptor Blockers (ARBs)**

Losartan and other angiotensin receptor blockers (see Chap. 52) are similar to ACE inhibitors in their effects on cardiac function, although the mechanism of action is at the angiotensin II receptor site rather than inhibiting the conversion of angiotensin I to angiotensin II. All ARBs are approved for treatment of hypertension; however, only valsartan has received FDA approval for treatment of patients with moderate to severe HF and those unable to tolerate an ACE

inhibitor due to adverse effects such as cough. Studies indicate that the addition of an ARB to a regimen that includes ACE inhibitors may result in a decrease in hospitalizations, but does not reduce the mortality rate.

**Beta-Adrenergic Blocking Agents**

Although beta blockers (see Chaps. 18, 49, and 52) were formerly considered contraindicated, numerous research studies indicate they decrease morbidity (i.e., symptoms and hospitalizations) and mortality in patients with chronic HF. The change evolved from a better understanding of the mechanisms causing chronic HF.

Beta blockers suppress activation of the sympathetic nervous system and the resulting catecholamine excess that eventually damages myocardial cells, reduces myocardial beta receptors, and reduces cardiac output. As a result, over time, ventricular remodeling regresses, the heart returns toward a more normal shape and function, and cardiac output increases.

Beta blockers are not recommended for patients in acute HF because of the potential for an initial decrease in myocardial contractility. A beta blocking agent is started after normal blood volume is restored and edema and other symptoms are relieved. The goal of beta blocker therapy is to shrink the ventricle back to its normal size (reverse remodeling). The beta blocker is added to the ACE-inhibitor/diuretic regimen, usually near the end of a hospital stay or as outpatient therapy. Most studies have been done with bisoprolol, carvedilol, or metoprolol; it is not yet known whether some beta blockers are more effective than others. When used in patients with chronic HF, recommendations include starting with a low dose (because symptoms may initially worsen in some patients), titrating the dose upward at approximately 2-week intervals, and monitoring closely. Significant hemodynamic improvement usually requires 2 to 3 months of therapy, but effects are long lasting. Beneficial effects can be measured by increases in the left ventricular ejection fraction (i.e., cardiac output).

The FDA has issued a **BLACK BOX WARNING** for patients with coronary artery disease withdrawing from oral forms of atenolol, metoprolol, nadolol, propranolol, and timolol; abrupt withdrawal has resulted in exacerbation of angina, the incidence of ventricular dysrhythmias, and the occurrence of myocardial infarctions.

**Diuretics**

Diuretics (see Chap. 53) are used in treating both acute and chronic HF. Thiazides (e.g., hydrochlorothiazide) can be used for mild diuresis in patients with normal renal function; loop diuretics (e.g., furosemide) should be used in patients who have impaired renal function or who need strong diuresis.

For patients in acute HF, which is characterized by fluid accumulation, a diuretic is the initial treatment. It acts to decrease plasma volume (extracellular fluid volume) and increase excretion of sodium and water, thereby decreasing preload. With early or mild HF, starting or increasing the dose of an oral thiazide may be effective. With moderate to severe HF (pulmonary edema), an IV loop diuretic is indicated.

IV furosemide also has a vasodilatory effect that helps relieve vasoconstriction (afterload). Although diuretic therapy relieves symptoms, it does not improve left ventricular function and decrease mortality rates. Some patients may also need drugs to increase myocardial contractility and vasodilators to decrease preload, afterload, or both.

In patients with chronic HF, an oral diuretic is a common component of treatment regimens. Depending on the severity of symptoms or degree of HF, the regimen may also include an ACE inhibitor or ARB, a beta blocker, and digoxin.

Potassium-sparing diuretics (e.g., amiloride, triamterene) are often given concurrently with potassium-losing diuretics (e.g., thiazides or loop diuretics) to help maintain normal serum potassium levels. Concomitant use of ACE inhibitors and nonsteroidal anti-inflammatory drugs and the presence of diabetes mellitus increase risks of hyperkalemia.

With all diuretic therapy, serum potassium levels must be measured periodically to monitor for hypokalemia and hyperkalemia. Both hypokalemia and hyperkalemia are cardiotoxic and impair heart function.

**Aldosterone Antagonist**

Increasingly, spironolactone has been added to the drug regimen for patients with moderate to severe HF since the publication of the randomized Aldactone evaluation study (RALES). The study demonstrated that the addition of spironolactone to ACE inhibition decreases mortality in HF. Increased aldosterone, a major factor in the pathophysiology of HF, results in increased interstitial fibrosis that may decrease systolic function and increase the risk of ventricular dysrhythmias. Spironolactone is an aldosterone antagonist that reduces the aldosterone-induced retention of sodium and water and

impaired vascular function. Although ACE inhibitors also decrease aldosterone initially, this effect is transient. Spironolactone is given in a daily dose of 12.5 to 25 mg, along with standard doses of an ACE inhibitor, a loop diuretic, and usually digoxin. In patients with adequate renal function (i.e., serum creatinine 2.5 mg/dL or less), the addition of spironolactone usually allows smaller doses of loop diuretics and potassium supplements. Overall, studies indicate that the addition of spironolactone improves cardiac function and reduces symptoms, hospitalizations, and mortality. A second drug, eplerenone, is approved for use in the management of HF after a myocardial infarction to improve survival.

**Vasodilators**

Vasodilators are essential components of treatment regimens for HF, and the beneficial effects of ACE inhibitors and angiotensin II receptor antagonists stem significantly from their vasodilating effects (i.e., preventing or decreasing angiotensin-induced vasoconstriction). Other vasodilators may also be used. Venous dilators (e.g., nitrates) decrease preload; arterial dilators (e.g., hydralazine) decrease afterload. Isosorbide dinitrate and hydralazine may be combined to decrease both preload and afterload. The combination has similar effects to those of an ACE inhibitor or an ARB, but may not be as well tolerated by patients. Nitrates are discussed in Chapter 50; hydralazine and other vasodilators are discussed in Chapter 52.

Oral vasodilators usually are used in patients with chronic HF and parenteral agents are reserved for those who have severe HF or are unable to take oral medications. Vasodilators should be started at low doses, titrated to desired hemodynamic effects, and discontinued slowly to avoid rebound vasoconstriction.

## Drugs at a Glance: Drugs for Heart Failure (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Phosphodiesterase Inhibitor</b>		
<b>Milrinone</b> (Primacor)	IV bolus infusion (loading dose), 50 mcg/kg over 10 min IV continuous infusion (maintenance dose), 0.375–0.75 mcg/kg/min, diluted in 0.9% or 0.45% NaCl or 5% dextrose solution	Not established
<b>Human B-Type Natriuretic Peptide</b>		
<b>Nesiritide</b> (Natrecor)	IV bolus infusion (loading dose), 2 mcg/kg followed by continuous infusion of 0.01 mcg/kg/min. Use for >48 hours not studied.	Safety not established

Therapeutic serum levels of digoxin are 0.5 to 2 nanograms per milliliter; toxic serum levels are above 2. In the elderly and in the presence of renal failure, therapeutic serum levels are 0.5 to 1.3 nanograms per milliliter. Research in the past decade has suggested that serum levels of 1.0 nanograms per milliliter or less are more appropriate in those with HF. However, toxicity may occur at virtually any serum level. Dosage must be reduced in the presence of renal failure because most of the digoxin (60%–70%) is excreted unchanged by the kidneys to prevent drug accumulation and toxicity. The remainder is metabolized or excreted by nonrenal routes.

### Mechanisms of Action

In HF, digoxin exerts a cardiotonic or positive *inotropic* effect that improves the contractility and pumping ability of the heart. The mechanism by which digoxin increases the force of myocardial contraction is thought to be inhibition of Na,K-adenosine triphosphatase (Na,K-ATPase), an enzyme in cardiac cell membranes that decreases the movement of sodium out of myocardial cells after contraction. As a result, calcium enters the cell in exchange for sodium, causing additional calcium to be released from intracellular binding sites increasing myocardial contractility. Overall, digoxin helps to relieve symptoms and decrease hospitalizations but does not prolong survival. In HF, it is given concomitantly with a diuretic and an ACE inhibitor or ARB.

In patients with atrial dysrhythmias (see Chap. 49), digoxin slows the rate of ventricular contraction (negative chronotropic effect). Negative chronotropic effects are probably caused by several factors. First, digoxin has a direct depressant effect on cardiac conduction tissues, especially the atrioventricular node. This action decreases the number of electrical impulses allowed to reach the ventricles from supraventricular sources. Second, digoxin indirectly stimulates the vagus nerve. Third, increased efficiency of myocardial contraction and vagal stimulation decrease compensatory

tachycardia that results from the sympathetic nervous system response to inadequate circulation.

### Indications for Use

The clinical uses of digoxin include management of HF, atrial fibrillation, and atrial flutter. Digoxin may be used in patients with acute or chronic conditions, for digitalization, or for maintenance therapy. Although the use of digoxin in patients with normal sinus rhythm has been questioned, studies indicate improved ejection fraction and exercise tolerance in patients who receive digoxin. In addition, in patients with HF who are stabilized on digoxin, a diuretic, and an ACE inhibitor or ARB, symptoms worsen if digoxin is discontinued.

### Contraindications to Use

Digoxin is contraindicated in patients with severe myocarditis, ventricular tachycardia, or ventricular fibrillation and must be used cautiously in those with acute myocardial infarction, heart block, Adams-Stokes syndrome, Wolff-Parkinson-White syndrome (risk of fatal dysrhythmias), electrolyte imbalances (hypokalemia, hypomagnesemia, hypercalcemia), and renal impairment.

### Administration and Digitalization

Digoxin is given orally or IV. Although it can be given intramuscularly, this route is not recommended because pain and muscle necrosis may occur at injection sites. When given orally, onset of action occurs in 30 minutes to 2 hours, and peak effects occur in approximately 6 hours. When given IV, the onset of action occurs within 10 to 30 minutes, and peak effects occur in 1 to 5 hours.

In the heart, maximum drug effect occurs when a steady-state tissue concentration has been achieved. This occurs in approximately 1 week (five half-lives) unless loading doses are given for more rapid effects. Traditionally, a *loading dose* is called a digitalizing dose. Digitalization (administration of an amount sufficient to produce therapeutic effects) may be

accomplished rapidly by giving a total dose of 0.75 to 1.5 milligrams of digoxin in divided doses, 6 to 8 hours apart, over a 24-hour period. Because rapid digitalization engenders higher risks of toxicity, it is usually done for atrial tachydysrhythmias, with continuous cardiac monitoring, rather than for HF. Slow digitalization may be accomplished by initiating therapy with a *maintenance dose* of digoxin. When digoxin is discontinued, elimination of the drug requires approximately 1 week.

### Applying Your Knowledge 48-1

Ms. Motsinger is due for her first dose of digoxin. Her physician has decided to digitalize the patient. What does digitalization involve and why would this be desirable in Ms. Motsinger's case?

### Digoxin Toxicity

Digoxin has a narrow *therapeutic index* so a dose adequate for therapeutic effects may produce signs of toxicity. Individuals with hypokalemia can develop digoxin toxicity even when digoxin levels are not considered elevated. Signs of toxicity include potentially life-threatening heart rhythm disturbances, ranging from very slow to rapid ventricular rhythms. Other side effects include nausea, vomiting, loss of appetite, abdominal discomfort, blurred vision, and mental changes. Digoxin toxicity may result from many contributing factors:

- Accumulation of larger-than-necessary maintenance doses
- Rapid loading or digitalization, whether by one or more large doses or frequent administration of small doses
- Impaired renal function, which delays excretion of digoxin
- Age extremes (young or old)
- Electrolyte imbalance (e.g., hypokalemia, hypomagnesemia, hypercalcemia)
- Hypoxia due to heart or lung disease, which increases myocardial sensitivity to digoxin
- Hypothyroidism, which slows digoxin metabolism and may cause accumulation
- Concurrent treatment with other drugs affecting the heart, such as quinidine, verapamil, or nifedipine

### Applying Your Knowledge 48-2

Ms. Motsinger has been taking digoxin for 2 days. You must assess her drug level before administration of digoxin; blood for the test was drawn this morning. What should her drug level be to be in the therapeutic range?

### Phosphodiesterase Inhibitors

**Milrinone** IV (Primacor) is the most commonly used cardiotropic-inotropic agent for short-term management of acute, severe HF that is not controlled by digoxin, diuretics, and

vasodilators. The drug increases levels of cyclic adenosine monophosphate (cAMP) in myocardial cells by inhibiting phosphodiesterase, the enzyme that normally metabolizes cAMP. Milrinone also relaxes vascular smooth muscle to produce vasodilation and decrease preload and afterload. In HF, inotropic and vasodilator effects increase cardiac output. The effects of this drug are additive to those of digoxin and may be synergistic with those of adrenergic drugs (e.g., dobutamine). There is a time delay before the drug reaches therapeutic serum levels as well as inter-individual variability in therapeutic doses.

Milrinone is a potent inotropic agent that is given IV by bolus injection followed by continuous infusion. Flow rate is titrated to maintain adequate circulation. Milrinone can be used alone or with other drugs such as dobutamine and nitroprusside. Its dosage should be reduced in the presence of renal impairment. Dose-limiting adverse effects of the drugs include tachycardia, atrial or ventricular dysrhythmias, and hypotension. Hypotension is more likely to occur in patients who are hypovolemic. Milrinone has a long half-life of approximately 80 hours and may accumulate with prolonged infusions.

### Human B-Type Natriuretic Peptide (Nesiritide)

**Nesiritide** (Natrecor) is the first in this class of drugs to be used in the management of acute HF. Produced by recombinant DNA technology, nesiritide is identical to endogenous human B-type natriuretic peptide (BNP), which is secreted primarily by the ventricles in response to fluid and pressure overload. This drug acts to compensate for deteriorating cardiac function by reducing preload and afterload, increasing diuresis and secretion of sodium, suppressing the renin-angiotensin-aldosterone system, and decreasing secretion of the neurohormones *endothelin* and norepinephrine. Onset of action is immediate with peak effects attained in 15 minutes with a bolus dose followed by continuous IV infusion. Administration should be by a separate IV line because nesiritide is incompatible with many other drugs. Hemodynamic monitoring of pulmonary artery pressure is indicated to determine drug effectiveness. Clearance of the drug is proportional to body weight and partially by the kidneys; however, no adjustment in dosing is required for age, gender, race/ethnicity, or renal function impairment.

### Nursing Process

#### Assessment

Assess patients for current or potential HF.

- Identify risk factors for HF.
  - **Cardiovascular disorders:** atherosclerosis, hypertension, coronary artery disease, myocardial infarction, cardiac dysrhythmias, and cardiac valvular disease

*Nursing Process continues on page 770*

- **Noncardiovascular disorders:** severe infections, hyperthyroidism, pulmonary disease (e.g., cor pulmonale—right-sided HF resulting from lung disease)
- **Other factors:** excessive amounts of IV fluids, rapid infusion of IV fluids or blood transfusions, advanced age
- Interview and observe for signs and symptoms of **chronic HF**. Within the clinical syndrome of HF, clinical manifestations vary from few and mild to many and severe, including the following:
  - **Mild HF:** Common signs and symptoms of mild HF are ankle edema, dyspnea on exertion, and fatigue with ordinary physical activity. Edema results from increased venous pressure, which allows fluids to leak into tissues; dyspnea and fatigue result from tissue hypoxia.
  - **Moderate or severe HF:** More extensive edema, dyspnea, and fatigue at rest are likely to occur. Additional signs and symptoms include orthopnea, postnocturnal dyspnea, and cough (from congestion of the respiratory tract with venous blood); mental confusion (from cerebral hypoxia); oliguria and decreased renal function (from decreased blood flow to the kidneys); and anxiety.
- Observe for signs and symptoms of **acute HF**. Acute pulmonary edema indicates acute HF and is a medical emergency. Pulmonary edema occurs when left ventricular failure results in accumulation of blood and fluid in pulmonary veins and tissues. Causes include acute myocardial infarction, cardiac dysrhythmias, severe hypertension, acute fluid or salt overload, and certain drugs (e.g., quinidine and other cardiac depressants; propranolol and other antiadrenergics; phenylephrine, norepinephrine, and other alpha-adrenergic stimulants). As a result, the person experiences severe dyspnea, hypoxia, hypertension, tachycardia, hemoptysis, frothy respiratory tract secretions, and anxiety.

Assess patients for signs and symptoms of atrial tachydysrhythmias.

- Record the rate and rhythm of apical and radial pulses. Atrial fibrillation, the most common atrial dysrhythmia, is characterized by tachycardia, pulse deficit (faster apical rate than radial rate), and a very irregular rhythm. Fatigue, dizziness, and fainting may occur.
- Check the electrocardiogram (ECG) for abnormal P waves, rapid rate of ventricular contraction, and QRS complexes of normal configuration but irregular intervals.

Assess baseline vital signs; weight; edema; laboratory results for potassium, magnesium, and calcium levels; and other tests of cardiovascular function when available.

Assess a baseline ECG before digoxin therapy when possible. If a patient is in normal sinus rhythm, later ECGs may aid recognition of digitalis toxicity (i.e., drug-induced dysrhythmias). If a patient has an atrial tachydysrhythmia and is

receiving digoxin to slow the ventricular rate, later ECGs may aid recognition of therapeutic and adverse effects. For patients who are already receiving digoxin at the initial contact, a baseline ECG can still be valuable because changes in later ECGs may promote earlier recognition and management of drug-induced dysrhythmias.

## Nursing Diagnoses

- Ineffective Tissue Perfusion related to decreased cardiac output
- Anxiety related to chronic illness and lifestyle changes
- Impaired Gas Exchange related to venous congestion and fluid accumulation in lungs
- Activity intolerance related to impaired gas exchange and fatigue
- Imbalanced Nutrition: Less Than Body Requirements related to digoxin-induced anorexia, nausea, and vomiting
- Noncompliance related to the need for long-term drug therapy and regular medical supervision
- Deficient Knowledge: Managing drug therapy regimen safely and effectively

## Planning/Goals

### The patient will

- Take digoxin and other medications safely and accurately
- Experience improved breathing and less fatigue and edema
- Maintain serum digoxin levels within therapeutic ranges
- Be closely monitored for therapeutic and adverse effects, especially during digitalization; when dosage is being changed; and when other drugs are added to or removed from the management regimen
- Keep appointments for follow-up monitoring of vital signs, serum potassium levels, serum digoxin levels, and renal function

## Interventions

- Use measures to prevent or minimize HF and atrial dysrhythmias. In the broadest sense, preventive measures include sensible eating habits (a balanced diet; avoiding excess saturated fat and salt; weight control), avoiding cigarette smoking, and regular exercise. In the patient at risk for development of HF and dysrhythmias, preventive measures include the following:
  - Treatment of hypertension
  - Avoidance of hypoxia
  - Weight control
  - Avoidance of excess sodium in the diet
  - Avoidance of fluid overload, especially in elderly patients

- Maintenance of management programs for HF, atrial dysrhythmias, and other cardiovascular or noncardiovascular disorders
- Monitor vital signs, weight, urine output, and serum potassium level regularly, and compare with baseline values.
- Monitor ECGs when available, and compare with baseline or previous tracings.
- Provide appropriate teaching related to drug therapy (see accompanying display).

### Evaluation

- Interview and observe for relief of symptoms (weight loss, increased urine output, less extremity edema, easier breathing, improved activity tolerance and self-care ability, slower heart rate).
- Observe serum drug levels for normal or abnormal values, when available.
- Interview regarding compliance with instructions for taking the drug.
- Interview and observe for adverse drug effects, especially cardiac dysrhythmias.

### Applying Your Knowledge 48-3

#### How Can You Avoid This Medication Error?

You are giving Ms. Motsinger her morning medication. The pharmacy has sent Lanoxicaps for today's dose of digoxin. You administer the 0.125-mg capsule.

## Principles of Therapy

### Goals of Therapy

The goals for patients with compensated HF are to maintain function as nearly normal as possible and to prevent symptomatic (acute, congestive, or decompensated) HF, hospitalizations, and death. When symptoms (decompensation) occur, the goals are to relieve symptoms, restore function, and prevent progressive cardiac deterioration.

### Nonpharmacologic Management Measures

- Prevent or treat conditions that precipitate cardiac decompensation and failure (e.g., fluid and sodium retention, factors that impair myocardial contractility or increase cardiac workload).
- Restrict dietary sodium intake to reduce edema and other symptoms and allow a decrease in diuretic dosage. For most patients, sodium restriction need not be severe. A common order, “no added salt,” may be accomplished by avoiding

obviously salty foods (e.g., ham, potato chips, snack foods) and by not adding salt during cooking or eating. For patients with more severe HF, dietary intake may be more restricted (e.g., no more than 2 g daily). A major source of sodium intake is table salt: A level teaspoonful contains 2300 milligrams of sodium.

- If hyponatremia (serum sodium < 130 mEq/L) develops from sodium restrictions and diuretic therapy, fluids may need to be restricted (e.g., 1.5 L/day or less) until the serum sodium level increases. Severe hyponatremia (<125 mEq/L) may lead to dysrhythmias.
- For patients who are obese, weight loss is desirable to decrease systemic vascular resistance and myocardial oxygen demand.
- Reduce physical activity in patients with symptomatic HF. This decreases the workload and oxygen consumption of the myocardium. If bed rest is instituted, antithrombotic measures such as compression stockings/devices or heparin therapy should be prescribed to prevent deep vein thrombosis.
- Administer oxygen, if needed, to relieve dyspnea, improve oxygen delivery, reduce the work of breathing, and decrease constriction of pulmonary blood vessels (which is a compensatory measure in patients with hypoxemia).
- Prepare patient and family for heart transplant, if indicated.

## Pharmacologic Management

### Drug Selection

A combination of drugs is the standard of care for both acute and chronic HF. Specific drug components depend on the patient's symptoms and hemodynamic status.

#### Acute Heart Failure

For acute HF, the first drugs of choice may include an IV loop diuretic, a cardiotonic–inotropic agent (e.g., digoxin, dobutamine, milrinone), and vasodilators (e.g., nitroglycerin and hydralazine or nitroprusside). For patients with decompensated acute HF, nesiritide may be used for initial treatment (<48 hours) or may be given in combination with diuretics, inotropes, or vasodilators. These combinations reduce preload and afterload and increase myocardial contractility.

In acute HF, there is a high risk of hypokalemia because large doses of potassium-losing diuretics are often given. Serum potassium levels should be monitored regularly and supplemental potassium may be needed.

#### Chronic Heart Failure

For chronic HF, an ACE inhibitor or ARB and a diuretic are the basic standard of care. Digoxin, a beta-adrenergic blocking agent, and spironolactone may also be added. Although the use of digoxin in patients with normal sinus rhythm has been questioned, studies indicate improved ejection fraction and exercise tolerance in patients who receive digoxin. In addition, in patients stabilized on digoxin, a diuretic, and an ACE inhibitor or ARB, symptoms worsen if digoxin is discontinued.

## Patient Teaching Guidelines Digoxin

### General Considerations

- This drug is prescribed for two types of heart disease. One type is heart failure, in which digoxin strengthens your heartbeat and helps to relieve such symptoms as ankle swelling, shortness of breath, and fatigue. The other type is a fast heartbeat called *atrial fibrillation*, in which digoxin slows the heartbeat and decreases symptoms such as fatigue. Because these are chronic conditions, digoxin therapy is usually long term. Ask your health care provider why you are being given digoxin and what effects you can expect, both beneficial and adverse.
- It is extremely important to take digoxin (and other cardiovascular medications) as prescribed, usually once daily. The drug must be taken regularly to maintain therapeutic blood levels, but overuse can cause serious adverse effects.
- Precautions to increase the drug's safety and effectiveness include the following:
  - As a general rule, *do not miss a dose*. It is helpful to develop a routine of taking the medication at approximately the same time each day and maintaining a written record, such as a dated checklist. If you forget a dose at the usual time and remember it within a few hours (approximately 6), go ahead and take the daily dose.
  - *Do not take an extra dose*. For example, do not take a double dose to make up for a missed dose.
  - *Do not take other prescription or nonprescription* (e.g., antacids, cold remedies, diet pills) drugs without consulting the health care provider who prescribed digoxin. Many drugs interact with digoxin to increase or decrease its effects.
  - You will need periodic physical examinations, electrocardiograms, and blood tests to check digoxin and electrolyte (sodium, potassium, magnesium) levels to monitor your response to digoxin and see whether changes in dosage are needed.
- Digoxin is often one drug in a management regimen of several drugs for heart disease. The drugs are all needed to help the heart and blood vessels work better. Together, the drugs help maintain a balance in the cardiovascular system. As a result, changing any aspect of one of the drugs can upset the balance and lead to symptoms. For example, stopping one drug because of adverse effects can lead to problems. If you think a drug needs to be stopped or its dosage reduced, talk with a health care provider. *Do not*

make changes on your own; serious illness or even death could result.

- Small doses (e.g., 0.125 milligrams [125 micrograms] daily or every other day) are usually given to older adults, and other people with impaired kidney function. Digoxin is eliminated through the kidneys; it can accumulate and cause adverse effects if dosage is not reduced in patients with kidney impairment.
- You may need to limit your salt (sodium chloride) intake and get an adequate supply of potassium. Follow your health care provider's recommendations about any diet changes. People taking digoxin are often taking a diuretic, a drug that increases urine production and loss of sodium and potassium from the body. If potassium levels get too low, adverse effects of digoxin are more likely to occur. However, too much potassium can also be harmful. Do not use salt substitutes (potassium chloride) without consulting a health care provider.
- Report adverse drug effects (e.g., undesirable changes in heart rate or rhythm, nausea and vomiting, or visual problems) to a health care provider. These symptoms may indicate that digoxin dosage needs to be reduced.
- Use the same brand and type of digoxin all the time. For example, whether using generic digoxin or trade-name Lanoxin tablets, get the same one each time a prescription is refilled. In addition, there is a capsule form and a liquid form. These forms and concentrations are different and cannot be used interchangeably. Underdoses and overdoses may occur. Lanoxin tablets are the most commonly used formulation.

### Self- or Caregiver Administration

- If instructed to do so by your health care provider, count your pulse before each dose. In some circumstances, you may be advised to skip that scheduled dose. *Do not skip doses unless specifically instructed to do so.*
- Take or give digoxin tablets approximately the same time each day to maintain more even blood levels and help in remembering to take the drug. The tablets may be crushed and can be taken with or after food, if desired, although milk and dairy products may delay absorption.
- Digoxin capsules should be swallowed whole.
- If taking or giving a liquid form of digoxin, it is extremely important to measure it accurately. A few drops more could produce overdosage, with serious adverse effects; a few drops less could produce underdosage, with a loss or decrease of therapeutic effects.

In chronic HF, hypokalemia may be less likely to occur because lower doses of potassium-losing diuretics are usually being given. In addition, there may be more extensive use of potassium-sparing diuretics (e.g., amiloride, triamterene) and the aldosterone antagonist, spironolactone. Note, however, that hyperkalemia must also be prevented because it is cardiotoxic. Overall, these drugs improve patients' quality of life by decreasing their symptoms and increasing their ability to function in activities of daily living. They also decrease hospitalizations and deaths from HF.

### Digoxin Dosage and Administration

Digoxin dosages must be interpreted with consideration of specific patient characteristics including age, weight, gender, renal function, general health state, and concurrent drug therapy. Loading or digitalizing doses are necessary for initiating therapy as digoxin's long half-life make therapeutic serum levels difficult to obtain without loading. Loading doses should be used cautiously in patients who have taken digoxin within the previous 2 or 3 weeks. Maintenance doses, which are much smaller than loading doses, are always used for long-term ther-

apy. They may be safely used to initiate digoxin therapy, but therapeutic serum levels may not be achieved for weeks. In general, larger doses of digoxin are needed to slow the heart rate in atrial tachydysrhythmias than to increase myocardial contractility in HF. A small group of individuals (about 10%) have digoxin-metabolizing bacteria in their colons require larger doses of digoxin to reach therapeutic serum levels. Members of this group are at risk for development of digoxin toxicity if they are concomitantly given antibacterial drugs that destroy colonic bacteria.

When converting from the oral to IV route, the dosage of digoxin should be reduced by 20% to 30%. When a maintenance dose is given IV, the onset and peak occur earlier, although the duration of action remains the same. Cardiac monitoring should be used in patients receiving IV loading regimens.

Smaller doses (loading and maintenance) should be given to patients who are elderly or have hypothyroidism. Because metabolism and excretion of digoxin are delayed in such people, the drug may accumulate and cause toxicity if dosage is not reduced. Dosage also should be reduced in patients with hypokalemia, extensive myocardial damage, or cardiac conduction disorders. These conditions increase risks of digoxin-induced dysrhythmias.

Dosage can be titrated according to patient response. In HF, severity of symptoms, ECGs, and serum drug concentrations are useful. In atrial fibrillation, dosage can be altered to produce the desired decrease in the ventricular rate of contraction. Optimal dosage is the lowest amount that relieves signs and symptoms of HF or alters heart rate and rhythm toward normal without producing toxicity.

Digoxin dosage must be reduced by approximately half in patients with renal failure to avoid drug accumulation and toxicity. Dosage should be based on signs and symptoms of toxicity, creatinine clearance, and serum drug levels.

Dosage of digoxin must be reduced by approximately half when certain drugs are given concurrently to avoid drug accumulation and toxicity. For example, amiodarone, quinidine, nifedipine, and verapamil slow digoxin excretion and increase serum digoxin levels.

When a hospitalized patient is unable to take a daily maintenance dose of digoxin at the scheduled time because of diagnostic tests, treatment measures, or other reasons, the dose should usually be given later rather than omitted. If the patient is having surgery, the nurse often must ask the surgeon whether the drug should be given on the day of surgery (i.e., orally with a small amount of water or parenterally) and if the drug should be reordered after surgery. Many patients require continued digoxin therapy. However, if a dose is missed, probably no ill effects will occur because the pharmacologic actions of digoxin persist longer than 24 hours.

Electrolyte balance must be monitored and maintained during digoxin therapy, particularly normal serum levels of potassium (3.5–5 mEq/L), magnesium (1.5–2.5 mg/100 mL), and calcium (8.5–10 mg/100 mL). Hypokalemia and hypomagnesemia increase cardiac excitability and ectopic pacemaker

activity, leading to dysrhythmias; hypercalcemia enhances the effects of digoxin. These electrolyte abnormalities increase the risk of digoxin toxicity. Hypocalcemia increases excitability of nerve and muscle cell membranes and causes myocardial contraction to be weak (leading to a decrease in digoxin effect).

## Digoxin Toxicity: Recognition and Management

Digitalis toxicity is one of the most commonly encountered drug-related reasons for hospitalization. Digoxin has a narrow therapeutic index (a small difference between toxic and therapeutic doses), and the endpoint of effective therapy is often difficult to define and measure. Recognition of digoxin toxicity may be difficult because of nonspecific early manifestations (e.g., anorexia, nausea, confusion) and the similarity between the signs and symptoms of heart disease for which digoxin is given and the signs and symptoms of digoxin intoxication. Continued atrial fibrillation with a rapid ventricular response may indicate inadequate dosage. However, other dysrhythmias may indicate toxicity. Premature ventricular contractions commonly occur. Serum drug levels and ECGs may be helpful in verifying suspected toxicity. Blood for serum digoxin testing should be drawn just before a dose. Drug distribution to tissues requires about 6 hours after a dose is given; if the blood is drawn before 6 hours, the level may be high.

When digoxin toxicity occurs, management may include any or all of the following interventions, depending on the patient's condition:

- Digoxin should be discontinued, not just reduced in dosage. Most patients with mild or early toxicity recover completely within a few days after the drug is stopped.
- If serious cardiac dysrhythmias are present, several drugs may be used, including
  - **Potassium chloride**, if serum potassium level is low. It is a myocardial depressant that acts to decrease myocardial excitability. The dose depends on the severity of toxicity, serum potassium level, and patient response. Potassium is contraindicated in renal failure and should be used with caution in the presence of cardiac conduction defects.
  - **Lidocaine**, an antidysrhythmic local anesthetic agent used to decrease myocardial irritability
  - **Atropine** or **isoproterenol**, used in the management of bradycardia or conduction defects
  - Other antidysrhythmic drugs may be used but are in general less effective in digoxin-induced dysrhythmias than in dysrhythmias due to other causes.
  - **Digoxin immune fab** (Digibind) is a digoxin-binding antidote derived from antidigoxin antibodies produced in sheep. It is recommended only for serious toxicity. It combines with digoxin and pulls digoxin out of tissues and into the bloodstream. This causes serum digoxin levels to be high, but the drug is bound to the antibody and therefore inactive. Digoxin immune fab is given IV, as a bolus injection if the patient is in danger of immediate

cardiac arrest, but preferably over 15 to 30 minutes. Dosage varies and is calculated according to the amount of digoxin ingested or serum digoxin levels (see manufacturer's instructions).

## Use in Special Populations

### Use in Children

Digoxin is commonly used in children for the same indications as for adults and should be prescribed or supervised by a pediatric cardiologist when possible. The response to a given dose varies with age, size, and renal and hepatic function. There may be little difference between a therapeutic dose and a toxic dose. Very small amounts are often given to children. These factors increase the risks of dosage errors in children. In a hospital setting, institutional policies may require that each dose be verified with another nurse before it is administered. Liquid digoxin must be precisely measured in a syringe and the dose should not be rounded. ECG monitoring is desirable when digoxin therapy is started.

As in adults, dosage of digoxin should be individualized and carefully titrated. Digoxin is primarily excreted by the kidneys, and dosage must be reduced with impaired renal function. In general, divided daily doses should be given to infants and children younger than 10 years, and adult dosages adjusted to their weight should be given to children older than 10 years of age. Larger doses are usually needed to slow a too-rapid ventricular rate in children with atrial fibrillation or flutter. Differences in bioavailability of different preparations (parenterals, capsules, elixirs, and tablets) must be considered when switching from one preparation to another.

Neonates vary in tolerance of digoxin depending on their degree of maturity. Premature infants are especially sensitive to drug effects. Dosage must be reduced, and digitalization should be even more individualized and cautiously approached than in more mature infants and children. Early signs of toxicity in newborns are undue slowing of sinus rate, sinoatrial arrest, and prolongation of the P–R interval.

### Use in Older Adults

Digoxin is widely used and a frequent cause of adverse effects in older adults. Reduced dosages are usually required because of decreased liver or kidney function, decreased lean body weight, and advanced cardiovascular disease. All of these characteristics are common in older adults. Impaired renal function leads to slower drug excretion and increased risk of accumulation. Dosage must be reduced by approximately 50% with renal failure or concurrent administration of amiodarone, quinidine, nifedipine, or verapamil. These drugs increase serum digoxin levels and increase risks of toxicity if dosage is not reduced. The most commonly recommended dose is 0.125 milligrams daily. Antacids decrease absorption of oral digoxin and should not be given at the same time.

### Use in Patients With Renal Impairment

Digoxin should be used cautiously, in reduced dosages, because renal impairment delays its excretion. Both loading and maintenance doses should be reduced. Patients with advanced renal

impairment can achieve therapeutic serum concentrations with a dosage of 0.125 milligrams three to five times per week.

In addition, in patients with reduced blood flow to the kidneys (e.g., fluid volume depletion, acute HF), digoxin may be reabsorbed in renal tubules. As a result, less digoxin is excreted through the kidneys and maintenance doses may need even greater decreases than those calculated according to creatinine clearance. Thus, digoxin toxicity develops more often and lasts longer in renal impairment. Patients with renal impairment who are receiving digoxin, even in small doses, should be monitored closely for adverse effects, and serum digoxin levels should be monitored periodically.

With milrinone, which is also excreted primarily by the kidneys, renal impairment significantly increases elimination half-life, drug accumulation, and adverse effects. Dosage should be reduced according to creatinine clearance (see manufacturer's instructions).

### Use in Patients With Hepatic Impairment

Hepatic impairment has little effect on digoxin clearance, and no dosage adjustments are needed.

### Use in Patients With Critical Illness

Critically ill patients often have multiple cardiovascular and other disorders that require drug therapy. Acute HF may be the primary critical illness. It may also be precipitated by other illnesses or treatments that alter fluid balance, impair myocardial contractility, or increase the workload of the heart beyond its capacity to accommodate. Management is often symptomatic, with choice of drug and dosage requiring careful titration and frequent monitoring of the patient's response. Cardiotonic, diuretic, and vasodilator drugs are often required. All of the drugs should be used with caution in critically ill patients.

### Use in Home Care

Most digoxin is taken at home, and the home care nurse shares responsibility for teaching patients how to use the drug effectively and circumstances to be reported to a health care provider. Accurate dosing is vitally important because underuse may cause recurrence of symptoms and overuse may cause toxicity. Either condition may be life threatening and require emergency care. The home care nurse also needs to monitor patients' responses to the drug and changes in conditions or drug therapy that increases risks of toxicity.

When patients are receiving a combination of drugs for management of HF, the nurse needs to assist them in understanding that the different types of drugs have different actions and produce different responses. As a result, they work together to be more effective and maintain a more balanced state of cardiovascular function. Changing drugs or dosages can upset the balance and lead to acute and severe symptoms that require hospitalization and may even cause death from HF. Thus, it is extremely important that they take all the medications as prescribed. If unable to take the medications for any reason, patients or caregivers should notify the prescribing health care provider. They should be instructed not to wait until symptoms become severe before seeking care.

## Use in Patients Taking Herbal and Dietary Supplements

Use of nonprescription herbal and dietary supplements is frequently not reported by the patient even though one third of the adults in the United States use these agents. Significant interactions can occur between supplements and prescribed

drugs. Natural licorice blocks the effects of spironolactone and causes sodium retention and potassium loss, effects that may worsen HF and potentiate the effects of digoxin. Hawthorn should be used cautiously as it may increase the effects of ACE inhibitors and digoxin. Use of ginseng can result in digoxin toxicity. Patients may utilize herbs such as dandelion root and juniper berries for their diuretic effect. Herbal and dietary supplements should not be taken instead of prescribed drug therapies.

### Nursing Actions

### Cardiotonic-Inotropic Drugs

#### NURSING ACTIONS

#### RATIONALE/EXPLANATION

##### 1. Administer accurately

##### a. With digoxin:

- (1) Read the drug label and the health care provider's order carefully when preparing a dose.
- (2) Give only the ordered dosage form (e.g., tablet, Lanoxi-cap, or elixir).
- (3) Check the apical pulse before each dose. If the rate is less than 60 in adults, 70 in older children, or 100 in younger children and infants, omit the dose, and notify the health care provider.
- (4) Have the same nurse give digoxin to the same patients when possible because it is important to detect changes in rate and rhythm (*see Observe for therapeutic effects and Observe for adverse effects*, later).
- (5) Give oral digoxin with food or after meals.

For accurate administration

Digoxin formulations vary in concentration and bioavailability and cannot be used interchangeably. Bradycardia is an adverse effect.

- (6) Inject intravenous (IV) digoxin slowly (over at least 5 min).

This may minimize gastric irritation and symptoms of anorexia, nausea, and vomiting. However, these symptoms probably arise from drug stimulation of chemoreceptors in the medulla rather than as a direct irritant effect of the drug on the gastrointestinal (GI) tract. Digoxin should be given slowly because the diluent, propylene glycol, has toxic effects on the cardiac conduction system if given too rapidly. Digoxin may be given undiluted or diluted with a fourfold or greater volume of sterile water for injection, 0.9% sodium chloride injection, or 5% dextrose injection. If diluted, use the solution immediately.

##### b. With milrinone:

- (1) Dilute with 0.9% or 0.45% sodium chloride or 5% dextrose solution; use the diluted solution within 24 hours.
- (2) Give the loading dose by bolus infusion over 10 minutes.
- (3) Give maintenance infusions at a standard rate of 0.5 mcg/kg/min; this rate may be increased or decreased according to response.

Manufacturer's recommendations

Manufacturer's recommendations

##### c. With nesiritide:

- (1) Dilute with 5 mL of 0.9% or 0.45% sodium chloride or 5% dextrose solution from a 250 mL IV container; add mixed drug to the container and use diluted solution within 24 hours.
- (2) Prime infusion tubing with 25 mL prior to connecting to the patient; withdraw a bolus loading dose from infusion solution.
- (3) Give a bolus injection of 2 mcg/kg over 1 minute.
- (4) Give the maintenance infusion at a rate of 0.01 mcg/kg/min.
- (5) Do not mix with any other drug solution; administer through a separate line.

Manufacturer's recommendations

Manufacturer's recommendations

Incompatible with most drugs

## Nursing Actions **Cardiotonic-Inotropic Drugs** (continued)

### NURSING ACTIONS

#### 2. Observe for therapeutic effects

a. When the drugs are given in heart failure (HF), observe for:

(1) Fewer signs and symptoms of pulmonary congestion (dyspnea, orthopnea, cyanosis, cough, hemoptysis, crackles, anxiety, restlessness)

(2) Decreased edema—absence of pitting, decreased size of ankles or abdominal girth, decreased weight

(3) Increased tolerance of activity

b. When digoxin is given in atrial dysrhythmias, observe for:

(1) Gradual slowing of the heart rate to 70 to 80 beats/min

(2) Elimination of the pulse deficit

(3) Change in rhythm from irregular to regular

#### 3. Observe for adverse effects

a. With digoxin observe for:

(1) Cardiac dysrhythmias:

(a) Premature ventricular contractions (PVCs)

(b) Bradycardia

(c) Paroxysmal atrial tachycardia with heart block

(d) AV nodal tachycardia

(e) AV block (second- or third-degree heart block)

(2) Anorexia, nausea, vomiting

(3) Headache, drowsiness, confusion

(4) Visual disturbances (e.g., blurred vision, photophobia, altered perception of colors, flickering dots)

b. With milrinone, observe for ventricular dysrhythmias, hypotension, and headache.

### RATIONALE/EXPLANATION

The pulmonary symptoms that develop with HF are a direct result of events initiated by inadequate cardiac output. The left side of the heart is unable to accommodate incoming blood flow from the lungs. The resulting back pressure in pulmonary veins and capillaries causes leakage of fluid from blood vessels into tissue spaces and alveoli. Fluid accumulation may result in severe respiratory difficulty and pulmonary edema, a life-threatening development. The improved strength of myocardial contraction resulting from cardiotonic-inotropic drugs reverses this potentially fatal chain of events. Diuresis and decreased edema result from improved circulation and increased renal blood flow.

Indicates a more adequate supply of blood to tissues

In patients with atrial fibrillation, slowing of the heart rate and elimination of the pulse deficit are clinical indicators that digitalization has been achieved.

There is a high incidence of adverse effects with digoxin therapy. Therefore, every patient receiving digoxin requires close observation. Severity of adverse effects can be minimized with early detection and treatment.

Digoxin toxicity may cause any type of cardiac dysrhythmia. These are the most serious adverse effects associated with digoxin therapy. They are detected as abnormalities in electrocardiograms and in pulse rate or rhythm.

PVCs are among the most common digoxin-induced dysrhythmias. They are not specific for digoxin toxicity because there are many possible causes. They are usually perceived as “skipped” heartbeats by patients.

Excessive slowing of the heart rate is an extension of the drug's therapeutic action of slowing conduction through the atrioventricular (AV) node and probably depressing the sinoatrial node as well.

Electrocardiogram study is necessary for identification of nodal rhythms and heart block.

These GI effects commonly occur with digoxin therapy. Because they are caused at least in part by stimulation of the vomiting center in the brain, they occur with parenteral and oral administration. The presence of these symptoms raises suspicion of digitalis toxicity, but they are not specific because many other conditions may cause anorexia, nausea, and vomiting. Also, patients receiving digoxin are often taking other medications that cause these side effects, such as diuretics and potassium supplements.

These central nervous system effects are most common in older adults.

These are due mainly to drug effects on the retina and may indicate acute toxicity.

Ventricular dysrhythmias reportedly occur in 12% of patients, hypotension and headache in approximately 3% of patients.

**NURSING ACTIONS**

c. With nesiritide, observe for hypotension, headache, nausea, back pain, ventricular tachycardia, dizziness, anxiety, insomnia, bradycardia, and vomiting.

**4. Observe for drug interactions**

a. Drugs that *increase* effects of digoxin:

- (1) Adrenergic drugs (e.g., ephedrine, epinephrine, isoproterenol)
- (2) Antidysrhythmics (e.g., amiodarone, propafenone, quinidine)

(3) Anticholinergics

(4) Calcium preparations

(5) Calcium channel blockers (e.g., diltiazem, felodipine, nifedipine, verapamil)

b. Drugs that *decrease* effects of digoxin:

- (1) Antacids, cholestyramine, colestipol, laxatives, oral aminoglycosides (e.g., neomycin)

**RATIONALE/EXPLANATION**

Hypotension occurs in approximately 11% of patients; headache in 8%; nausea and back pain in 4%; and other adverse effects in 1%–3%.

Most significant drug interactions increase risks of toxicity. Some alter absorption or metabolism to produce underdigitalization and decreased therapeutic effect.

Increase risks of cardiac dysrhythmias

Decrease clearance of digoxin, thereby increasing serum digoxin levels and risks of toxicity. Dosage of digoxin should be reduced if one of these drugs is given concurrently (25% with propafenone and 50% with amiodarone and quinidine). Increase absorption of oral digoxin by slowing transit time through the GI tract

Increase risks of cardiac dysrhythmias. IV calcium salts are contraindicated in digitalized patients.

Decrease clearance of digoxin, thereby increasing serum digoxin levels and risks of toxicity. Dosage of digoxin should be reduced 25% if verapamil is given concurrently.

Decrease absorption of oral digoxin

**Key Concepts**

- Heart failure may result from impaired myocardial contraction during systole (systolic dysfunction), impaired relaxation and filling of ventricles during diastole (diastolic dysfunction), or a combination of systolic and diastolic dysfunction.
- The most common conditions leading to HF are coronary artery disease and hypertension.
- Cardinal manifestations of HF are dyspnea and fatigue, which can lead to exercise intolerance and fluid retention, resulting in pulmonary congestion and peripheral edema.
- Beta blockers are not recommended for patients in acute HF because of the potential for an initial decrease in myocardial contractility.
- For acute HF, the first drugs of choice may include an IV loop diuretic, a cardiotonic–inotropic agent (e.g., digoxin, dobutamine, milrinone), and vasodilators (e.g., nitroglycerin and hydralazine or nitroprusside).
- Digitalis toxicity is one of the most commonly encountered drug-related reasons for hospitalization because the drug has a narrow therapeutic index and the end-point of effective therapy is often difficult to define and measure.
- The normal digoxin level is 0.5 to 2.0 ng/mL. Toxic serum levels are greater than 2 ng/mL; however, toxicity may occur at any serum level.

**Review and Application Exercises****Short Answer Exercises**

1. What signs and symptoms usually occur with HF? How would you assess for these?
2. What are the physiologic effects of digoxin on the heart?
3. How does digoxin produce or assist diuresis?
4. Differentiate between a loading dose of digoxin and a daily maintenance dose.
5. Why do nurses need to check heart rate and rhythm before giving digoxin?
6. When is it appropriate to withhold a dose of digoxin?
7. What are adverse effects associated with digoxin, and how may they be prevented or minimized?
8. Why is it important to maintain a therapeutic serum potassium level during digoxin therapy?
9. What is the specific antidote for severe digoxin toxicity?

### NCLEX-Style Questions

10. A 65-year-old patient that you are caring for develops digoxin toxicity 1 month after beginning 0.25 mg of digoxin PO daily. Which factor will affect the duration of such an adverse reaction?
  - a. daily drug dosage
  - b. half-life of the drug
  - c. form of the drug prescribed
  - d. duration of therapy
11. A 5-year-old child that you are caring for has an order to be placed on digoxin. You know that the electrolyte imbalance that will place her at the greatest risk for digoxin toxicity is
  - a. hyponatremia
  - b. hyperkalemia
  - c. hypocalcemia
  - d. hypokalemia
12. When administering the daily dose of digoxin 0.125 mg PO to a patient with a history of type 1 diabetes mellitus who is now in heart failure, it is most important for the nurse to
  - a. give it with orange juice
  - b. monitor for dysrhythmias
  - c. administer it 1 hour before the morning insulin
  - d. withhold it if the apical pulse rate is less than 80 beats per minute
13. A 44-year-old patient develops blurring of the vision with yellow spots in his visual fields while taking digoxin. The nurse recognizes that the visual changes may indicate
  - a. a need for a vision exam
  - b. adjustment of the retina to the drug
  - c. acute toxicity
  - d. therapeutic effects
14. As the nurse prepares to administer a scheduled dose of digoxin to an adult patient, she reviews lab results from earlier in the day and notes that the plasma level of digoxin is 1.5 ng/mL. Based on this report, the nurse should
  - a. Withhold the drug and notify the health care provider during rounds.
  - b. Withhold the drug and notify the health care provider immediately.
  - c. Administer Digibind to counteract the toxicity.
  - d. Check the patient's pulse and if it is greater than 60 beats per minute, administer the dose of digoxin.

# Antidysrhythmic Drugs

## KEY TERMS

- Absolute refractory period
- Antidysrhythmic
- Arrhythmias
- Automaticity
- Dysrhythmias
- Ectopic
- Excitability
- Relative refractory period

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Provide an overview of the cardiac electrophysiology and specific cardiac dysrhythmias effecting rhythm.
2. Discuss the roles of sodium channel, beta-adrenergic, potassium channel, and calcium channel blockers along with two unclassified drugs in the management of dysrhythmias.
3. Describe the nursing process implications and actions related to caring for patients using selected antidysrhythmic drugs.
4. Describe principles of therapy to include nonpharmacologic and pharmacologic measures to manage tachydysrhythmias.
5. Differentiate between supraventricular and ventricular dysrhythmias in terms of etiology and hemodynamic effect on the patient.
6. Discuss the effects of dysrhythmias in special populations.

## Applying Your Knowledge

Tyrone Brown is a 74-year old man with cardiovascular disease. He has just undergone cardiac bypass surgery for three coronary artery bypasses. During the postoperative period, Mr. Brown develops premature ventricular complexes (PVCs) and atrial fibrillation (AF).

## Introduction

Antidysrhythmic agents are medications used for prevention and treatment of cardiac dysrhythmias. *Dysrhythmias*, sometimes called *arrhythmias*, are abnormalities in heart rate or rhythm. They become significant when they interfere with cardiac function and the ability to perfuse body tissues. To aid in understanding of antidysrhythmic drug therapy, the physiology of the cardiac conduction system is reviewed.

## Cardiac Electrophysiology

The heart is an electrical pump. The “electrical” activity resides primarily in the specialized tissues that can generate and conduct an electrical impulse. Although impulses are conducted through muscle cells, the rate is much slower. The mechanical or “pump” activity resides in contractile tissue. Normally, these activities result in effective cardiac contraction and distribution of blood throughout the body. Each heartbeat occurs at regular intervals and consists of four events: *stimulation* from an electrical impulse, *transmission* of the electrical impulse to adjacent conductive or contractile tissue, *contraction* of atria and then ventricles, and *relaxation* of atria and then ventricles.

## Automaticity

*Automaticity* is the heart's ability to generate an electrical impulse. Any part of the conduction system can spontaneously start an impulse, but the sinoatrial (SA) node normally has the fastest rate of automaticity and therefore the faster rate of spontaneous impulse formation. With this faster rate of electrical discharge or depolarization than other parts of the conduction system, the SA node serves as the pacemaker site.

Initiation of an electrical impulse depends predominately on the movement of sodium and calcium ions into a myocardial cell and movement of potassium ions out of the cell. Normally, the cell membrane becomes more permeable to sodium and opens channels to allow rapid movement into the cell. Calcium ions follow sodium ions into the cell at a slower rate and through different channels. As sodium and calcium ions move into cells, potassium ions move out of cells. The movement of the ions changes the membrane from its resting state of electrical neutrality to an activated state of electrical energy buildup. After the electrical energy is discharged (depolarization), muscle contraction occurs.

The ability of a cardiac muscle cell to respond to an electrical stimulus is called *excitability*. The stimulus must reach a certain threshold to cause contraction. After contraction, sodium and calcium ions return to the extracellular space, potassium ions return to the intracellular space, muscle relaxation occurs, and the cell prepares for the next electrical stimulus followed by contraction.

Following contraction there is also a period of decreased excitability (called the *absolute refractory period*) during which the cell cannot respond to a new stimulus. Before the resting membrane potential is reached, a stimulus greater than normal

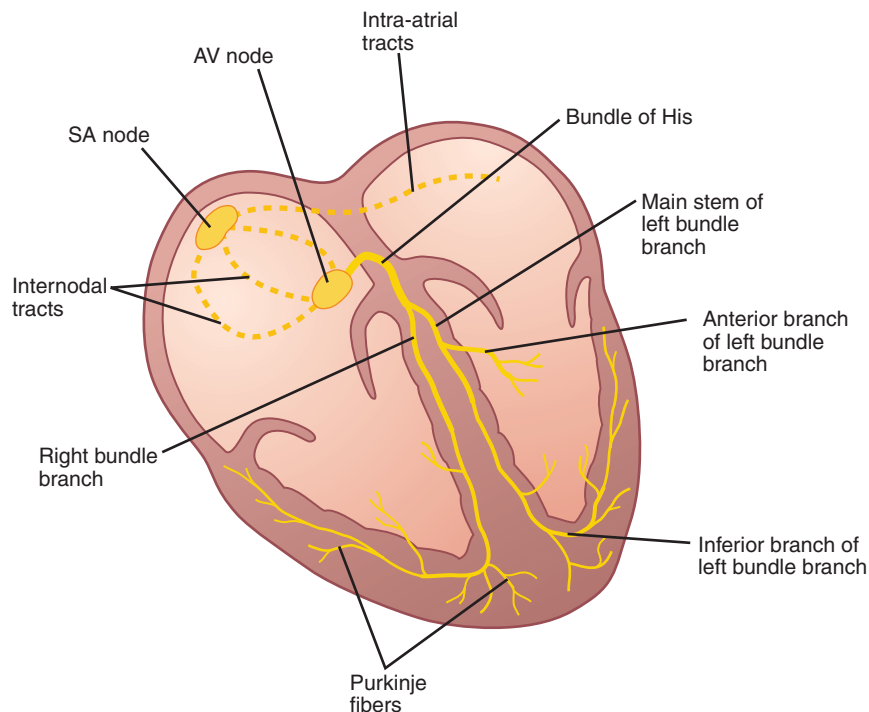

can evoke a response in the cell. This period is called the *relative refractory period*.

## Conductivity

Conductivity is the ability of cardiac tissue to transmit electrical impulses. The orderly, rhythmic transmission of impulses to all cells is needed for effective myocardial contraction. The cardiac conduction system is shown in Figure 49-1. Normally, electrical impulses originate in the SA node and are transmitted through internodal pathways to the atrioventricular (AV) node, where the impulse is delayed for a period of time. Then the impulse travels through the bundle of His, bundle branches, Purkinje fibers, and throughout the ventricular muscle.

## Cardiac Dysrhythmias

Cardiac dysrhythmias can originate in any part of the conduction system or from atrial or ventricular muscle. They result from disturbances in electrical impulse formation (automaticity), conduction (conductivity), or both. The characteristic of automaticity allows myocardial cells other than the SA node to depolarize and initiate the electrical impulse that culminates in contraction. This may occur when the SA node fails to initiate an impulse or does so too slowly. When the electrical impulse arises anywhere other than the SA node, it is an abnormal or *ectopic* focus. If the ectopic focus depolarizes at a rate faster than the SA node, the ectopic focus becomes the dominant pacemaker. Ectopic pacemakers may be activated by hypoxia, ischemia, or hypokalemia. Ectopic foci indicate myocardial irritability (increased responsiveness to stimuli) and potentially serious impairment of cardiac function.

**Figure 49.1** ■ The conducting system of the heart. Impulses originating in the SA node are transmitted through the atria, into the AV node to the bundle of His, and by way of Purkinje fibers through the ventricles.

Dysrhythmias may be clinically significant if they interfere with cardiac function (i.e., the heart's ability to pump sufficient blood to body tissues). The normal heart can maintain an adequate cardiac output with ventricular rates ranging from 40 to 150 beats per minute. The diseased heart, however, may not be able to maintain an adequate cardiac output with heart rates below 60 or above 120 beats per minute. Dysrhythmias are usually categorized by rate, location, or patterns of conduction. Various types of dysrhythmias are described in Box 49-1.

## General Characteristics of Antidysrhythmic Drugs

Antidysrhythmic drugs alter the heart's electrical conduction system. Atropine for bradycardias is discussed in Chapter 20; digoxin and its use in treating atrial fibrillation (A-Fib) are discussed in Chapter 48. The focus of this chapter is the drugs used for *tachydysrhythmias*. These drugs are described in the following sections and listed in Table 49-1.

Clinical use of antidysrhythmic drugs for tachydysrhythmias has undergone changes. One change is that the goal of drug therapy is to prevent or relieve symptoms or prolong survival, not just suppress dysrhythmias. This change resulted from study outcomes in which patients treated for some dysrhythmias had a higher mortality rate than patients who did not receive antidysrhythmic drug therapy. The higher mortality rate was attributed to prodysrhythmic effects (i.e., worsening existing dysrhythmias or causing new dysrhythmias).

Another change is the greater use of nonpharmacologic management of dysrhythmias. These treatments include destroying dysrhythmogenic areas within the heart with radio waves through radiofrequency catheter ablation or surgical procedures, thereby implanting devices for sensing, cardioverting, defibrillating, and/or pacing the patient (e.g., the implantable cardioverter–defibrillator [ICD]).

### Indications for Use

Antidysrhythmic drug therapy is commonly indicated in the following conditions:

- Conversion of atrial fibrillation (A-Fib) or atrial flutter to normal sinus rhythm (NSR)
- Maintaining NSR after conversion from A-Fib or atrial flutter
- Suppression of a fast or irregular ventricular rate which alters the cardiac output. Altered cardiac output leads to symptoms of decreased coronary, cerebral, and/or systemic circulation.
- Presence of dangerous dysrhythmias that may be fatal if not quickly terminated. For example, ventricular tachycardia may cause cardiac arrest.

### Mechanisms of Action

Drugs used for the treatment of rapid dysrhythmias mainly reduce automaticity (spontaneous depolarization of myocardial

cells, including ectopic pacemakers), slow conduction of electrical impulses through the heart, and prolong the refractory period of myocardial cells (so they are less likely to be prematurely activated by adjacent cells). Several different groups of drugs perform one or more of these actions. They are classified according to their mechanisms of action and effects on the conduction system, even though they differ in other respects. Additionally, some drugs have characteristics of more than one classification.

## Classifications and Individual Drugs

### Class I Sodium Channel Blockers

Class I drugs block cardiac sodium channels and slow conduction velocity, prolonging refractoriness and decreasing automaticity of sodium-dependent tissue. This results in a membrane-stabilizing effect and decreases formation and conduction of electrical impulses.

#### Class IA

Class IA drugs have a broad spectrum of *antidysrhythmic* effects that block sodium and potassium channels. They are used for maintenance of normal sinus rhythm (NSR) after conversion of atrial fibrillation (A-Fib) or atrial flutter; treatment of symptomatic premature ventricular contractions (PVCs), supraventricular tachycardia (SVT), and ventricular tachycardia (VT); and prevention of ventricular fibrillation (V-Fib).

**P Quinidine**, the prototype, reduces automaticity, slows conduction, and prolongs the refractory period. Quinidine is well absorbed after oral administration. Therapeutic serum levels (2–5 mcg/mL) are attained within 1 hour and persist for 6 to 8 hours. Quinidine is highly bound to serum albumin and has a half-life of about 6 hours. It is metabolized by the liver (about 80%) and excreted in the urine (about 20%). In alkaline urine (i.e., pH > 7), renal excretion of quinidine decreases, and serum levels may rise. Serum levels greater than 5 micrograms per milliliter are toxic. Quinidine is usually contraindicated in patients with severe, uncompensated heart failure or with heart block because it depresses myocardial contractility and conduction through the AV node.

**Procainamide** is related to the local anesthetic procaine and is similar to quinidine in actions and uses. Quinidine may be preferred for long-term use because procainamide produces a high incidence of adverse effects, including a syndrome resembling lupus erythematosus. Procainamide has a short duration of action (3–4 hours); sustained-release tablets (Procanbid) prolong action to about 6 hours. Therapeutic serum levels are 4 to 8 micrograms per milliliter.

**Disopyramide** is similar to quinidine in pharmacologic actions and may be given orally to adults with ventricular tachydysrhythmias. It is well absorbed after oral administration and reaches peak serum levels (2–8 mcg/mL) within 30 to 60 minutes. Toxic serum level is greater than 8 micrograms per milliliter. Drug half-life is 4 to 10 hours. Disopyramide is

## Drugs at a Glance: Antidysrhythmic Drugs

Drugs for Tachydysrhythmias	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Class I Sodium Channel Blockers</b>		
<b>Class 1A</b>		
Maintenance of normal sinus rhythm (NSR) after conversion of atrial fibrillation (A-Fib) or atrial flutter; treatment of symptomatic premature ventricular contractions (PVCs), supraventricular tachycardia (SVT), and ventricular tachycardia (VT); prevention of ventricular fibrillation (V-fib).		
Quinidine	PO 100–600 mg q4–6h; maximum dose, 3–4 g/d; maintenance dose, PO 200–600 mg q4–6h, or extended-action tablets, 324–972 mg q8–12h	Safety and efficacy not established PO 30 mg/kg/d in doses every q4–6h
Procainamide (Pronestyl, Procanbid)	PO loading dose 1 g initially, then 250–500 mg q3–6h (500–1000 mg q6h for sustained-release tablets) IM loading dose, 500–1000 mg followed by oral maintenance doses IV loading dose 50–100 mg; may repeat q5–10 min or 15–18 mg/kg (max 1–1.5 g); then maintenance infusion 3–4 mg/min	PO 15–50 mg/kg/d in divided doses q3–6h IV loading dose 3–6 mg/kg over 5 min (max 100 mg); may repeat q5–10 min to max total dose of 15 mg/kg; then maintenance dose of 20–80 mcg/kg/min; max 2 g/d
Disopyramide (Norpace)	PO (weighing 50 kg and more) 150 mg q6h (300 mg q12h extended release); (weighing less than 50 kg) 100 mg q6h (200 mg q12h with extended release)	12–18 y: 6–15 mg/kg/d in 4 divided doses 5–11 y: 10–15 mg/kg/d in 4 divided doses 1–4 y: 10–20 mg/kg/d in 4 divided doses <1 y: 10–30 mg/kg/d in 4 divided doses
<b>Class 1B</b>		
Treatment of symptomatic premature ventricular contractions (PVCs) and ventricular tachycardia (VT); prevention of ventricular fibrillation (V-fib).		
Lidocaine (Xylocaine)	IV 1 mg/kg bolus, not to exceed 50–100 mg, as a single bolus injection at 25–50 mg/min, may be repeated in 5 min; give no more than 200–300 mg in 1 h followed by a continuous infusion of 1–4 mg/min; maximum dose IM 4.3 mg/kg as a single dose; may repeat in 60–90 min	IV injection 0.5–1 mg/kg bolus, may repeat but total dose not to exceed 3–5 mg/kg; followed by IV infusion of 10–50 mcg/kg/min
Mexiletine (Mexitil)	PO 200 mg q8h initially, increased by 50–100 mg every 2–3 d if necessary to a maximum of 1200 mg/d	1.4–5 mg/kg per dose, given every 8 h
Tocainide (Tonocard)	PO 400 mg q8h initial dose; 1.2–1.8 g/d in divided doses q8h maintenance dose	Safety and efficacy not established
Phenytoin (Dilantin)	PO, loading dose 250 mg 4 times a day for 1 day; 250 mg 2 times a day for 2 days; maintenance dose 300–400 mg/d 1–4 times per day IV loading dose 1.25 mg/kg q5min; may repeat up to total dose of 15 mg/kg	PO 5–10 mg/kg/d in 2–3 divided doses IV loading dose 1.25 mg/kg q5 min; may repeat up to total dose of 15 mg/kg; maintenance dose 5–10 mg/kg/d in 2–3 divided doses
<b>Class IC</b>		
Treatment of life-threatening ventricular tachycardia (VT) or ventricular fibrillation (V-fib) and supraventricular tachycardia (SVT) unresponsive to other drugs		

(continued on page 784)

Table 49-1

## Drugs at a Glance: Antidysrhythmic Drugs (continued)

Drugs for Tachydysrhythmias	ROUTES AND DOSAGE RANGES	
	Adults	Children
Flecainide (Tambocor)	PO 100 mg q12h initially, increased by 50 mg q12h every 4 d until effective; maximum dose, 400 mg/d	Initial 1–3 mg/kg/d in 3 divided doses; usual 3–6 mg/kg/d in 3 divided doses up to 8 mg/kg/d
Propafenone (Rythmol)	PO 150 mg q8h initially, increase at 3–4 day intervals to 225 mg q8h, then to 300 mg q8h; maximum dose of 900 mg/d  PO (extended release) 225 mg q12h initially, may increase at 5 day intervals; maximum 425 mg q12h	Safety and efficacy not established
Moricizine (Ethmozine)	PO 200–300 mg q8h; maximum dose 900 mg/d	Safety and efficacy not established
<b>Class II Beta-Adrenergic Blockers</b>		
Treatment of supraventricular tachycardia		
Acebutolol (Sectral) Beta <sub>1</sub>	PO 200 mg q12h, increased gradually to 600–1200 mg/d in 2 divided doses	Safety and efficacy not established
Atenolol (Tenormin) Beta <sub>1</sub>	IV push 5 mg over 5 min; may repeat in 10 min. Give IV infusion over 15 min PO 50–100 mg/d	No dosing for this indication
Bisoprolol (Zebeta) Beta <sub>1</sub>	PO 2.5–5 mg/d. May increase up to 20 mg/d.	Safety and efficacy not established
Carteolol (Cartrol) Beta <sub>1</sub> Beta <sub>2</sub>	PO 2.5–10 mg/d	No dosing for this indication
Esmolol (Brevibloc) Beta <sub>1</sub>	IV 500 mcg/kg/min initially as a loading dose for 1 min, followed by a maintenance dose of 50 mcg/kg/min over 4 min. If no response in 5 min, repeat the same loading dose, and increase maintenance doses to 100 mcg/kg/min for 4 min, continue to increase by 50 mcg/kg/min up to 200 mcg/kg/min for 4 min. Once desired response is attained, stop leading dose and increase infusion by no more than 25 mcg/kg/min. Average maintenance dose 100 mcg/kg/min. Infusion administered over 24–48 h.	IV infusion 500 mcg/kg/min initially as a loading dose over 1 min, with a maximum dose of 50–250 mcg/kg/min
Metoprolol (Lopressor) Beta <sub>1</sub>	IV injection 1–5 mg over 1 min every 2 min for 3 doses, followed by 50 mg PO q6h for 48 h. Begin oral dose 15 min after last IV dose. PO 50–450 mg/d	Safety and efficacy not established
Nadolol (Corgard) Beta <sub>1</sub>	PO 40 mg/d, may increase by 40–80 mg at 3–7 day intervals. Maximum 240–360 mg/d	Safety and efficacy not established
Propranolol (Inderal) Beta <sub>1</sub> Beta <sub>2</sub>	PO 10–20 mg q6–8h; may gradually increase dose to 40–320 mg/d IV 0.5–3 mg repeat once in 2 min, additional doses at intervals of at least 4 h; maximum 5 mg total	PO 0.5–1 mg/kg/d in divided doses q6–8 h; may increase every 3–5 days; usual dose 2–4 mg/kg/d; maximum 16 mg/kg/d

<b>ROUTES AND DOSAGE RANGES</b>		
<b>Drugs for Tachydysrhythmias</b>	<b>Adults</b>	<b>Children</b>
		IV injection 0.01–0.1 mg/kg slow IVP over 10 min, with a maximum dose of 3 mg; infant maximum dose of 1 mg
Sotalol (Betapace) Beta <sub>1</sub> Beta <sub>2</sub>	PO 80 mg q12h initially, titrated to response; average dose, 160–320 mg daily. See manufacturer's recommendations for dosing in renal failure.	Safety and efficacy not established
Timolol (Blocadren) Beta <sub>1</sub> Beta <sub>2</sub>	PO 10 mg twice a day beginning 1–4 wk after infarction	Safety and efficacy not established
<b>Class III Potassium Channel Blockers</b>		
Treatment of ventricular tachycardia (VT) and ventricular fibrillation (V-fib); conversion of atrial flutter or atrial fibrillation to sinus rhythm; maintenance of sinus rhythm (amiodarone)		
Amiodarone (Cordarone)	Loading dose, IV 150 mg over 10 min (15 mg/min), then 360 mg over the next 6 h (1 mg/min), then 540 mg over the next 18 h (0.5 mg/min); maintenance dose, IV 720 mg/24 h (0.5 mg/min) Loading dose, PO 800–1600 mg/d for 1–3 wk, with a gradual decrease to 600–800 mg/d for 1 month; maintenance dose, PO 400 mg/d	IV safety and efficacy not established Loading dose, PO 10–15 mg/kg/d in 1–2 divided doses for up to 14 d or until dysrhythmia controlled. Dose should then be reduced to 5 mg/kg/d once daily for several weeks. Minimal maintenance dose, PO 2.5 mg/kg/d for 5–7 d/wk
Dofetilide (Tikosyn)	IV 500 mcg twice daily with creatinine clearance > 60 mL/min, adjusted to manage adverse effects	Safety and efficacy not established
Ibutilide (Corvert)	Weight > 60 kg: IV infusion over 10 min, 1 mg Weight < 60 kg: IV infusion over 10 min, 0.01 mg/kg The dose can be repeated once, after 10 min, if necessary.	Safety and efficacy not established
Sotalol (Betapace) Class II and class III effects	PO 80 mg q12h initially, titrated to response; average dose, 160–320 mg daily. See manufacturer's recommendations for dosing in renal failure.	Safety and efficacy not established
<b>Class IV Calcium Channel Blockers</b>		
Treatment of supraventricular tachycardia		
Diltiazem (Cardizem)	IV injection 0.25 mg/kg (average dose 20 mg) over 2 min. A second dose of 0.35 mg/kg (average, 25 mg) may be given in 15 min, and an IV infusion of 5–15 mg/h may be given up to 24 h, if necessary.	Safety and efficacy not established
Verapamil (Calan, Isoptin)	PO 40–120 mg q6–8h IV 5–10 mg initially, then 10 mg 30 min later, if necessary	1–15 y: IV injection 0.1–0.3 mg/kg (usual range 2–5 mg for a single dose) over 2 min with continuous ECG monitoring; repeat in 30 min if necessary <1 y: IV injection 0.1–0.2 mg/kg (usual range, 0.75–2.0 mg for a single dose) over 2 min with continuous ECG monitoring
<b>Unclassified</b>		
Adenosine is used to treat supraventricular tachycardia; magnesium sulfate is used to treat torsades de pointes		
Adenosine (Adenocard)	IV 6 mg given rapidly over 1–2 sec. If first dose does not slow the	Neonates: Initial IV dose 0.05 mg/kg. If first dose does not slow the

ECG, electrocardiogram; IVP, intravenous push.

excreted by the kidneys and the liver in almost equal proportions. Dosage must be reduced in renal insufficiency based on creatinine clearance. The U.S. Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** for disopyramide due to its known prodysrhythmic properties; the drug should be reserved for patients with life-threatening ventricular dysrhythmias.

#### Class IB

Class IB drugs shorten the repolarization phase.

**P Lidocaine** as an antidysrhythmic is the prototype of class IB drugs. It is the drug of choice for treating serious ventricular dysrhythmias associated with acute myocardial infarction, cardiac catheterization, cardiac surgery, and digitalis-induced ventricular dysrhythmias. Lidocaine decreases myocardial irritability (automaticity) in the ventricles. It has little effect on atrial tissue and thus is not useful in treating atrial dysrhythmias. It differs from quinidine in that it

- Must be given by injection
- Does not decrease AV conduction with usual therapeutic doses
- Has a rapid onset and short duration of action. After intravenous (IV) administration of a bolus dose, therapeutic effects occur within 1 to 2 minutes and last approximately 10 to 20 minutes. This characteristic is advantageous in emergency management but limits lidocaine use to intensive care settings.
- Is metabolized in the liver; thus dosage must be reduced in patients with hepatic insufficiency or right-sided heart failure to avoid drug accumulation and toxicity.
- Uncommonly does not have serious adverse reactions

Therapeutic serum levels of lidocaine are 1.5 to 6 micrograms per milliliter. Toxic serum levels are greater than 6 micrograms per milliliter. Lidocaine is contraindicated in patients allergic to related local anesthetics (e.g., procaine). Anaphylactic reactions may occur in sensitized individuals.

**Mexiletine** is an oral analog of lidocaine with similar pharmacologic actions. The drug is used to suppress ventricu-

lar tachycardia or ventricular fibrillation. It is well absorbed from the GI tract, and peak serum levels are obtained within 3 hours. Taking the drug with food delays but does not decrease absorption.

**Tocainide** is used for the suppression and prevention of ventricular dysrhythmias, including frequent unifocal and multifocal PVCs. It is rapidly and completely absorbed following oral administration and is metabolized in the liver and excreted in the urine. Therapeutic serum levels are 4 to 10 micrograms per milliliter, and toxic serum levels have not been established.

**Phenytoin** may be used to treat dysrhythmias produced by digoxin intoxication. Phenytoin decreases automaticity and improves conduction through the AV node. Decreased automaticity helps control dysrhythmias, whereas enhanced conduction may improve cardiac function. Further, because heart block may result from digoxin, quinidine, or procainamide, phenytoin may relieve dysrhythmias without intensifying heart block. Phenytoin is not a cardiac depressant. Its only quinidine-like action is to suppress automaticity; otherwise, it counteracts the effects of quinidine and procainamide largely by increasing the rate of conduction. Phenytoin also has a longer half-life (22–36 hours) than other antidysrhythmic drugs. Given IV, a therapeutic plasma level (10–20 mcg/mL) can be obtained rapidly. Given orally, however, the drug may not reach a steady-state concentration for approximately 1 week unless loading doses are given initially.

#### Applying Your Knowledge 49-1

You are assigned to care for Mr. Brown. He is prescribed lidocaine and started on IV lidocaine to control his PVCs. What therapeutic level should you monitor for?

.....

#### Class IC

Class IC drugs have no effect on the repolarization phase but slow conduction velocity and the refractory period. **Flecainide** and **propafenone** are oral agents that greatly decrease conduction in the ventricles. Along with **morizine**, these drugs may

cause new dysrhythmias or aggravate pre-existing dysrhythmias, sometimes causing sustained VT or V-Fib; thus therapy should be initiated in hospitalized patients with continuous electrocardiographic (ECG) monitoring. These effects are more likely to occur with high doses and rapid dose increases. The drugs are recommended for use in life-threatening ventricular dysrhythmias.

## Class II Beta-Adrenergic Blockers

These agents (see Chap. 18) exert antidysrhythmic effects by slowing the sympathetic nervous system stimulation of beta receptors in the heart, slowing the SA and AV nodal conduction. Blockage of receptors in the SA node and ectopic pacemakers decreases automaticity and blockage of receptors in the AV node increases the refractory period. The drugs are effective for management of dysrhythmias resulting from excessive sympathetic activity. They are most often used to slow the ventricular rate of contraction in atrial flutter and A-Fib.

As a class II, beta-adrenergic blockers are being used more extensively because of their effectiveness in reducing mortality in post-myocardial infarction and heart failure patients. Reduced mortality may result from the drugs' ability to prevent ventricular fibrillation.

Propranolol may be given orally for chronic therapy to prevent ventricular dysrhythmias, especially those precipitated by exercise. It may be given IV for life-threatening dysrhythmias or for those occurring during anesthesia. **Esmolol** has a rapid onset and short duration of action. It is given IV for SVT and A-Fib or atrial flutter, especially during anesthesia, surgery, or other emergency situations when the ventricular rate must be reduced rapidly. It is not used for chronic therapy.

Dizziness is usually the first sign of impending hypotension. If pulse is 60 or less or systolic BP is 90 mmHg or less, withhold the beta-adrenergic blocker and contact a physician. **Acebutolol** may be given orally for chronic therapy to prevent ventricular dysrhythmias, especially those precipitated by exercise. A variety of beta-adrenergic blockers are listed in Table 49-1 that may be used for the treatment of dysrhythmias.

## Class III Potassium Channel Blockers

These drugs act to prolong duration of the action potential, slow repolarization, and prolong the refractory period in both atria and ventricles. This is accomplished by blocking the cardiac potassium channels. Although the drugs share a common mechanism of action, they are very different drugs.

Although classified as a potassium channel blocker, **amiodarone** also has electrophysiologic characteristics of sodium channel blockers, beta blockers, and calcium channel blockers. Thus, it has vasodilating effects and decreases systemic vascular resistance, it prolongs conduction in all cardiac tissues and decreases heart rate, and it decreases contractility of the left ventricle.

Intravenous and oral amiodarone differ in their electrophysiologic effects. When given IV, the major effect is slowing

conduction through the AV node and prolonging the effective refractory period. Thus, it is given IV mainly for acute suppression of refractory, hemodynamically destabilizing ventricular tachycardia and ventricular fibrillation. The drug has assumed an increasing role as a preferred agent in the American Heart Association Advanced Cardiac Life Support (ACLS) algorithm for this purpose. It is given orally to treat recurrent ventricular tachycardia or ventricular fibrillation and to maintain an NSR after conversion of A-Fib and atrial flutter. Low doses (100–200 mg/day) may prevent recurrence of A-Fib with less toxicity than higher doses of amiodarone or usual doses of other agents.

Amiodarone is extensively metabolized in the liver and produces active metabolites. The drug and its metabolites accumulate in the liver, lungs, fat, skin, and other tissues. With IV administration, the onset of action usually occurs within several hours. With oral administration, the action may be delayed from 3 days up to 3 weeks. Because of its long serum half-life, loading doses are usually given. These loading doses reduce the time required for therapeutic effects. However, effects may persist for several weeks after the drug is discontinued.

Amiodarone is an iodine-rich drug that has been associated with thyroid dysfunction, with hypothyroidism occurring more frequently than hyperthyroidism. Other adverse effects include serious, potentially fatal pulmonary toxicity (pulmonary fibrosis, pneumonitis, acute respiratory distress syndrome [ARDS]) which may begin with progressive dyspnea and cough with crackles, decreased breath sounds, pleurisy, heart failure, or hepatotoxicity. The FDA has issued a **BLACK BOX WARNING** for amiodarone recommending use only in patients with life-threatening dysrhythmias due to this substantial toxicity potential.

Corneal microdeposits are noted in almost all patients treated for more than 2 months and can lead to blurry vision. Most adverse effects are considered dose dependent and reversible. However, maintenance dose selection is difficult because absorption and elimination are variable.

When oral amiodarone is used long term, it also increases the effects of numerous drugs, worsening existing dysrhythmias or producing new dysrhythmias. Other drug interactions include beta blockers, oral anticoagulants, digoxin, and phenytoin.

**Dofetilide** is indicated for the maintenance of NSR in symptomatic patients who are in A-Fib of more than 1 week's duration. Adverse effects increase with decreasing creatinine clearance levels so renal function must be assessed and initial dosage is dependent on creatinine clearance levels. High dosages in patients with renal dysfunction result in drug accumulation and prodysrhythmia (torsades de pointes). The drug has an elimination half-life of approximately 8 hours with the kidneys being the major route of elimination. The drug should initially be administered in a setting with personnel and equipment available for emergency use.

**Ibutilide** is indicated for management of recent onset of A-Fib or atrial flutter, in which the goal is conversion to NSR. The drug enhances the efficacy of cardioversion. Ibutilide is

structurally similar to sotalol but lacks clinically significant beta-blocking activity. Ibutilide is widely distributed and has an elimination half-life of about 6 hours. Most of a dose is metabolized, and the metabolites are excreted in urine and feces. Adverse effects include supraventricular and ventricular dysrhythmias (particularly torsades de pointes) and hypotension. Ibutilide should be administered in a setting with personnel and equipment available for emergency use.

**Sotalol** has both beta-adrenergic–blocking and potassium channel–blocking activity. Beta-blocking effects predominate at lower doses and class III effects predominate at higher doses. The drug is well absorbed after oral administration, and peak serum level is reached in 2 to 4 hours. It has an elimination half-life of approximately 12 hours, and 80% to 90% is excreted unchanged by the kidneys. Sotalol is approved for prevention or management of ventricular tachycardia and fibrillation. It has also been used, usually in smaller doses, to prevent or treat A-Fib. However, it is less effective than amiodarone in the prophylaxis of A-Fib. It is contraindicated in patients with asthma, sinus bradycardia, heart block, cardiogenic shock, heart failure, and previous hypersensitivity to sotalol. Dosage should be individualized, reduced with renal impairment, and increased slowly (e.g., every 2 to 3 days with normal renal function, at longer intervals with impaired renal function). Dysrhythmogenic effects are most likely to occur when therapy is started or when dosage is increased. Heart failure may occur in patients with markedly depressed left ventricular systolic function. Most adverse effects are attributed to beta-blocking activity.

Like amiodarone, sotalol may be preferred over a class I agent because it is more effective in reducing recurrent ventricular tachycardia, ventricular fibrillation, and death.

### Applying Your Knowledge 49-2

Mr. Brown's AF is converted to NSR pharmacologically. The physician prescribes amiodarone at 200 mg PO daily. Why is Mr. Brown given this drug and what adverse effects should you monitor?

## Class IV Calcium Channel Blockers

Calcium channel blockers (see Chap. 50) block the movement of calcium into conductile and contractile myocardial cells by inhibiting the influx of calcium through its channels, causing a slower conduction through the sinus and AV nodes. As anti-dysrhythmic agents, they act primarily against tachycardias at SA and AV nodes because the cardiac cells and slow channels that depend on calcium influx are found mainly at these sites. Thus, they reduce automaticity of the SA and AV nodes, slow conduction, and prolong the refractory period in the AV node. They are effective only in supraventricular tachycardias.

**Diltiazem** and **verapamil** are the only calcium channel blockers approved for management of dysrhythmias. Both drugs may be given IV to terminate acute paroxysmal

supraventricular tachycardia (PSVT), usually within 2 minutes, and in A-Fib and atrial flutter. They are also effective in exercise-related tachycardias. When given IV, the drugs act within 15 minutes and last up to 6 hours. Oral verapamil may be used in the chronic management of the aforementioned dysrhythmias. Diltiazem and verapamil are metabolized by the liver, and metabolites are primarily excreted by the kidneys. The drugs are contraindicated in digoxin toxicity because they may worsen heart block. If used with propranolol or digoxin, caution must be exercised to avoid further impairment of myocardial contractility. Do not use IV verapamil with IV propranolol; potentially fatal bradycardia and hypotension may occur.

## Unclassified Drugs

**Adenosine**, a naturally occurring component of all body cells, differs chemically from other antidysrhythmic drugs but acts like the calcium channel blockers. It depresses conduction at the AV node and is used to restore NSR in patients with PSVT; it is ineffective in other dysrhythmias. The drug has a very short duration of action (serum half-life is less than 10 seconds) and a high degree of effectiveness. It must be given by a rapid bolus injection, preferably through a central venous line. If given slowly, it is eliminated before it can reach cardiac tissues and exert its action.

**Magnesium sulfate** is given IV in the management of several dysrhythmias, including prevention of recurrent episodes of torsades de pointes and management of digitalis-induced dysrhythmias. Its antidysrhythmic effects may derive from imbalances of magnesium, potassium, and calcium.

Hypomagnesemia increases myocardial irritability and is a risk factor for both atrial and ventricular dysrhythmias. Thus, serum magnesium levels should be monitored in patients at risk and replacement therapy instituted when indicated. However, in some instances, the drug seems to have antidysrhythmic effects even when serum magnesium levels are normal.

## Nursing Process

### Assessment

- Assess the patient's condition in relation to cardiac dysrhythmias.
- Identify conditions or risk factors that may precipitate dysrhythmias. These include the following:
  - Hypoxia
  - Electrolyte imbalances (e.g., hypokalemia, hypomagnesemia, hypocalcemia)
  - Acid–base imbalances
  - Acute coronary syndrome (angina pectoris, myocardial infarction)

- Cardiac valvular disease
  - Febrile illness
  - Respiratory disorders (e.g., chronic lung disease)
  - Exercise
  - Emotional upset
  - Excessive ingestion of caffeine-containing beverages (e.g., coffee, tea, colas)
  - Cigarette smoking
  - Drug therapy use of digoxin, antidysrhythmic drugs, CNS stimulants, anorexiant, and tricyclic antidepressants
  - Hyperthyroidism
- Observe for clinical signs and symptoms of dysrhythmias. Mild or infrequent dysrhythmias may be perceived by the patient as palpitations or skipped heartbeats. More severe dysrhythmias may produce manifestations that reflect decreased cardiac output and other hemodynamic changes, as follows:
    - Hypotension, bradycardia or tachycardia, and irregular rhythm
    - Shortness of breath, dyspnea, and cough from impaired respiration
    - Syncope or mental confusion from reduced cerebral blood flow
    - Chest pain from decreased coronary artery blood flow. Angina pectoris or myocardial infarction may occur.
    - Oliguria from decreased renal blood flow
  - When ECG monitoring is available (e.g., 12-lead ECG or continuous ECG monitoring), assess for indications of dysrhythmias.

## Nursing Diagnoses

- Decreased Cardiac Output related to ineffective rhythm of the heart
- Decreased Tissue Perfusion, cerebral and peripheral, related to compromised cardiac output or medication-induced hypotension
- Activity Intolerance related to weakness and fatigue
- Impaired Gas Exchange related to decreased tissue perfusion
- Anxiety related to potentially serious illness
- Deficient Knowledge: Pharmacologic and nonpharmacologic management of dysrhythmias
- Excess Fluid Volume: Peripheral edema and pulmonary congestion related to alteration in cardiac output

## Planning/Goals

### The patient will

- Receive or take antidysrhythmic drugs accurately
- Avoid conditions that precipitate dysrhythmias, when feasible
- Experience improved heart rate, circulation, and activity tolerance
- Be monitored for therapeutic and adverse drug effects
- Avoid preventable adverse drug effects
- Have adverse drug effects promptly recognized and treated if they occur
- Keep follow-up appointments for monitoring responses to treatment measures

## Interventions

- Use measures to detect, prevent, and/or minimize dysrhythmias.
- Treat underlying disease processes that contribute to dysrhythmia development. These include cardiovascular (e.g., acute myocardial infarction) and noncardiovascular (e.g., chronic lung disease) disorders.
- Prevent or treat other conditions that predispose to dysrhythmias (e.g., hypoxia, electrolyte imbalance, pain, acid-base imbalance, fluid alterations).
- Help the patient understand the negative effects of cigarette smoking, overeating, excessive coffee drinking, and other habits that may cause or aggravate dysrhythmias. Encourage patient to avoid such behaviors. Long-term supervision and counseling may be needed.
- For the patient receiving antidysrhythmic drugs, implement measures to minimize the incidence and severity of acute dysrhythmias and help the patient comply with drug therapy.
- Monitor heart rate and rhythm and blood pressure every 4 to 6 hours (or as often as is the standard for the care environment where seeing the patient).
- Check laboratory reports of serum electrolytes and serum drug levels when available. Report and treat abnormal values using established protocols and/or physician orders.
- Provide appropriate patient teaching related to drug therapy (see accompanying display).

## Evaluation

- Check vital signs for improved heart rate and rhythm.
- Interview and observe for relief of symptoms and improved functioning in activities of daily living.
- Interview and observe for irregular rhythms, hypotension, and other adverse drug effects.
- Interview and observe for compliance with instructions for taking antidysrhythmic drugs and other aspects of care.

## Patient Teaching Guidelines

## Antidysrhythmic Drugs

### General Considerations

- A fast heartbeat normally occurs in response to exercise, fever, and other conditions so that more blood can be pumped and carried to body tissues. An irregular heartbeat occurs occasionally in most individuals. However, when you are prescribed a long-term medication to slow or regularize your heartbeat, this means that you have a potentially serious condition. In addition, the medications can cause potentially serious adverse effects. So, it is extremely important that you take the medications exactly as prescribed. Taking extra doses is dangerous; skipping doses or waiting longer between doses may lead to loss of control of the heart problem.
- You may be given a drug classified as an antidysrhythmic or a drug from another group that has antidysrhythmic effects (e.g., a beta blocker such as propranolol, a calcium channel blocker such as verapamil or diltiazem, or digoxin). Instructions should be provided for the specific drug ordered.
- Be sure you know the names (generic and brand) of the medication, why you are receiving it, and what effects you can expect (therapeutic and adverse).
- You will need continued medical supervision, along with periodic measurements of heart rate and blood pressure, blood tests, and electrocardiograms.
- Try to learn the triggers for your irregular heartbeats and avoid them when possible (e.g., excessive caffeinated beverages, strenuous or excessive exercise).
- Avoid over-the-counter cold and asthma remedies, appetite suppressants, and antisleep preparations. These drugs are stimulants that can cause or aggravate irregular heartbeats.

### Self- or Caregiver Administration

- Take or give medications at evenly spaced intervals to maintain adequate blood levels. Take your medications at the same time each day.
- Take or give amiodarone, mexiletine, and quinidine with food to decrease gastrointestinal symptoms.
- Do not crush or chew sustained-release tablets or capsules.
- Report dizziness or fainting spells. This may mean the medication is decreasing your blood pressure too much, which is more likely to occur when starting or increasing the dose of an antidysrhythmic drug. Drug dosages may need to be adjusted.

## Applying Your Knowledge 49-3

### How Can You Avoid This Medication Error?

While Mr. Brown is receiving his IV lidocaine, his heart rate decreases to 52 beats per minute with continued PVCs. You continue to monitor the IV and the ECG.

## Principles of Therapy

### Nonpharmacologic Management of Dysrhythmias

Nonpharmacologic management is preferred, at least initially, for several dysrhythmias. For example, sinus tachycardia usually results from such disorders as dehydration, fever, infection, or hypotension and intervention and management should attempt to relieve the underlying cause. For PSVT with mild or moderate symptoms, Valsalva's maneuver, carotid sinus massage, or other measures to increase vagal tone are preferred. For ventricular fibrillation, immediate defibrillation is the initial management of choice.

In addition to these strategies, others are being increasingly used. The impetus for nonpharmacologic management developed mainly from studies demonstrating that antidysrhythmic drugs could worsen existing dysrhythmias, cause new dysrhythmias, and cause higher mortality rates in patients receiving the drugs than patients not receiving the drugs. Current technology allows clinicians to insert pacemakers and defibrillators (e.g., ICD) to control bradydysrhythmias or

tachydysrhythmias and to use radio waves (radiofrequency catheter ablation) or surgery to deactivate ectopic foci.

Patients with stable coronary heart disease can benefit from practicing transcendental meditation, which appears to help control certain physiologic factors associated with the metabolic syndrome. Metabolic syndrome is characterized by insulin resistance, elevated blood pressure, visceral obesity, and dyslipidemia. These signs are considered an indicator of risk for coronary heart disease. The study suggests that the transcendental meditation practice modulates the physiologic response to stress by affecting neurohumoral pathways that play a role in the syndrome.

Nonpharmacologic management for atrial fibrillation specifically is determined based on the following criteria. Some patients with persistent atrial fibrillation will satisfy criteria for either an initial rate-control or a rhythm-control strategy (e.g., age > 65 years but also symptomatic):

- Indications are regarded weighing the potential advantages and disadvantages of each strategy of which the patient concurs
- Account for comorbidities
- Appropriate antithrombotic treatment is used.

A rate-control strategy is the preferred initial option in patients with the following conditions with persistent atrial fibrillation:

- Age greater than 65 years
- Coronary artery disease
- Contraindications to antiarrhythmic drugs

- Unsuitable for cardioversion
- No history of heart failure

A rhythm-control strategy is the preferred initial option in patients with the following conditions with persistent atrial fibrillation:

- Those who are symptomatic
- Younger patients
- First time presenters with lone atrial fibrillation
- Those with atrial fibrillation due to a precipitated event that is being treated or corrected
- Those with heart failure

Patients unsuitable for cardioversion include those with

- Contraindications to anticoagulation
- Structural heart disease (e.g., large left atrium, mitral stenosis) that precludes long-term maintenance of sinus rhythm
- Long duration of atrial fibrillation > 12 months
- Multiple failed attempts at cardioversion and/or relapses, even with use of antiarrhythmic drugs or nonpharmacologic approaches
- Ongoing but reversible cause of atrial fibrillation (e.g., thyrotoxicosis)

## Pharmacologic Management of Dysrhythmias

Rational drug therapy for cardiac dysrhythmias requires accurate identification of the dysrhythmia, understanding of the basic mechanisms causing the dysrhythmia, observation of the hemodynamic and ECG effects of the dysrhythmia, knowledge of the pharmacologic actions of specific antidysrhythmic drugs, and the expectation that therapeutic effects will outweigh potential adverse effects. Even when these criteria are met, antidysrhythmic drug therapy is somewhat empiric. Although some dysrhythmias usually respond to particular drugs, different drugs or combinations of drugs are often required. General trends and guidelines for drug therapy of supraventricular and ventricular dysrhythmias (which may result from prolonged QT intervals) are described in the following sections. General trends include the following:

- Cardiotoxic effects occur most commonly with IV administration, particularly at high concentrations, and are observed as conduction changes (widening of the QRS complex, prolonging of the QT interval, flattened T waves, and disappearance of the P wave) ventricular tachycardia, or frequent PVCs.
- Patients with the highest priority for QT interval monitoring are those started on a drug that has been shown to cause the malignant ventricular dysrhythmia, torsades de pointes.
- Patients treated in hospital units are at higher risk than outpatients, who are started on the same prodysrhythmic drugs, for a number of reasons.

- Older adults are hospitalized patients who may receive intravenous administration of a QT-prolonging drug or multiple QT-prolonging drugs.
- Females and the elderly are both risk factors for torsades de pointes.
- Hospitalized patients have additional risk factors for torsades de pointes.
  - Impaired elimination due to renal or hepatic dysfunction
  - Electrolyte abnormalities (especially hypokalemia or hypomagnesemia)
  - Heart disease (left-ventricular hypertrophy or heart failure)
  - Dysrhythmias with slow rates
  - Recent conversion of atrial fibrillation
  - Catheter ablation of rapid tachycardias
  - Neurologic disorders (especially subarachnoid hemorrhage).
- Class II and class III drugs are being used increasingly, because of demonstrated benefits in relieving symptoms and decreasing mortality rates in patients with heart disease.

## Treatment of Supraventricular Tachydysrhythmias

- **Propranolol** and other beta blockers are being increasingly used for tachydysrhythmias, especially in patients with myocardial infarction, heart failure, or exercise-induced dysrhythmias. In addition to controlling dysrhythmias, the drugs decrease the mortality rate in these patients. Also, a beta blocker is the management of choice if a rapid heart rate is causing angina or other symptoms in a patient with known coronary artery disease.
- Atrial fibrillation is the most common dysrhythmia. Management priorities include rate and rhythm control.
  - In patients with permanent atrial fibrillation, who need treatment for rate control
    - Beta blockers or rate-limiting calcium antagonists are preferred for initial treatment
    - Digoxin is only considered as monotherapy in sedentary patients
  - In patients with permanent atrial fibrillation, where monotherapy is inadequate
    - Control of the heart rate only during normal activities
      - Beta blockers or rate-limiting calcium antagonists are given with digoxin
    - Control of the heart rate during both normal activities and exercise
      - Calcium antagonists that are rate-limiting are administered with digoxin

- Management may involve conversion to NSR by electrical or pharmacologic means or long-term drug therapy to slow and control the rate of ventricular response. Advantages of conversion to NSR include improvement of symptoms and decreased risks of heart failure or thromboembolic problems. If pharmacologic conversion is chosen, IV **adenosine**, **dofetilide**, **ibutilide**, **verapamil**, or **diltiazem** may be used. After being converted to NSR, patients usually require long-term drug therapy.
- Low-dose **amiodarone** is a pharmacologic choice for preventing recurrent A-Fib after electrical or pharmacologic conversion. The low doses cause fewer adverse effects than the higher ones used for life-threatening ventricular dysrhythmias.

In addition to amiodarone, other drugs used to slow the heart rate include a **beta blocker**, **digoxin**, **verapamil**, or **diltiazem**. In most patients, a beta blocker, verapamil, or diltiazem may be preferred. In patients with heart failure, digoxin may be preferred. In addition, the class IC agents **flecainide** or **propafenone** may be used to suppress paroxysmal atrial flutter and fibrillation in patients with minimal or no heart disease.

IV **adenosine**, **ibutilide**, **verapamil**, or **diltiazem** may be used to convert PSVT to an NSR. These drugs block conduction across the AV node.

### Treatment of Ventricular Dysrhythmias

Treatment of asymptomatic PVCs and nonsustained ventricular tachycardia is not recommended. Treatment of symptomatic ventricular tachycardia is treated with **amiodarone**, **lidocaine**, and then **procainamide**. However, concurrent electrotherapy offers better outcomes in this unstable population. **Moricizine** is infrequently used in the United States because of its potential for causing undesirable cardiac events. It may be used to treat life-threatening ventricular dysrhythmias (e.g., sustained ventricular tachycardia) that have not responded to safer drugs.

## Use in Special Populations

### Use in Children

Antidysrhythmic drugs are less often needed in children than in adults, and their use has decreased with increased use of catheter ablative techniques. Catheter ablation uses radio waves to destroy dysrhythmia-producing foci in cardiac tissue and reportedly causes fewer adverse effects and complications than long-term antidysrhythmic drug therapy.

Antidysrhythmic drug therapy is also less clear-cut in children. However, pediatric cardiologists have used various drugs and developed guidelines for their use, especially dosages. As with adults, the drugs should be used only when clearly indicated, and children should be monitored closely because all of the drugs can cause adverse effects, including hypotension and new or worsened dysrhythmias.

Supraventricular tachydysrhythmias are the most common sustained dysrhythmias in children. IV adenosine,

digoxin, procainamide, or propranolol can be used acutely to terminate supraventricular tachydysrhythmias. Adenosine is administered like the adult dosing for children over 50 kilograms. For children weighing less than 50 kilograms, initially 0.1 milligram per kilogram IV push is given, with a maximum dose administration of 6 milligrams. If this initial dose is ineffective, a repeat dose of 0.2 milligrams per kilogram, up to the maximum of 12 milligrams, may be administered IV push.

Considerations for IV digoxin include that premature infants are more susceptible to toxicity. Digoxin or a beta blocker may be used for long-term management of supraventricular tachydysrhythmias. In addition, IV procainamide and verapamil do not have age-related precautions noted for use in children.

Propranolol is the beta blocker most commonly used in children. It is one of the few antidysrhythmic drugs available in a liquid solution. When given IV, antidysrhythmic effects are rapid, and patients require careful monitoring for bradycardia and hypotension.

Lidocaine may be used to treat ventricular dysrhythmias precipitated by cardiac surgery or digitalis toxicity. Class I or III drugs are usually started in a hospital setting, at lower dosage ranges, because of prodysrhythmic effects. Prodysrhythmia is more common in children with structural heart disease or significant dysrhythmias. In general, serum levels should be monitored medications. Serious adverse reactions to lidocaine are uncommon.

As in adults, most antidysrhythmic drugs and their metabolites are excreted through the kidneys and may accumulate in children with impaired renal function.

### Use in Older Adults

Cardiac dysrhythmias are common in older adults, but in general only those causing symptoms of circulatory impairment should be treated with antidysrhythmic drugs. Compared with younger adults, older adults are more likely to experience serious adverse drug effects, including aggravation of existing dysrhythmias, production of new dysrhythmias, hypotension, and heart failure. Cautious use is required, and dosage usually needs to be reduced to compensate for heart disease or impaired drug-elimination processes. Many elderly have an increased sensitivity to medications, this is true for antidysrhythmics.

### Use in Patients With Renal Impairment

Antidysrhythmic drug therapy in patients with renal impairment should be very cautious, with close monitoring of drug effects (e.g., plasma drug levels, ECG changes, symptoms that may indicate drug toxicity). The kidneys excrete most antidysrhythmic drugs and their metabolites. As a result, decreased renal perfusion or other renal impairment can reduce drug elimination and lead to accumulation and adverse effects if dosage is not reduced. As a general rule, dosage of digoxin, disopyramide, lidocaine, procainamide, propafenone, quinidine, and sotalol should be reduced in patients with significant impairment of renal function. Dosage of adenosine, amiodarone, ibutilide, and mexiletine does not require reduction.

### Use in Patients With Hepatic Impairment

As with renal impairment, antidysrhythmic drug therapy in patients with hepatic impairment should be very cautious, with close monitoring of drug effects (e.g., plasma drug levels, ECG changes, symptoms that may indicate drug toxicity).

Amiodarone may be hepatotoxic and cause serious, sometimes fatal, liver disease. Hepatic enzyme levels are often elevated without accompanying symptoms of liver impairment. However, liver enzymes should be monitored regularly, especially in patients receiving relatively high maintenance doses. If enzyme levels are above three times the normal range or double in a patient whose baseline levels were elevated, dosage reduction or drug discontinuation should be considered.

Hepatic impairment increases plasma half-life of several antidysrhythmic drugs, and dosage usually should be reduced. Dosages of digoxin, disopyramide, propafenone, and quinidine should be reduced in patients with impairment of hepatic function. Dosages of adenosine and ibutilide are unlikely to need reductions in patients with hepatic impairment.

### Use in Patients With Critical Illness

Critically ill patients often have multiple cardiovascular and other disorders that increase their risks for development of acute, serious, and potentially life-threatening dysrhythmias. They may also have refractory dysrhythmias that require strong, potentially toxic antidysrhythmic drugs. Thus, antidys-

rhythmic drugs are often given IV in critical care settings for rapid reversal of a fast rhythm. After reversal, IV or oral drugs may be given to prevent recurrence of the dysrhythmia.

Because serious problems may stem from either dysrhythmias or their treatment, health care providers should be adept in preventing, recognizing, and treating conditions that predispose to the development of serious dysrhythmias (e.g., electrolyte imbalances, hypoxia). If dysrhythmias cannot be prevented, early recognition and treatment are needed.

Overall, any antidysrhythmic drug therapy in critically ill patients is preferably performed or at least initiated in critical care units or other facilities with appropriate equipment and personnel. For example, nurses who work in emergency departments or critical care units must be certified in cardiopulmonary resuscitation and ACLS. With ACLS, the American Heart Association and others have developed algorithms to guide drug therapy of dysrhythmias.

### Use in Home Care

Patients receiving chronic antidysrhythmic drug therapy are likely to have significant cardiovascular disease. With each visit, the home care nurse needs to assess the patient's physical, mental, and functional status and evaluate pulse and blood pressure. In addition, patients and caregivers should be taught to report symptoms (e.g., dizziness or fainting, chest pain) and avoid over-the-counter agents unless discussed with a health care provider.

## Nursing Actions Antidysrhythmic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Check apical and radial pulses before each dose. Hold the dose and check with the physician if marked changes are noted in rate, rhythm, or quality of pulses.
- b. Check blood pressure at least once every shift, usually every 4 hours is the standard for hospitalized patients.
- c. During intravenous (IV) administration of antidysrhythmic drugs, maintain continuous cardiac monitoring and check blood pressure about every 1–5 minutes, depending on the onset of action.
- d. Give oral drugs at evenly spaced intervals.
- e. With oral amiodarone, give once daily or in two divided doses if stomach upset occurs.
- f. With IV amiodarone, mix and give loading and maintenance infusions according to the manufacturer's instructions.
- g. Give mexiletine and quinidine with food.
- h. Give lidocaine parenterally only, as a bolus injection or a continuous drip. Use only solutions labeled "For cardiac dysrhythmias," and do not use solutions containing epinephrine. Give an IV bolus over 2 minutes.

### RATIONALE/EXPLANATION

Bradycardia may indicate impending heart block or cardiovascular collapse.

To detect hypotension, which is most likely to occur when antidysrhythmic drug therapy is being initiated or altered. For early detection of hypotension and impending cardiac collapse. These drug side effects are more likely to occur with IV use.

To maintain adequate blood levels

Specific instructions are required for accurate mixing and administration, partly because concentrations and infusion rates vary. The drug should be given in a critical care setting, by experienced personnel, preferably through a central venous catheter.

To decrease gastrointestinal (GI) symptoms. Lidocaine solutions that contain epinephrine are used for local anesthesia only. They should never be given IV to patients with cardiac dysrhythmias because the epinephrine can cause or aggravate dysrhythmias. Rapid injection (within approximately 30 sec) produces transient blood levels several times greater than therapeutic range limits. Therefore, there is increased risk of toxicity without a concomitant increase in therapeutic effectiveness.

## Nursing Actions Antidysrhythmic Drugs (continued)

### NURSING ACTIONS

#### 2. Observe for therapeutic effects

- a. Conversion to normal sinus rhythm
- b. Improvement in rate, rhythm, and quality of apical and radial pulses and the electrocardiogram (ECG)
- c. Signs of increased cardiac output—blood pressure near normal range, urine output more adequate, no complaints of dizziness
- d. Serum drug levels (mcg/mL) within therapeutic ranges (Table 49-2)

#### 3. Observe for adverse effects

- a. Heart block—may be indicated on the ECG by a prolonged PR interval or presence of more P waves than QRS complexes; or presence of bundle branch block noted in a prolonged QRS complex
- b. Dysrhythmias—aggravation of existing dysrhythmia, tachycardia, bradycardia, premature ventricular contractions, ventricular tachycardia, or fibrillation
- c. Hypotension
- d. Additional adverse effects with specific drugs:
  - (1) Disopyramide—mouth dryness, blurred vision, urinary retention, heart failure, prodysrhythmic effects other anticholinergic effects
  - (2) Lidocaine—drowsiness, agitation, muscle twitching, seizures, paraesthesias and prodysrhythmic effects
  - (3) Phenytoin—nystagmus, ataxia, slurring of speech, tremors, drowsiness, confusion, gingival hyperplasia
  - (4) Propranolol—bradycardia, hypotension, depression, nightmares, fatigue, sexual dysfunction
  - (5) Quinidine—diarrhea, hypotension, nausea, vomiting, cinchonism, fever, thrombocytopenia, prodysrhythmic effects
  - (6) Tocainide—drowsiness, agitation, muscle twitching, seizures, paresthesias, prodysrhythmic effects, nausea, vomiting, diarrhea, agranulocytosis

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of antidysrhythmics:
  - (1) Antidysrhythmic agents
  - (2) Antihypertensives, diuretics, phenothiazine antipsychotic agents
  - (3) Cimetidine
- b. Drugs that *decrease* effects of antidysrhythmic agents:
  - (1) Atropine sulfate
  - (2) Phenytoin, rifampin

### RATIONALE/EXPLANATION

After a single oral dose, peak plasma levels are reached in approximately 1–4 hours with quinidine, procainamide, and propranolol and in 6–12 hours with phenytoin. Equilibrium between plasma and tissue levels is reached in 1 or 2 days with quinidine, procainamide, and propranolol; in approximately 1 week with phenytoin; in 1–3 weeks with amiodarone; and in just a few minutes with IV lidocaine.

Serum drug levels must be interpreted in light of the patient's clinical status.

Due to depressant effects on the cardiac conduction system

Because they affect the cardiac conduction system, antidysrhythmic drugs may worsen existing dysrhythmias or cause new dysrhythmias.

Due to decreased cardiac output

These effects commonly occur.

Most adverse reactions result from drug effects on the central nervous system (CNS). Convulsions are most likely to occur with high doses. Hypersensitivity reactions may occur in individuals who are allergic to related local anesthetic agents. CNS changes are caused by depressant effects.

The beta-adrenergic blocking action of propranolol blocks the normal sympathetic nervous system response to activity and exercise. Patients may have symptoms caused by deficient blood supply to body tissues.

These are the most frequent adverse effects.

These drugs may potentiate therapeutic effects or increase risk of toxicity.

When antidysrhythmic drugs are combined, there are additive cardiac depressant effects.

Additive hypotension

Decreases metabolism and increases blood concentrations of calcium channel blockers, lidocaine, metoprolol, phenytoin, propranolol

Atropine is used to reverse propranolol-induced bradycardia. Decreases effects by inducing drug-metabolizing enzymes in the liver and accelerating the metabolism of quinidine, disopyramide, and mexiletine

Table 49-2

## Therapeutic Serum Drug Level Ranges of Common Antidysrhythmics

DRUG	THERAPEUTIC RANGE (mcg/mL)
<b>Class IA</b>	
Quinidine	2–5
Procainamide	4–8
Disopyramide	2–8
<b>Class IB</b>	
Lidocaine	1.5–6
Mexiletine	0.5–2
Tocainide	4–10
Phenytoin	10–20
<b>Class IC</b>	
Flecainide	0.2–1
Propafenone	0.06–1
<b>Class II</b>	
Propranolol	0.05–0.1
<b>Class III</b>	
Amiodarone	0.5–2.5
<b>Class IV</b>	
Verapamil	0.08–0.3

## Key Concepts

- Atrial fibrillation is the most common dysrhythmia.
- Initiation of an electrical impulse depends predominately on the movement of sodium and calcium ions into a myocardial cell and movement of potassium ions out of the cell.
- Quinidine, the prototype of class IA antidysrhythmics, reduces automaticity, slows conduction, and prolongs the refractory period. Phenytoin may be used to treat dysrhythmias produced by digoxin intoxication.
- Lidocaine is the prototype of class IB antidysrhythmics used for treating serious ventricular dysrhythmias associated with acute myocardial infarction, cardiac catheterization, cardiac surgery, and digitalis-induced ventricular dysrhythmias.
- Flecainide, propafenone, and moricizine are class IC drugs and have no effect on the repolarization phase but greatly decrease conduction in the ventricles.
- As a class II drug, beta-adrenergic blockers are being used more extensively because of their effectiveness in reducing mortality in post–myocardial infarction and heart failure patients.
- As class IV drugs, diltiazem and verapamil are the only calcium channel blockers approved for management of dysrhythmias.
- The FDA has issued a **BLACK BOX WARNING** for disopyramide due to its known prodysrhythmic properties; the drug should be reserved for patients with life-threatening ventricular dysrhythmias.
- Amiodarone is a potassium channel blocker that prolongs conduction in all cardiac tissues and decreases heart rate, and it decreases contractility of the left ventricle.
- The FDA has issued a **BLACK BOX WARNING** for amiodarone recommending use only in patients with life-threatening dysrhythmias due to the risk of developing potentially fatal pulmonary toxicity with its use.

## Review and Application Exercises

### Short Answer Exercises

1. Which tissues in the heart are able to generate an electrical impulse and therefore serve as a pacemaker?
2. What risk factors predispose a patient to development of dysrhythmias?
3. Name interventions that patients or health care providers can perform to decrease risks of dysrhythmias.
4. Differentiate the hemodynamic effects of common dysrhythmias.
5. What are the classes of antidysrhythmic drugs?
6. How do beta-adrenergic blocking agents act on the conduction system to slow heart rate?
7. What are common and potentially serious adverse effects of antidysrhythmic drugs?

### NCLEX-Style Questions

8. The clinical use of class III agents is increasing over the use of class I agents for patients with heart disease, because they are associated with
  - a. less ventricular fibrillation
  - b. increased mortality
  - c. more sustained effects
  - d. mild adverse effects
9. A patient being monitored in the critical care unit has been receiving quinidine. The nurse notes that the patient's serum quinidine level is 8 mcg/mL, and the patient has developed diarrhea. The most appropriate action by the nurse is to
  - a. Hold the medication and report the findings to the health care prescriber immediately.
  - b. Administer the medication as ordered.
  - c. Anticipate that the dosage of the medication will be increased.
  - d. Anticipate that the dosage of the medication will be decreased.
10. Mr. Conley, age 53, is about to be discharged from the hospital after treatment for recurrent ventricular fibrillation unresponsive to other agents. To prevent further ventricular ectopy, the health care provider prescribes amiodarone (Cordarone), 1000 mg PO daily as a loading dose for 2 weeks. Why is such a large loading dose required?
  - a. Most of the drug is destroyed in the GI tract.
  - b. Males require larger dosages because of their faster metabolisms.
  - c. A history of ventricular dysrhythmia necessitates a higher dose.
  - d. The drug has a long serum half-life.
11. Phenytoin, an anticonvulsant, may be used to treat dysrhythmias produced by
  - a. digoxin toxicity
  - b. quinidine intoxication
  - c. lidocaine overdose
  - d. procainamide toxicity
12. Ms. Ferguson, age 58, is admitted to the coronary care unit for treatment of an acute anterior myocardial infarction. That evening, she experiences frequent runs of ventricular tachycardia. The health care provider tells the nurse to prepare an IV bolus dose of lidocaine. Why is lidocaine administered IV instead of orally?
  - a. Lidocaine absorption is too erratic when administered orally.
  - b. Lidocaine is inactivated by hydrochloric acid.
  - c. Most of an absorbed oral dose undergoes first-pass metabolism in the liver.
  - d. Onset of action for oral lidocaine is over 8 hours.

# Antianginal Drugs

## KEY TERMS

- Atherosclerosis
- Angina pectoris
- Coronary artery disease
- Metabolic syndrome
- Myocardial infarction

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the types, causes, and effects of angina pectoris.
2. Describe general characteristics and types of antianginal drugs.
3. Discuss nitrate antianginals in terms of indications for use, routes of administration, adverse effects, nursing process implications, and drug tolerance.
4. Differentiate between short-acting and long-acting dosage forms of nitrate antianginal drugs.
5. Teach patients ways to prevent, minimize, or manage acute anginal attacks.
6. Use the nursing process in the care of individuals on antianginal and adjunctive therapy for treatment of myocardial ischemia.

## Applying Your Knowledge

Richard Gerald is a 72-year-old man with a history of hypertension, coronary artery disease (CAD), and a myocardial infarction (MI). He stopped smoking and began a regular exercise program after his MI.

## Introduction

*Angina pectoris* is a clinical syndrome characterized by episodes of chest pain. It occurs when there is a deficit in myocardial oxygen supply (myocardial ischemia) in relation to myocardial oxygen demand. It is most often caused by atherosclerotic plaque in the coronary arteries but may also be caused by coronary vasospasm. The development and progression of atherosclerotic plaque is called *coronary artery disease* (CAD). Atherosclerotic plaque narrows the lumen, decreases elasticity, and impairs dilation of coronary arteries. The result is impaired blood flow to the myocardium, especially with exercise or other factors that increase the cardiac workload and need for oxygen.

The continuum of CAD progresses from angina to *myocardial infarction* (MI). There are three main types of angina: classic angina, variant angina, and unstable angina (Box 50-1). The Canadian Cardiovascular Society classifies patients with angina according to the amount of physical activity they can tolerate before anginal pain occurs (Box 50-2). These categories can assist in clinical assessment and evaluation of therapy.

Classic anginal pain is usually described as substernal chest pain of a constricting, squeezing, or suffocating nature. It may radiate to the jaw, neck, or shoulder; down the left or both arms; or to the back. The discomfort is sometimes mistaken for arthritis or for indigestion, because the pain may be associated with nausea, vomiting, dizziness, diaphoresis, shortness of breath, or fear of

## Box 50-1

## Types of Angina Pectoris

**Classic**

Classic angina (also called *stable*, *typical*, or *exertional angina*) occurs when atherosclerotic plaque obstructs coronary arteries and the heart requires more oxygenated blood than the blocked arteries can deliver. Chest pain is usually precipitated by situations that increase the workload of the heart, such as physical exertion, exposure to cold, and emotional upset. Recurrent episodes of classic angina usually have the same pattern of onset, duration, and intensity of symptoms. Pain is usually relieved by rest, a fast-acting preparation of nitroglycerin, or both.

**Variant**

Variant angina (also called *atypical*, *Prinzmetal's*, or *vasospastic angina*) is caused by spasms of the coronary artery that decrease blood flow to the myocardium. The spasms occur most often in coronary arteries that are already partly blocked by atherosclerotic plaque. Variant angina usually occurs during rest or with minimal exercise and often occurs at night. It often occurs at the same time each day. Pain is usually relieved by nitroglycerin. Long-term management includes avoidance of conditions that precipitate vasospasm, when possible (e.g., exposure to cold, smoking, and emotional stress), as well as antianginal drugs.

**Unstable**

Unstable angina (also called *rest*, *preinfarction*, and *crescendo angina*) is a type of myocardial ischemia that falls between classic angina and myocardial infarction. It usually occurs in patients with advanced coronary atherosclerosis and produces increased frequency, intensity, and duration of symptoms. It often leads to myocardial infarction.

Unstable angina usually develops when a minor injury ruptures atherosclerotic plaque. The resulting injury to the

endothelium causes platelets to aggregate at the site of injury, form a thrombus, and release chemical mediators that cause vasoconstriction (e.g., thromboxane, serotonin, platelet-derived growth factor). The disrupted plaque, thrombus, and vasoconstriction combine to obstruct blood flow further in the affected coronary artery. When the plaque injury is mild, blockage of the coronary artery may be intermittent and cause silent myocardial ischemia or episodes of anginal pain at rest. Thrombus formation and vasoconstriction may progress until the coronary artery is completely occluded, producing myocardial infarction. Endothelial injury, with subsequent thrombus formation and vasoconstriction, may also result from therapeutic procedures (e.g., angioplasty, atherectomy).

The Agency for Healthcare Research and Quality, in its clinical practice guidelines for the management of angina, defines unstable angina as meeting one or more of the following criteria:

- Anginal pain at rest that usually lasts longer than 20 minutes
- Recent onset (<2 months) of exertional angina of at least Canadian Cardiovascular Society Classification (CCSC) class III severity
- Recent (<2 months) increase in severity as indicated by progression to at least CCSC class III

However, myocardial ischemia may also be painless or silent in a substantial number of patients. Overall, the diagnosis is usually based on chest pain history, electrocardiographic evidence of ischemia, and other signs of impaired cardiac function (e.g., heart failure).

Because unstable angina often occurs hours or days before acute myocardial infarction, early recognition and effective management are extremely important in preventing progression to infarction, heart failure, or sudden cardiac death.

## Box 50-2

## Canadian Cardiovascular Society Classification of Patients with Angina Pectoris

**Class I:** Ordinary physical activity (e.g., walking, climbing stairs) does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.

**Class II:** Slight limitation of ordinary activity. Angina occurs on walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or in cold, in wind, or under emotional stress. Walking more than two blocks on the level and climbing more than one flight of ordinary

stairs at a normal pace and in normal conditions can elicit angina.

**Class III:** Marked limitations of ordinary physical activity. Angina occurs on walking one or two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace.

**Class IV:** Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest.

impending doom. The discomfort is usually brief, typically lasting 5 minutes or less until the balance of oxygen supply and demand is restored.

Current research indicates that gender differences exist in the type and quality of cardiac symptoms, with women reporting epigastric or back discomfort. Additionally, older adults may have atypical symptoms of CAD and may experience “silent” ischemia that may delay them from seeking professional help. Individuals with diabetes mellitus may present without classic angina, although they may experience related symptoms. The American Heart Association has released guidelines for the management of angina.

Numerous overlapping factors contribute to the development and progression of CAD. To aid understanding of drug therapy for angina, these factors are described in the following sections.

## Coronary Atherosclerosis

*Atherosclerosis* begins with accumulation of lipid-filled macrophages (i.e., foam cells) on the inner lining of coronary arteries. Foam cells, which promote growth of atherosclerotic plaque, develop in response to elevated blood cholesterol levels. These early lesions progress to fibrous plaques containing foam cells covered by smooth muscle cells and connective tissue. Advanced lesions also contain hemorrhages, ulcerations, and scar tissue. Factors contributing to plaque development and growth include endothelial injury, lipid infiltration (i.e., cholesterol), recruitment of inflammatory cells (mainly monocytes and T lymphocytes), and smooth muscle cell proliferation. Endothelial injury may be the initiating factor in plaque formation because it allows monocytes, platelets, cholesterol, and other blood components to come in contact with and stimulate abnormal growth of smooth muscle cells and connective tissue in the arterial wall.

Atherosclerosis commonly develops in the coronary arteries. As the plaque lesions develop over time, they become larger and extend farther into the lumen of the artery. The lesions may develop for decades before they produce symptoms of reduced blood flow. Eventually, a partially or completely occluded artery precipitates myocardial ischemia. Thus, serious impairment of blood flow may occur with a large atherosclerotic plaque or a relatively small plaque with superimposed vasospasm and thrombosis. If stenosis blocks approximately 80% of the artery, blood flow cannot increase in response to increased need; if stenosis blocks 90% or more of the artery, blood flow is impaired when the patient is at rest.

When coronary atherosclerosis develops slowly, collateral circulation develops to increase blood supply to the heart. Collateral circulation develops from anastomotic channels that connect the coronary arteries and allow perfusion of an area by more than one artery. Endothelium-derived relaxing factors such as nitric oxide (NO) can dilate collateral vessels and facilitate regional myocardial blood flow. Although collateral circulation may prevent myocardial ischemia in the patient at rest, it has limited ability to increase myocardial perfusion with increased cardiac workload.

Myocardial ischemia impairs blood flow to the myocardium, especially with exercise, mental stress, exposure to cold, or other factors that increase the cardiac workload. Most individuals with myocardial ischemia have advanced coronary atherosclerosis. Hypertension is also a major risk factor for myocardial ischemia.

## Myocardial Ischemia

Myocardial ischemia occurs when the coronary arteries are unable to provide sufficient blood and oxygen for normal cardiac functions. Also known as ischemic heart disease, CAD, and coronary heart disease, myocardial ischemia may present as an acute coronary syndrome with three main consequences. One consequence is unstable angina, with the occurrence of pain (symptomatic myocardial ischemia). A second is MI that is silent or asymptomatic and diagnosed by biochemical markers only. A third is MI, with or without ST-segment elevation, which occurs when the ischemia is persistent or severe.

## Resultant Cardiovascular Impairments

With normal cardiac function, coronary blood flow can increase to meet needs for an increased oxygen supply with exercise or other conditions that increase cardiac workload. When coronary arteries are partly blocked by atherosclerotic plaque, vasospasm, or thrombi, blood flow may not be able to increase sufficiently.

The endothelium of normal coronary arteries synthesizes numerous substances (see Chap. 47) that protect against vasoconstriction and vasospasm, bleeding and clotting, inflammation, and excessive cell growth. Impaired endothelium (e.g., by rupture of atherosclerotic plaque or the shear force of hypertension) leads to vasoconstriction, vasospasm, clot formation, formation of atherosclerotic plaque, and growth of smooth muscle cells in blood vessel walls.

One important substance produced by the endothelium of coronary arteries is NO (also called endothelium-derived relaxing factor). NO, which is synthesized from the amino acid arginine, is released by shear stress on the endothelium, sympathetic stimulation of exercise, and interactions with acetylcholine, histamine, prostacyclin, serotonin, thrombin, and other chemical mediators. NO relaxes vascular smooth muscle and inhibits adhesion and aggregation of platelets. When the endothelium is damaged, these vasodilating and antithrombotic effects are lost. At the same time, production of strong vasoconstrictors (e.g., angiotensin II, endothelin-1, thromboxane A<sub>2</sub>) is increased. In addition, inflammatory cells enter the injured area and growth factors stimulate growth of smooth muscle cells. All of these factors participate in blocking coronary arteries.

Sympathetic nervous system stimulation normally produces dilation of coronary arteries, tachycardia, and increased myocardial contractility to handle an increased need for oxygenated blood. Atherosclerosis of coronary arteries, especially if severe, may cause vasoconstriction as well as decrease blood flow by obstruction.

In a healthy heart, about two thirds of the energy (adenosine triphosphate [ATP] production), for cellular function is obtained from the free fatty acid pathway; additional energy is obtained from glucose oxidation and lactate. In hypoxic conditions myocardial cells speed up glucose uptake to produce adequate ATP. Severe ischemia rapidly induces an imbalance between the cardiac supply and demand causing alterations in contraction and electrical conduction, resulting in failure and dysrhythmias. At the cellular level, hypoxia increases anaerobic metabolism with resultant cellular acidosis. The free fatty acid pathway is slowed down, resulting in less ATP production. These metabolic changes lead to disruption of cell homeostasis and ultimately, cell death.

## Nonpharmacologic Management of CAD

Nonpharmacologic management of angina and MI include risk factor modification, patient education, and revascularization procedures. For patients at any stage of CAD development, irrespective of symptoms of myocardial ischemia, optimal management involves lifestyle changes and medications, if necessary, to control or reverse risk factors for disease progression. *The Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults* (NCEP III) defines *metabolic syndrome* as a cluster of several cardiovascular risk factors linked with obesity: elevated waist circumference, elevated triglycerides, reduced high-density lipoprotein cholesterol, elevated blood pressure, and elevated fasting glucose. These risk factors frequently produce an additive effect on CAD and result in significant morbidity and mortality. Thus, efforts are needed to assist patients in reducing blood pressure, weight, and serum cholesterol levels, when indicated, and developing an exercise program. For patients with diabetes mellitus, glucose and blood pressure control can reduce the microvascular changes associated with the condition.

In addition, patients should avoid circumstances known to precipitate acute attacks, and those who smoke should stop. Smoking is harmful to patients because

- Nicotine increases catecholamines which, in turn, increase heart rate and blood pressure.
- Carboxyhemoglobin, formed from the inhalation of carbon monoxide in smoke, decreases delivery of blood and oxygen to the heart, decreases myocardial contractility, and increases the risks of life-threatening cardiac dysrhythmias (e.g., ventricular fibrillation) during ischemic episodes.
- Both nicotine and carbon monoxide increase platelet adhesiveness and aggregation, thereby promoting thrombosis.
- Smoking increases the risks for MI, sudden cardiac death, cerebrovascular disease (e.g., stroke), peripheral vascular disease (e.g., arterial insufficiency), and hypertension. It also reduces high-density lipoprotein, the “good” cholesterol.

Additional nonpharmacologic management strategies include surgical revascularization (e.g., coronary artery bypass

graft) and interventional procedures that reduce blockages (e.g., percutaneous transluminal coronary angioplasty [PTCA], intracoronary stents, laser therapy, rotational atherectomy). Additionally, the use of supersaturated oxygen (SSO<sub>2</sub>) has shown significant improvement in limiting myocardial damage in patients with anterior MIs. In the AMIHOT II trial, infusing SSO<sub>2</sub> into the previously blocked artery after performing an angioplasty procedure reduced infarct zone size by 6.5%.

Nonpharmacologic management improves patient outcomes. However, most patients still require antianginal and other cardiovascular medications to manage their disease.

## Drug Management

Drugs used for myocardial ischemia are the organic nitrates, the beta-adrenergic blocking agents, and the calcium channel blocking agents. These drugs relieve anginal pain by reducing myocardial oxygen demand or increasing blood supply to the myocardium. A new classification of drug, metabolic modulators, appears to increase the heart's effectiveness in energy production to preserve cardiac function without decreasing heart rate or blood pressure. The drug class is approved as second-line therapy in patients who continue to experience angina despite treatment with another class of antianginal medications. Nitrates, beta blockers, and metabolic modulators are described in the following sections; dosage ranges for these drugs are listed in Table 50-1. Calcium channel blockers are described in a following section; indications for use and dosage ranges are listed in Table 50-2.

## Antianginal Drugs: Classifications and Individual Drugs

### Organic Nitrates

#### General Characteristics

Organic nitrates relax smooth muscle in blood vessel walls. This action produces vasodilation, which relieves anginal pain by several mechanisms. First, dilation of veins reduces venous pressure and venous return to the heart. This decreases blood volume and pressure within the heart (preload), which in turn decreases cardiac workload and oxygen demand. Second, nitrates dilate coronary arteries at higher doses and can increase blood flow to ischemic areas of the myocardium. Third, nitrates dilate arterioles, which lowers peripheral vascular resistance (afterload). This results in lower systolic blood pressure and, consequently, reduced cardiac workload. The prototype and most widely used nitrate is **nitroglycerin**.

Nitrates are converted to NO in vascular smooth muscle. NO activates guanylate cyclase, an enzyme that catalyzes formation of cyclic guanine monophosphate, which decreases calcium levels in vascular smooth muscle cells. Because intracellular calcium is required for contraction of vascular smooth muscle, the result of decreased calcium is vasodilation.

Table 50-1

**Drugs at a Glance: Nitrate, Beta-Blocker, and Metabolic Modulator Antianginal Drugs**

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Nitrates</b>		
<b>P Nitroglycerin</b> (Nitro-Bid, others)	Relieve acute angina Prevent exercise-induced angina Long-term prophylaxis to decrease the frequency and severity of acute anginal episodes	PO immediate-release tablets, 2.5–9 mg 2 or 3 times per day PO sustained-release tablets or capsules, 2.5 mg 3 or 4 times per day SL 0.15–0.6 mg PRN for chest pain Translingual spray, one or two metered doses (0.4 mg/dose) sprayed onto oral mucosa at onset of anginal pain, to a maximum of 3 doses in 15 min Transmucosal tablet, 1 mg q3–5h while awake, placed between upper lip and gum or cheek and gum Topical ointment, 1/2–2 inches q4–8h; do not rub in Topical transdermal disc, applied once daily IV 5–10 mcg/min initially, increased in 10- to 20-mcg/min increments up to 100 mcg/min or more if necessary to relieve pain
<b>Isosorbide dinitrate</b> (Isordil)	Treatment and prevention of angina	SL 2.5–10 mg PRN or q2–4h PO regular tablets, 5–40 mg 4 times/d PO chewable tablets, 5–10 mg q2–3h PO sustained-release capsules, 40 mg q6–12h
<b>Isosorbide mononitrate</b> (Ismo, Imdur)	Treatment and prevention of angina	PO 5–20 mg twice daily, with first dose on arising and the second dose 7 h later PO extended-release tablets (Imdur), 30–60 mg once daily in the morning, increased after several days; maximum dose 240 mg once daily
<b>Beta Blockers</b>		
<b>P Propranolol</b> (Inderal)	Long-term management of angina, to reduce frequency and severity of anginal episodes	PO 10–80 mg 2 to 4 times per day IV 0.5–3 mg q4h until desired response is obtained
<b>Atenolol</b> (Tenormin)	Long-term management of angina, to reduce frequency and severity of anginal episodes	PO 50 mg once daily, initially, increased to 100 mg/d after 1 wk if necessary
<b>Metoprolol</b> (Lopressor)	Long-term management of angina, to reduce frequency and severity of anginal episodes	PO 100–450 mg/d in 2–3 divided doses
<b>Nadolol</b> (Corgard)	Long-term management of angina, to reduce frequency and severity of anginal episodes	PO 40–240 mg/d in a single dose
<b>Metabolic Modulator</b>		
<b>Ranolazine</b> (Ranexa)	Long-term management of angina, not responsive to other antianginal medications	PO 500 mg twice daily, if needed; maximum recommended dose is 1000 mg twice daily

SL, sublingual.

Table 50-2

## Drugs at a Glance: Calcium Channel Blockers

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Amlodipine</b> (Norvasc)	Angina Hypertension	PO 5–10 mg once daily
<b>Diltiazem</b> (Cardizem)	Angina Hypertension Atrial fibrillation and flutter PSVT	Angina or hypertension, immediate-release, PO 60–90 mg 4 times daily before meals and at bedtime Hypertension, sustained-release only, PO 120–180 mg twice daily Dysrhythmias (Cardizem IV only), IV injection 0.25 mg/kg (average dose 20 mg) over 2 min with a second dose of 0.35 mg/kg (average dose 25 mg) in 15 min if necessary, followed by IV infusion of 5–15 mg/h up to 24 h
<b>Felodipine</b> (Plendil)	Hypertension	PO 5–10 mg once daily
<b>Isradipine</b> (DynaCirc)	Hypertension	PO 2.5–5 mg twice daily
<b>Nicardipine</b> (Cardene)	Angina Hypertension	Angina, immediate-release only, PO 20–40 mg 3 times daily Hypertension, immediate-release, same as for angina, above; sustained-release, PO 30–60 mg twice daily
<b>Nifedipine</b> (Adalat, Procardia)	Angina Hypertension	Angina, immediate-release, PO 10–30 mg 3 times daily; sustained-release, PO 30–60 mg once daily Hypertension, sustained-release only, 30–60 mg once daily
<b>Nimodipine</b> (Nimotop)	Subarachnoid hemorrhage	PO 60 mg q4h for 21 consecutive days. If patient unable to swallow, aspirate contents of capsule into a syringe with an 18-gauge needle, administer by nasogastric tube, and follow with 30 mL normal saline.
<b>Nisoldipine</b> (Sular)	Hypertension	PO, initially 20 mg once daily, increased by 10 mg/wk or longer intervals to a maximum of 60 mg daily. Average maintenance dose, 20–40 mg daily. Adults with liver impairment or >65 y, PO, initially 10 mg once daily
<b>Verapamil</b> (Calan, Isoptin)	Angina Atrial fibrillation or flutter PSVT Hypertension	Angina, PO 80–120 mg 3 times daily Dysrhythmias, PO 80–120 mg 3 to 4 times daily; IV injection, 5–10 mg over 2 min or longer, with continuous monitoring of electrocardiogram and blood pressure Hypertension, PO 80 mg 3 times daily or 240 mg (sustained-release) once daily

PSVT, paroxysmal supraventricular tachycardia.

The NO derived from nitrate medications can be considered a replacement or substitute for the NO that a damaged endothelium can no longer produce.

Clinical indications for nitroglycerin and other nitrates are management and prevention of acute chest pain caused by myocardial ischemia. For acute angina and prophylaxis before a situation deemed likely to precipitate acute angina, fast-acting preparations (sublingual or chewable tablets,

transmucosal spray or tablet) are used. For management of recurrent angina, long-acting preparations (oral and sustained-release tablets or transdermal ointment and discs) are used. However, they may not be effective long term because tolerance develops to their hemodynamic effects. Intravenous (IV) nitroglycerin is used to manage angina that is unresponsive to organic nitrates via other routes or beta-adrenergic blocking agents. It also may be used to control blood pressure

in perioperative or emergency situations and to reduce preload and afterload in severe heart failure.

Contraindications include hypersensitivity reactions, severe anemia, hypotension, and hypovolemia. The drugs should be used cautiously in the presence of head injury or cerebral hemorrhage because they may increase intracranial pressure. Additionally, males taking nitroglycerin or any other nitrate should not take phosphodiesterase enzyme type 5 inhibitors such as sildenafil (Viagra) and vardenafil (Levitra) for erectile dysfunction. Nitrates and phosphodiesterase enzyme type 5 inhibitors decrease blood pressure and the combined effect can produce profound, life-threatening hypotension.

### Individual Nitrates

**P Nitroglycerin** (Nitro-Bid, others), the prototype drug, is used to relieve acute angina pectoris, prevent exercise-induced angina, and decrease the frequency and severity of acute anginal episodes. Oral dosage forms are rapidly metabolized in the liver, and relatively small proportions of doses reach the systemic circulation. In addition, oral doses act slowly and do not help relieve acute chest pain.

For these reasons, several alternative dosage forms have been developed, including transmucosal tablets and sprays administered sublingually or buccally, transdermal ointments and adhesive discs applied to the skin, and an IV preparation. When given sublingually, nitroglycerin is absorbed directly into the systemic circulation. It acts within 1 to 3 minutes and lasts 30 to 60 minutes. When applied topically to the skin, nitroglycerin is also absorbed directly into the systemic circulation. However, absorption occurs at a slower rate, and topical nitroglycerin has a longer duration of action than other forms. It is available in an ointment, which is effective for 4 to 8 hours, and in a transdermal disc, which is effective for about 12 hours. An IV form of nitroglycerin is used to relieve acute anginal pain that does not respond to other agents. Regardless of the route, nitroglycerin has a half-life of 1 to 5 minutes, supporting the beneficial use of transdermal patches and sustained-release tablets.

**Isosorbide dinitrate** (Isordil) is used to reduce the frequency and severity of acute anginal episodes. When given sublingually or in chewable tablets, it acts in about 2 minutes, and its effects last 2 to 3 hours. When higher doses are given orally, more drug escapes metabolism in the liver and produces systemic effects in approximately 30 minutes. Therapeutic effects last about 4 hours after oral administration. The effective oral dose is usually determined by increasing the dose until headache occurs, indicating the maximum tolerable dose. Sustained-release capsules also are available.

**Isosorbide mononitrate** (Ismo, Imdur) is the metabolite and active component of isosorbide dinitrate. It is well absorbed after oral administration and almost 100% bioavailable. Unlike other oral nitrates, this drug is not subject to first-pass hepatic metabolism. Onset of action occurs within 1 hour, peak effects occur between 1 and 4 hours, and the elimination half-life is approximately 5 hours. It is used only for prophylaxis of angina; it does not act rapidly enough to relieve acute attacks.

## Applying Your Knowledge 50-1

### How Can You Avoid This Medication Error?

Mr. Gerald is prescribed nitroglycerin in both sublingual form and as a transdermal patch. While reviewing his medication instructions with Mr. Gerald, the nurse learns he has had a history of erectile dysfunction and has sildenafil medication in the medicine cabinet that was prescribed for him before his MI. The nurse leaves the patient information instructions for the nitroglycerin with Mr. Gerald and leaves the room.

## Beta-Adrenergic Blocking Agents

### General Characteristics

Beta-adrenergic blocking agents are often prescribed in a variety of clinical conditions. Their actions, uses, and adverse effects are discussed in Chapter 18. In this chapter, the drugs are discussed only in relation to their use in angina pectoris.

Sympathetic stimulation of beta<sub>1</sub> receptors in the heart increases heart rate and force of myocardial contraction, both of which increase myocardial oxygen demand and may precipitate acute anginal attacks. Beta-blocking drugs prevent or inhibit sympathetic stimulation. Thus, the drugs reduce heart rate and myocardial contractility, particularly when sympathetic output is increased during exercise. A slower heart rate may improve coronary blood flow to the ischemic area. Beta blockers also reduce blood pressure, which in turn decreases myocardial workload and oxygen demand. Studies indicate that beta blockers are more effective than nitrates or calcium channel blockers in decreasing the likelihood of silent ischemia and improving the mortality rate after transmural MI. In angina pectoris, beta-adrenergic blocking agents are used in long-term management to decrease the frequency and severity of anginal attacks, decrease the need for sublingual nitroglycerin, and increase exercise tolerance. When a beta blocker is being discontinued after prolonged use, it should be tapered in dosage and gradually discontinued or rebound angina can occur.

These drugs should not be given to patients with known or suspected coronary artery spasms because they may intensify the frequency and severity of vasospasm. This probably results from unopposed stimulation of alpha-adrenergic receptors, which causes vasoconstriction, when beta-adrenergic receptors are blocked by the drugs. Patients who continue to smoke may have reduced efficacy with the use of beta blockers. Patients with asthma should be observed for bronchospasm from blockage of beta<sub>2</sub> receptors in the lung. Beta blockers should be used with caution in patients with diabetes mellitus because they can conceal signs of hypoglycemia (except for sweating).

### Individual Drugs

**P Propranolol**, the prototype beta blocker, is used to reduce the frequency and severity of acute attacks of angina. It is usually added to the antianginal drug regimen when nitrates do not prevent anginal episodes. It is especially useful in

preventing exercise-induced tachycardia, which can precipitate anginal attacks.

Propranolol is well absorbed after oral administration. It is then metabolized extensively in the liver; a relatively small proportion of an oral dose (approximately 30%) reaches the systemic circulation. For this reason, oral doses of propranolol are much higher than IV doses. Onset of action is 30 minutes after oral administration and 1 to 2 minutes after IV injection. Because of variations in the degree of hepatic metabolism, patients vary widely in the dosages required to maintain a therapeutic response.

**Atenolol**, **metoprolol**, and **nadolol** have the same actions, uses, and adverse effects as propranolol, but they have long half-lives and can be given once daily. They are excreted by the kidneys, and dosage must be reduced in patients with renal impairment.

### Applying Your Knowledge 50-2

In addition to nitroglycerin, the physician prescribes metoprolol. Mr. Gerald understands why nitroglycerin is beneficial to his condition. He asks about the metoprolol and why he needs to take this medication. How should you respond?

## Calcium Channel Blocking Agents

Calcium channel blockers act on contractile and conductive tissues of the heart and on vascular smooth muscle. For these cells to function normally, the concentration of intracellular calcium must be increased. This is usually accomplished by movement of extracellular calcium ions into the cell (through calcium channels in the cell membrane) and release of bound calcium from the sarcoplasmic reticulum in the cell. Thus, calcium plays an important role in maintaining vasomotor tone, myocardial contractility, and conduction. Calcium channel blocking agents prevent the movement of extracellular calcium into the cell. As a result, coronary and peripheral arteries are dilated, myocardial contractility is decreased, and the conduction system is depressed in relation to impulse formation (automaticity) and conduction velocity (Fig. 50-1).

In angina pectoris, the drugs improve the blood supply to the myocardium by dilating coronary arteries and decrease the workload of the heart by dilating peripheral arteries. In variant angina, calcium channel blockers reduce coronary artery vasospasm. In atrial fibrillation or flutter and other supraventricular tachyarrhythmias, **diltiazem** and **verapamil** slow the rate of ventricular response. In hypertension, the drugs lower blood pressure primarily by dilating peripheral arteries.

Calcium channel blockers are well absorbed after oral administration but undergo extensive first-pass metabolism in the liver. Most of the drugs are more than 90% protein bound and reach peak plasma levels within 1 to 2 hours (6 hours or longer for sustained-release forms). Most also have short elimination half-lives (<5 hours), so doses must be given three or

**Figure 50-1** ■ Calcium channel blockers: mechanism of action. (A) During muscle relaxation, potassium ions are inside the muscle cell and calcium and sodium ions are outside the muscle cell. (B) For muscle contraction to occur, potassium ions leave the cell and sodium and calcium ions enter the cell through open channels in the cell membrane. (C) When calcium channels are blocked by drug molecules, muscle contraction is decreased because calcium ions cannot move through the cell membrane into the muscle cell.

four times daily unless sustained-release formulations are used. **Amlodipine** (30–50 hours) and **felodipine** (11–16 hours) have long elimination half-lives and therefore can be given once daily. The drugs are metabolized in the liver, and dosage should be reduced in patients with severe liver disease. Dosage reductions are not required with renal disease.

The calcium channel blockers approved for use in the United States vary in their chemical structures and effects on body tissues. Seven of these are chemically dihydropyridines, of which **nifedipine** is the prototype. Diltiazem and verapamil differ chemically from the dihydropyridines and each other. Nifedipine and related drugs act mainly on vascular smooth muscle to produce vasodilation, whereas verapamil and diltiazem have greater effects on the cardiac conduction system.

The drugs also vary in clinical indications for use; most are used for angina or hypertension, and only diltiazem and verapamil are used to manage supraventricular tachyarrhythmias.

In patients with CAD, the drugs are effective as monotherapy but are commonly prescribed in combination with beta blockers. In addition, **nimodipine** is approved for use only in subarachnoid hemorrhage, in which it decreases spasm in cerebral blood vessels and limits the extent of brain damage. In animal studies, nimodipine exerted greater effects on cerebral arteries than on other arteries, probably because it is highly lipid soluble and penetrates the blood–brain barrier.

Contraindications to use include second- or third-degree heart block, cardiogenic shock, and severe bradycardia, heart failure, or hypotension. The drugs should be used cautiously with milder bradycardia, heart failure, or hypotension and with renal or hepatic impairment.

### Applying Your Knowledge 50-3

Mr. Gerald has had anginal pain at rest and his physician prescribes diltiazem. He asks what this new medication will do for him. How do you respond?

## Metabolic Modulator

### General Characteristics

A metabolic modulator is a miscellaneous second-line cardiovascular agent used in chronic angina in combination with amlodipine, beta blockers, or nitrates. The drug does not relieve acute anginal attacks but is given to patients with chronic angina who have not had adequate antianginal responses with other agents. Although the mechanism of action is not clearly understood, **ranolazine**, the only drug currently in the drug class is thought to be a partial fatty acid oxidation (PFox) inhibitor, increasing the efficiency of ATP production in the presence of hypoxia. The drug decreases ischemia but does not possess negative inotropic (contractility) or chronotropic (rate) effects; minimal effects on heart rate and blood pressure were reported during clinical trials. Ranolazine is also a late sodium channel inhibitor.

### Individual Drugs

**Ranolazine** (Ranexa) represents the new classification of a metabolic modulator used in individuals with chronic angina. The drug is labeled for use in combination with amlodipine, beta blockers, or nitrates. After oral administration, peak plasma concentrations are reached within 2 to 5 hours. The drug is rapidly and extensively metabolized in the liver. Due to a risk of dose-dependent QT prolongation on electrocardiogram, ranolazine is reserved for the treatment of patients with chronic angina who have not achieved a satisfactory antianginal response with traditional drugs. Baseline and follow-up electrocardiography should be performed to evaluate the QT interval. Ranolazine is contraindicated in patients with pre-existing QT prolongation. The drug can be taken with or without meals and, because it is an extended-release tablet, should be swallowed whole and not crushed, chewed, or broken. Avoid

giving with grapefruit juice. If a dose is missed, it should be taken at the next scheduled time; no dose should be doubled.

## Adjunctive Antianginal Drugs

In addition to antianginal drugs, several other drugs may be used to control risk factors and prevent progression of myocardial ischemia to MI and sudden cardiac death:

- **Aspirin.** This drug has become the standard of care because of its antiplatelet (i.e., antithrombotic) effects. Recommended doses vary from 81 mg daily to 325 mg daily or every other day; apparently all doses are beneficial in reducing the possibility of myocardial reinfarction, stroke, and death. **Clopidogrel** (see Chap. 54), 75 mg/day, is an acceptable alternative for individuals with aspirin allergy.
- **Antilipemics.** These drugs (see Chap. 55) may be needed by patients who are unable to lower serum cholesterol levels sufficiently with a low-fat diet. **Lovastatin** or a related “statin” is often used. The goal is usually to reduce the serum cholesterol level below 200 mg/dL and low-density lipoprotein cholesterol to below 130 mg/dL.
- **Antihypertensives.** These drugs (see Chap. 52) may be needed for patients with hypertension. Because beta blockers and calcium channel blockers are used to manage hypertension as well as angina, one of these drugs may be effective for both disorders.

## Nursing Process

### Assessment

Assess the patient's condition in relation to angina pectoris. Specific assessment data vary with each patient but usually should include the following:

- During the initial nursing history interview, try to answer the following questions:
  - How long has the patient been taking antianginal drugs? For what purpose are they being taken (prophylaxis, treatment of acute attacks, or both)?
  - What is the frequency and duration of acute anginal attacks? Has either increased recently? (An increase could indicate worsening coronary atherosclerosis and increased risk of MI.)
  - Do symptoms other than chest pain occur during acute attacks (e.g., sweating, nausea)?
  - Are there particular activities or circumstances that provoke acute attacks? Do attacks ever occur when the patient is at rest? Where does the patient fit in the Canadian Cardiovascular Society classification system?
  - What measures relieve symptoms of acute angina?

*Nursing Process continues on page 806*

- If the patient takes nitroglycerin, ask how often it is required, how many tablets are needed for relief of pain, how often the supply is replaced, and where the patient stores or carries the drug.
- Assess blood pressure and pulse, electrocardiogram (ECG) reports, serum cholesterol, and cardiac enzyme reports. Elevated cholesterol is a significant risk factor for coronary atherosclerosis and angina, and the risk is directly related to the degree of elevation. Cardiac enzyme levels, such as troponin, creatine kinase (CK), lactate dehydrogenase (LDH), and aspartate aminotransferase (AST), should all be normal in patients with angina.
- During an acute attack, assess the following:
  - Location and quality of the pain. Chest pain is nonspecific. It may be a symptom of numerous disorders, such as pulmonary embolism, esophageal spasm or inflammation (heartburn), costochondritis, or anxiety. Chest pain of cardiac origin is caused by myocardial ischemia and may indicate angina pectoris or MI.
  - Precipitating factors. For example, what was the patient doing, thinking, or feeling just before the onset of chest pain?
  - Has the patient had invasive procedures to diagnose or treat his or her CAD (e.g., cardiac catheterization, angioplasty, revascularization surgery)?

## Nursing Diagnoses

- Decreased Cardiac Output related to altered stroke volume or drug therapy
- Acute pain in chest related to inadequate perfusion of the myocardium
- Activity Intolerance related to chest pain
- Deficient Knowledge related to management of disease process and drug therapy
- Ineffective Individual Coping related to chronic disease process
- Sexual Dysfunction related to fear of precipitating chest pain

## Planning/Goals

### The patient will

- Receive or take antianginal drugs accurately
- Experience relief of acute chest pain
- Have fewer episodes of acute chest pain
- Have increased activity tolerance
- Identify and manage situations that precipitate anginal attacks
- Be closely monitored for therapeutic and adverse effects, especially when drug therapy is started
- Avoid preventable adverse effects

- Verbalize essential information about the disease process, needed dietary and lifestyle changes to improve health status, and drug therapy
- Recognize signs and symptoms that necessitate professional intervention
- Keep appointments for follow-up care and monitoring

## Interventions

Use the following measures to prevent acute anginal attacks.

- Assist in preventing, recognizing, and managing contributory disorders, such as atherosclerosis, hypertension, hyperthyroidism, hypoxia, and anemia. For example, hypertension is a common risk factor for CAD and morbidity and mortality increase progressively with the degree of either systolic or diastolic elevation. Management of hypertension reduces morbidity and mortality rates. However, most studies indicate that the reductions stem more from fewer strokes, less renal failure, and less heart failure, than from less CAD.
- Help the patient recognize and avoid precipitating factors (e.g., heavy meals, strenuous exercise) when possible. If anxiety is a factor, relaxation techniques or psychological counseling may be helpful.
- Help the patient develop a more healthful lifestyle in terms of diet and weight control, adequate rest and sleep, regular exercise, and not smoking. Ideally, these self-help interventions are practiced before illness occurs; they can help prevent or delay illness. However, most individuals are unmotivated until illness develops, and perhaps after it develops as well. These interventions are beneficial at any stage of CAD. For example, for a patient who already has angina, a supervised exercise program helps develop collateral circulation. Smoking has numerous ill effects on the patient with angina and decreases effectiveness of antianginal drugs.

During an acute anginal attack in a patient known to have angina or CAD, take the following actions.

- Assume that any chest pain may be of cardiac origin.
- Have the patient lie down or sit down to reduce cardiac workload and provide rest.
- Check vital signs and compare them with baseline values.
- Record the characteristics of chest pain and the presence of other signs and symptoms.
- Have the patient take a fast-acting nitroglycerin preparation (previously prescribed), up to three sublingual tablets or three oral sprays, each 5 minutes apart, as necessary.
- If chest pain is not relieved with rest and nitroglycerin, assume that an MI has occurred until proven otherwise. In a health care setting, keep the patient at rest and notify the client's physician immediately. Outside of a health care setting, call 911 for immediate assistance.

- Leave sublingual nitroglycerin at the bedside of hospitalized patients (per hospital policy). The tablets or spray should be within reach so that they can be used immediately. Record the number of tablets used daily, and ensure that an adequate supply is available.

Provide appropriate patient teaching related to drug therapy (see accompanying display).

### Evaluation

- Observe and interview for relief of acute chest pain.
- Observe and interview regarding the number of episodes of acute chest pain.
- Identify CAD lifestyle factors that are being successfully modified or require modification (e.g., diet, weight, activity, smoking cessation).
- Interview regarding success and compliance with drug therapy.

## Principles of Therapy

### Goals of Therapy

The goals of drug therapy are to relieve acute anginal pain, reduce the number and severity of acute anginal attacks, improve exercise tolerance and quality of life, delay progression of CAD, prevent MI, and prevent sudden cardiac death.

### Drug Selection and Dosage

For relief of acute angina and prophylaxis before events that cause acute angina, nitroglycerin (sublingual tablets or translingual spray) is usually the primary drug of choice. Sublingual or chewable tablets of isosorbide dinitrate also may be used. For long-term prevention or management of recurrent angina, oral or topical nitrates, beta-adrenergic blocking agents, or calcium channel blocking agents are used. Combination drug therapy with a nitrate and one of the other drugs is common and effective. Patients taking one or more long-acting antianginal drugs should carry a short-acting drug as well to be used for acute attacks.

Dosage of all antianginal drugs should be individualized to achieve optimal benefit and minimal adverse effects. This is usually accomplished by starting with relatively small doses and increasing them at appropriate intervals as necessary. Doses may vary widely among individuals.

### Tolerance to Long-Acting Nitrates

Patients who take long-acting dosage forms of nitrates on a regular schedule develop tolerance to the vasodilating (antianginal) effects of the drug. The patients more likely to develop tolerance are those on high-dose, uninterrupted therapy. Although tolerance decreases the adverse effects of hypotension, dizziness, and headache, therapeutic effects also may be

decreased. As a result, episodes of chest pain may occur more often or be more severe than expected. In addition, short-acting nitrates may be less effective in relieving acute pain.

Opinions seem divided about the best way to prevent or manage nitrate tolerance. Some authorities recommend using short-acting nitrates when needed and avoiding the long-acting forms. Others recommend using the long-acting forms for 12 to 16 hours daily during active periods and omitting them during inactive periods or sleep. Thus, a dose of an oral nitrate or topical ointment would be given every 6 hours for three doses daily, allowing a rest period of 6 hours without a dose. Transdermal discs should be removed at bedtime. If anginal symptoms occur during sleeping hours, short-acting nitrates may be beneficial in relieving the symptoms. All nitrates should be administered at the lowest effective dosage.

## Use in Special Populations

### Use in Children

The safety and effectiveness of antianginal drugs have not been established for children. Nitroglycerin has been given IV for heart failure and intraoperative control of blood pressure, with the initial dose adjusted for weight and later doses titrated to response.

### Use in Older Adults

The prevalence of CAD increases with age and is the major cause of disability, morbidity, and mortality in older adults. The elderly have a higher incidence of multivessel coronary disease, decreased left ventricular function, and comorbid conditions. Antianginal drugs are often used because cardiovascular disease and myocardial ischemia are common problems in older adults. Traditional antianginal drugs that act via hemodynamic mechanisms (e.g., beta blockers, calcium antagonists, nitrates) can pose a problem in older adults because of the associated higher risk of drug interaction and greater incidence of adverse drug effects. Adverse effects, such as hypotension and syncope, are likely to occur, and they may be more severe than in younger adults. Blood pressure and ability to ambulate safely should be closely monitored, especially when drug therapy is started or dosages are increased. Ambulatory patients also should be monitored for their ability to take the drugs correctly.

With calcium channel blockers, older adults may have higher plasma concentrations of verapamil, diltiazem, nifedipine, and amlodipine. This is attributed to decreased hepatic metabolism of the drugs, probably because of decreased hepatic blood flow. In addition, older adults may experience more hypotension with verapamil, nifedipine, and felodipine than younger patients. Blood pressure should be monitored with these drugs.

### Use in Patients With Renal Impairment

Little information is available about the use of antianginal drugs in patients with impaired renal function. A few studies indicate that advanced renal failure may alter the pharmacokinetics of calcium channel blockers. Although the pharmacokinetics of diltiazem and verapamil are quite similar in patients

## Patient Teaching Guidelines Antianginal Drugs

### General Considerations

- Angina is chest pain that occurs because your heart is not getting enough blood and oxygen. The most common causes are hypertension and atherosclerosis of the coronary arteries. The chest pain usually lasts less than 5 minutes and episodes can be managed for years without causing permanent heart damage. However, if the pain is severe or prolonged, a heart attack and heart damage may develop. You need to seek information about your heart condition to prevent or decrease episodes of angina and prevent a heart attack.
- Several types of drugs are used in angina, and you may need a combination of drugs for the best effects. Most patients take one or more long-acting drugs to prevent anginal attacks and a fast, short-acting drug (usually nitroglycerin tablets that you dissolve under your tongue, or a nitroglycerin solution that you spray into your mouth) to relieve acute attacks. You should seek emergency care immediately if rest and three sublingual tablets or oral sprays 5 minutes apart do not relieve your chest pain. The long-acting medications are not effective in relieving sudden anginal pain.
- As with any medications for serious or potentially serious conditions, it is extremely important to take antianginal medications as prescribed. Do not increase dosage or discontinue the drugs without specific instructions from your health care provider.
- With sublingual nitroglycerin tablets, keep them in the original container; carry them so that they are always within reach but not where they are exposed to body heat; and replace them approximately every 6 months because they become ineffective.
- It may be helpful to record the number and severity of anginal episodes, the number of nitroglycerin tablets required to relieve the attack, and the total number of tablets taken daily. Such a record can help your health care provider know when to change your medications or your dosages.
- Headache and dizziness may occur with nitrate antianginal drugs, especially sublingual nitroglycerin. These effects are usually temporary and dissipate with continued therapy. If dizziness occurs, avoid strenuous activity and stand up slowly for approximately an hour after taking the drugs. If headache is severe, you may take aspirin or acetaminophen with the nitrate drug. Do not reduce drug dosage or take the drug less often to avoid headache; loss of effectiveness may occur.
- Keep family members or support individuals informed about the location and use of antianginal medications in case help is needed.
- Avoid over-the-counter decongestants, cold remedies, and diet pills, which stimulate the heart and constrict blood vessels and thus may cause angina.
- With nitrate antianginal drugs, avoid alcohol. Both the drugs and alcohol dilate blood vessels and an excessive reduction in blood pressure (with dizziness and fainting) may occur with the combination.
- With a metabolic modulator, avoid concurrent intake of grapefruit juice: Grapefruit juice increases serum drug levels.
- Several calcium channel blockers are available in both immediate-acting and long-acting (sustained-release) forms. The brand names often differ very little (e.g., Procardia is a brand name of immediate-release nifedipine; Procardia XL is a long-acting formulation). It is extremely important that the correct formulation is used consistently.

### Self- or Caregiver Administration

- Take or give as instructed; specific instructions differ with the type of antianginal drug being taken.
- Take or give antianginal drugs on a regular schedule, at evenly spaced intervals. This increases drug effectiveness in preventing acute attacks of angina.
- With nitroglycerin and other nitrate preparations:
  - Use according to instructions for the particular dosage form. The dosage forms were developed for specific routes of administration and are not interchangeable.
  - For sublingual nitroglycerin tablets, place them under the tongue until they dissolve. Take at the first sign of an anginal attack, before severe pain develops. If chest pain is not relieved in 5 minutes, dissolve a second tablet under the tongue. If pain is not relieved within another 5 minutes, dissolve a third tablet. If pain continues or becomes more severe, notify your health care provider immediately or report to the nearest hospital emergency room. Sit down when you take the medications. This may help to relieve your pain and prevent dizziness from the drug.
  - For the translingual solution of nitroglycerin, spray onto or under the tongue; do not inhale the spray.
  - For transmucosal tablets of nitroglycerin, place them under the upper lip or between the cheek and gum and allow them to dissolve slowly over 3 to 5 hours. Do not chew or swallow the tablets.
  - Take oral nitrates on an empty stomach with a glass of water. Oral isosorbide dinitrate is available in regular and chewable tablets; be sure each type is taken appropriately. Do not crush or chew sustained-release nitrate tablets.
  - For sublingual isosorbide dinitrate tablets, place them under the tongue until they dissolve.
  - If an oral nitrate and topical nitroglycerin are being used concurrently, stagger the times of administration. This minimizes dizziness from low blood pressure and headache, which are common adverse effects of nitrate drugs.
  - For nitroglycerin ointment, use the special paper to measure the dose. Place the ointment on a nonhairy part of the upper body and apply with the applicator paper. Cover the area with plastic wrap or tape. Rotate application sites (because the ointment can irritate the skin) and wipe off the previous dose before applying a new dose. Wash hands after applying the ointment.
  - The measured paper must be used for accurate dosage. The paper is used to apply the ointment because the drug is readily absorbed through the skin. Skin contact should be avoided except on the designated area of the body. Plastic wrap or tape aids absorption and prevents removal of the drug. It also prevents soiling of clothes and linens.

- For nitroglycerin patches, apply at the same time each day to clean, dry, hairless areas on the upper body or arms. Rotate sites. Avoid applying below the knee or elbow or in areas of skin irritation or scar tissue. Correct application is necessary to promote effective and consistent drug absorption. The drug is not as well absorbed from distal portions of the extremities because of decreased blood flow. Rotation of sites decreases skin irritation. Also, used patches must be disposed of properly because there is enough residual nitroglycerin to be harmful, especially to children and pets.
- With sustained-release forms of calcium channel blockers, which are usually taken once daily, do not take more often than prescribed and do not crush or chew.

with normal and impaired renal function, caution is still advised. With verapamil, about 70% of a dose is excreted as metabolites in urine.

Dosage reductions are considered unnecessary with verapamil and diltiazem but may be needed with nifedipine and several other dihydropyridine derivatives. With nifedipine, protein binding is decreased and the elimination half-life is prolonged with renal impairment. In a few patients, reversible elevations in blood urea nitrogen and serum creatinine have occurred. With nicardipine, plasma concentrations are higher in patients with renal impairment, and dosage should be reduced.

### Use in Patients With Hepatic Impairment

Nitrates, beta blockers (see Chap. 18), and calcium channel blockers are metabolized in the liver, and all should be used with caution in patients with significant impairment of hepatic function from reduced blood flow or disease processes.

With oral nitrates, it is difficult to predict effects. On the one hand, first-pass metabolism is reduced, which increases the bioavailability (amount of active drug) of a given dose. On the other hand, the nitrate reductase enzymes that normally deactivate the drug may increase if large doses are given. In this case, more enzymes are available and the drug is metabolized more rapidly, possibly reducing therapeutic effects of a given dose. Relatively large doses of oral nitrates are sometimes given to counteract the drug tolerance (reduced hemodynamic effects) associated with chronic use. In addition, metabolism of nitroglycerin and isosorbide dinitrate normally produces active metabolites. Thus, if metabolism is reduced by liver impairment, drug effects may be decreased and shorter in duration.

A metabolic modulator is contraindicated in patients with hepatic impairment. Prolongation of QT interval may be more significant in patients with liver dysfunction.

With calcium channel blockers, impairment of liver function has profound effects on the pharmacokinetics and pharmacodynamics of most of these drugs. Thus, the drugs should be used with caution, dosages should be substantially reduced, and patients should be closely monitored for drug effects (including periodic measurements of liver enzymes). These recommendations stem from the following effects:

- An impaired liver produces fewer drug-binding plasma proteins such as albumin. This means that a greater proportion of a given dose is unbound and therefore active.
- In patients with cirrhosis, bioavailability of oral drugs is greatly increased and metabolism (of both oral and parenteral drugs) is greatly decreased. Both of these effects

increase plasma levels of drug from a given dose (essentially an overdose). The effects result from shunting of blood around the liver so that drug molecules circulating in the bloodstream do not come in contact with drug-metabolizing enzymes and therefore are not metabolized. For example, the bioavailability of verapamil, nifedipine, felodipine, and nisoldipine is approximately double and their clearance is approximately one third that of patients without cirrhosis.

- Although hepatotoxicity is uncommon, clinical symptoms of hepatitis, cholestasis, or jaundice and elevated liver enzymes (e.g., alkaline phosphatase, creatine kinase [CK], lactate dehydrogenase [LDH], aspartate aminotransferase [AST], alanine aminotransferase [ALT]) have occurred, mainly with diltiazem, nifedipine, and verapamil. These changes resolve if the causative drug is stopped.

### Use in Patients With Critical Illness

Antianginal drugs have multiple cardiovascular effects and may be used alone or in combination with other cardiovascular drugs in patients with critical illness. They are probably used most often to manage severe angina, severe hypertension, or serious cardiac dysrhythmias. For example, IV nitroglycerin may be used for angina and hypertension; an IV beta blocker or calcium channel blocker may be used to improve cardiovascular function with angina, hypertension, or supraventricular tachydysrhythmias. With any of these drugs, dosage must be carefully titrated and patients must be closely monitored for hypotension and other drug effects.

In addition, absorption of oral drugs or topical forms of nitroglycerin may be impaired in patients with extensive edema, heart failure, hypotension, or other conditions that impair blood flow to the gastrointestinal tract or skin.

### Use in Home Care

The role of the home care nurse may vary, depending largely on the severity of the patient's illness. Initially, the nurse should assess the frequency and severity of anginal attacks and how the attacks are managed. In addition, the nurse can assess the home setting for lifestyle and environmental factors that may precipitate myocardial ischemia. When causative factors are identified, plans can be developed to avoid or minimize them. Other aspects of home care may include monitoring the patient's response to antianginal medications; teaching patients and caregivers how to use, store, and replace medications to ensure a constant supply; and discussing circumstances for which the patient should seek emergency care.

## Nursing Actions Antianginal Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- Check blood pressure and heart rate before each dose of an antianginal drug. Withhold the drug if systolic blood pressure is below 90 mm Hg. If the dose is omitted, record and report to the health care provider.
- Give antianginal drugs on a regular schedule, at evenly spaced intervals.
- If oral nitrates and topical nitroglycerin are being used concurrently, stagger times of administration.
- For sublingual nitroglycerin and isosorbide dinitrate, instruct the patient to place the tablets under the tongue until they dissolve.
- For oral isosorbide dinitrate, regular and chewable tablets are available. Be sure each type of tablet is taken appropriately.
- For sublingual nitroglycerin, check the expiration date on the container.
- To apply nitroglycerin ointment, use the special paper to measure the dose. Place the ointment on a nonhairy part of the body, and apply with the applicator paper. Cover the area with plastic wrap or tape. Rotate application sites and wipe off previous ointment before applying a new dose.
- For nitroglycerin patches, apply at the same time each day to clean, dry, hairless areas on the upper body or arms. Rotate sites. Avoid applying below the knee or elbow or in areas of skin irritation or scar tissue.
- For intravenous (IV) nitroglycerin, dilute the drug and give by continuous infusion, with frequent monitoring of blood pressure and heart rate. Use only with the special administration set supplied by the manufacturer to avoid drug adsorption onto tubing.
- With IV verapamil, inject slowly, over 2–3 minutes.

#### 2. Observe for therapeutic effects

- Relief of chest pain with acute attacks
- Reduced incidence and severity of acute attacks with prophylactic antianginal drugs
- Increased exercise tolerance

#### 3. Observe for adverse effects

- With nitrates, observe for hypotension, dizziness, lightheadedness, tachycardia, palpitations, and headache.
- With beta-adrenergic blocking agents, observe for hypotension, bradycardia, bronchospasm, and heart failure.

### RATIONALE/EXPLANATION

Hypotension is an adverse effect of antianginal drugs. Bradycardia is an adverse effect of propranolol and nadolol. Dosage adjustments may be necessary if these effects occur.

To increase effectiveness in preventing acute attacks of angina

To minimize risks of additive hypotension and headache

Sublingual tablets of nitroglycerin are volatile. After the bottle has been opened, they become ineffective after approximately 6 months and should be replaced.

The measured paper must be used for accurate dosage. The paper is used to apply the ointment because the drug is readily absorbed through the skin. Skin contact should be avoided except on the designated area of the body. Plastic wrap or tape aids absorption and prevents removal of the drug. It also prevents soiling of clothes and linens. Application sites should be rotated because the ointment can irritate the skin.

To promote effective and consistent drug absorption. The drug is not as well absorbed from distal portions of the extremities because of decreased blood flow. Rotation of sites decreases skin irritation.

The drug should not be given by direct IV injection. The drug is potent and may cause hypotension. Dosage (flow rate) is adjusted according to response (pain relief or drop in systolic blood pressure of 20 mm Hg).

To decrease hypotension and other adverse effects

Sublingual nitroglycerin usually relieves pain within 5 minutes. If pain is not relieved, two additional tablets may be given, 5 minutes apart. If pain is not relieved after three tablets, report to the health care provider or seek emergency care.

Adverse effects are extensions of pharmacologic action. Vasodilation causes hypotension, which in turn causes dizziness from cerebral hypoxia and tachycardia from compensatory sympathetic nervous system stimulation. Hypotension can decrease blood flow to coronary arteries and precipitate angina pectoris or myocardial infarction. Hypotension is most likely to occur within an hour after drug administration. Vasodilation also causes headache, the most common adverse effect of nitrates.

Beta blockers lower blood pressure by decreasing myocardial contractility and cardiac output. Excessive bradycardia may contribute to hypotension and cardiac dysrhythmias. Bronchospasm is more likely to occur in patients with asthma or other chronic respiratory problems.

**NURSING ACTIONS**

- c. With calcium channel blockers, observe for hypotension, dizziness, lightheadedness, weakness, peripheral edema, headache, heart failure, pulmonary edema, nausea, and constipation. Bradycardia may occur with verapamil and diltiazem; tachycardia may occur with nifedipine and nicardipine.

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of antianginal drugs:
- (1) Antidysrhythmics, antihypertensive drugs, diuretics, phenothiazine antipsychotic agents
  - (2) Cimetidine
  - (3) Digoxin
  - (4) With nitrates, PDE type 5 inhibitors like Viagra (contraindicated)
- b. Drugs that *decrease* effects of antianginal drugs:
- (1) Adrenergic drugs (e.g., epinephrine, isoproterenol)
  - (2) Anticholinergic drugs
  - (3) Calcium salts
  - (4) Carbamazepine, phenytoin, rifampin

**RATIONALE/EXPLANATION**

Adverse effects result primarily from reduced smooth muscle contractility. These effects, except constipation, are much more likely to occur with nifedipine and other dihydropyridines. Nifedipine may cause profound hypotension, which activates the compensatory mechanisms of the sympathetic nervous system and the renin-angiotensin-aldosterone system. Peripheral edema may require the administration of a diuretic. Constipation is more likely to occur with verapamil. Diltiazem reportedly causes few adverse effects.

Additive hypotension

May increase beta-blocking effects of propranolol by slowing its hepatic clearance and elimination. Increases effects of all calcium channel blockers by inhibiting hepatic metabolism and increasing serum drug levels.

Additive bradycardia when given with beta-blocking agents. Potentially life-threatening hypotension may occur.

Adrenergic drugs, which stimulate beta receptors, can reverse bradycardia induced by beta blockers.

Drugs with anticholinergic effects can increase heart rate, offsetting slower heart rates produced by beta blockers.

May decrease therapeutic effectiveness of calcium channel blockers

May decrease effects of calcium channel blockers by inducing hepatic enzymes and thereby increasing their rate of metabolism

**Key Concepts**

- Angina pectoris results from deficit in myocardial oxygen supply (myocardial ischemia) in relation to myocardial oxygen demand, most often caused by atherosclerotic plaque in the coronary arteries.
- The goals of antianginal drug therapy are to relieve acute anginal pain, reduce the number and severity of acute anginal attacks, improve exercise tolerance and quality of life, delay progression of CAD, prevent MI, and prevent sudden cardiac death.
- Because oral nitroglycerin is rapidly metabolized in the liver, relatively small proportions reach systemic circulation; transmucosal, transdermal, and IV preparations are more effective.
- Common drugs used for myocardial ischemia are the organic nitrates, the beta-adrenergic blocking agents, and the calcium channel blocking agents.
- Beta blockers are more effective than nitrates or calcium channel blockers in decreasing the likelihood of silent ischemia and improving the mortality rate after transmural MI.
- Traditional antianginal drugs that act via hemodynamic mechanisms (e.g., beta blockers, calcium antagonists, nitrates) can pose a problem in older adults because of the associated higher risk of drug interaction and greater incidence of adverse drug effects.
- Patients who take long-acting dosage forms of nitrates on a regular schedule develop tolerance to the vasodilating (antianginal) effects of the drug.
- In angina pectoris, calcium channel blockers improve blood supply to the myocardium by dilating coronary arteries and decrease the workload of the heart by dilating peripheral arteries; in variant angina, the drugs reduce coronary artery vasospasm.
- Aspirin, antilipemics, and antihypertensives are used in conjunction with antianginal drugs to prevent progression of myocardial ischemia to MI.
- Starting with relatively small doses of antianginal drugs and increasing them at appropriate intervals as necessary should achieve optimal benefit and minimal adverse effects.

## Review and Application Exercises

### Short Answer Exercises

1. What is angina pectoris?
2. What is the role of endothelial dysfunction in the development of coronary artery atherosclerosis and myocardial ischemia?
3. How do nitrates relieve angina?
4. Develop a teaching plan for a patient who is beginning nitrate therapy.
5. How do beta blockers relieve angina?
6. Why should beta blockers be tapered and discontinued slowly in patients with angina?
7. How do calcium channel blockers relieve angina?
8. Develop a teaching plan for a patient taking a calcium channel blocker.

### NCLEX-Style Questions

9. The nurse removes a patient's transdermal nitroglycerin disc at bedtime as ordered to minimize nitrate tolerance. The patient awakens during the night and complains of anginal symptoms. The nurse's first action is to
  - a. Notify the health care provider.
  - b. Apply a new transdermal disc.
  - c. Obtain further history of complaints.
  - d. Administer a short-acting nitrate as ordered.
10. The health care provider prescribes nitroglycerin 2% ointment, 1.5-inch dose every 4 hours. To accurately apply the ointment, the patient should be instructed to
  - a. Rub the ointment into the skin to enhance absorption.
  - b. Leave previous ointment on for 4 hours after applying a new dose.
  - c. Rotate application sites to decrease skin irritation.
  - d. Place the ointment on a distal part of the lower body to increase absorption.
11. Concurrent use of nitrates in any form or route of administration with phosphodiesterase enzyme inhibitors produces
  - a. enhanced erectile potential
  - b. significant tachycardia
  - c. severe hypotensive effects
  - d. mild bronchodilation
12. A patient who is taking metoprolol (Lopressor) is seen in the cardiac clinic following an MI and reports that he continues to smoke. The nurse recognizes that smoking may contribute to what effect on beta-blocking activity?
  - a. reduce the efficacy
  - b. potentiate an increase in intracranial pressure
  - c. precipitate ventricular fibrillation
  - d. increase the incidence of side effects
13. A patient with angina pectoris, being discontinued from his beta blockers, asks the nurse, "Why can't I just stop taking the drug today if it's not working anyway?" The nurse instructs the patient that failure to taper the drug slowly may lead to
  - a. worsening of his angina symptoms
  - b. significant bronchoconstriction
  - c. development of congestive heart failure
  - d. drug fever
14. In caring for a patient with chronic angina who has been prescribed the new drug, ranolazine (Ranexa), the nurse is correct in counseling that
  - a. This drug may be crushed if necessary.
  - b. This drug must not be taken with beta blockers.
  - c. This drug must not be taken with meals.
  - d. This drug should not be taken with grapefruit juice.

# Drugs Used in Hypotension and Shock

## KEY TERMS

- Anaphylactic shock
- Cardiogenic shock
- Distributive shock
- Hypovolemic shock
- Neurogenic shock
- Septic shock
- Vasogenic shock

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify patients at risk for development of hypovolemia and shock.
2. Identify common causes of hypotension and shock.
3. Discuss an assessment of a patient in shock.
4. Describe therapeutic and adverse effects of vasopressor drugs used in the management of hypotension and shock.

## Applying Your Knowledge

Karim Alrashed is a 65 year-old man who has been admitted to ICU suffering from hypovolemic shock. He has had aggressive fluid resuscitation; however, his BP remains low. The physician orders IV dopamine to keep his systolic BP above 90 mm Hg.

## Introduction

Shock is a clinical condition of insufficient perfusion of cells and vital organs, causing tissue hypoxia. Clinical symptoms depend on the degree of impaired perfusion of vital organs (e.g., brain, heart, kidneys). Common signs and symptoms include oliguria, heart failure, mental confusion, cool extremities, and coma. Most, but not all, people in shock are hypotensive. An additional consequence of inadequate blood flow to tissues is that cells change from aerobic (oxygen-based) to anaerobic metabolism. Lactic acid produced by anaerobic metabolism leads to generalized metabolic acidosis and eventually to organ failure and death if blood flow is not promptly restored.

## Types of Shock

There are three general categories of shock that are based on the circulatory mechanisms involved. These mechanisms are intravascular volume, the ability of the heart to pump, and vascular tone.

*Hypovolemic* shock involves a loss of intravascular fluid volume that may be due to actual blood loss or relative loss from fluid shifts within the body.

*Cardiogenic* shock occurs when the myocardium has lost its ability to contract efficiently and maintain an adequate cardiac output.

*Distributive* or *vasogenic* shock is characterized by massive vasodilation, which results in a relative hypovolemia. Distributive shock is further divided into anaphylactic, neurogenic, and septic shock.

- *Anaphylactic* shock is due to massive vasodilation caused by release of histamine in response to a severe allergic reaction.
- *Neurogenic* shock is due to massive vasodilation caused by a suppression of the sympathetic nervous system.

- *Septic shock* is due to massive vasodilation caused by release of mediators of the inflammatory process in response to overwhelming infection. Almost any organism that gains access to the bloodstream can cause septic shock, but the most often is associated with gram-negative and gram-positive bacterial infections and fungi.

It is important to know the etiology of shock because management varies among the types. The types of shock, with their causes and symptoms, are summarized in Table 51-1.

## General Characteristics of Antishock Drugs

Drugs used in the management of shock are primarily the adrenergic drugs, which are discussed more extensively in

Chapter 17. In this chapter, the drugs are discussed only in relation to their use in hypotension and shock. In these conditions, drugs with alpha-adrenergic activity (e.g., norepinephrine, phenylephrine) are used to increase peripheral vascular resistance and raise blood pressure. Drugs with beta-adrenergic activity (e.g., dobutamine) are used to increase myocardial contractility and heart rate, which in turn raises blood pressure. Some drugs have both alpha- and beta-adrenergic activity (e.g., dopamine, epinephrine). In many cases, a combination of drugs is used, depending on the type of shock and the patient's response to treatment. In an emergency, the drugs may be used to maintain adequate perfusion of vital organs until sufficient fluid volume is replaced and circulation is restored.

Adrenergic drugs with beta activity may be relatively contraindicated in shock states precipitated or complicated by cardiac dysrhythmias. Beta-stimulating drugs are used cautiously

Table 51-1

Types of Shock

TYPE OF SHOCK	POSSIBLE CAUSES	CLINICAL MANIFESTATION
<b>Hypovolemic</b>	Trauma Gastrointestinal bleed Genital-urinary bleed Ruptured aneurysms Third spacing Dehydration	Hypotension Tachycardia Cool, clammy skin Diaphoresis Pallor Oliguria
<b>Cardiogenic</b>	Acute myocardial infarction Cardiac surgery Dysrhythmias Cardiomyopathy Heart failure Ventricular aneurysm Ventricular hypertrophy Ventricular dysfunction	Signs and symptoms of heart failure Signs and symptoms of decreased cardiac output
<b>Distributive</b> Anaphylactic	Chemicals Contrast dyes Drugs Insect bites Foods	Hypotension Hives Bronchospasm, dyspnea, cough, stridor, wheezing Nausea, abdominal cramping, abdominal pain Flushing, warm to hot skin Restlessness, change in level of consciousness
<b>Neurogenic</b>	Spinal cord damage Spinal anesthesia Insulin shock Severe pain Drugs	Hypotension Bradycardia Hypothermia Neurologic deficit Warm, dry skin
<b>Septic</b>	Infection (e.g., urinary tract, upper respiratory infections) Immunosuppression Invasive procedures	Hypotension Cool or warm, dry skin Hypothermia or hyperthermia

in cardiogenic shock after myocardial infarction because increased contractility and heart rate will increase myocardial oxygen consumption and extend the area of infarction. Individual drugs are described in the following section; indications for use and dosage ranges are listed in Table 51-2.

### Applying Your Knowledge 51-1

What nursing measures should the nurse implement for the safe administration of the dopamine drip?

## Individual Drugs

**Dobutamine** is a synthetic catecholamine developed to provide less vascular activity than dopamine. It acts mainly on beta<sub>1</sub> receptors in the heart to increase the force of myocardial contraction with a minimal increase in heart rate. Dobutamine also may increase blood pressure with large doses. It is less

likely to cause tachycardia, dysrhythmias, and increase myocardial oxygen consumption than dopamine. It is most useful in cases of shock that require increased cardiac output without the need for blood pressure support. It is recommended for short-term use only. It may be used with dopamine to augment the beta<sub>1</sub> activity that is sometimes overridden by alpha effects when dopamine is used alone at doses greater than 20 micrograms per kilogram per minute.

Dobutamine has a short plasma half-life and therefore must be administered by continuous intravenous (IV) infusion. A loading dose is not required because the drug has a rapid onset of action and reaches steady state within approximately 10 minutes after the infusion is begun. It is rapidly metabolized to inactive metabolites.

**Dopamine** is a naturally occurring catecholamine that functions as a neurotransmitter. Dopamine exerts its actions by stimulating alpha, beta, or dopaminergic receptors, depending on the dose being used. In addition, dopamine acts indirectly by releasing norepinephrine from sympathetic nerve endings and the adrenal glands. Peripheral dopamine receptors are located in splanchnic and renal vascular beds. At doses

Table 51-2

Drugs at a Glance: Drugs Used for Hypotension and Shock

Generic/Trade Name	Indications for Use/Action	ROUTES AND DOSAGE RANGES	
		Adults	Children
Dobutamine (Dobutrex)	Management of cardiac decompensation Increase cardiac output	IV 2.5–20 mcg/kg/min, increased to 40 mcg/kg/min if necessary  Reconstitute the 250-mg vial with 10 mL of sterile water or 5% dextrose injection. The resulting solution should be diluted to 250–500 mL with IV solution before administering (5000 mcg/mL). Add 250 mg of drug to 500 mL of diluent for a concentration of 500 mcg/mL.	2–15 mcg/kg/min
Dopamine (Intropin)	Acute hypotension and shock Increase cardiac output	IV 1 mcg/kg/min initially, gradually increasing to 50 mcg/kg/min  Prepare by adding 200 mg of dopamine to 250 mL of IV fluid for a final concentration of 800 mcg/mL or to 500 mL IV fluid for a final concentration of 400 mcg/mL.	1–20 mcg/kg/min
Epinephrine (Adrenalin)	Treat anaphylactic shock Reverse bronchoconstriction Increase cardiac output Treat cardiac arrest	IV 1–10 mcg/min. Prepare the solution by adding 2 mg (2 mL) of epinephrine injection 1:1000 to 250 or 500 mL of IV fluid. The final concentration is 8 or 4 mcg/mL, respectively.	IV infusion, 0.01 mcg/kg/min.

Generic/Trade Name	Indications for Use/Action	ROUTES AND DOSAGE RANGES	
		Adults	Children
Metaraminol	Treat hypotension due to spinal anesthesia	IM 2–10 mg IV injection, 0.5–5 mg IV infusion, add 15–500 mg of metaraminol to 250 or 500 mL of IV fluid. Adjust flow rate (dosage) to maintain the desired blood pressure.	IM 0.1 mg/kg IV injection, 0.01 mg/kg IV infusion, 1 mg/25 mL of diluent. Adjust flow rate to maintain the desired blood pressure.
Milrinone (Primacor)	Inotropic agent Increase cardiac output in cardiogenic shock	IV injection (loading dose), 50 mcg/kg over 10 min IV infusion (maintenance dose), 0.375–0.75 mcg/kg/min diluted in 0.9% or 0.45% sodium chloride or 5% dextrose solution. Maximum dose, 0.59–1.13 mg/kg/d	Safety and efficacy not established
Norepinephrine (Levophed)	Stimulate beta and alpha receptors Treat hypotension Increase cardiac output	IV infusion, 0.5–1 mcg/min initially, titrate to a maximum of 30 mcg/min. Prepare solution by adding 4 mg to 250 mL of IV fluid. Final concentration not > 128 mcg/mL.	IV infusion, 0.05–0.1 mcg/kg/min; maximum 1–2 mcg/kg/min Range 0.5–3 mcg/min
Phenylephrine (Neo-Synephrine)	Stimulate alpha receptors Treat hypotension	IM, Sub-Q: 2–5 mg/dose q1–2h IV injection: 0.1–0.5 mg every 10–15 min. IV infusion: 100–180 mcg/min initially, then 40–60 mcg/min Prepare solution by adding 10 mg of phenylephrine to 250 or 500 mL of IV fluid. Final concentration is 20 or 40 mcg/mL, respectively.	IM, Sub-Q: 0.1 mg/kg q1–2h IV injection: 5–20 mcg/kg/dose q10–15 min IV infusion : 0.1–0.5 mcg/kg/min Titrate to effect

greater than 10 micrograms per kilogram per minute, beta receptors are stimulated, and there is an increase in heart rate, myocardial contractility, and blood pressure. At the highest doses (20–50 mcg/kg/min), beta activity remains, but increasing alpha stimulation (vasoconstriction) may overcome its actions.

Dopamine is useful in hypovolemic and cardiogenic shock. Adequate fluid therapy is necessary for the maximal pressor effect of dopamine. Acidosis decreases the effectiveness of dopamine.

**Epinephrine** is a naturally occurring catecholamine produced by the adrenal glands. At low doses, epinephrine stimulates beta receptors, which increases cardiac output by increasing the rate and force of myocardial contractility. It also causes bronchodilation. Larger doses act on alpha receptors to increase blood pressure.

Epinephrine is the drug of choice for management of anaphylactic shock because of its rapid onset of action and antiallergic effects. It prevents the release of histamine and other

mediators that cause symptoms of anaphylaxis, thereby reversing vasodilation and bronchoconstriction. In early management of anaphylaxis, it may be given subcutaneously to produce therapeutic effects within 5 to 10 minutes, with peak activity in approximately 20 minutes.

Epinephrine is also used to manage other kinds of shock and is usually given by continuous IV infusion. However, bolus doses may be given in emergencies, such as cardiac arrest. Epinephrine may produce excessive cardiac stimulation, ventricular dysrhythmias, and reduced renal blood flow. Epinephrine has an elimination half-life of about 2 minutes and is rapidly inactivated to metabolites, which are then excreted by the kidneys.

**Metaraminol** is used mainly for hypotension associated with spinal anesthesia. It acts indirectly by releasing norepinephrine from sympathetic nerve endings. Thus, its vasoconstrictive actions are similar to those of norepinephrine, except that metaraminol is less potent and has a longer duration of action.

**Milrinone** is discussed in Chapter 48 as a treatment for heart failure. It is also used to manage cardiogenic shock in combination with other inotropic agents or vasopressors. It increases cardiac output and decreases systemic vascular resistance without significantly increasing heart rate or myocardial oxygen consumption. The increased cardiac output improves renal blood flow, which then leads to increased urine output, decreased circulating blood volume, and decreased cardiac workload.

**Norepinephrine** (Levophed) is a pharmaceutical preparation of the naturally occurring catecholamine norepinephrine. It stimulates alpha-adrenergic receptors and thus increases blood pressure primarily by vasoconstriction. It also stimulates beta<sub>1</sub> receptors and therefore increases heart rate, force of myocardial contraction, and coronary artery blood flow. It is useful in cardiogenic and septic shock, but reduced renal blood flow limits its prolonged use. As with all drugs used to manage shock, blood pressure should be monitored frequently during infusion.

**Phenylephrine** (Neo-Synephrine) is an adrenergic drug that stimulates alpha-adrenergic receptors. As a result, it constricts arterioles and raises systolic and diastolic blood pressures. Phenylephrine resembles epinephrine but has fewer cardiac effects and a longer duration of action. Reduction of renal and mesenteric blood flow limits prolonged use.

### Applying Your Knowledge 51-2

The IV infusion of dopamine infiltrates and the physician orders phentolamine to be administered. What is the purpose of this drug?

## Nursing Process

### Assessment

- Assess the patient's condition in relation to hypotension and shock.
- Check blood pressure; heart rate; urine output; skin temperature and color of extremities; level of consciousness; orientation to person, place, and time; and adequacy of respiration. Abnormal values are not specific indicators of hypotension and shock, but they may indicate a need for further evaluation. In general, report blood pressure less than 90 mm Hg systolic, mean blood pressure greater than 65 mmHg, heart rate greater than 100 beats/minute, and urine output less than 30 mL/hour.
- Assess electrocardiogram and cardiac status for alterations in rhythm or rate.
- Monitor and optimize hemodynamic status noting and acting on indications of impaired cardiac function. Trend mixed venous oxygen saturation (SVO<sub>2</sub>), stroke index

(SI), cardiac index (CI), pulmonary artery occlusive pressure (PAOP), and central venous pressure (CVP) values for effectiveness of treatments and indications for progress of patient toward goals.

- Monitor available laboratory reports for abnormal values (e.g., decreased oxygen saturation levels indicate decreased oxygenation of tissues; abnormal arterial blood gases may indicate metabolic acidosis; an increased hematocrit may indicate hypovolemia; an increased eosinophil count may indicate anaphylaxis; the presence of bacteria in blood cultures may indicate sepsis; increased serum creatinine and blood urea nitrogen may indicate impending renal failure).

### Nursing Diagnoses

- Decreased Cardiac Output related to altered stroke volume
- Ineffective Tissue Perfusion: Decreased related to compromised cardiac output
- Deficient Fluid Volume related to fluid loss or vasodilation
- Anxiety related to potentially life-threatening illness
- Risk for Injury: Myocardial infarction, stroke, or renal damage related to decreased blood flow to vital organs

### Planning/Goals

- Improve tissue perfusion and relief of symptoms
- Improve hemodynamic status signs
- Guard against recurrence of hypotension and shock if possible
- Assess for therapeutic and adverse effects of adrenergic drugs
- Avoid preventable adverse effects of adrenergic drugs

### Interventions

- Use measures to prevent or minimize hypotension and shock.
- General measures include those to maintain the airway, maintain fluid balance, control hemorrhage, manage infections, prevent hypoxia, and control other causative factors.
- Recognize impending shock so management can be initiated early. Do not wait until symptoms are severe. The earlier the management, the greater the likelihood of reversing shock and preventing end-stage organ damage.
- Recognize and manage the underlying cause of shock in a particular patient (e.g., replacing fluids; preventing further loss of blood or other body fluids).
- Monitor patients during shock and vasopressor drug therapy.
- Titrate adrenergic drug infusions to maintain blood pressure and tissue perfusion without causing hypertension.
- Check hemodynamic indices, including SVO<sub>2</sub>, SI, CI, PAOP, and CVP, every hour and blood pressure and pulse

constantly or at least every 5 to 15 minutes during acute shock and titration of vasopressor drug therapy. Intra-arterial monitoring is more reliable than cuff blood-pressure measurements in shock conditions.

- Monitor mental status, distal pulses, urine output, and skin temperature and color closely to assess tissue perfusion.
- Administer all vasoactive medications via a central access line. Assess venipuncture sites frequently for signs of infiltration or extravasation. If peripheral sites are present, have phentolamine (Regitine), an alpha-adrenergic blocking agent that reverses vasoconstriction, readily available in any setting where IV adrenergic drugs are used. If infiltration occurs, instill phentolamine through the IV catheter prior to removal. If catheter has been removed, phentolamine may be administered subcutaneously, around the area of extravasation.
- Keep family members informed about patient status and management measures, including drug therapy, monitoring equipment, and the need for close observation of vital signs, IV infusion site, and urine output.
- Provide patient teaching regarding drug therapy.

### Evaluation

- Observe for improved hemodynamic status, vital signs, color and temperature of skin, urine output, and mental responsiveness.

## Principles of Therapy

### Goal of Therapy

The goal of adrenergic drug therapy in hypotension and shock is to restore and maintain adequate tissue perfusion, especially to vital organs.

### Drug Selection

The choice of drug depends primarily on the pathophysiology involved. For cardiogenic shock and decreased cardiac output, dobutamine is given. With severe heart failure characterized by decreased cardiac output and high peripheral vascular resistance, vasodilator drugs (e.g., nitroprusside, nitroglycerin) may be given along with the cardiogenic drug. The combination increases cardiac output and decreases cardiac workload by decreasing preload and afterload. However, vasodilators should not be used alone because of the risk of severe hypotension and further compromising tissue perfusion. Milrinone may be given when other drugs fail.

For distributive shock characterized by severe vasodilation and decreased peripheral vascular resistance, a vasopressor drug, such as norepinephrine, is the first drug of choice. Drug dosage must be carefully titrated to avoid excessive vasocon-

striction and hypertension, which causes impairment rather than improvement in tissue perfusion.

### Guidelines for Management of Hypotension and Shock

The overall goal in the treatment of hypotension and shock is to maximize oxygen delivery to the tissues by maintaining vascular volume and optimal hemoglobin levels. Volume replacement is administered to optimize the  $SVO_2$  (saturation of venous oxygen, thus mixed venous oxygen consumption) yet avoid hypothermia. Depending on the rationale for the volume loss, fluid is administered to reach specific end-points. Crystalloid fluids may consist of normal saline or lactated Ringer's. Colloids consist of albumin, plasma protein fraction, dextran, or hetastarch. Blood and blood products are also colloids but usually have specific indications for administration of these products.

The overall type of shock determines the type of volume replacement. In hypovolemic shock, blood products are administered if hemorrhage is present. If the hypovolemia is pure volume loss, a combination of crystalloids and colloids may be administered. In addition, neurogenic shock is initially treated with crystalloids and colloids. Burn victims are usually treated with crystalloids; sepsis and anaphylaxis patients are usually treated with crystalloids, at least initially. Following the initial fluid resuscitation, medications are administered to produce the desired effect.

Vasopressor drugs are less effective in the presence of inadequate blood volume, electrolyte abnormalities, and acidosis. These conditions also must be treated if present. In addition, normalizing the blood pH and body temperature facilitates the release of oxygen and unloads it from hemoglobin to the cells with a shift of the oxyhemoglobin dissociation curve to the right.

Minimal effective doses of adrenergic drugs are recommended because of the extreme vasoconstrictive effects that can produce lactic acidosis at the cell level and create metabolic acidosis. Because catecholamine drugs have short half-lives, varying the flow rate of IV infusions can easily control dosage. Dosage and flow rates usually are titrated to maintain  $SVO_2$  values. Such titration depends on frequent and accurate measurement of evidence-based parameters.

Cardiogenic shock may be complicated by pulmonary congestion, for which diuretic drugs are indicated and IV fluids are contraindicated (except to maintain a patent IV line). Use of the intra-aortic balloon pump (IABP) may be indicated if the patient is unable to respond with the use of medications. Other support may be ordered (e.g., left ventricular assist device).

Anaphylactic shock is often managed by nonadrenergic drugs as well as epinephrine. For example, the histamine-induced cardiovascular symptoms (e.g., vasodilation and increased capillary permeability) are thought to be mediated through both types of histamine receptors.

Septic shock due to bacterial infection requires appropriate antibiotic therapy in addition to other management

measures (see Section 5). If an abscess is the source of infection, it must be surgically drained.

## Use in Special Populations

### Use in Children

Little information is available about adrenergic drugs for the management of hypotension and shock in children. Children who lose up to one fourth of their circulating blood volume may produce minimal changes in arterial blood pressure and a relatively low heart rate. In general, management is the same as for adults, with drug dosages adjusted for weight.

### Use in Older Adults

Older adults often have disorders such as atherosclerosis, peripheral vascular disease, and diabetes mellitus and may not demonstrate common symptoms of volume depletion (e.g., thirst, skin turgor changes). Also, when adrenergic drugs are given, the vasoconstricting effects may decrease blood flow and increase risks of tissue ischemia and thrombosis. Careful monitoring of vital signs, skin color and temperature, urine output, and mental status is essential. In addition, in older adults the contractility of the myocardial protein fibers is altered; thus this age-related phenomenon is considered.

### Use in Patients With Renal Impairment

Although adrenergic drugs may be life saving, they can reduce renal blood flow and cause renal failure because of their vasoconstrictive effects. Renal impairment may occur in patients with previously normal renal function and may be worsened in patients whose renal function is already impaired.

Most adrenergic drugs are metabolized in the liver, and the metabolites are excreted in the urine. However, little accumulation of the drugs or metabolites is likely because the drugs have short half-lives.

### Use in Patients With Hepatic Impairment

Catecholamine drugs are metabolized by monoamine oxidase (MAO) and catechol-O-methyl transferase (COMT). MAO is widely distributed in most body tissues, whereas COMT is located mainly in the liver. Thus, the drugs are eliminated mainly by liver metabolism and must be used cautiously in patients with impaired liver function. Patients should be monitored closely, and drug dosage should be adjusted as symptoms warrant. However, the half-life of most adrenergic drugs is very brief, and this decreases the chances of drug accumulation in hepatically impaired patients.

### Use in Patients With Critical Illness

The adrenergic catecholamines (e.g., dobutamine, dopamine, epinephrine, norepinephrine) are widely used in patients with a low cardiac output that persists despite adequate fluid replacement and correction of electrolyte imbalance.

By improving circulation, the drugs also help to prevent tissue injury from ischemia (e.g., renal failure).

Although the drugs may be used initially in almost any setting, most patients with hypotension and shock are managed in critical care units. Dobutamine is usually the cardiostimulant agent of choice in critically ill patients. Dopamine varies in clearance rate in adult and pediatric patients. However, this variance may result from the use of non-steady-state plasma concentrations in calculating the clearance rate. When a dopamine IV infusion is started, it may take 1 to 2 hours to achieve a steady-state plasma level. Relatively large doses of dopamine are given for cardiostimulant and vasoconstrictive effects.

Epinephrine and norepinephrine are also widely used in critically ill patients. Recommended infusion rates in critically ill patients vary from 1 to 10 micrograms per minute for epinephrine and from 0.05 to 0.30 micrograms per minute for norepinephrine. All patients receiving drugs for management of hypotension and shock should be closely monitored regarding hemodynamic status, vital signs, drug dosage, relevant laboratory test results, as well as other indicators of clinical status.

Continuous invasive hemodynamic monitoring using a mixed venous oxygen pulmonary artery catheter and an arterial catheter is indicated to titrate drug dosage and monitor response to drug therapy. Close monitoring of the critically ill is essential as these patients often have multiple organ impairments and are clinically unstable.

## Applying Your Knowledge 51-3

### How Can You Avoid This Medication Error?

Mr. Alrashed's BP remains below 90 mm Hg and his physician orders norepinephrine to be administered. The nurse retrieves the solution from the medication storage machine and hangs the brownish colored solution.

## Evidence-Based Practice

### 51-1 Polyclonal Intravenous Immunoglobulin Therapy with Sepsis

A meta-analysis was done to evaluate the effect of polyclonal intravenous immunoglobulin therapy on death in critically ill adult patients with sepsis. The main rationale for this treatment for individuals with primary or secondary antibody deficiency (as with sepsis) is antibody substitution. Polyclonal intravenous immunoglobulin therapy was associated with an overall survival benefit (risk ratio, 0.74 [95% CI, 0.62 to 0.89]) compared with placebo or no intervention. A survival benefit was observed for patients with sepsis who received polyclonal intravenous immunoglobulin therapy compared with those who received placebo or no intervention. Substituting polyclonal antibodies could assist the immunocompromised individuals resist the attacks of pathogenic microbes.

## Nursing Actions Drugs Used in Hypotension and Shock

### NURSING ACTIONS

#### 1. Administer accurately

- a. Use a large vein for the venipuncture site.
- b. Dilute drugs for continuous infusion in 250 or 500 mL of intravenous (IV) fluid. For use of other IV fluids, consult drug manufacturers' literature. Dilute drugs for bolus injections to at least 10 mL with sodium chloride or water for injection.
- c. Use a dedicated IV line setup.
- d. Use an infusion pump.
- e. Discard any solution with a brownish color or precipitate.
- f. Start the adrenergic drug slowly, and increase as necessary to obtain desired outcome in hemodynamic function.
- g. Stop the drug gradually.
- h. Manage the patient, not the monitor.

#### 2. Observe for therapeutic effects

- a.  $SVO_2$  normal is 60–75. SI is 25–45 mL/beat/ $m^2$ . CI is 2.5–4.0 L/min/ $m^2$ . PAOP is 8–12 mm Hg, CVP is 2–6 mm Hg.
- b. Mean blood pressure of >65 mm Hg
- c. Heart rate of 60–100 beats/minute, improved quality of peripheral pulses
- d. Improved urine output
- e. Improved skin color and temperature
- f. Pulmonary capillary wedge pressure between 15 and 20 mm Hg in cardiogenic shock

#### 3. Observe for adverse effects

- a. Bradycardia
- b. Tachycardia
- c. Dysrhythmias
- d. Hypertension
- e. Hypotension
- f. Angina pectoris—chest pain, dyspnea, palpitations
- g. Tissue necrosis if extravasation occurs

### RATIONALE/EXPLANATION

- To decrease risk of extravasation  
To avoid adverse effects, which are more likely to occur with concentrated drug solutions
- This allows the adrenergic drug solution to be regulated or discontinued without disruption of other IV lines.  
To administer the drug at a consistent rate and prevent alterations in hemodynamic function  
Most of the solutions are stable for 24–48 hours. Epinephrine and isoproterenol decompose on exposure to light, producing a brownish discoloration.  
Flow rate (dosage) is titrated according to patient response.
- Abrupt discontinuance of pressor drugs may cause rebound hypotension.  
Monitor values and trend parameters before adjusting medication dosage.
- These levels are adequate for tissue perfusion.
- However, higher levels may be necessary to maintain cerebral blood flow in older adults.  
These indicate improved tissue perfusion and cardiovascular function.  
Increased urine output indicates improved blood flow to the kidneys.  
These indicate improved peripheral tissue perfusion.  
Higher levels are required to maintain cardiac output in cardiogenic shock.
- Reflex bradycardia may occur with norepinephrine, metaraminol, and phenylephrine.  
This is more likely to occur with dopamine, but may occur with epinephrine.  
Serious dysrhythmias may occur with any of the agents used in hypotension and shock. Causes may include high doses that result in excessive adrenergic stimulation of the heart, low doses that result in inadequate perfusion of the myocardium, or the production of lactic acid by ischemic tissue.  
This is most likely to occur with high doses of norepinephrine, metaraminol, and phenylephrine.  
This is most likely to occur with lower doses of dopamine due to vasodilation.  
All pressor agents may increase myocardial oxygen consumption and induce myocardial ischemia.  
This may occur with solutions containing dopamine, norepinephrine, metaraminol, and phenylephrine due to local vasoconstriction and impaired blood supply. Tissue necrosis may be prevented by injecting 5–10 mg of phentolamine (Regitine) through the catheter preferably or subcutaneously around the area of extravasation. Phentolamine is most effective if injected within 12 hours after extravasation.

## Nursing Actions Drugs Used in Hypotension and Shock (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 4. Observe for drug interactions

##### a. Drugs that increase effects of pressor agents:

(1) General anesthetics (e.g., halothane)

(2) Anticholinergic drugs (e.g., atropine)

(3) Monoamine oxidase (MAO) inhibitors (e.g., tranylcypromine)

(4) Oxytocics (e.g., oxytocin)

##### b. Drugs that decrease effects of pressor agents:

(1) Beta-blocking agents (e.g., propranolol)

Halothane and other halogenated anesthetics increase cardiac sensitivity to sympathomimetic drugs and increase the risks of cardiac dysrhythmias.

Atropine and other drugs with anticholinergic activity may potentiate the tachycardia that often occurs with pressor agents.

All effects of exogenously administered adrenergic drugs are magnified in patients taking MAO inhibitors because MAO is the circulating enzyme responsible for metabolism of adrenergic agents.

The risk of severe hypertension is increased.

Beta-blocking agents antagonize the cardiac stimulation of some pressor agents (e.g., dobutamine). Decreased heart rate, myocardial contractility, and blood pressure may result.

## Key Concepts

- Shock is a clinical condition of insufficient perfusion of cells and vital organs, causing tissue hypoxia.
- The overall goal in the treatment of hypotension and shock is to maximize oxygen delivery to the tissues by maintaining vascular volume and optimal hemoglobin levels.
- For all drugs used to manage shock, blood pressure should be monitored frequently during infusion.
- In hypotension and shock, drugs with alpha-adrenergic activity (e.g., norepinephrine, phenylephrine) are used to increase peripheral vascular resistance and raise blood pressure.
- The adrenergic catecholamines (e.g., dobutamine, dopamine, epinephrine, norepinephrine) are widely used in patients with a low cardiac output that persists despite adequate fluid replacement and correction of electrolyte imbalance. Dobutamine is usually the cardiogenic agent of choice in critically ill patients.

## Review and Application Exercises

### Short Answer Exercises

1. How do adrenergic drugs improve circulation in hypotension and shock?
2. Which adrenergic drug should be readily available for management of anaphylactic shock?
3. What are major adverse effects of adrenergic drugs?
4. How would you assess the patient for therapeutic or adverse effects of an adrenergic drug being given by continuous IV infusion?
5. Why is it important to prevent extravasation of adrenergic drug infusions into tissues surrounding the vein?
6. In hypovolemic shock, should fluid volume be replaced before or after an adrenergic drug is given? Why?

### NCLEX-Style Questions

7. During administration of dopamine, a patient complains of pain at the infusion site. The nurse should recognize that the
  - a. Patient is hypersensitive to the drug, and infusion should be stopped.
  - b. Infusion rate is too fast and should be slowed.
  - c. Medication should be stopped, phentolamine should be infused, and the infusion site should be changed.
  - d. Medication is probably not effective and therefore patient response should be assessed once all the medication is infused.

8. A patient in cardiogenic shock is started on dobutamine (Dobutrex). The health care provider's order reads dobutamine 10 mcg/kg/min IV. What effect should the nurse expect after beginning drug therapy?
  - a. enhanced cardiac contraction and contractility via stimulation of  $\alpha_1$ ,  $\beta_1$ , and  $\beta_2$  receptors
  - b. dilated blood vessels via stimulation of dopamine receptors
  - c. increased cardiac output through stimulation of  $\beta_1$  receptors
  - d. constricted blood vessels and increased cardiac output through stimulation of  $\alpha_1$  receptors
  
9. A patient receiving norepinephrine (Levophed) for shock has an arterial line in place. The patient's blood pressure has been near 90/42 mm Hg for most of the morning. The blood pressure reading on the continuous monitor suddenly shows a blood pressure of 130/80. The nurse should
  - a. Decrease the rate of the norepinephrine.
  - b. Call the health care provider.
  - c. Stop the norepinephrine infusion.
  - d. Confirm the blood pressure with a manual reading.
  
10. A patient who is in anaphylactic shock presents to the emergency department. The nurse should anticipate that the drug of choice for this type of shock would be
  - a. dobutamine
  - b. dopamine
  - c. isoproterenol
  - d. epinephrine

# Antihypertensive Drugs

## KEY TERMS

- Angiotensin-converting enzyme inhibitor
- Angiotensin II receptor blocker
- Antiadrenergics
- Autoregulation
- Bradykinin
- Diuretics
- First-dose phenomenon
- Histamine
- Prostaglandins
- Serotonin
- Vasodilators

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe factors that control blood pressure.
2. Define/describe hypertension.
3. Identify patients at risk for development of hypertension and its sequelae.
4. Discuss nonpharmacologic measures to control hypertension.
5. Review the effects of alpha-adrenergic blockers, beta-adrenergic blockers, calcium channel blockers, and diuretics in hypertension.
6. Discuss angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers in terms of mechanisms of action, indications for use, adverse effects, and nursing process implications.
7. Describe the rationale for using combination drugs in the management of hypertension.
8. Discuss interventions to increase therapeutic effects and minimize adverse effects of antihypertensive drugs.
9. Discuss the use of antihypertensive drugs in special populations.

## Applying Your Knowledge

Harold Olms is a 55-year-old, African-American man. He is married, has four children, and works as an automobile salesman. Mr. Olms has experienced hypertension for the past 15 years. His current drug regimen to keep his blood pressure at less than 140/90 mm Hg consists of

Valsartan 80 mg PO daily  
 Amlodipine 10 mg PO daily  
 Hydrochlorothiazide 12.5 mg PO daily

## Introduction

Antihypertensive drugs are used to treat hypertension, a common, chronic disorder affecting an estimated 50 to 60 million adults and an unknown number of children and adolescents in the United States. Hypertension increases risks of myocardial infarction, heart failure, cerebral infarction and hemorrhage, and renal disease. To understand hypertension and antihypertensive drug therapy, it is necessary first to understand the physiologic mechanisms that normally control blood pressure, characteristics of hypertension, and characteristics of antihypertensive drugs.

## Regulation of Blood Pressure

Arterial blood pressure reflects the force exerted on arterial walls by blood flow. Blood pressure normally remains constant because of homeostatic mechanisms that adjust blood flow to meet tissue needs. The two major determinants of arterial blood pressure are cardiac output (systolic pressure) and peripheral vascular resistance (diastolic pressure).

Cardiac output equals the product of the heart rate and stroke volume ( $CO = HR \times SV$ ). Stroke volume is the amount of blood ejected with each heartbeat (approximately 60–90 mL). Thus, cardiac output depends on the force of myocardial contraction, blood volume, and other factors. Peripheral vascular resistance is determined by local blood flow and the degree of constriction or dilation in arterioles and arteries (vascular tone).

### Autoregulation of Blood Flow

*Autoregulation* is the ability of body tissues to regulate their own blood flow. Local blood flow is regulated primarily by nutritional needs of the tissue, such as lack of oxygen or accumulation of products of cellular metabolism (e.g., carbon dioxide, lactic acid). Local tissues produce vasodilating and vasoconstricting substances to regulate local blood flow. Important tissue factors include histamine, bradykinin, serotonin, and prostaglandins.

*Histamine* is found mainly in mast cells surrounding blood vessels and is released when these tissues are injured. In some tissues, such as skeletal muscle, mast cell activity is mediated by the sympathetic nervous system (SNS), and histamine is released when SNS stimulation is blocked or withdrawn. In this case, vasodilation results from increased histamine release and the withdrawal of SNS vasoconstrictor activity. *Bradykinin*

is released from a protein in body fluids. Kinins dilate arterioles, increase capillary permeability, and constrict venules. *Serotonin* is released from aggregating platelets during the blood clotting process. It causes vasoconstriction and plays a major role in control of bleeding. *Prostaglandins* are formed in response to tissue injury and include vasodilators (e.g., prostacyclin) and vasoconstrictors (e.g., thromboxane  $A_2$ ).

An important component of regulating local blood flow is the production of several vasoactive substances by the endothelial cells that line blood vessels. Vasoconstricting substances, which increase vascular tone and blood pressure, include angiotensin II, endothelin-1, and thromboxane  $A_2$ . Vasodilating substances, which decrease vascular tone and blood pressure, include nitric oxide and prostacyclin. Excessive vasoconstrictors or deficient vasodilators may contribute to the development of atherosclerosis, hypertension, and other diseases. Injury to the endothelial lining of blood vessels (e.g., by the shear force of blood flow with hypertension, by rupture of atherosclerotic plaque) leads to vasoconstriction, vasospasm, thrombus formation, and thickening of the blood vessel wall. All of these factors narrow the blood vessel lumen and increase peripheral vascular resistance.

Overall, regulation of blood pressure involves a complex, interacting, overlapping network of hormonal, neural, and vascular mechanisms, and any condition that affects heart rate, stroke volume, or peripheral vascular resistance affects arterial blood pressure. Many of these mechanisms are compensatory effects that attempt to restore balance when hypotension or hypertension occurs. The mechanisms are further described in Box 52-1 and are referred to in the following discussion of antihypertensive drugs and their actions in lowering high blood pressure.

### Box 52-1

## Mechanisms That Regulate Blood Pressure

### Neural

Neural regulation of blood pressure mainly involves the sympathetic nervous system (SNS). In the heart, SNS neurons control heart rate and force of contraction. In blood vessels, SNS neurons control muscle tone by maintaining a state of partial contraction, with additional constriction or dilation accomplished by altering this basal state. When hypotension and inadequate tissue perfusion occur, the SNS is activated and produces secretion of epinephrine and norepinephrine by the adrenal medulla; constriction of blood vessels in the skin, gastrointestinal tract, and kidneys; and stimulation of beta-adrenergic receptors in the heart, which increases heart rate and force of myocardial contraction. All of these mechanisms act to increase blood pressure and tissue perfusion, especially of the brain and heart.

The SNS is activated by the vasomotor center in the brain, which constantly receives messages from baroreceptors and chemoreceptors located in the circulatory system. Adequate function of these receptors is essential for rapid and short-term

regulation of blood pressure. The vasomotor center interprets the messages from these receptors and modifies cardiovascular functions to maintain adequate blood flow.

More specifically, baroreceptors detect changes in pressure or stretch. For example, when a person moves from a lying to a standing position, blood pressure falls and decreases stretch in the aorta and arteries. This elicits increased heart rate and vasoconstriction to restore adequate circulation. The increased heart rate occurs rapidly and blood pressure is adjusted within 1 to 2 minutes. This quick response prevents orthostatic hypotension with dizziness and possible syncope. (Antihypertensive medications may blunt this response and cause orthostatic hypotension.)

Chemoreceptors, which are located in the aorta and carotid arteries, are in close contact with arterial blood and respond to changes in the oxygen, carbon dioxide, and hydrogen ion content of blood. Although their main function is to regulate ventilation, they also communicate with the vasomotor center and can induce vasoconstriction. Chemoreceptors are

## Box 52-1

## Mechanisms That Regulate Blood Pressure (continued)

stimulated when blood pressure drops to a certain point because oxygen is decreased and carbon dioxide and hydrogen ions are increased in arterial blood.

The central nervous system (CNS) also regulates vasomotor tone and blood pressure. Inadequate blood flow to the brain results in ischemia of the vasomotor center. When this occurs, neurons in the vasomotor center stimulate widespread vasoconstriction in an attempt to raise blood pressure and restore blood flow. This reaction, the CNS ischemic response, is an emergency measure to preserve blood flow to vital brain centers. If blood flow is not restored within 3 to 10 minutes, the neurons of the vasomotor center are unable to function, the impulses that maintain vascular muscle tone stop, and blood pressure drops to a fatal level.

### Hormonal

The renin–angiotensin–aldosterone (RAA) system and vasopressin are important hormonal mechanisms in blood pressure regulation.

The RAA system is activated in response to hypotension and acts as a compensatory mechanism to restore adequate blood flow to body tissues. Renin is an enzyme that is synthesized, stored, and released from the kidneys in response to decreased blood pressure, SNS stimulation, or decreased sodium concentration in extracellular fluid. When released into the bloodstream, where its action lasts 30 to 60 minutes, renin converts angiotensinogen (a plasma protein) to angiotensin I. Angiotensin-converting enzyme (ACE) in the endothelium of pulmonary blood vessels then acts on angiotensin I to produce angiotensin II. Angiotensin II strongly constricts arterioles (and weakly constricts veins), increases peripheral resistance, and increases blood pressure by direct vasoconstriction, stimulation of the SNS, and stimulation of catecholamine release from the adrenal medulla. It also stimulates secretion of aldosterone from the adrenal cortex, which then causes the kidneys to retain sodium and water. Retention of sodium and water increases blood volume, cardiac output, and blood pressure.

Vasopressin, also called antidiuretic hormone or ADH, is a hormone secreted by the posterior pituitary gland that regulates reabsorption of water by the kidneys. It is released in response to decreased blood volume and decreased blood pressure. It causes retention of body fluids and vasoconstriction, both of which act to raise blood pressure.

### Vascular

The endothelial cells that line blood vessels synthesize and secrete several substances that play important roles in regulating cardiovascular functions, including blood pressure. These substances normally maintain a balance between vasoconstriction and vasodilation. When the endothelium is damaged (e.g., by trauma, hypertension, hypercholesterolemia, or atherosclerosis), the resulting imbalance promotes production of vasoconstricting substances and also causes blood vessels to lose their ability to relax in response to dilator substances. In

addition, changes in structure of endothelial and vascular smooth muscle cells (vascular remodeling) further impair vascular functions.

*Vasoconstrictors* increase vascular tone (i.e., constrict or narrow blood vessels so that higher blood pressure is required to pump blood to body tissues). Vasoconstricting substances produced by the endothelium include angiotensin II, endothelin-1, platelet-derived growth factor (PDGF), and thromboxane  $A_2$ . Endothelin-1 is the strongest endogenous vasoconstrictor known. Angiotensin II and thromboxane  $A_2$  can also be produced by other types of cells, but endothelial cells can produce both. Thromboxane  $A_2$ , a product of arachidonic acid metabolism, also promotes platelet aggregation and thrombosis.

*Vasodilators* decrease vascular tone and blood pressure. Major vasodilating substances produced by the endothelium include nitric oxide and prostacyclin (prostaglandin I<sub>2</sub>)

*Nitric oxide (NO)* is a gas that can diffuse through cell membranes, trigger biochemical reactions, and then dissipate rapidly. It is formed by the action of the enzyme NO synthase on the amino acid L-arginine and continually released by normal endothelium. Its production is tightly regulated and depends on the amount of ionized calcium in the fluid portion of endothelial cells. Several substances (e.g., acetylcholine, bradykinin, catecholamines, substance P, and products of aggregating platelets such as adenosine diphosphate and serotonin) act on receptors in endothelial cell membranes to increase the cytosolic concentration of ionized calcium, activate NO synthase, and increase NO production. In addition, increased blood flow or blood pressure increases shear stress at the endothelial surface and stimulates production of NO.

Once produced, endothelium-derived NO produces vasodilation primarily by activating guanylyl cyclase in vascular smooth muscle cells and increasing intracellular cyclic 3,5'-guanosine monophosphate as a second messenger. NO also inhibits platelet aggregation and production of platelet-derived vasoconstricting substances. Because NO is released into the vessel wall (to relax smooth muscle) and into the vessel lumen (to inactivate platelets), it is thought to have protective effects against vasoconstriction and thrombosis.

NO is also produced in leukocytes, fibroblasts, and vascular smooth muscle cells and may have pathologic effects when large amounts are produced. In these tissues, NO seems to have other functions, such as modifying nerve activity in the nervous system.

*Prostacyclin* is synthesized and released from endothelium in response to stimulation by several factors (e.g., bradykinin, interleukin-1, serotonin, thrombin, PDGF). It produces vasodilation by activating adenylyl cyclase and increasing levels of cyclic adenosine monophosphate in smooth muscle cells. In addition, like NO, prostacyclin also inhibits platelet aggregation and production of platelet-derived vasoconstricting substances. The vasodilating effects of prostacyclin may occur independently or in conjunction with NO.

Overall, excessive vasoconstrictors or deficient vasodilators may contribute to the development of atherosclerosis, hypertension, and other diseases. Injury to the endothelial lining of

blood vessels (e.g., by the shear force of blood flow with hypertension or by rupture of atherosclerotic plaque) decreases vasodilators and leads to vasoconstriction, vasospasm, thrombus formation, and thickening of the blood vessel wall. All of these factors require the blood to flow through a narrowed lumen and increase blood pressure.

### Vascular Remodeling

Vascular remodeling is similar to the left ventricular remodeling that occurs in heart failure (see Chap. 48). It results from endothelial dysfunction and produces a thickening of the blood vessel wall and a narrowing of the blood vessel lumen. Thickening of the wall makes blood vessels less flexible and less able to respond to vasodilating substances. There are also changes in endothelial cell structure (i.e., the connections between endothelial cells become looser) that lead to increased permeability. The mechanisms of these vascular changes, which promote and aggravate hypertension, are described below.

As discussed in previous chapters, normal endothelium helps maintain a balance between vasoconstriction and vasodilation, procoagulation and anticoagulation, proinflammation and antiinflammation, and progrowth and antigrowth. In the inflammatory process, normal endothelium acts as a

physical barrier against the movement of leukocytes into the subendothelial space. Endothelial products such as nitric oxide may also inhibit leukocyte activity. However, inflammatory cytokines such as tumor necrosis factor- $\alpha$  and interleukin-1 activate endothelial cells to produce adhesion molecules (which allow leukocytes to adhere to the endothelium), interleukin-8 (which attracts leukocytes to the endothelium and allows them to accumulate in subendothelial cells), and foam cells (lipid-filled monocyte/macrophages that form fatty streaks, the beginning lesions of atherosclerotic plaque). Although activation of endothelial cells may be a helpful component of the normal immune response, the resulting inflammation may contribute to disease development.

In terms of cell growth, normal endothelium limits the growth of vascular smooth muscle that underlies the endothelium and forms the vessel wall. Growth-inhibiting products of the endothelium include nitric oxide, which also inhibits platelet activation and production of growth-promoting substances. When the endothelium is damaged, endothelial cells become activated and also produce growth-promoting products. Other endothelial products (e.g., angiotensin II and endothelin-1) may also stimulate growth of vascular smooth muscle cells. Thus, damage or loss of endothelial cells stimulates growth of smooth muscle cells in the intimal layer of the blood vessel wall.

### Response to Hypotension

When hypotension (and decreased tissue perfusion) occurs, the SNS is stimulated, the hormones epinephrine and norepinephrine are secreted by the adrenal medulla, angiotensin II and aldosterone are formed, and the kidneys retain fluid. These compensatory mechanisms raise the blood pressure. Specific effects include the following:

- Constriction of arterioles, which increases peripheral vascular resistance
- Constriction of veins and increased venous tone
- Stimulation of cardiac beta-adrenergic receptors, which increases heart rate and force of myocardial contraction
- Activation of the renin-angiotensin-aldosterone mechanism

### Response to Hypertension

When arterial blood pressure is elevated, the following sequence of events occurs:

- Kidneys excrete more fluid (increase urine output).
- Fluid loss reduces both extracellular fluid volume and blood volume.
- Decreased blood volume reduces venous blood flow to the heart and therefore decreases cardiac output.
- Decreased cardiac output reduces arterial blood pressure.
- The vascular endothelium produces vasodilating substances (e.g., nitric oxide, prostacyclin), which reduce blood pressure.

### Hypertension

Hypertension is persistently high blood pressure that results from abnormalities in regulatory mechanisms. It is usually defined as a systolic pressure above 140 mm Hg or a diastolic pressure above 90 mm Hg on multiple blood pressure measurements.

Primary or essential hypertension (that for which no cause can be found) makes up 90% to 95% of known cases. Secondary hypertension may result from renal, endocrine, or central nervous system disorders and from drugs that stimulate the SNS or cause retention of sodium and water. Primary hypertension can be controlled with appropriate therapy; secondary hypertension can sometimes be cured by surgical therapy.

*The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)*, guidelines published in 2003, classified blood pressures in adults (in mm Hg) as follows:

- Normal = systolic < 120 and diastolic < 80
- Prehypertension = systolic 120–139 or diastolic 80–89
- Stage 1 hypertension = systolic 140–159 or diastolic 90–99
- Stage 2 hypertension = systolic >160 or diastolic 100 or more

This classification is markedly different from the four stages previously defined. The addition of a prehypertension stage targets individuals who are twice as likely to progress to hypertension as those with lower pressure values. Stages 3 and 4 have been eliminated. These newer guidelines also

recommend a goal blood pressure for those with diabetes or renal disease of less than 130/80 mm Hg. A systolic pressure of 140 or above, with a diastolic pressure below 90, is called isolated systolic hypertension and is more common in the elderly. New JNC8 guidelines are expected to be released in 2009.

Hypertension profoundly alters cardiovascular function by increasing the workload of the heart and causing thickening and sclerosis of arterial walls. As a result of increased cardiac workload, the myocardium hypertrophies as a compensatory mechanism and heart failure eventually occurs. As a result of endothelial dysfunction and arterial changes (vascular remodeling), the arterial lumen is narrowed, blood supply to tissues is decreased, and risks of thrombosis are increased. In addition, necrotic areas may develop in arteries, and these may rupture with sustained high blood pressure. The areas of most serious damage are the heart, brain, kidneys, and eyes. These are often called target organs.

Initially and perhaps for years, primary hypertension may produce no symptoms. If symptoms occur, they are usually vague and nonspecific. Hypertension may go undetected, or it may be incidentally discovered when blood pressure measurements are taken as part of a routine physical examination, screening test, or assessment of other disorders. Eventually, symptoms reflect target organ damage. Hypertension is often discovered after a person experiences angina pectoris, myocardial infarction, heart failure, stroke, or renal disease.

Hypertensive emergencies are episodes of severely elevated blood pressure that may be an extension of malignant (rapidly progressive) hypertension or caused by cerebral hemorrhage, dissecting aortic aneurysm, renal disease, pheochromocytoma, or eclampsia. These require immediate management, usually with intravenous (IV) antihypertensive drugs, to lower blood pressure. Symptoms include severe headache, nausea, vomiting, visual disturbances, neurologic disturbances, disorientation, and decreased level of consciousness (drowsiness, stupor, coma). Hypertensive emergencies require immediate blood pressure reduction with parenteral antihypertensive drugs to limit damage to target organs. Hypertensive urgencies are episodes of marked elevation in blood pressure without target organ damage and are often managed with oral drugs. The goal of management is to lower blood pressure within 24 hours. In most instances, it is better to lower blood pressure gradually and to avoid wide fluctuations in blood pressure.

## Antihypertensives: Classifications and Individual Drugs

Drugs used in the management of primary hypertension belong to several different groups, including *angiotensin-converting enzyme (ACE) inhibitors*; *angiotensin II receptor blockers (ARBs)*, also called *angiotensin II receptor antagonists (AIIRAs)*; *antiadrenergics*; *calcium channel blockers*; *diuretics*; and *direct vasodilators*. In general, these drugs act to decrease blood

pressure by decreasing cardiac output or peripheral vascular resistance.

Antihypertensive agents are shown in Table 52-1; antihypertensive–diuretic combination products are listed in Table 52-2. Adult dosages are based on product labeling and JNC 7 recommendations. Pediatric dosages are based on product labeling and recommendations from the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents (2004).

### Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (also called kininase) is mainly located in the endothelial lining of blood vessels, which is the site of production of most angiotensin II. This same enzyme also metabolizes bradykinin, an endogenous substance with strong vasodilating properties.

ACE inhibitors block the enzyme that normally converts angiotensin I to the potent vasoconstrictor angiotensin II. By blocking production of angiotensin II, the drugs decrease vasoconstriction (having a vasodilating effect) and decrease aldosterone production (reducing retention of sodium and water). In addition to inhibiting formation of angiotensin II, the drugs also inhibit the breakdown of bradykinin, prolonging its vasodilating effects. These effects and possibly others help to prevent or reverse the remodeling of heart muscle and blood vessel walls that impairs cardiovascular function and exacerbates cardiovascular disease processes. Because of their effectiveness in hypertension and beneficial effects on the heart, blood vessels, and kidneys, these drugs are increasing in importance and use. Widely used to treat heart failure and hypertension, the drugs may also decrease morbidity and mortality in other cardiovascular disorders. They improve post-myocardial infarction survival when added to the standard therapy of aspirin, a beta blocker, and a thrombolytic.

ACE inhibitors may be used alone or in combination with other antihypertensive agents, such as thiazide diuretics. Although the drugs can cause or aggravate proteinuria and renal damage in nondiabetic people, they decrease proteinuria and slow the development of nephropathy in diabetic patients.

Most ACE inhibitors (captopril, enalapril, fosinopril, lisinopril, ramipril, and quinapril) also are used in the management of heart failure because they decrease peripheral vascular resistance, cardiac workload, and ventricular remodeling. **P** **Captopril** and other ACE inhibitors are recommended as first-line agents for treating hypertension in diabetic patients, particularly those with type 1 diabetes and/or diabetic nephropathy, because they reduce proteinuria and slow progression of renal impairment.

ACE inhibitors are well absorbed with oral administration, produce effects within 1 hour that last approximately 24 hours, have prolonged serum half-lives with impaired renal function, and most are metabolized to active metabolites that are excreted in urine and feces. These drugs are well tolerated, with a low incidence of serious adverse effects (e.g., neutropenia, agranulocytosis, proteinuria, glomerulonephritis, angioedema).

Table 52-1

## Drugs at a Glance: Antihypertensive Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children 1–17 Years of Age (Unless Otherwise Stated)
<b>Angiotensin-Converting Enzyme (ACE) Inhibitors</b>		
<b>Benazepril</b> (Lotensin)	PO 10 mg once daily initially, increased to 40 mg daily if necessary, in 1 or 2 doses	
<b>P Captopril</b> (Capoten)	PO 25 mg, 2 to 3 times daily initially, gradually increased to 50, 100, or 150 mg 2 to 3 times daily, if necessary; maximum dose, 450 mg/d	PO 1.5 mg/kg/d in divided doses, q8h; maximum dose, 6 mg/kg/d Neonates: PO 0.03–0.15 mg/kg/d, q8–24h; maximum dose, 2 mg/kg/d
<b>Enalapril</b> (Vasotec)	PO 5 mg once daily, increased to 10–40 mg daily, in 1 or 2 doses, if necessary	PO 0.15 mg q12–24h
<b>Fosinopril</b> (Monopril)	PO 10 mg once daily initially, increased to 40 mg daily if necessary in 1 or 2 doses	
<b>Lisinopril</b> (Prinivil, Zestril)	PO 10 mg once daily, increased to 40 mg if necessary	
<b>Moexipril</b> (Univasc)	PO initial dose 7.5 mg (3.75 mg for those who have renal impairment or are taking a diuretic). Maintenance dose, 7.5–30 mg daily, in 1 or 2 doses, adjusted according to blood-pressure control	
<b>Perindopril</b> (Aceon)	PO 4–16 mg daily, in 1 or 2 doses	
<b>Quinapril</b> (Accupril)	PO 10 mg once daily initially, increased to 20, 40, or 80 mg daily if necessary, in 1 or 2 doses. Wait at least 2 wk between dose increments.	
<b>Ramipril</b> (Altace)	PO 2.5 mg once daily, increased to 20 mg daily if necessary, in 1 or 2 doses	
<b>Trandolapril</b> (Mavik)	PO initial dose 1 mg once daily (0.5 mg for those who have hepatic or renal impairment or are taking a diuretic; 2 mg for African Americans). Maintenance dose, 2–4 mg daily, in a single dose, adjusted according to blood-pressure control	
<b>Angiotensin II Receptor Blockers</b>		
<b>Candesartan</b> (Atacand)	PO 16 mg once daily initially, increased if necessary to a maximum of 32 mg daily, in 1 or 2 doses	
<b>Irbesartan</b> (Avapro)	PO 150 mg once daily initially, increased up to 300 mg once daily, if necessary	
<b>Losartan</b> (Cozaar)	PO 50 mg once daily initially (25 mg for those who have hepatic impairment or are taking a diuretic). Maintenance dose, 35–100 mg daily, in 1 or 2 doses, adjusted according to blood-pressure control	
<b>Olmесartan</b> (Benicar)	PO 20 mg once daily initially, increased to 40 mg after 2 wk	
<b>Telmisartan</b> (Micardis)	PO 40 mg once daily initially, increased to a maximum of 80 mg daily if necessary	

(continued on page 830)

Table 52-1

## Drugs at a Glance: Antihypertensive Drugs (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children 1–17 Years of Age (Unless Otherwise Stated)
<b>Valsartan</b> (Diovan)	PO 80 mg once daily initially, when used as monotherapy in clients who are not volume depleted. Maintenance dose may be increased. However, adding a diuretic is more effective than increasing dose beyond 80 mg.	
<b>Antiadrenergic Agents</b>		
<b>Alpha<sub>1</sub>-adrenergic Blocking Agents</b>		
<b>Doxazosin</b> (Cardura)	PO 1 mg once daily initially, increased to 2 mg, then to 4, 8, and 16 mg daily if necessary	
<b>Prazosin</b> (Minipress)	PO 1 mg 2 to 3 times daily initially, increased if necessary to 20 mg in divided doses. Average maintenance dose, 6–15 mg daily	
<b>Terazosin</b> (Hytrin)	PO 1 mg at bedtime initially, may be increased gradually. Usual maintenance dose, 1–5 mg once daily	
<b>Alpha<sub>2</sub> Agonists</b>		
<b>Clonidine</b> (Catapres)	PO 0.1 mg 2 times daily initially, gradually increased up to 2.4 mg daily, if necessary. Average maintenance dose, 0.2–0.8 mg daily	PO 5–25 mcg/kg/d, in divided doses, q6h; increase at 5- to 7-day intervals, if needed
<b>Guanfacine</b> (Tenex)	PO 1 mg daily at bedtime, increased to 2 mg after 3–4 wk, then to 3 mg if necessary	
<b>Methyldopa</b>	PO 250 mg 2 or 3 times daily initially, increased gradually until blood pressure is controlled or a daily dose of 3 g is reached	PO 10 mg/kg/d in 2 to 4 divided doses initially, increased or decreased according to response. Maximum dose, 65 mg/kg/d or 3 g daily, whichever is less
<b>Beta-Adrenergic Blocking Agents</b>		
<b>Acebutolol</b> (Sectral)	PO 400 mg once daily initially, increased to 800 mg daily if necessary	
<b>Atenolol</b> (Tenormin)	PO 50 mg once daily initially, increased in 1–2 wk to 100 mg once daily, if necessary	
<b>Bisoprolol</b> (Zebeta)	PO 5 mg once daily, increased to a maximum of 20 mg daily if necessary	
<b>Metoprolol</b> (Lopressor)	PO 50 mg twice daily, gradually increased in weekly or longer intervals if necessary. Maximum dose, 450 mg daily	
<b>Nadolol</b> (Corgard)	PO 40 mg once daily initially, gradually increased if necessary. Average dose, 80–320 mg daily	
<b>Pindolol</b> (Visken)	PO 5 mg 2 or 3 times daily initially, increased by 10 mg/d at 3- to 4-wk intervals to a maximum of 60 mg daily	
<b>Propranolol</b> (Inderal)	PO 40 mg twice daily initially, gradually increased to 160–640 mg daily	PO 1 mg/kg/d initially, gradually increased to a maximum of 10 mg/kg/d
<b>Timolol</b> (Blocadren)	PO 10 mg twice daily initially, increased gradually if necessary. Average daily dose, 20–40 mg; maximal daily dose, 60 mg	

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children 1–17 Years of Age (Unless Otherwise Stated)
<b>Alpha-Beta-Adrenergic Blocking Agents</b>		
<b>Carvedilol</b> (Coreg)	PO 6.25 mg twice daily for 7–14 days, then increase to 12.5 mg twice daily for 7–14 days, then increase to a maximal dose of 25 mg twice daily if tolerated and needed	
<b>Labetalol</b> (Trandate, Normodyne)	PO 100 mg twice daily, increased by 100 mg twice daily every 2–3 days if necessary. Usual maintenance dose, 200–400 mg twice daily. Severe hypertension may require 1200–2400 mg daily. IV injection, 20 mg slowly over 2 min, followed by 40–80 mg every 10 min until the desired blood pressure is achieved or 300 mg has been given IV infusion, add 200 mg to 250 mL of 5% dextrose or 0.9% sodium chloride solution and infuse at a rate of 2 mg/min. Adjust flow rate according to blood pressure, and substitute oral labetalol when blood pressure is controlled.	
<b>Calcium Channel Blocking Agents</b>		
<b>Amlodipine</b> (Norvasc)	PO 5–10 mg once daily	
<b>Diltiazem</b> (sustained release) (Cardizem SR)	PO 60–120 mg twice daily. Extended-release tablets; swallow whole, do not crush or chew.	
<b>Felodipine</b> (Plendil)	PO 5–10 mg once daily. Extended-release tablets; swallow whole, do not crush or chew.	
<b>Isradipine</b> (DynaCirc)	PO 2.5–5 mg twice daily	
<b>Nicardipine</b> (Cardene, Cardene SR, Cardene IV)	PO 20–40 mg three times daily Sustained-release, PO 30–60 mg twice daily; IV infusion 5–15 mg/h	
<b>Nifedipine</b> (Adalat, Procardia, Procardia XL)	Sustained-release only, PO 30–60 mg once daily, increased over 1–2 wk if necessary	
<b>Nisoldipine</b> (Sular)	PO, 20 mg once daily initially, increased by 10 mg/wk or longer intervals to a maximum of 60 mg daily. Average maintenance dose, 20–40 mg daily Adults with liver impairment or >65 y, PO, 10 mg once daily initially	
<b>Verapamil</b> (Calan, Calan SR, Isoptin SR)	Immediate-release, PO 80 mg 3 times daily Sustained-release, PO 240 mg once daily IV, see manufacturer's instructions	IV, see manufacturer's instructions
<b>Other Vasodilators</b>		
<b>Fenoldopam</b> (Corlopam)	IV infusion, initial dose based on body weight, then flow rate titrated to achieve desired response. Mix with 0.9% sodium chloride or 5% dextrose to a concentration of 40 mcg/mL (e.g., 40 mg of drug [4 mL of concentrate] in 1000 mL of IV fluid).	

(continued on page 832)

Table 52-1

## Drugs at a Glance: Antihypertensive Drugs (continued)

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children 1–17 Years of Age (Unless Otherwise Stated)
<b>Hydralazine</b> (Apresoline)	Chronic hypertension, PO 10 mg 4 times daily for 2–4 d, gradually increased up to 300 mg/d, if necessary  Hypertensive crisis, IM, IV 10–20 mg, increased to 40 mg if necessary. Repeat dose as needed.	Chronic hypertension, 0.75 mg/kg/d initially in 4 divided doses. Gradually increase over 3–4 wk to a maximal dose of 7.5 mg/kg/d if necessary.  Hypertensive crisis, IM, IV 0.1–0.2 mg/kg every 4–6 h as needed
<b>Minoxidil</b> (Loniten)	PO 5 mg once daily initially, increased gradually until blood pressure is controlled. Average daily dose, 10–40 mg; maximal daily dose, 100 mg in single or divided doses	<12 y, PO 0.2 mg/kg/d initially as a single dose, increased gradually until blood pressure is controlled. Average daily dose, 0.25–1.0 mg/kg; maximal dose, 50 mg/d
<b>Sodium nitroprusside</b> (Nipress)	IV infusion 0.5–10 mcg/kg/min; average dose, 3 mcg/kg/min. Prepare solution by adding 50 mg of sodium nitroprusside to 250–1000 mL of 5% dextrose in water, and cover promptly to protect from light.	Same as for adults

However, a persistent cough develops in approximately 10% to 20% of patients and may lead to stopping the drug. Also, acute hypotension may occur when an ACE inhibitor is started, especially in patients with fluid volume deficit. This reaction may be prevented by starting with a low dose taken at bedtime or by stopping diuretics and reducing dosage of other antihypertensive drugs temporarily. Hyperkalemia may develop in patients who have diabetes mellitus or renal impairment or who are taking nonsteroidal anti-inflammatory drugs, potassium supplements, or potassium-sparing diuretics.

These drugs are contraindicated during pregnancy and should be discontinued when pregnancy is recognized. The U.S. Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** during pregnancy for drugs that directly affect the renin-angiotensin system as their use can cause injury and even death to a developing fetus.

### Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) were developed to block the strong blood pressure-raising effects of angiotensin II. Instead of decreasing production of angiotensin II, as the ACE inhibitors do, these drugs compete with angiotensin II for tissue binding sites and prevent angiotensin II from combining with its receptors in body tissues. Although multiple types of receptors have been identified, the AT<sub>1</sub> receptors located in brain, renal, myocardial, vascular, and adrenal tissue determine most of the effects of angiotensin II on cardiovascular and renal functions. ARBs block the angiotensin II AT<sub>1</sub> receptors and decrease arterial blood pressure by decreasing systemic vascular resistance (Fig. 52-1).

These drugs are similar to ACE inhibitors in their effects on blood pressure and hemodynamics and are as effective as

ACE inhibitors in the management of hypertension and probably heart failure. They are less likely to cause hyperkalemia than ACE inhibitors, and the occurrence of a persistent cough is rare. Overall, the drugs are well tolerated, and the incidence of most adverse effects is similar to that of placebo. However, the FDA has issued a **BLACK BOX WARNING** during pregnancy for drugs that directly affect the renin-angiotensin system as their use can cause injury and even death to a developing fetus.

**P Losartan**, the first ARB, is readily absorbed and rapidly metabolized by the cytochrome P450 liver enzymes to an active metabolite. Both losartan and the metabolite are highly bound to plasma albumin, and losartan has a shorter duration of action than its metabolite. When losartan therapy is started, maximal effects on blood pressure usually occur within 3 to 6 weeks. If losartan alone does not control blood pressure, a low dose of a diuretic may be added. A combination product of losartan and hydrochlorothiazide is available.

### Antiadrenergics

Antiadrenergic (sympatholytic) drugs inhibit activity of the SNS. When the SNS is stimulated (see Chap. 16), the nerve impulse travels from the brain and spinal cord to the ganglia. From the ganglia, the impulse travels along postganglionic fibers to effector organs (e.g., heart, blood vessels). Although SNS stimulation produces widespread effects in the body, the effects relevant to this discussion are the increases in heart rate, force of myocardial contraction, cardiac output, and blood pressure that occur. When the nerve impulse is inhibited or blocked at any location along its pathway, the result is decreased blood pressure (see Chap. 18).

Alpha<sub>1</sub>-adrenergic receptor blocking agents (e.g., *prazosin*) dilate blood vessels and decrease peripheral vascular

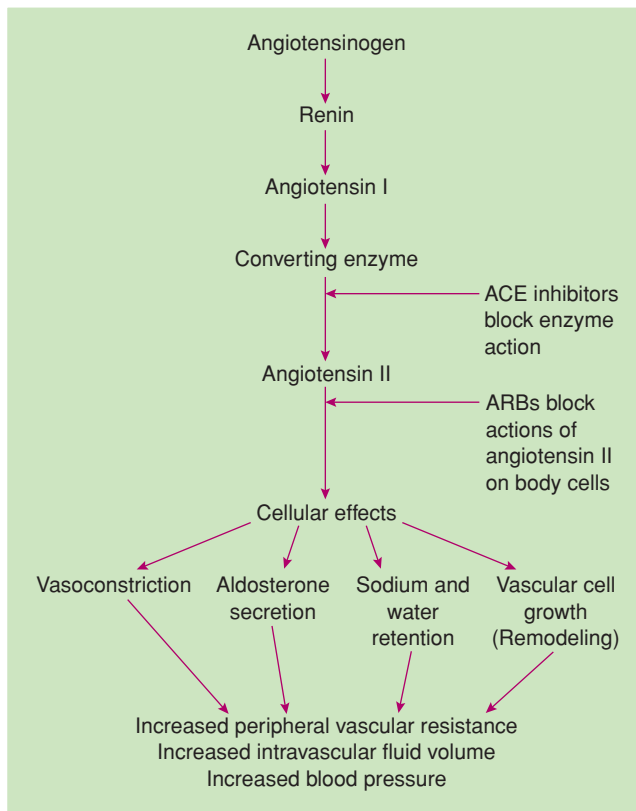

Table 52-2

## Drugs at a Glance: Oral Antihypertensive Combination Products\*

## COMPONENTS

Trade Name	Angiotensin II Receptor Blocker	Angiotensin-Converting Enzyme Inhibitor	Beta Blocker	Calcium channel Blocker	Diuretic	Non-Beta-Blocker Antidiuretic	Dosage Ranges
Avalide	Irbesartan 150 or 300 mg				HCTZ 12.5 mg		1 tablet once daily
Capozide		Captopril 25 or 50 mg			HCTZ 15 or 25 mg		1 tablet 2 to 3 times daily
Corzide			Nadolol 40 or 80 mg		Bendroflumethiazide 5 mg		1 tablet daily
Diovan HCT	Valsartan 80 or 160 mg				HCTZ 12.5 mg		1 tablet daily
Hyzaar	Losartan 50 mg				HCTZ 12.5 mg		1 tablet once daily
Inderide			Propranolol 40 or 80 mg		HCTZ 25 mg		1–2 tablets twice daily
Lexxel		Enalapril 5 mg		Felodipine 5 mg			1–2 tablets once daily
Lopressor HCT			Metoprolol 50 or 100 mg		HCTZ 25 or 50 mg		1–2 tablets daily
Lotensin HCT		Benazepril 5, 10, or 20 mg			HCTZ 12.5 or 25 mg		1 tablet daily
Lotrel		Benazepril 10 or 20 mg		Amlodipine 2.5 or 5 mg			1 capsule daily
Minizide					Polythiazide 0.5 mg		1 capsule 2 to 3 times daily
Prinzide		Lisinopril 20 mg			HCTZ 12.5 or 25 mg		1 tablet daily
Tarka		Trandolapril 1, 2, or 4 mg		Verapamil 180 or 240 mg		Prazosin 1, 2, or 5 mg	1 tablet daily
Tenoretic			100 mg		Chlorthalidone 25 mg		1 tablet daily
Vaseretic		Enalapril 5 mg			HCTZ 12.5 mg		1–2 tablets daily
Zestoretic		Lisinopril 10 or 20 mg	Timolol 10 mg		HCTZ 12.5 or 25 mg		1 tablet daily
Ziac		Bisoprolol 2.5, 5, or 10 mg			HCTZ 6.25 mg		1 tablet daily

\*Note that one trade-name product may be available in multiple formulations, with variable amounts of antihypertensive, diuretic, or both components. HCTZ, hydrochlorothiazide.

**Figure 52-1** ■ Angiotensin-converting enzyme (ACE) inhibitors inhibit angiotensin-converting enzyme and thereby prevent formation of angiotensin II. Angiotensin II receptor blockers (ARBs) prevent angiotensin II from connecting with its receptors and thereby prevent it from acting on body tissues containing those receptors (e.g., blood vessels, adrenal cortex).

resistance. These drugs can be used alone or in multidrug regimens. One adverse effect, called the *first-dose phenomenon*, results in orthostatic hypotension with palpitations, dizziness, and perhaps syncope 1 to 3 hours after the first dose or an increased dose. To prevent this effect, first doses and first increased doses are taken at bedtime. Another effect, associated with long-term use or higher doses, leads to sodium and fluid retention and a need for concurrent diuretic therapy. Centrally acting sympatholytics (e.g., *clonidine*) stimulate presynaptic  $\alpha_2$  receptors in the brain and are classified as  $\alpha_2$  receptor agonists. When these drugs are taken, less norepinephrine is released and sympathetic outflow from the vasomotor center is reduced. Stimulation of presynaptic  $\alpha_2$  receptors peripherally may also contribute to the decreased sympathetic activity. Reduced sympathetic activity leads to decreased cardiac output, heart rate, peripheral vascular resistance, and blood pressure. Chronic use of clonidine and related drugs may result in sodium and fluid retention, especially with higher doses.

Beta-adrenergic blocking agents (e.g., *propranolol*) decrease heart rate, force of myocardial contraction, cardiac output, and renin release from the kidneys. The FDA has

issued a **BLACK BOX WARNING** for in patients with CAD withdrawing from oral forms of atenolol, metoprolol, nadolol, propranolol, and timolol; abrupt withdrawal has resulted in exacerbation of angina, the incidence of ventricular dysrhythmias and the occurrence of MIs.

Other antiadrenergics include alpha blockers (*phentolamine* and *phenoxybenzamine*), which occasionally are used in hypertension resulting from catecholamine excess. Individual antiadrenergic drugs are discussed in Chapter 18 and listed in Tables 18-1 and 18-2.

## Calcium Channel Blocking Agents

Calcium channel blockers (e.g., *verapamil*) are used for several cardiovascular disorders. The mechanism of action and use in the management of tachydysrhythmias and angina pectoris are discussed in Chapters 49 and 50, respectively. In hypertension, the drugs mainly dilate peripheral arteries and decrease peripheral vascular resistance by relaxing vascular smooth muscle.

Most of the available drugs are approved for use in hypertension. **Nifedipine**, a short-acting calcium channel blocker, has been used to treat hypertensive emergencies or urgencies, often by puncturing the capsule and squeezing the contents under the tongue or having the patient bite and swallow the capsule. Such use is no longer recommended, because this practice is associated with an increased risk of adverse cardiovascular events precipitated by a rapid and severe decrease in blood pressure.

As a group, the calcium channel blockers are well absorbed from the gastrointestinal tract following oral administration and are highly bound to protein. The drugs are metabolized in the liver and excreted in urine.

## Diuretics

Antihypertensive effects of diuretics are usually attributed to sodium and water depletion. In fact, diuretics usually produce the same effects as severe dietary sodium restriction. In many cases of hypertension, diuretic therapy alone may lower blood pressure. When diuretic therapy is begun, blood volume and cardiac output decrease. With long-term administration of a diuretic, cardiac output returns to normal, but there is a persistent decrease in peripheral vascular resistance. This has been attributed to a persistent small reduction in extracellular water and plasma volume, decreased receptor sensitivity to vasopressor substances such as angiotensin, direct arteriolar vasodilation, and arteriolar vasodilation secondary to electrolyte depletion in the vessel wall. In moderate or severe hypertension that does not respond to a diuretic alone, the diuretic may be continued and another antihypertensive drug added, or monotherapy with a different type of antihypertensive drug may be tried.

Thiazide diuretics (e.g., *hydrochlorothiazide*) are most commonly used in the management of hypertension. Loop diuretics (e.g., *furosemide*) or potassium-sparing diuretics (e.g., *spironolactone*) may be useful in some circumstances. Diuretics are discussed in Chapter 53 and listed in Table 53-1.

## Vasodilators (Direct Acting)

Vasodilator antihypertensive drugs directly relax smooth muscle in blood vessels, resulting in dilation and decreased peripheral vascular resistance. They also reduce afterload and may be used in management of heart failure. *Hydralazine* and *minoxidil* act mainly on arterioles; *nitroprusside* acts on arterioles and venules. These drugs have a limited effect on hypertension when used alone because the vasodilating action that lowers blood pressure also stimulates the SNS and triggers reflexive compensatory mechanisms (vasoconstriction, tachycardia, and increased cardiac output), which raise blood pressure. This effect can be prevented during long-term therapy by also giving a drug that prevents excessive sympathetic stimulation (e.g., propranolol, an adrenergic blocker). These drugs also cause sodium and water retention, which may be minimized by concomitant diuretic therapy. The FDA has issued a **BLACK BOX WARNING** for minoxidil as the drug can exacerbate angina and precipitate pericardial effusion (which can progress to cardiac tamponade).

### Applying Your Knowledge 52-1

Mr. Olms is noncompliant with his drug regimen. How should you react?

## Nursing Process

### Assessment

Assess the patient's condition in relation to hypertension.

- Identify conditions and risk factors that may lead to hypertension. These include
  - Obesity
  - Elevated serum cholesterol (total and low-density lipoprotein) and triglycerides
  - Cigarette smoking
  - Sedentary lifestyle
  - Family history of hypertension or other cardiovascular disease
  - African-American race
  - Renal disease (e.g., renal artery stenosis)
  - Adrenal disease (e.g., hypersecretion of aldosterone, pheochromocytoma)
  - Other cardiovascular disorders (e.g., atherosclerosis, left ventricular hypertrophy)
  - Diabetes mellitus
  - Use of oral contraceptives, corticosteroids, appetite suppressants, nasal decongestants, nonsteroidal anti-inflammatory agents
  - Neurologic disorders (e.g., brain damage)

- Observe for signs and symptoms of hypertension.
  - Check blood pressure accurately and repeatedly. As a rule, multiple measurements in which systolic pressure is greater than 140 mm Hg, and/or diastolic pressure is greater than 90 mm Hg, are necessary to establish a diagnosis of hypertension.

The importance of accurate blood pressure measurements cannot be overemphasized because there are many possibilities for errors. Some ways to improve accuracy and validity include using correct equipment (e.g., proper cuff size), having the patient rested and in the same position each time blood pressure is measured (e.g., sitting or supine with arm at heart level), and using the same arm for repeated measurements.

- In most cases of early hypertension, elevated blood pressure is the only clinical manifestation. If symptoms do occur, they are usually nonspecific (e.g., headache, weakness, fatigue, tachycardia, dizziness, palpitations, epistaxis).
- Eventually, signs and symptoms occur as target organs are damaged. Heart damage is often evidenced as angina pectoris, myocardial infarction, or heart failure. Chest pain, tachycardia, dyspnea, fatigue, and edema may occur. Brain damage may be indicated by transient ischemic attacks or strokes of varying severity with symptoms ranging from syncope to hemiparesis. Renal damage may be reflected by proteinuria, increased blood urea nitrogen (BUN), and increased serum creatinine. Ophthalmoscopic examination may reveal hemorrhages, sclerosis of arterioles, and inflammation of the optic nerve (papilledema). Because arterioles can be visualized in the retina of the eye, damage to retinal vessels may indicate damage to arterioles in the heart, brain, and kidneys.

### Nursing Diagnoses

- Decreased Cardiac Output related to disease process or drug therapy
- Ineffective Coping related to long-term lifestyle changes and drug therapy
- Noncompliance related to lack of knowledge about hypertension and its management, costs and adverse effects of drug therapy, and psychosocial factors
- Disturbed Body Image related to the need for long-term management and medical supervision
- Fatigue related to antihypertensive drug therapy
- Deficient Knowledge related to hypertension, antihypertensive drug therapy, and nondrug lifestyle changes
- Sexual Dysfunction related to adverse drug effects

*Nursing Process continues on page 836*

## Planning/Goals

### The patient will

- Receive or take antihypertensive drugs correctly
- Be monitored closely for therapeutic and adverse drug effects, especially when drug therapy is started, when changes are made in choice of drugs, and when dosages are increased or decreased
- Use nondrug measures to assist in blood pressure control
- Avoid, manage, or report adverse drug reactions
- Verbalize or demonstrate knowledge of prescribed drugs and recommended lifestyle changes
- Keep follow-up appointments

## Interventions

Implement measures to prevent or minimize hypertension. Preventive measures are mainly lifestyle changes to reduce risk factors. These measures should be started in childhood and continued throughout life. After hypertension is diagnosed, lifetime adherence to a therapeutic regimen may be necessary to control the disease and prevent complications. The nurse's role is important in the prevention, early detection, and management of hypertension. Some guidelines for intervention at community, family, and personal levels include the following:

- Participate in programs to promote healthful lifestyles (e.g., improving eating habits, increasing exercise, managing stress more effectively, avoiding cigarette smoking).
- Participate in community screening programs, and make appropriate referrals when abnormal blood pressures are detected. If hypertension develops in women taking oral contraceptives, the drug should be discontinued for 3 to 6 months to see whether blood pressure decreases without antihypertensive drugs.
- Help the hypertensive patient comply with prescribed therapy (see accompanying patient teaching display). Noncompliance is high among patients with hypertension. Reasons given for noncompliance include lack of symptoms; lack of motivation and self-discipline to make needed lifestyle changes (e.g., lose weight, stop smoking, restrict salt intake); perhaps experiencing more symptoms from medications than from hypertension; the cost of therapy; and the patient's failure to realize the importance of effective management, especially as related to prevention of major cardiovascular diseases (myocardial infarction, stroke, and death). In addition, several studies have shown that compliance decreases as the number of drugs and number of doses increase.

The nurse can help increase compliance by teaching the patient about hypertension, helping the patient make necessary lifestyle changes, and maintaining supportive interpersonal relationships. Losing weight, stopping

smoking, and other changes are most likely to be effective if attempted one at a time.

- Use recommended techniques for measuring blood pressure. Poor techniques are too often used (e.g., the patient's arm up or down rather than at heart level; cuff applied over clothing, too loosely, deflated too rapidly, or reinflated before completely deflated; a regular-sized cuff used on large arms that need a large cuff; using the stethoscope diaphragm rather than the bell). It is disturbing to think that antihypertensive drugs may be prescribed and dosages changed on the basis of inaccurate blood pressures.

## Evaluation

- Observe for blood pressure measurements within goal or more nearly normal ranges.
- Observe and interview regarding compliance with instructions about drug therapy and lifestyle changes.
- Observe and interview regarding adverse drug effects.

## Principles of Therapy

### Therapeutic Regimens

After the diagnosis of hypertension is established, a therapeutic regimen must be designed and implemented. The goal of management for most patients is to achieve and maintain blood pressure below 140/90 mm Hg. The target blood pressure for diabetic patients is 130/80 mm Hg. If the goal cannot be achieved, lowering blood pressure to any extent is still considered beneficial in decreasing the incidence of coronary artery disease and stroke.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) recommends management guidelines in which initial interventions are lifestyle modifications (i.e., reduction of weight and sodium intake, regular physical activity, moderate alcohol intake, and no smoking) to maintain normal blood pressure or for those in the prehypertension group. If these modifications do not produce goal blood pressure or substantial progress toward goal blood pressure, antihypertensive drug therapy should be initiated and the lifestyle modifications should be continued. The JNC 7 guidelines suggest thiazide diuretics be used as first-line therapy, either alone (monotherapy) or with a beta blocker, ACE inhibitor, ARB, or calcium channel blocker. If the initial drug (and dose) does not produce the desired blood pressure, options for further management include increasing the drug dose, substituting another drug, or adding a second drug from a different group. If the response is still inadequate, a second or third drug may be added, including a diuretic if not previously prescribed. When current management is ineffective, reassess the patient's compliance with lifestyle modifications and drug therapy. In addition, review other factors that may decrease the therapeutic response, such as the use of

## Patient Teaching Guidelines Antihypertensive Drugs

### General Considerations

- Hypertension is a major risk factor for heart attack, stroke (sometimes called brain attack), and kidney failure. Although it rarely causes symptoms unless complications occur, it can be controlled by appropriate management. Consequently, you need to learn all you can about the disease process, the factors that cause or aggravate it, and its management. In few other conditions is your knowledge and understanding about your condition as important as with hypertension.
- For many people, lifestyle changes (i.e., a diet to avoid excessive salt and control weight and fat intake; regular exercise; and avoiding smoking) may be sufficient to control blood pressure. If drug therapy is prescribed, these measures should be continued.
- When drug therapy is needed, your prescriber will try to choose a drug and develop a regimen that works for you. There are numerous antihypertensive drugs and many can be taken once a day, which makes their use more convenient and less disruptive of your usual activities of daily living. You may need several office visits to find the right drug or combination of drugs and the right dosage. Changes in drugs or dosages may also be needed later, especially if you develop other conditions or take other drugs that alter your response to the antihypertensive drugs.
- Antihypertensive drug therapy is usually long term, may require more than one drug, and may produce side effects. You need to know the brand and generic names of any prescribed drugs and how to take each drug for optimal benefit and minimal adverse effects.
- Antihypertensive drugs must be taken as prescribed for optimal benefits, even if you do not feel well when a medication is started or when dosage is increased. *No antihypertensive drug should be stopped abruptly. If problems develop, they should be discussed with the health care provider who is treating the hypertension.* If treatment is stopped, blood pressure usually increases gradually as the medications are eliminated from the body. However, sometimes blood pressure rapidly increases to pretreatment levels or even higher. With any of these situations, you are at risk of a heart attack or stroke. In addition, stopping one drug of a multidrug regimen may lead to increased adverse effects as well as decreased antihypertensive effectiveness. To avoid these problems, antihypertensive drugs should be tapered in dosage and discontinued gradually, as directed by your health care provider.
- Blood pressure measurements are the only way you can tell if your medication is working. Thus, you may want to monitor your blood pressure at home, especially when starting drug therapy, changing medications, or changing dosages. If so, a blood pressure machine may be purchased at a medical supply store. Follow instructions regarding use, take your blood pressure approximately the same time(s) each day (e.g., before morning and evening meals), and keep a record to show to your health care provider.
- People sometimes feel dizzy or faint while taking antihypertensive medications. This usually means your blood pressure drops momentarily and is most likely to occur when you start a medication, increase dosage, or stand up suddenly from a sitting or lying position. This can be prevented or decreased by moving to a standing position slowly, sleeping with the head of the bed elevated, wearing elastic stockings, exercising legs, avoiding prolonged standing, and avoiding hot baths. If episodes still occur, you should sit or lie down to avoid a fall and possible injury.
- It is very important to keep appointments for follow-up care.

### Self-or Caregiver Administration

- Take or give antihypertensive drugs at prescribed time intervals, about the same time each day. For example, take once-daily drugs as close to every 24 hours as you can manage; twice-a-day drugs should be taken every 12 hours. If ordered four times daily, take approximately every 6 hours. Taking doses too close together can increase dizziness, weakness, and other adverse effects. Taking doses too far apart may not control blood pressure adequately and may increase risks of heart attack or stroke.
- Take oral captopril on an empty stomach. Food decreases drug absorption.
- Take most oral antihypertensive agents with or after food intake to decrease gastric irritation. Candesartan (Atacand), irbesartan (Avapro), losartan (Cozaar), telmisartan (Micardis), and valsartan (Diovan) may be taken with or without food.
- With prazosin, doxazosin, or terazosin, take the first dose and the first increased dose at bedtime to prevent dizziness and possible fainting.
- With the clonidine skin patch, apply to a hairless area on the upper arm or torso once every 7 days. Rotate sites.

over-the-counter appetite suppressants, dietary or herbal supplements, or nasal decongestants, which raise blood pressure.

The World Health Organization and the International Society of Hypertension guidelines for management of hypertension include considering age, ethnicity, and concomitant cardiovascular disorders when choosing an antihypertensive drug; starting with a single drug, in the lowest available dose; changing to a drug from a different group, rather than increasing dosage of the first drug or adding a second drug, if the initial drug is ineffective or not well tolerated; and using long-acting drugs (i.e., a single dose effective for 24 hours). The guidelines also note that many patients require two or more

drugs to achieve adequate blood pressure control. When this is the case, fixed-dose combinations or long-acting agents may be preferred, as they decrease the number of drugs and doses that are required and may increase compliance.

### Applying Your Knowledge 52-2

The JNC 7 has identified specific management guidelines for the patient with hypertension. What should you teach a patient with hypertension relative to the guidelines?

.....

## Drug Selection

Because many effective antihypertensive drugs are available, choices depend primarily on patient characteristics and responses. Some general guidelines are as follows.

ACE inhibitors may be effective alone in Caucasian hypertensive patients or in combination with a diuretic in African-American hypertensive patients. They are also recommended for hypertensive adults with diabetes mellitus and kidney damage because they slow the progression of albuminuria. Based on research studies that indicate reduced morbidity and mortality from cardiovascular diseases, these drugs are increasingly being prescribed as a component of a multidrug regimen.

ARBs have therapeutic effects similar to those of ACE inhibitors, with fewer adverse effects. They may be used in most patients with hypertension.

Antiadrenergics may be effective in any hypertensive population. Alpha agonists and antagonists are most often used in multidrug regimens in stage 2 hypertension, because they may cause postural hypotension and syncope. Clonidine is available in a skin patch that is applied once a week and reportedly reduces adverse effects and increases compliance. An additional advantage of transdermal clonidine is that patients who cannot take oral medications can use it. A disadvantage of this system is a delayed onset of effect (2–3 days), so other antihypertensive medications must also be given during the first 2 to 3 days of clonidine transdermal therapy. Other disadvantages include cost, a 20% incidence of local skin rash or irritation, and a 2- to 3-day delay in “offset” of action when transdermal therapy is discontinued.

Beta adrenergic blockers are the drugs of first choice for patients younger than 50 years of age with high-renin hypertension, tachycardia, angina pectoris, myocardial infarction, or left ventricular hypertrophy. Most beta blockers are approved for use in hypertension and are probably equally effective. However, the cardioselective drugs (see Chap. 18) are preferred for hypertensive patients who also have asthma, peripheral vascular disease, or diabetes mellitus. Research studies demonstrate reduced morbidity and mortality with diuretics and beta blockers used in combination, especially after a myocardial infarction.

Calcium channel blockers may be used for monotherapy or in combination with other drugs. They may be especially useful for hypertensive patients who also have angina pectoris or other cardiovascular disorders. The JNC 7 recommends that calcium channel blockers be considered the drug of first choice in African Americans with stage 2 hypertension. Note that sustained-release forms of nifedipine, diltiazem, verapamil and other long-acting drugs (e.g., amlodipine, felodipine) are recommended rather than the short-acting forms because they do not cause precipitous lowering of pressure.

Diuretics are preferred for initial therapy in all patients, but specifically in older and African-American hypertensive patients. They should be included in any multidrug regimen for these and other populations. Thiazide and related diuretics are equally effective. Hydrochlorothiazide is most commonly used.

## Evidence-Based Practice

### 52-1 Enhanced Compliance With Fixed-Dose Combinations of Antihypertensive Medications.

A meta-analysis of nine studies (11,925 patients) was performed exploring compliance with medication administration using fixed-dose combinations compared with a regimen of drugs given individually (e.g., 1 pill of lisinopril plus hydrochlorothiazide versus lisinopril and hydrochlorothiazide given as 2 separate pills). A subgroup analysis of four retrospective studies on hypertension from this group showed individuals who were prescribed fixed-dose combinations of antihypertensive medications reduced the likelihood of noncompliance by 24% over those who took the same medications as individual pills. Since evidence now suggests that the majority of individuals with hypertension will require combinations of antihypertensive medications to achieve optimal blood pressure control, simplifying the drug regimen with fixed-combination drugs can improve compliance and produce better health outcomes (Bangalore, Kamalakkannan, Parkar, & Messerli, 2007).

Diazoxide, usually in parenteral form, is indicated for short-term treatment of malignant hypertension. Loop diuretics are indicated in those with renal insufficiency. Potassium-sparing diuretics may precipitate hyperkalemia. Recently, the selective aldosterone blocker, eplerenone, has demonstrated efficacy in African Americans.

Vasodilators are used in combination with a beta blocker and a diuretic to prevent hypotension-induced compensatory mechanisms (stimulation of the SNS and fluid retention) that raise blood pressure.

Combination products usually combine two drugs with different mechanisms of action (e.g., a thiazide or related diuretic plus a beta blocker or other antiadrenergic, an ACE inhibitor, an ARB, or a calcium channel blocker). Most are available in various formulations (see Table 52-2). Potential advantages of fixed-dose combination products include comparable or improved effectiveness, smaller doses of individual components, fewer adverse effects, improved compliance, and possibly decreased costs (see Evidence-Based Practice Box 52-1:Enhanced Compliance with Fixed-Dose Combinations of Antihypertensive Medications).

## Drug Dosage

Dosage of antihypertensive drugs must be titrated according to individual response. Dosage should be started at minimal levels and increased if necessary. Lower doses decrease the incidence and severity of adverse effects.

For many patients, it may be more beneficial to change drugs or add another drug rather than increase dosage. Two or three drugs in small doses may be more effective and cause fewer adverse effects than a single drug in large doses. When two or more drugs are given, the dose of each drug may need to be reduced.

Patients who maintain control of their blood pressure for 1 year or so may be candidates for reduced dosages or reduced numbers of drugs. Any such adjustments must be gradual and carefully supervised by a health care provider. Expected benefits include fewer adverse effects and greater compliance.

## Dietary Management of Blood Pressure

Key behavioral determinants of blood pressure are related to dietary consumption of calories and salt; the prevalence of hypertension rises proportionally to average body mass index. The Dietary Approaches to Stop Hypertension (DASH) study demonstrated that patients with prehypertension or stage 1 hypertension can reduce their blood pressures by adhering to a diet abundant in fresh fruits and vegetables and low-fat dairy products even without restricting calorie or sodium intake. The effects of the DASH diet demonstrate blood pressure-lowering effects that parallel the degree of benefit from drug monotherapy, can be augmented by dietary sodium restriction, and are observed in all ethnic groups, particularly African Americans. Information regarding the DASH diet can be obtained at [www.nhlbi.nih.gov/health/public/heart/hbp/dash/](http://www.nhlbi.nih.gov/health/public/heart/hbp/dash/).

Therapeutic regimens for hypertension may include sodium restriction. Severe restrictions usually are not acceptable to patients; however, moderate restrictions (4–6 g of salt a day) are beneficial and more easily implemented. Avoiding heavily salted foods (e.g., cured meats, sandwich meats, pretzels, potato chips) and not adding salt to food at the table can achieve this. Research and clinical observations indicate the following:

- Sodium restriction alone reduces blood pressure.
- Sodium restriction potentiates the antihypertensive actions of diuretics and other antihypertensive drugs. Conversely, excessive sodium intake decreases the antihypertensive actions of all antihypertensive drugs. Patients with unrestricted salt intake who are taking thiazides may lose excessive potassium and become hypokalemic.
- Sodium restriction may decrease dosage requirements of antihypertensive drugs, thereby decreasing the incidence and severity of adverse effects.

## Use in Special Populations

### Use in Various Ethnic Groups

Nearly 70% of the familial considerations related to blood pressure are credited to shared genes rather than to shared environment. For most antihypertensive drugs, there have been few research studies comparing their effects in different genetic or ethnic groups. However, several studies indicate that beta blockers have greater effects in people of Asian heritage compared with their effects in Caucasians. For hypertension, Asians in general need much smaller doses because they metabolize and excrete beta blockers slowly. Other populations known to metabolize beta blockers slowly include Arab and Egyptian Americans and possibly German Americans. In

African Americans, diuretics are effective and recommended as initial drug therapy; calcium channel blockers,  $\alpha_1$  receptor blockers, and the  $\alpha$ - $\beta$  blocker labetalol are reportedly equally effective in African Americans and Caucasians. ACE inhibitors, some ARBs (e.g., losartan, telmisartan), and beta blockers are less effective as monotherapy in African Americans. When beta blockers are used, they are usually one component of a multidrug regimen, and higher doses may be required. Overall, African Americans are more likely to have severe hypertension and require multiple drugs as a result of having low circulating renin, increased salt sensitivity, and a higher incidence of obesity.

### Use in Children

Most principles of managing adult hypertension apply to managing childhood and adolescent hypertension; some additional management elements should be considered.

Routine blood pressure measurement is especially important for children who are overweight or who have a hypertensive parent. Increased blood pressure in children often correlates with hypertension in young adults.

In recent years, increased blood pressure measurements during routine pediatric examinations have led to the discovery of significant asymptomatic hypertension and the realization that mild elevations in blood pressure are more common during childhood, especially in adolescents, than previously thought. Hypertension in children and adolescents may indicate underlying disease processes (e.g., cardiac, endocrine, renovascular, renal parenchymal disorders) or the early onset of primary hypertension.

The National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents produced the fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents in 2004. These guidelines established parameters for blood pressure in children and adolescents of comparable age, body size (height and weight), and sex. Normal blood pressure is defined as systolic and diastolic values less than the 90th percentile; prehypertension is defined as an average of systolic or diastolic pressures within the 90th to 95th percentiles; hypertension is defined as pressures beyond the 95th percentile. Blood pressure values obtained with a child or adolescent should be compared with norms and recorded in permanent health care records. Measurements are recorded on three or more occasions. Multiple accurate measurements are especially important in diagnosing hypertension because blood pressure may be more labile in children and adolescents.

Children have a greater incidence of secondary hypertension than adults. In general, the higher the blood pressure and the younger the child, the greater the likelihood of secondary hypertension. Diagnostic tests may be needed to rule out renovascular disease or coarctation of the aorta in those younger than 18 years of age with blood pressure above 140/90 mm Hg and young children with blood pressures above the 95th percentile for their age group. Oral contraceptives may cause secondary hypertension in adolescents.

The goals of management are to reduce blood pressure to below the 95th percentile and prevent the long-term effects of persistent hypertension. As in adults, prevention of obesity, avoiding excessive sodium intake, and exercise are important nonpharmacologic measures. Obese adolescents who lose weight may lower their blood pressure, especially when they also increase physical activity.

Most children with secondary hypertension require drug therapy, which should be directed at the cause of hypertension if known. Drug therapy should be cautious and conservative because few studies have been done in children and long-term effects are unknown. The fewest drugs and the lowest doses should be used. Thus, if an initial drug is ineffective, it may be better to give a different single drug than to add a second drug to the regimen.

Based on the current recommendations of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents released in 2004, guidelines for choosing drugs include the following:

- Beta blockers are used in children of all ages and are the preferential drug for children with hypertension and migraine headache; they should probably be avoided in children with resting pulse rates under 60.
- Thiazide diuretics may be used, and they do not commonly produce hyperglycemia, hyperuricemia, or hypercalcemia in children as they do in adults.
- ACE inhibitors have been used to treat hypertension in children 6 years of age and over. The safety and efficacy of these drugs is continually being documented with studies and clinical practice. ACE inhibitors are preferred for managing hypertension in children who also have coexisting diabetes, microalbuminuria, or proteinuric renal diseases. Also, because of teratogenic effects, these drugs should be used very cautiously, if at all, in adolescent girls who may be sexually active.
- ARBs may be used in children 6 years of age or older who do not tolerate ACE inhibitors in the same way the JNC 7 recommends for adults. Further research and documentation regarding safety and efficacy are continuing.
- Calcium channel blockers are used in treating acute and chronic childhood hypertension. With chronic hypertension, immediate-release forms have a short duration of action and require frequent administration. Amlodipine may be given once daily and has specific pediatric labeling information.
- Hydralazine seems to be less effective in childhood and adolescent hypertension than in adult disease.
- Fixed-dose combination preparations, with the exception of bisoprolol and hydrochlorothiazide, have not had extensive study and are not recommended for routine use.

Although all patients with primary hypertension need regular supervision and assessment of blood pressure, this is

especially important with young children and adolescents because of growth and developmental changes.

### Use in Older Adults

Most principles of managing hypertension in other populations apply to older adults (>65 years). In addition, the following factors require consideration.

There are basically two types of hypertension in older adults. One is systolic hypertension, in which systolic blood pressure is above 140 mm Hg but diastolic pressure is below 90 mm Hg. The other type, systolic–diastolic hypertension, involves elevations of both systolic and diastolic pressures. Both types increase cardiovascular morbidity and mortality, especially heart failure and stroke, and should be treated.

Nonpharmacologic management should be tried alone or with drug therapy. For example, weight reduction, limited alcohol intake, moderate sodium restriction, and smoking cessation may be the initial treatment of choice if the patient is hypertensive and overweight.

If antihypertensive drug therapy is required, drugs used for younger adults may be used alone or in combination. A diuretic is usually the drug of first choice in older adults and may be effective alone. ACE inhibitors and calcium channel blocking agents may also be effective as monotherapy; beta blockers are usually less effective as monotherapy. Some ACE inhibitors (e.g., lisinopril, ramipril, quinapril, moexipril) or their active metabolites produce higher plasma concentrations in older adults than in younger ones. This is attributed to decreased renal function rather than age itself. Additional guidelines include the following:

- The goal of drug therapy for systolic–diastolic hypertension is usually a systolic pressure below 140 mm Hg and a diastolic below 90 mm Hg in patients with no other complications. For those with diabetes or renal failure, the goal is a systolic pressure below 130 mm Hg and a diastolic below 80 mm Hg. However, the latter goal may be difficult for most patients to meet because it requires rather stringent lifestyle restrictions and may require the use of two or more antihypertensive drugs.
- Older adults may be especially susceptible to the adverse effects of antihypertensive drugs because their homeostatic mechanisms are less efficient. For example, if hypotension occurs, the mechanisms that raise blood pressure are less efficient and syncope may occur. In addition, renal and liver function may be reduced, making accumulation of drugs more likely.
- Initial drug doses should be approximately half of the recommended doses for younger adults, and increases should be smaller and spaced at longer intervals. Lower drug dosages (e.g., hydrochlorothiazide 12.5 mg daily) are often effective and reduce risks of adverse effects.
- Blood pressure should be reduced slowly to facilitate adequate blood flow through arteriosclerotic vessels. Rapid lowering of blood pressure may produce cerebral insufficiency (syncope, transient ischemic attacks, stroke).

- A further incentive for successful management of hypertension in older patients is the benefit of reducing the incidence of dementia with antihypertensives.
- If blood pressure control is achieved and maintained for approximately 6 to 12 months, drug dosage should be gradually reduced, if possible.

### Use in Patients With Renal Impairment

Antihypertensive drugs are frequently required by patients with renal impairment ranging from mild insufficiency to end-stage failure. A temporary decrease in renal function may occur in these patients when blood pressure is initially lowered. Guidelines include the following considerations:

- In hypertensive patients with primary renal disease or diabetic nephropathy, drug therapy may slow progression of renal impairment.
- Diuretics are usually required because sodium retention is an important element of hypertension in these patients. Loop diuretics, such as furosemide, are more often used, and relatively large doses may be required. Thiazides are usually contraindicated because they are ineffective if serum creatinine is above 2 mg/dL. However, metolazone, a thiazide-related drug, may be used and relatively large doses may be required.
- ACE inhibitors are usually effective in patients with renal impairment, but responses may vary and the following factors should be considered. Careful monitoring is required, especially during the first few weeks of therapy, to prevent irreversible renal failure. For some patients, it may not be possible to normalize blood pressure and maintain adequate renal perfusion.
- In patients with severe atherosclerosis, especially those with stenosis of renal arteries, ACE inhibitors can impair renal blood flow and worsen renal impairment (i.e., increase BUN and serum creatinine). This may require discontinuing the drug or a reduction in dosage.
- Approximately 25% of patients taking an ACE inhibitor for heart failure experience an increase in BUN and serum creatinine levels. These patients usually do not require drug discontinuation unless they have severe, pre-existing renal impairment. In patients with severe heart failure, whose renal function may depend on the activity of the renin–angiotensin–aldosterone system, management with an ACE inhibitor may worsen renal impairment. However, acute renal failure rarely occurs.
- The mechanisms are unclear, but ACE inhibitors also have renal protective effects in hypertensive patients with some renal impairment and patients with diabetic nephropathy. A possible mechanism is less damage to the endothelium and less vascular remodeling (i.e., less narrowing of the lumen and less thickening of the vessel wall).
- The elimination half-life of most ACE inhibitors and their active metabolites is prolonged in patients with renal impairment. Dosage may need to be reduced with benazepril, lisinopril, quinapril, and ramipril. Fosinopril

requires no dosage adjustment as it is excreted by the hepatobiliary pathway.

- All ARBs are metabolized by the liver and do not need dose reduction with renal impairment.
- Most beta blockers are eliminated primarily by the kidneys and serum half-life is prolonged in patients with renal impairment. Most of the drugs should be used with caution and in reduced dosages. Dosage of metoprolol does not need to be reduced. An additional consideration is that cardiac output and blood pressure should not be lowered enough to impair renal blood flow and aggravate renal impairment.
- None of the commonly used calcium channel blockers is significantly cleared by the kidney and does not require a dosage adjustment as half-life is not altered significantly in renal impairment. Verapamil or diltiazem may be preferred to other calcium channels blockers due to their ability to limit proteinuria. Calcium channel blockers are effective and well tolerated in renal impairment, and they maintain renal blood flow even during blood pressure reduction in most patients. However, cautious use is still recommended because several agents produce active metabolites that are excreted by the kidneys (see “Use in Patients With Renal Impairment,” Chap. 53).

### Use in Patients With Hepatic Impairment

Little information is available about the use of antihypertensive drugs in patients with impaired hepatic function. However, many of the drugs are metabolized in the liver and hepatic impairment can increase and prolong plasma concentrations.

Patients who have jaundice or marked elevations of hepatic enzymes while taking an ACE inhibitor should have the drug discontinued as the drugs have been associated with cholestatic jaundice and can progress to hepatic necrosis and possible death. In addition, therapeutic effects can be decreased with several of the drugs (e.g., fosinopril, quinapril, ramipril) because less of a given dose is converted to an active metabolite. Fosinopril may require a dosage adjustment with hepatic impairment as it is excreted by the hepatobiliary pathway. Clearance of fosinopril, quinapril, and probably other ACE inhibitors that are metabolized is reduced in patients with alcoholic or biliary cirrhosis.

ARBs should be used cautiously in patients with biliary tract obstruction or hepatic impairment. For some of these drugs (e.g., candesartan, irbesartan, valsartan), dosage reduction is unnecessary. However, a lower starting dose is recommended for losartan because plasma concentrations of the drug and its active metabolite are increased and clearance is decreased approximately 50%. With telmisartan, plasma concentrations are increased and bioavailability approaches 100%. In addition, the drug is eliminated mainly by biliary excretion, and patients with biliary tract obstruction or hepatic impairment have reduced clearance. The drug should be used with caution, but dosage forms that allow dosage reduction below 40 milligrams are not available. Thus, an alternative drug should probably be considered for patients with hepatic impairment.

Beta blockers that normally undergo extensive first-pass hepatic metabolism (e.g., acebutolol, metoprolol, propranolol, timolol) may produce excessive blood levels in patients with cirrhosis because the blood containing the drug is shunted around the liver into the systemic circulation. Dosage should be started at a low dose and titrated carefully in these patients. Dosage of bisoprolol and pindolol should also be reduced in patients with cirrhosis or other hepatic impairment.

Calcium channel blockers should be used with caution, dosages should be substantially reduced, liver enzymes should be monitored periodically, and patients should be closely monitored for drug effects (see “Use in Patients With Hepatic Impairment,” Chap. 50).

### Use in Patients Undergoing Surgery

Drug therapy should be continued until surgery and restarted as soon as possible after surgery. If patients cannot take drugs orally, parenteral diuretics, antiadrenergic agents, ACE inhibitors, calcium channel blockers, or vasodilators may be given to avoid the rebound hypertension associated with abrupt discontinuance of some antiadrenergic antihypertensive agents. Transdermal clonidine also may be used. The anesthesiologist and surgeon must be informed about the patient’s hypertension and medication status.

### Use in Patients With Critical Illness

Antihypertensive drugs are frequently prescribed for patients with critical illness and must be used cautiously, usually with reduced dosages and careful monitoring of responses. In many cases, the drugs are continued during critical illnesses caused by both cardiovascular and noncardiovascular disorders. If the patient cannot take oral drugs, drug choices are narrowed because many commonly used drugs are not available in a dosage form that can be given parenterally, by gastrointestinal tube, or topically (e.g., like a clonidine skin patch). Thus, patients’ drug therapy must usually be re-titrated. In one way, this may be more difficult, because critically ill patients are often unstable in their conditions and responses to drug therapy. In another way, it may be easier in a critical care unit, where hemodynamic monitoring is commonly used. The goal of management is usually to maintain adequate tissue perfusion while avoiding both hypotension and hypertension.

Antihypertensive drugs are also used to treat hypertensive urgencies and emergencies, which involve dangerously high blood pressures and actual or potential damage to target organs. Although there are risks with severe hypertension, there are also risks associated with lowering blood pressure excessively or too rapidly, including stroke, myocardial infarction, and acute renal failure. Thus, the goal of management is usually to lower blood pressure over several minutes to several hours, with careful titration of drug dosage to avoid precipitous drops.

Urgencies can be treated with oral antihypertensive agents such as captopril 25 to 50 milligrams every 1 to 2 hours

or clonidine 0.2 milligrams initially, then 0.1 milligrams hourly until diastolic blood pressure falls below 110 mm Hg or 0.7 milligrams has been given.

A hypertensive emergency, defined as a diastolic pressure of 120 mm Hg or higher and target organ damage, requires an IV drug. The goal of management is usually to lower diastolic pressure to 100 to 110 mm Hg and maintain it there for several days to allow adjustment of the physiologic mechanisms that normally regulate blood pressure. Then, the blood pressure can be lowered to normotensive levels.

Several drugs can be given to treat a hypertensive emergency. Fenoldopam is a fast-acting drug indicated only for short-term use (<48 hours) in hospitalized patients. Dosage is calculated according to body weight and desired effects on blood pressure. Administration is by an infusion pump, with frequent monitoring of blood pressure. Nitroglycerin is especially beneficial in patients with both severe hypertension and myocardial ischemia. The dose is titrated according to blood pressure response and may range from 5 to 100 micrograms per minute. Tolerance develops to IV nitroglycerin over 24 to 48 hours. Nitroprusside, which has a rapid onset and short duration of action, is given as a continuous infusion at a rate of 0.5 to 8 micrograms per kilogram of body weight per minute. Intra-arterial blood pressure should be monitored during the infusion. Nitroprusside is metabolized to thiocyanate, and serum thiocyanate levels should be measured if the drug is given longer than 72 hours. The infusion should be stopped after 72 hours if the serum thiocyanate level is more than 12 milligrams per deciliter; it should be stopped at 48 hours in patients with renal impairment. Symptoms of thiocyanate toxicity (e.g., nausea, vomiting, muscle twitching or spasm, seizures) can be reversed with hemodialysis. Other drugs that may be used include IV hydralazine, labetalol, and nicardipine; see Table 52-1.

### Use in Home Care

Antihypertensive drugs are commonly self-administered in the home setting. The home care nurse is most likely to be involved when making home visits for other reasons. Whether the patient or another member of the household is taking antihypertensive medications, the home care nurse may be helpful in teaching about the drugs, monitoring for drug effects, and promoting compliance with the prescribed regimen (pharmacologic and lifestyle modifications).

Noncompliance with prescribed antihypertensive drug therapy is a major problem, and consequences may be catastrophic. The home care nurse is well situated to assess for actual or potential barriers to compliance. For example, several antihypertensive medications are quite expensive and patients may not take the drugs at all or they may take fewer than the prescribed number of doses. If the nurse’s assessment reveals this sort of situation, he or she may contact the prescribing health care provider and discuss the possibility of using less expensive drugs. If the provider is unwilling to try alternative drugs, the nurse may be able to identify resources for obtaining the needed medications.

## Use in Patients Taking Herbal and Dietary Supplements

Use of nonprescription herbal and dietary supplements is frequently not reported by the patient even though one third of adults in the United States use these agents. Significant interactions can occur between herbs or dietary supplements and prescribed drugs. Many nonprescription medications such as antihistamines, cold/cough preparations, and weight loss

products can decrease the effectiveness of antihypertensive drugs or worsen hypertension. Caffeine, by its stimulating effects, may increase blood pressure. Yohimbe, used to treat erectile dysfunction, is a central nervous system stimulant and can affect blood pressure.

### Applying Your Knowledge 52-3

Mr. Olms asks you why amlodipine was chosen to control his hypertension. What is the most appropriate response?

.....

## Nursing Actions Antihypertensive Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- Give oral captopril and moexipril on an empty stomach, 1 hour before meals.
- Give most other oral antihypertensives with or after food intake.
- Give angiotensin II receptor blockers with or without food.
- For intravenous injection of propranolol or labetalol, the patient should be attached to a cardiac monitor. In addition, parenteral atropine and isoproterenol (Isuprel) must be readily available.
- Give the first dose and the first increased dose of prazosin, doxazosin, and terazosin at bedtime.
- For administration of fenoldopam and nitroprusside, use the manufacturers' instructions to develop a unit protocol for preparation of infusion solutions, dosages, flow rates, durations of use, and monitoring of blood pressure during infusion.

#### 2. Observe for therapeutic effects

- Decreased blood pressure. The usual goal is a normal blood pressure (i.e., less than 140/90 mm Hg).

#### 3. Observe for adverse effects

- Orthostatic hypotension, dizziness, weakness
- Sodium and water retention; increased plasma volume; perhaps edema and weight gain
- Prolonged atrioventricular conduction, bradycardia
- Gastrointestinal disturbances, including nausea, vomiting, and diarrhea
- Mental depression (with reserpine)

### RATIONALE/EXPLANATION

Food decreases drug absorption.

To decrease gastric irritation

Food does not impair drug absorption.

For early detection and management of excessive myocardial depression and dysrhythmias. Atropine may be used to treat excessive bradycardia. Isoproterenol may be used to stimulate myocardial contractility and increase cardiac output. To prevent orthostatic hypotension and syncope

These drugs are used to lower blood pressure rapidly in hypertensive emergencies, usually in an emergency department or critical care unit. They also have specific requirements for preparation and administration. A protocol established beforehand can save valuable time in an emergency situation.

The choice of drugs and drug dosages often requires adjustment to maximize beneficial effects and minimize adverse effects. Thus, optimal therapeutic effects may not occur immediately after drug therapy is begun.

Adverse effects are most likely to occur in patients who are elderly, have impaired renal function, and are receiving multiple antihypertensive drugs or large doses of antihypertensive drugs.

This is an extension of the expected pharmacologic action. Orthostatic hypotension results from drug blockage of compensatory reflexes (vasoconstriction, decreased venous pooling in extremities and increased venous return to the heart) that normally maintain blood pressure in the upright position. This adverse reaction may be aggravated by other conditions that cause vasodilation (e.g., exercise, heat or hot weather, and alcohol consumption).

These effects result from decreased renal perfusion. This reaction can be prevented or minimized by concurrent administration of a diuretic.

Due to increased vagal tone and stimulation

These effects are more likely to occur with hydralazine, methyl dopa, propranolol, and captopril.

Apparently caused by decreased levels of catecholamines and serotonin in the brain

## Nursing Actions Antihypertensive Drugs (continued)

### NURSING ACTIONS

- f. Bronchospasm (with nonselective beta blockers)
- g. Hypertensive crisis (with abrupt withdrawal of clonidine or guanabenz)
- h. Cough and hyperkalemia with angiotensin-converting enzyme (ACE) inhibitors

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of antihypertensives:
  - (1) Other antihypertensive agents
  - (2) Alcohol, other central nervous system depressants (e.g., opioid analgesics, phenothiazine antipsychotics)
  - (3) Digoxin
- b. Drugs that *decrease* effects of antihypertensives:
  - (1) Adrenergics
  - (2) Antacids
  - (3) Nonsteroidal anti-inflammatory drugs, oral contraceptives

### RATIONALE/EXPLANATION

The drugs may cause bronchoconstriction and are contraindicated in patients with asthma and other bronchoconstrictive lung disorders.

This may be prevented by tapering dosage over several days before stopping the drug.

A chronic, nonproductive cough is a relatively common adverse effect; hyperkalemia occurs in 1%–4% of patients.

Combinations of two or three drugs with different mechanisms of action are often given for their additive effects and efficacy in controlling blood pressure when a single drug is ineffective.

These drugs have hypotensive effects when used alone and increased hypotension occurs when they are combined with antihypertensive drugs.

Additive bradycardia with beta blockers

These drugs stimulate the sympathetic nervous system and raise blood pressure. They include over-the-counter nasal decongestants, cold remedies, bronchodilators, and appetite suppressants.

May decrease bioavailability of ACE inhibitors, especially captopril. Give antacids 2 hours before or after ACE inhibitors. These drugs tend to increase blood pressure by causing retention of sodium and water.

## Key Concepts

- Hypertension is defined in adults as a systolic pressure above 140 mm Hg or a diastolic pressure above 90 mm Hg on multiple blood pressure measurements.
- Key behavioral determinants of blood pressure are related to dietary consumption of calories and salt; the prevalence of hypertension rises proportionally to average body mass index.
- Alpha<sub>1</sub>-adrenergic receptor blocking agents should be administered at bedtime to minimize the first-dose phenomenon.
- ACE inhibitors and ARBs are equally effective at controlling blood pressure.
- Beta-adrenergic blockers are the drugs of first choice for patients younger than 50 years of age with high-renin hypertension, tachycardia, angina pectoris, myocardial infarction, or left ventricular hypertrophy.
- In general, individuals with hypertension of Asian descent require much smaller doses of beta blockers because they metabolize and excrete the drugs slowly.
- African Americans are more likely to have severe hypertension and require multiple drugs as a result of having low circulating renin, increased salt sensitivity, and a higher incidence of obesity.
- The FDA has issued a **BLACK BOX WARNING** for patients with CAD withdrawing from oral forms of atenolol, metoprolol, nadolol, propranolol, and timolol; abrupt withdrawal has resulted in exacerbation of angina, the incidence of ventricular dysrhythmias, and the occurrence of MIs.
- The FDA has issued a **BLACK BOX WARNING** for ACE inhibitors and ARBs during pregnancy as their use can cause injury and even death to a developing fetus.
- The FDA has issued a **BLACK BOX WARNING** for minoxidil as the drug can exacerbate angina and precipitate effusion (which can progress to cardiac tamponade).

## Review and Application Exercises

### Short Answer Exercises

- Describe the physiologic mechanisms that control blood pressure.
- What are common factors that raise blood pressure?
- Why is it important to measure blood pressure accurately and repeatedly?
- How do ACE inhibitors, ARBs, alpha- and beta-adrenergic blockers, calcium channel blockers, and direct vasodilators lower blood pressure?
- What are adverse effects of each group of antihypertensive drugs, and how may they be prevented or minimized?
- List at least two major considerations in using antihypertensive drugs in children, older adults, and patients who have renal or hepatic impairment.
- How would you assess a patient being treated for hypertension for compliance with the prescribed lifestyle and drug therapy regimen?

### NCLEX-Style Questions

- In administering a newly initiated order for an ACE inhibitor to a patient, discharge instructions will include letting her know that which of the following is a common adverse reaction to therapy with an ACE inhibitor?
  - tinnitus
  - dry, nonproductive, persistent cough
  - muscle weakness
  - constipation
- A patient with a history of hypertension comes to the emergency department with double vision and a blood pressure of 240/120 mm Hg. The physician prescribes sodium nitroprusside (Nipress) by continuous infusion and continual blood pressure monitoring. The nurse understands that this drug's immediate action is to lower blood pressure by
  - increasing peripheral vascular resistance
  - increasing cardiac output
  - dilating venous and arterial vessels
  - decreasing heart rate
- Which of the following is indicated for initial drug therapy in a patient newly diagnosed with uncomplicated hypertension (stage 1)?
  - calcium channel blocker
  - potassium-sparing diuretic
  - direct-acting vasodilator
  - thiazide diuretic
- Orthostatic or postural hypotension is a potential outcome that places the elderly at risk for injury from falls. Instructions given to the patient to decrease this effect of antihypertensive therapy include
  - Take the dose in the early afternoon.
  - Change position slowly when rising from bed or chair.
  - Increase fluid intake by 500 mL/day.
  - Decrease the dose until symptoms disappear.
- Single-drug therapy with an ACE inhibitor would be least effective in
  - children
  - the elderly
  - Hispanics
  - African Americans

# Diuretics

## KEY TERMS

- Ceiling dose
- Convoluted tubules
- Edema
- Glomerular filtrate
- Hyperkalemia
- Hypokalemia
- Loop diuretics
- Nephron
- Osmotic diuretics
- Ototoxic
- Potassium-sparing diuretics
- Thiazides

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. List characteristics of diuretics in terms of mechanism of action, indications for use, principles of therapy, and nursing process implications.
2. Discuss major adverse effects of thiazide, loop, and potassium-sparing diuretics.
3. Identify patients at risk for developing adverse reactions to diuretic administration.
4. Recognize commonly used potassium-losing and potassium-sparing diuretics.
5. Discuss the rationale for using combination products containing a potassium-losing and a potassium-sparing diuretic.
6. Discuss the rationale for concomitant use of a loop diuretic and a thiazide or related diuretic.
7. Teach patients to manage diuretic therapy effectively.
8. Discuss important elements of diuretic therapy in special populations.

## Applying Your Knowledge

Agnes Bass is a 68-year-old woman who has lower-leg edema. She is being treated with furosemide 40 mg PO daily.

### Introduction

Diuretics are drugs that increase renal excretion of water, sodium, and other electrolytes, thereby increasing urine formation and output. They are important therapeutic agents widely used in the management of both edematous (e.g., heart failure, renal and hepatic disease) and nonedematous (e.g., hypertension, ophthalmic surgery) conditions. Diuretics are also useful in preventing renal failure by their ability to sustain urine flow. To aid understanding of diuretic drug therapy, renal physiology related to drug action and characteristics of edema are reviewed.

### Renal Physiology

The primary function of the kidneys is to regulate the volume, composition, and pH of body fluids. The kidneys receive approximately 25% of the cardiac output. From this large amount of blood flow, the normally functioning kidney is efficient in retaining substances needed by the body and eliminating those not needed.

## The Nephron

The *nephron* is the functional unit of the kidney; each kidney contains approximately 1 million nephrons. Each nephron is composed of a glomerulus and a tubule (Fig. 53-1). The glomerulus is a network of capillaries that receives blood from the renal artery. Bowman's capsule is a thin-walled structure that surrounds the glomerulus, then narrows and continues as the tubule. The tubule is a thin-walled structure of epithelial cells surrounded by peritubular capillaries. The tubule is divided into three main segments, the proximal tubule, loop of Henle, and distal tubule, which differ in structure and function. The tubules are often called *convoluted tubules* because of their many twists and turns. The convolutions provide a large surface area that brings the blood flowing through the peritubular capillaries and the glomerular filtrate flowing through the tubular lumen into close proximity. Consequently, substances can be readily exchanged through the walls of the tubules.

The nephron functions by three processes: glomerular filtration, tubular reabsorption, and tubular secretion. These processes normally maintain the fluid volume, electrolyte concentration, and pH of body fluids within a relatively narrow range. They also remove waste products of cellular metabolism. A minimum daily urine output of approximately 400 milliliters is required to remove normal amounts of metabolic end products.

### Glomerular Filtration

Arterial blood enters the glomerulus by the afferent arteriole at the relatively high pressure of approximately 70 mm Hg. This pressure pushes water, electrolytes, and other solutes out of the capillaries into Bowman's capsule and then to the proximal tubule. This fluid, called *glomerular filtrate*, contains the same components as blood except for blood cells, fats, and proteins that are too large to be filtered.

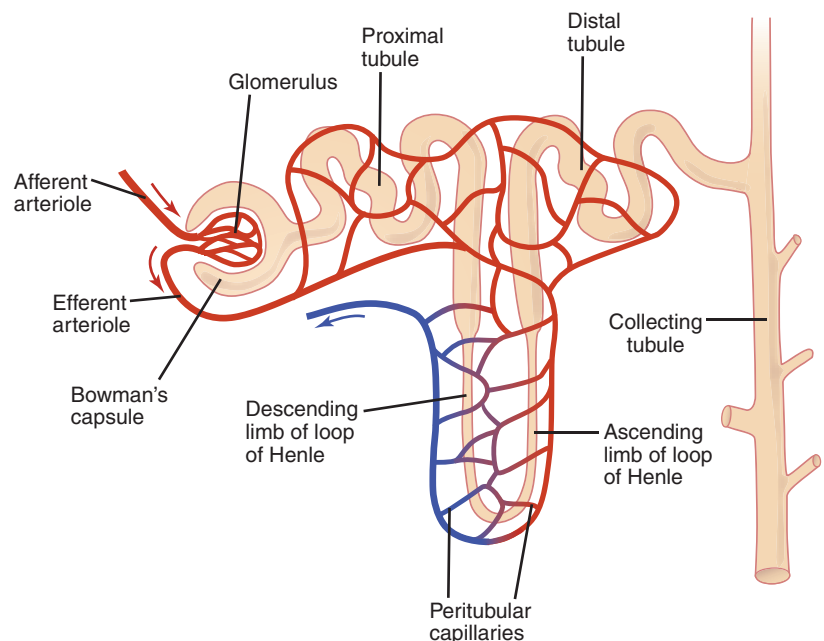

The glomerular filtration rate (GFR) is about 180 liters per day, or 125 milliliters per minute. Most of this fluid is reabsorbed as the glomerular filtrate travels through the tubules. The end product is about 2 liters of urine daily. Because filtration is a nonselective process, the reabsorption and secretion processes determine the composition of the urine. After it is formed, urine flows into collecting tubules, which carry it to the renal pelvis, then through the ureters, bladder, and urethra for elimination from the body.

Blood that does not become part of the glomerular filtrate leaves the glomerulus through the efferent arteriole. The efferent arteriole branches into the peritubular capillaries that eventually empty into veins, which return the blood to systemic circulation.

### Tubular Reabsorption

The term *reabsorption*, in relation to renal function, indicates movement of substances from the tubule (glomerular filtrate) to the blood in the peritubular capillaries. Most reabsorption occurs in the proximal tubule. Almost all glucose and amino acids are reabsorbed; about 80% of water, sodium, potassium, chloride, and most other substances is reabsorbed. As a result, about 20% of the glomerular filtrate enters the loop of Henle. In the descending limb of the loop of Henle, water is reabsorbed; in the ascending limb, sodium is reabsorbed. A large fraction of the total amount of sodium (up to 30%) filtered by the glomeruli is reabsorbed in the loop of Henle. Additional sodium is reabsorbed in the distal tubule, primarily by the exchange of sodium ions for potassium ions secreted by epithelial cells of tubular walls. Final reabsorption of water occurs in the distal tubule and small collecting tubules. The remaining water and solutes are now appropriately called urine.

Antidiuretic hormone from the posterior pituitary gland promotes reabsorption of water from the distal tubules and the

**Figure 53-1** ■ The nephron is the functional unit of the kidney.

collecting ducts of the kidneys. This conserves water needed by the body and produces more concentrated urine. Aldosterone, a hormone from the adrenal cortex, promotes sodium–potassium exchange mainly in the distal tubule and collecting ducts. Thus, aldosterone promotes sodium reabsorption and potassium loss.

### Tubular Secretion

The term *secretion*, in relation to renal function, indicates movement of substances from blood in the peritubular capillaries to glomerular filtrate flowing through the renal tubules. Secretion occurs in the proximal and distal tubules, across the epithelial cells that line the tubules. In the proximal tubule, uric acid, creatinine, hydrogen ions, and ammonia are secreted; in the distal tubule, potassium ions, hydrogen ions, and ammonia are secreted. Secretion of hydrogen ions is important in maintaining acid–base balance in body fluids.

### Alterations in Renal Function

Many clinical conditions alter renal function. In some conditions, excessive amounts of substances (e.g., sodium, water) are retained; in others, needed substances (e.g., potassium, proteins) are eliminated. These conditions include cardiovascular, renal, hepatic, and other disorders that may be managed with diuretic drugs.

### Edema

*Edema* is the excessive accumulation of fluid in body tissues. It is a symptom of many disease processes and may occur in any part of the body. Additional characteristics include the following:

- Edema formation results from one or more of the following mechanisms that allow fluid to leave the bloodstream (intravascular compartment) and enter interstitial (third) spaces:
  - Increased capillary permeability occurs as part of the response to tissue injury. Thus, edema may occur with burns and trauma or allergic and inflammatory reactions.
  - Increased capillary hydrostatic pressure results from a sequence of events in which increased blood volume (from fluid overload or sodium and water retention) or obstruction of venous blood flow causes a high venous pressure and a high capillary pressure. This is the primary mechanism for edema formation in heart failure, pulmonary edema, and renal failure.
  - Decreased plasma oncotic pressure may occur with decreased synthesis of plasma proteins (caused by liver disease or malnutrition) or increased loss of plasma proteins (caused by burn injuries or the nephrotic syndrome). Plasma proteins are important in keeping fluids within the bloodstream. When plasma proteins are lacking, fluid seeps through the capillaries and accumulates in tissues.
- Edema interferes with blood flow to tissues. Thus, it interferes with delivery of oxygen and nutrients and removal of

metabolic waste products. If severe, edema may distort body features, impair movement, and interfere with activities of daily living.

- Specific manifestations of edema are determined by its location and extent. A common type of localized edema occurs in the feet and ankles (dependent edema), especially with prolonged sitting or standing. A less common but more severe type of localized edema is pulmonary edema, a life-threatening condition that occurs with circulatory overload (e.g., of intravenous [IV] fluids, blood transfusions) or acute heart failure. Generalized massive edema (anasarca) interferes with the functions of many body organs and tissues.

## General Characteristics of Diuretic Drugs

Diuretic drugs act on the kidneys to decrease reabsorption of sodium, chloride, water, and other substances. Major subclasses are the thiazides and related diuretics, loop diuretics, and potassium-sparing diuretics, which act at different sites in the nephron (Fig. 53-2).

Major clinical indications for diuretics are edema, heart failure, and hypertension. In edematous states, diuretics mobilize tissue fluids by decreasing plasma volume. In hypertension, the exact mechanism by which diuretics lower blood pressure is unknown, but antihypertensive action is usually attributed to sodium depletion. Initially, diuretics decrease blood volume and cardiac output. With chronic use, cardiac output returns to normal, but there is a persistent decrease in plasma volume and peripheral vascular resistance. Sodium depletion may have a vasodilating effect on arterioles.

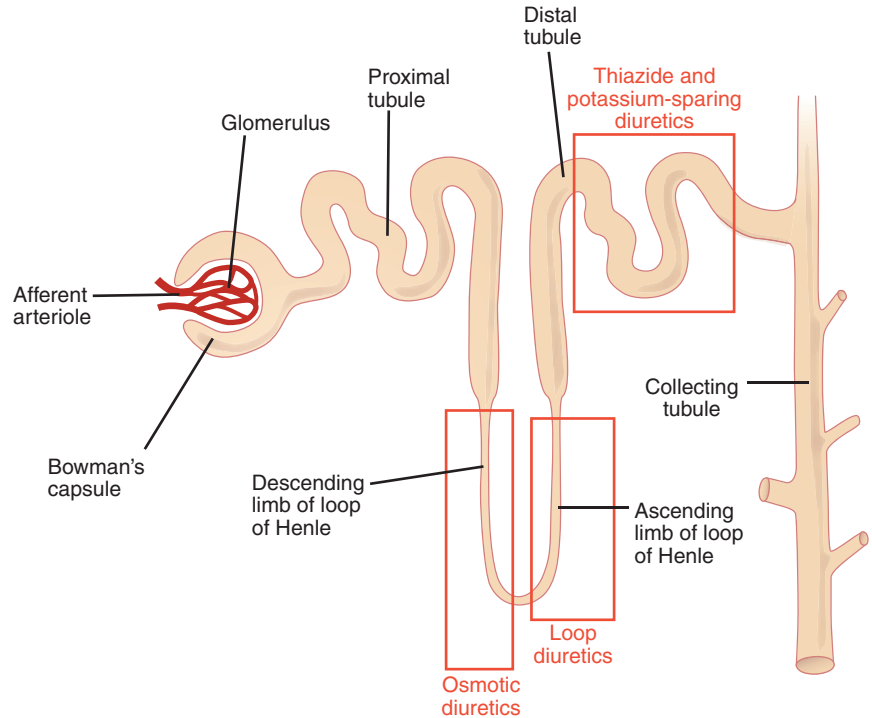

The use of diuretic agents in the management of heart failure and hypertension is discussed further in Chapters 48 and 52, respectively. Types of diuretics are described in the following section, and individual drugs are listed in Table 53-1.

## Types of Diuretics and Individual Drugs

### Thiazide and Related Diuretics

Thiazide diuretics are synthetic drugs that are chemically related to the sulfonamides and differ mainly in their duration of action. **Hydrochlorothiazide** is the most commonly used; chlorothiazide is the only one that can be given IV. Related diuretics are nonthiazides whose pharmacologic actions are essentially the same as those of the thiazides; they include chlorthalidone, and metolazone.

*Thiazides* and related diuretics are frequently prescribed in the long-term management of heart failure and hypertension. They act to decrease reabsorption of sodium, water, chloride, and bicarbonate in the distal convoluted tubule. Most sodium

**Figure 53-2** ■ Diuretic sites of action in the nephron. Diuretics act at different sites in the nephron to decrease reabsorption of sodium and water and to increase urine output.

is reabsorbed before it reaches the distal convoluted tubule and only a small amount is reabsorbed at this site. Thus, these drugs are not strong diuretics. In addition, they are ineffective when immediate diuresis is required (because of their slow onset of action) and relatively ineffective with decreased renal function. They work efficiently only when urine flow is adequate.

A dose of diuretic that yields a near-maximum diuretic response is called the *ceiling dose* or threshold. The ceiling dose is dependent on the type of diuretic and the extent of an individual's disease. Thiazide diuretics have a ceiling threshold. As the maximum effect is reached, a subsequent increase in dose does not enhance efficacy. In addition, there is a direct correlation between the dosage increase and the possible onset of adverse effects. When the diuretic dose is less than at ceiling, postdiuresis fluid retention results.

These drugs are well absorbed, widely distributed in body fluids, and highly bound to plasma proteins. They accumulate only in the kidneys. Diuretic effects usually occur within 2 hours, peak at 4 to 6 hours, and last 6 to 24 hours. Antihypertensive effects usually last long enough to allow use of a single daily dose. Most of the drugs are excreted unchanged by the kidneys within 3 to 6 hours; some (e.g., chlorthalidone) have longer durations of action (48–72 hours), attributed to slower excretion.

Thiazides and related drugs must be used cautiously in patients allergic to sulfonamide drugs as there is a known cross-sensitivity of some sulfonamide-allergic patients to a sulfonamide nonantibiotic. They must be used cautiously during pregnancy because they cross the placenta and may have adverse effects on the fetus by compromising placental perfusion.

## Loop Diuretics

*Loop diuretics* inhibit sodium and chloride reabsorption in the ascending limb of the loop of Henle, where reabsorption of most filtered sodium occurs. Thus, these potent drugs produce significant diuresis, their sodium-losing effect being up to 10 times greater than that of thiazide diuretics. Dosage can be titrated upward as needed to produce greater diuretic effects. Overall, loop diuretics are the most effective and versatile diuretics available for clinical use.

Loop diuretics may be given orally or IV. After oral administration, diuretic effects occur within 30 to 60 minutes, peak in 1 to 2 hours, and last 6 to 8 hours. After IV administration, diuretic effects occur within 5 minutes, peak within 30 minutes, and last about 2 hours. Thus, the drugs produce extensive diuresis for short periods, after which the kidney tubules regain their ability to reabsorb sodium. Actually, the kidneys reabsorb more sodium than usual during this postdiuretic phase, so a high dietary intake of sodium can cause sodium retention and reduce or cancel the diuretic-induced sodium loss. Thus, dietary sodium restriction is required to achieve optimum therapeutic benefits. The drugs are metabolized and excreted by the kidneys, and drug accumulation does not occur even with repeated doses.

Loop diuretics are the diuretics of choice when rapid effects are required (e.g., in pulmonary edema) and when renal function is impaired (creatinine clearance < 30 mL/min). The drugs are contraindicated during pregnancy unless absolutely necessary. The pharmacologic characteristics of all loop diuretics are similar; use of another loop diuretic after a lack of response to one loop diuretic at adequate doses is not

Table 53-1

## Drugs at a Glance: Diuretic Agents

Generic (trade) Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Thiazide and Related Diuretics</b>		
<b>Chlorothiazide</b> (Diuril)	PO 500–2000 mg/d divided in 1 to 2 times doses Elderly, PO 500 mg once daily or 1 g 3 times/wk IV 250–1000 mg once or twice daily; maximum dose 1000 mg	PO 22 mg/kg/d in 2 divided doses Infants <6 mo, 20–40 mg/kg/d in 2 divided doses; maximum dose 375 mg/d IV dosing not well established
<b>Chlorthalidone</b> (Hygroton, Thalitone)	PO 25–100 mg/d Elderly, PO 12.5–25 mg/d or every other day	Not approved in children
<b>Hydrochlorothiazide</b> (Esidrix, Oretic)	Edema: PO 25–100 mg/d; maximum dose 200 mg/d Hypertension: PO 12.5–50 mg 1 or 2 times daily Elderly, PO 12.5–25 mg/d	PO 2 mg/kg/d in two divided doses Infants <6 mo, 2–3 mg/kg/d in 2 divided doses
<b>Indapamide</b> (Lozol)	Edema: PO 2.5–5 mg/d Hypertension: PO 1.25 mg in morning may increase to 5 mg/d	Dosage not established
<b>Metolazone</b> (Zaroxolyn)	Edema: PO 2.5–20 mg/d, depending on severity of condition and response Hypertension: 2.5 mg/d Elderly: 2.5 mg/d or every other day	Dosage not established
<b>Loop Diuretics</b>		
<b>Bumetanide</b> (Bumex)	PO 0.5–2 mg daily as a single dose. May be repeated q4–6h to a maximal dose of 10 mg, if necessary. Giving on alternate days or for 3–4 d with rest periods of 1–2 d is recommended for long-term control of edema. IV, IM 0.5–1 mg, repeated in 2–3 h if necessary, to a maximal daily dose of 10 mg. Give IV injections over 1–2 min.	Not recommended for children <18 y
<b>Ethacrynic acid</b> (Edecrin)	Edema, PO 50–100 mg daily, increased or decreased according to severity of condition and response. Maximal daily dose, 400 mg Rapid mobilization of edema, IV 50 mg or 0.5–1 mg/kg injected slowly to a maximum of 100 mg/dose	PO 25 mg daily No recommended parenteral dose in children
<b>P Furosemide</b> (Lasix)	Edema, PO 20–80 mg as a single dose initially. If an adequate diuretic response is not obtained, dosage may be gradually increased by 20- to 40-mg increments at intervals of 6–8 h. For maintenance, dosage range and frequency of administration vary widely and must be individualized. Maximal daily dose, 600 mg Hypertension, PO 40 mg twice daily, gradually increased if necessary Rapid mobilization of edema, IV 20–40 mg initially, injected slowly. This dose may be repeated in 2 h. With acute pulmonary edema, initial dose is usually 40 mg, which may be repeated in 60–90 min.	PO 2 mg/kg 1 or 2 times daily initially, gradually increased by increments of 1–2 mg/kg per dose if necessary at intervals of 6–8 h. Maximal daily dose, 6 mg/kg IV 1 mg/kg initially. If diuretic response is not adequate, increase dosage by 1 mg/kg no sooner than 2 h after previous dose. Maximal dose, 6 mg/kg

ROUTES AND DOSAGE RANGES		
Generic (trade) Name	Adults	Children
	Acute renal failure, IV 40 mg initially, increased if necessary. Maximum dose, 1–2 g/24 h Hypertensive crisis, IV 40–80 mg injected over 1–2 min. With renal failure, much larger doses may be needed.	
<b>Torsemide</b> (Demadex)	PO, IV 5–20 mg once daily	
<b>Potassium-Sparing Diuretics</b>		
<b>Amiloride</b> (Midamor)	PO 5–20 mg daily	Dosage not established
<b>Spirolactone</b> (Aldactone)	PO 25–200 mg daily	PO 3.3 mg/kg/d in divided doses
<b>Triamterene</b> (Dyrenium)	PO 100–300 mg daily in divided doses	PO 2–4 mg/kg/d in divided doses
<b>Osmotic Agents</b>		
<b>Glycerin</b> (Osmoglyn)	PO 1–1.5 g/kg of body weight, usually given as a 50% or 75% solution, 1–2 h before ocular surgery	Same as adults
<b>Mannitol</b> (Osmitol)	Diuresis, IV infusion 50–200 g over 24 h, flow rate adjusted to maintain a urine output of 30–50 mL/h Oliguria and prevention of renal failure, IV 50–100 g Reduction of intracranial or intraocular pressure, IV 1.5–2 g/kg, given as a 20% solution, over 30–60 min	Same as adults

indicated. Instead, combining diuretics with different sites of action should be considered if aggressive diuresis is required.

**P Furosemide** is the most commonly used loop diuretic and serves as the prototype for the group. **Bumetanide** may be used to produce diuresis in some patients who are allergic to or no longer respond to furosemide. It is more potent than furosemide on a drug weight basis, and large doses can be given in small volumes. These drugs differ mainly in potency and produce similar effects at equivalent doses (e.g., furosemide 40 mg = bumetanide 1 mg).

### Potassium-Sparing Diuretics

Sodium is normally reabsorbed in the distal tubule in exchange for potassium and hydrogen ions. *Potassium-sparing diuretics* act at the distal tubule to decrease sodium reabsorption and potassium excretion. This group includes three drugs. One is **spironolactone**, an aldosterone antagonist. Aldosterone is a hormone secreted by the adrenal cortex. It promotes retention of sodium and water and excretion of potassium by stimulating the sodium–potassium exchange mechanism in the distal tubule. Spironolactone blocks the sodium-retaining effects of aldosterone, and aldosterone must be present for spironolactone to be effective. The other two drugs, **amiloride** and **triamterene**, act directly on the distal tubule to decrease the exchange of sodium for potassium, and have similar diuretic activity.

Potassium-sparing diuretics are weak diuretics when used alone. Thus, they are usually given in combination with

potassium-losing diuretics to increase diuretic activity and decrease potassium loss. They are contraindicated in the presence of renal insufficiency because their use may cause hyperkalemia through the inhibition of aldosterone and subsequent retention of potassium. Hyperkalemia is the major adverse effect of these drugs; patients receiving potassium-sparing diuretics should *not* be given potassium supplements and *should not be* encouraged to eat foods high in potassium or allowed to use salt substitutes. Salt substitutes contain potassium chloride rather than sodium chloride.

### Osmotic Diuretics

*Osmotic diuretics* produce rapid diuresis by increasing the solute load (osmotic pressure) of the glomerular filtrate. The increased osmotic pressure causes water to be pulled from extravascular sites into the bloodstream, thereby increasing blood volume and decreasing reabsorption of water and electrolytes in the renal tubules. **Mannitol** is useful in managing oliguria or anuria, and it may prevent acute renal failure during prolonged surgery, trauma, or infusion of cisplatin, an antineoplastic agent. Mannitol is effective even when renal circulation and GFR are reduced (e.g., in hypovolemic shock, trauma, dehydration). Other important clinical uses of hyperosmolar agents include reduction of intracranial pressure before or after neurosurgery, reduction of intraocular pressure before certain types of ophthalmic surgery, and urinary excretion of toxic substances. Further information is found in Table 53-1.

Table 53-2

## Drugs at a Glance: Combination Diuretic Products

TRADE NAME	THIAZIDE (POTASSIUM-LOSING) DIURETIC	POTASSIUM-SPARING DIURETIC	ADULT DOSAGE
<b>Aldactazide</b> 25/25	HCTZ 25 mg	Spironolactone 25 mg	PO 1–8 tablets daily
<b>Aldactazide</b> 50/50	HCTZ 50 mg	Spironolactone 50 mg	PO 1–4 tablets daily
<b>Dyazide, Maxzide</b> 25 mg	HCTZ 25 mg	Triamterene 37.5 mg	Hypertension, PO 1 capsule bid initially, then adjusted according to response Edema, PO 1–2 capsules bid
<b>Maxzide</b>	HCTZ 50 mg	Triamterene 75 mg	PO 1 tablet daily
<b>Moduretic</b>	HCTZ 50 mg	Amiloride 5 mg	PO 1–2 tablets daily with meals

bid, twice a day; HCTZ, hydrochlorothiazide.

### Combination Products

Thiazide and related diuretics are available in numerous fixed-dose combinations with nondiuretic antihypertensive agents (see Chap. 52) and with potassium-sparing diuretics (see Table 53-2 for combination diuretic products). A major purpose of the antihypertensive combinations is to increase patient convenience and compliance with drug therapy regimens. A major purpose of the diuretic combinations is to prevent potassium imbalances.

#### Applying Your Knowledge 53-1

While caring for Ms. Bass, she tells you that she enjoys snacks like potato chips and pretzels. What response would you have?

#### Applying Your Knowledge 53-2

Ms. Bass has spironolactone added to her treatment regimen to increase diuresis. Why was this added to her regimen instead of increasing her dose of furosemide?

## Nursing Process

### Assessment

Assess the patient's status in relation to baseline data and conditions in which diuretic drugs are used.

- Useful baseline data include serum electrolytes, creatinine, glucose, blood urea nitrogen (BUN), and uric acid, because diuretics may alter these values. Other data are

blood pressure readings, weight, amount and appearance of urine output, and measurement of edematous areas such as ankles or abdomen.

- Observe for edema. Visible edema often occurs in the feet and legs of ambulatory patients. Rapid weight gain may indicate fluid retention.
  - With heart failure, numerous signs and symptoms result from edema of various organs and tissues. For example, congestion in the gastrointestinal (GI) tract may cause nausea and vomiting; liver congestion may cause abdominal pain and tenderness; and congestion in the lungs (pulmonary edema) causes rapid, labored breathing; hypoxemia; frothy sputum; and other manifestations of severe respiratory distress.
  - Cerebral edema may be manifested by confusion, headache, dizziness, convulsions, unconsciousness, bradycardia, or failure of the pupils to react to light.
  - Ascites, which occurs with hepatic cirrhosis, is an accumulation of fluid in the abdominal cavity. The abdomen appears much enlarged.
- With heart failure, fatigue and dyspnea, in addition to edema, are common symptoms.
- Hypertension (blood pressure greater than 140/90 mm Hg on several measurements) may be the only clinical manifestation present.

### Nursing Diagnoses

- Excess Fluid Volume in edematous patients, related to retention of sodium and water
- Deficient Fluid Volume related to increased diuresis during diuretic drug therapy

- **Imbalanced Nutrition: Less Than Body Requirements** related to excessive loss of potassium with thiazide and loop diuretics
- **Risk for Injury: Hypotension and dizziness** as adverse drug effects
- **Deficient Knowledge** related to the need for and correct use of diuretics
- **Sexual Dysfunction** related to adverse drug effects

## Planning/Goals

### The patient will

- Take or receive diuretic drugs as prescribed
- Experience reduced edema and improved control of blood pressure
- Reduce dietary intake of sodium and increase dietary intake of potassium
- Avoid preventable adverse drug effects
- Keep appointments for follow-up monitoring of blood pressure, edema, and serum electrolytes

## Interventions

Promote measures to prevent or minimize conditions for which diuretic drugs are used.

- With edema, helpful measures include the following:
  - Decreasing dietary sodium intake
  - Losing weight, if obese
  - Elevating legs when sitting
  - Avoiding prolonged standing or sitting
  - Wearing support hose or elastic stockings
  - Treating the condition causing edema
- With heart failure and in older adults, administer IV fluids or blood transfusions carefully to avoid fluid overload and pulmonary edema. Fluid overload may occur with rapid administration or excessive amounts of IV fluids.
- With hypertension, helpful measures include decreasing dietary sodium intake, exercising regularly, and losing weight, if obese.
- With edematous patients, interventions to monitor fluid losses include weighing under standardized conditions, measuring urine output, and measuring edematous sites such as the ankles or the abdomen. After the patient reaches “dry weight,” these measurements stabilize and can be done less often.
- With patients who are taking digoxin, a potassium-losing diuretic, and a potassium supplement, help them understand that the drugs act together to increase therapeutic effectiveness and avoid adverse effects (e.g., hypokalemia, digoxin toxicity). Thus, stopping or changing dosage of one of these drugs can lead to serious illness.

Provide patient teaching regarding drug therapy (see accompanying display).

## Evaluation

- Observe for reduced edema and body weight.
- Observe for reduced blood pressure.
- Observe for increased urine output.
- Monitor serum electrolytes for normal values.
- Interview regarding compliance with instructions for diet and drug therapy.
- Monitor compliance with follow-up appointments in outpatients.

## Principles of Therapy

### Drug Selection

The choice of diuretic drug depends primarily on the patient's condition.

- **Thiazides and related diuretics** are the drugs of choice for most patients who require diuretic therapy, especially for long-term management of heart failure and hypertension. All the drugs in this group have similar effects. For most patients, hydrochlorothiazide is effective.
- A **loop diuretic** (e.g., furosemide) is preferred when rapid diuretic effects are required or when renal impairment is present.
- A **potassium-sparing diuretic** may be given concurrently with a potassium-losing diuretic to prevent or manage hypokalemia and to augment the diuretic effect. The two drugs can be given separately or in a fixed-dose combination product (see Table 53-2).
- Two **potassium-losing diuretics** are sometimes given concurrently when an inadequate diuretic response occurs with one of the drugs. The combination of a loop and a thiazide diuretic has synergistic effects because the drugs act in different segments of the renal tubule. The synergistic effects probably result from the increased delivery of sodium to the distal tubule (where thiazides act) because a loop diuretic blocks sodium reabsorption in the loop of Henle. A commonly used combination is furosemide and hydrochlorothiazide (chlorothiazide can be given IV in patients who are unable to take an oral drug). Furosemide and metolazone have also been used. Because a thiazide–loop diuretic combination can induce profound diuresis, with severe sodium, potassium, and volume depletion, its use should be reserved for hospitalized patients who can be closely monitored. If used for ambulatory patients, the thiazide diuretic should be given in very low doses or only occasionally to avoid serious adverse events.

### Drug Dosage and Administration

Dosage of diuretics depends largely on the patient's condition and response and should be individualized to administer the minimal effective amount.

## Patient Teaching Guidelines Diuretics

### General Considerations

- Diuretics increase urine output and are commonly used to manage hypertension, heart failure, and edema (swelling) from heart, kidney, liver, and other disorders.
- While taking a diuretic drug, you need to maintain regular medical supervision so drug effects can be monitored and dosages adjusted when indicated.
- Reducing sodium intake in your diet helps diuretic drugs be more effective and allows smaller doses to be taken. Smaller doses are less likely to cause adverse effects. Thus, you need to avoid excessive table salt and obviously salty foods (e.g., ham, packaged sandwich meats, potato chips, dill pickles, most canned soups). These foods may aggravate edema or hypertension by causing sodium and water retention.
- Diuretics may cause blood potassium imbalances, and either too little or too much damages heart function. Periodic measurements of blood potassium and other substances is one of the major reasons for regular visits to a health care provider.

Too little potassium (hypokalemia) may result from the use of potassium-losing diuretics such as hydrochlorothiazide, furosemide (Lasix), and several others. To prevent or treat hypokalemia, your doctor may prescribe a potassium chloride supplement or a combination of a potassium-losing and a potassium-saving diuretic (either separately or as a combined product such as Dyazide, Maxzide, or Aldactazide). He or she may also recommend increased dietary intake of potassium-containing foods (e.g., bananas, orange juice).

Too much potassium (hyperkalemia) can result from the use of potassium-saving diuretics, the overuse of potassium supplements, or from the use of salt substitutes. Potassium-saving diuretics are not a major cause of hyperkalemia because they are usually given along with a potassium-losing diuretic. If potassium supplements are prescribed, they should be taken as directed. You should **not** use salt substitutes without consulting your primary health care provider because they contain potassium chloride instead of sodium chloride. Hyperkalemia is most likely to occur in people with decreased kidney function, which often occurs in older adults and people with diabetes.

- With diuretic therapy, you will have increased urination, which usually lasts only a few days or weeks if you do not have edema. If you do have edema (e.g., in your ankles), you can expect weight loss and decreased swelling as well as increased urination. It is a good idea to check and record your weight 2 to 3 times per week (at same time of day with similar amount of clothing). Rapid changes in weight often indicate gain or loss of fluid.
- Some commonly used diuretics may increase blood sugar levels and cause or aggravate diabetes. If you have diabetes, you may need larger doses of your antidiabetic medications.
- Diuretics may cause sensitivity to sunlight. Thus, you need to avoid prolonged exposure to sunlight, use sunscreens, and wear protective clothing.
- Do not drink alcoholic beverages or take other medications without the approval of your health care provider.
- If you are taking a diuretic to lower your blood pressure, especially with other antihypertensive drugs, you may feel dizzy or faint when you stand up suddenly. This can be prevented or decreased by changing positions slowly. If dizziness is severe, notify your health care provider.

### Self- or Caregiver Administration

- Take or give a diuretic early in the day, if ordered daily, to decrease nighttime trips to the bathroom. Fewer bathroom trips means less interference with sleep and less risk of falls. Ask someone to help you to the bathroom if you are elderly, weak, dizzy, or unsteady in walking (or use a bedside commode).
- Take or give most diuretics with or after food to decrease stomach upset. Torsemide (Demadex) may be taken without regard to meals.
- If you are taking digoxin, a potassium-losing diuretic, and a potassium supplement, it is very important that you take these drugs as prescribed. This is a common combination of drugs for patients with heart failure and the drugs work together to increase beneficial effects and avoid adverse effects. Stopping or changing the dose of one of these medications while continuing the others can lead to serious illness.

- With hydrochlorothiazide, smaller doses (e.g., 12.5–25 mg daily) are effective for most people and produce fewer adverse effects (e.g., hypokalemia) than larger doses. Some of the fixed-dose combinations of hydrochlorothiazide and a potassium-sparing diuretic contain 50 mg of hydrochlorothiazide. As a result, despite the convenience of a combination product, it may be better to give the drugs separately so that dosage can be titrated to the patient's needs.
- Patients who do not achieve an adequate diuretic response with usual doses of an oral drug may need larger doses or an IV drug.
- With torsemide, which is highly bioavailable after oral administration, oral and IV doses are equivalent and patients may be switched from one route to the other without changing dosage.
- In liver disease, small doses of all diuretics are usually indicated because diuretic-induced electrolyte imbalances may precipitate or aggravate hepatic coma.
- In renal disease, furosemide is often given in large doses to achieve a diuretic response. Bumetanide may be a useful alternative, because it can be given in smaller dose volumes.
- When metolazone is given concurrently with furosemide, the initial dose is usually metolazone 2.5 to 10 mg. The dose is then doubled every 24 hours until the desired response is achieved. If an adequate diuretic effect occurs with the first dose of metolazone, the dose of furosemide can be decreased. Hydrochlorothiazide 50 mg may also be used with furosemide and may be safer than metolazone because of its shorter duration of action.

## Use in Edema

When diuretics are used to manage patients with edema, the underlying cause of the edema should be addressed, not just the edema itself. When treating such patients, it is preferable to aim for a weight loss of approximately 2 pounds (1 kg) per day. Rapid and excessive diuresis may cause dehydration and decreased blood volume with circulatory collapse. In some patients, giving a diuretic every other day or 3 to 5 days per week may be effective and is less likely to cause electrolyte imbalances.

## Use With Digoxin

When digoxin and diuretics are given concomitantly, as is common for patients with heart failure, the risk of digoxin toxicity is increased. Digoxin toxicity is related to diuretic-induced hypokalemia. Potassium is a myocardial depressant and antidysrhythmic; it has essentially opposite cardiac effects to those of digoxin. In other words, extracellular potassium decreases the excitability of myocardial tissue, but digoxin increases excitability. The higher the serum potassium, the less effective a given dose of digoxin will be. Conversely, decreased serum potassium increases the likelihood of digoxin-induced cardiac dysrhythmias, even with small doses and therapeutic serum levels of digoxin.

Supplemental potassium chloride, a potassium-sparing diuretic, and other measures to prevent hypokalemia are often used to maintain normal serum potassium levels (3.5–5.0 mEq/L).

## Prevention and Management of Potassium Imbalances

Potassium imbalances (see Chap. 57) may occur with diuretic therapy. Hypokalemia and hyperkalemia are cardiotoxic and should be prevented when possible.

- **Hypokalemia** (serum potassium level < 3.5 mEq/L) may occur with potassium-losing diuretics (e.g., hydrochlorothiazide, furosemide). Measures to prevent or manage hypokalemia include the following:
  - Giving low doses of the diuretic (e.g., 12.5–25 mg daily of hydrochlorothiazide)
  - Giving supplemental potassium, usually potassium chloride, in an average dosage range of 20 to 60 mEq daily. Sustained-release tablets are usually better tolerated than liquid preparations.
  - Giving a potassium-sparing diuretic along with the potassium-losing drug
  - Increasing food intake of potassium. Many texts advocate this approach as preferable to supplemental potassium or combination diuretic therapy, but its effectiveness is not clearly established. Although the minimal daily requirement of potassium is unknown, usual recommendations are 40 to 50 mEq daily for the healthy adult. Potassium loss with diuretic drugs may be several times this amount.

Some foods (e.g., bananas) have undeserved reputations for having high potassium content; actually, large amounts must be ingested. To provide 50 mEq of potassium daily, estimated amounts of certain foods include 1000 milliliters of orange juice, 1600 milliliters of apple or grape juice, 1200 milliliters of pineapple juice, four to six bananas, or 30 to 40 prunes. Some of these foods are high in calories and may be contraindicated, at least in large amounts, for obese patients. Also, the amount of carbohydrate in these foods may be a concern for patients with diabetes mellitus.

- Restricting dietary sodium intake. This reduces potassium loss by decreasing the amount of sodium available for exchange with potassium in renal tubules.
- **Hyperkalemia** (serum potassium level > 5 mEq/L) may occur with potassium-sparing diuretics. The following measures help prevent hyperkalemia:
  - Avoiding use of potassium-sparing diuretics and potassium supplements in patients with renal impairment
  - Avoiding excessive amounts of potassium chloride supplements
  - Avoiding salt substitutes
  - Maintaining urine output, the major route for eliminating potassium from the body

## Use in Special Populations

### Use in Children

Although they have not been extensively studied in children, diuretics are commonly used to manage heart failure, which often results from congenital heart disease; hypertension, which is usually related to cardiac or renal dysfunction; bronchopulmonary dysplasia and respiratory distress syndrome, which are often associated with pulmonary edema; and edema, which may occur with cardiac or renal disorders such as the nephrotic syndrome.

With most thiazides, safety and effectiveness have not been established for use in children. Hydrochlorothiazide is used in doses of approximately 2.2 milligrams per kilogram of body weight per day. IV chlorothiazide usually is not recommended. Thiazides do not commonly cause hyperglycemia, hyperuricemia, or hypercalcemia in children, as they do in adults.

Although metolazone, a thiazide-related drug, is not usually recommended, it is sometimes used. Metolazone has some advantages over a thiazide because it is a stronger diuretic, causes less hypokalemia, and can produce diuresis in renal failure. In children, it is most often used with furosemide, in which case it is most effective when given 30 to 60 minutes before the furosemide.

Furosemide is the loop diuretic used most often in children. Oral therapy is preferred when feasible, and doses above 6 milligrams per kilogram of body weight per day are not recommended. In preterm infants, furosemide stimulates production of prostaglandin E<sub>2</sub> in the kidneys and may increase the incidence of patent ductus arteriosus and neonatal respiratory

distress syndrome. In neonates, furosemide may be given with indomethacin to prevent nonsteroidal anti-inflammatory drug–induced nephrotoxicity during therapeutic closure of a patent ductus arteriosus. In both preterm and full-term infants, furosemide half-life is prolonged but becomes shorter as renal and hepatic functions develop.

Adverse effects of furosemide include fluid and electrolyte imbalances (e.g., hyponatremia, hypokalemia, fluid volume deficit) and ototoxicity. Serum electrolytes should be closely monitored in children because of frequent changes in kidney function and fluid distribution associated with growth and development. Ototoxicity, which is associated with high plasma drug levels (>50 mcg/mL), can usually be avoided by dividing oral doses and by slow injection or continuous infusion of IV doses.

Safety and effectiveness of bumetanide and torsemide have not been established. However, bumetanide may cause less ototoxicity and thus may be preferred for children who are taking other *ototoxic* drugs (e.g., premature and ill neonates are often given gentamicin, an aminoglycoside antibiotic). Bumetanide may also cause less hypokalemia. The half-life of bumetanide is about 2 hours in critically ill infants and 1 hour in children.

Spironolactone is the most widely used potassium-sparing diuretic in children. It is used with other diuretics to decrease potassium loss and hypokalemia. Spironolactone accumulates in renal failure, and dosage should be reduced. It usually should not be used in severe renal failure.

### Use in Older Adults

Thiazide diuretics are often prescribed for the management of hypertension and heart failure, which are common in older adults. Older adults are especially sensitive to adverse drug effects, such as hypotension and electrolyte imbalance. Thiazides may aggravate renal or hepatic impairment. With rapid or excessive diuresis, myocardial infarction, renal impairment, or cerebral thrombosis may occur from fluid volume depletion and hypotension. The smallest effective dose is recommended, usually a daily dose of 12.5 to 25 milligrams of hydrochlorothiazide or equivalent doses of other thiazides and related drugs. Risks of adverse effects may exceed benefits at doses of hydrochlorothiazide greater than 25 milligrams.

With loop diuretics, older adults are at greater risk of excessive diuresis, hypotension, fluid volume deficit, and possibly thrombosis or embolism. Rapid diuresis may cause urinary incontinence. With potassium-sparing diuretics, hyperkalemia is more likely to occur in older adults because of the renal impairment that occurs with aging.

### Use in Patients With Renal Impairment

Most patients with renal impairment require diuretics as part of their drug therapy regimens. In these patients, the diuretic response may be reduced and edema of the GI tract may limit absorption of oral medications.

Thiazides may be useful in managing edema due to renal disorders such as nephrotic syndrome and acute glomerulonephritis. However, their effectiveness decreases as the GFR

decreases, and the drugs become ineffective when the GFR is less than 30 milliliters per minute. The drugs may accumulate and increase adverse effects in patients with impaired renal function. Thus, renal function tests should be performed periodically. If progressive renal impairment becomes evident (e.g., a rising serum creatinine or BUN), a thiazide usually should be discontinued and metolazone, indapamide, or a loop diuretic may be given. Metolazone and indapamide are thiazide-related diuretics that may be effective in patients with significantly impaired renal function.

Loop diuretics are effective in patients with renal impairment. However, in chronic renal failure, they have lower peak concentrations at their site of action, which decreases diuresis. Renal elimination of the drugs is also prolonged. If renal dysfunction becomes more severe during treatment (e.g., oliguria, increases in BUN or creatinine), the diuretic may need to be discontinued. If high doses of furosemide are used, a volume-controlled IV infusion at a rate of 4 milligrams or less per minute may be used. For continuous infusion, furosemide should be mixed with normal saline or lactated Ringer's solution because D5W may accelerate degradation of furosemide. If IV bumetanide is given to patients with chronic renal impairment, a continuous infusion (e.g., 12 mg over 12 hours) produces more diuresis than equivalent-dose intermittent injections. Continuous infusion also produces lower serum drug levels and therefore may decrease adverse effects.

Potassium-sparing diuretics are contraindicated in patients with renal impairment because of the high risk of hyperkalemia. If they are used at all, frequent monitoring of serum electrolytes, creatinine, and BUN is needed.

### Use in Patients With Hepatic Impairment

Diuretics are often used to manage edema and ascites in patients with hepatic impairment. These drugs must be used with caution because diuretic-induced fluid and electrolyte imbalances may precipitate or worsen hepatic encephalopathy and coma. In patients with cirrhosis, diuretic therapy should be initiated in a hospital setting, with small doses and careful monitoring. To prevent hypokalemia and metabolic alkalosis, supplemental potassium or spironolactone may be needed.

### Use in Patients With Critical Illness

Fast-acting, potent diuretics such as furosemide and bumetanide are the most likely diuretics to be used in critically ill patients (e.g., those with pulmonary edema). In patients with severe renal impairment, high doses are required to produce diuresis. Large doses may produce fluid volume depletion and worsen renal function. Although IV bolus doses of the drugs are often given, continuous IV infusions may be more effective and less likely to produce adverse effects in critically ill patients.

### Use in Home Care

Diuretics are often taken in the home setting. The home care nurse may need to assist patients and caregivers in using the

drugs safely and effectively, monitor patient responses (e.g., with each home visit, assess nutritional status, blood pressure, weight, use of over-the-counter medications that may aggravate edema or hypertension), and provide information as indicated. In some cases, the home care nurse may need to assist the patient in obtaining medications or blood for blood tests (e.g., serum potassium levels).

### Applying Your Knowledge 53-3

#### How Can You Avoid This Medication Error?

The physician orders an extra dose of furosemide 20 mg IV for Ms. Bass, to be given now. You prepare the injection and administer it over 15 seconds.

## Nursing Actions Diuretics

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give in the early morning if ordered daily.
- b. Take safety precautions. Keep a bedpan or urinal within reach. Keep the call light within reach, and be sure the patient knows how to use it. Assist to the bathroom anyone who is elderly, weak, dizzy, or unsteady in walking.
- c. Give amiloride and triamterene with or after food.
- d. Give intravenous (IV) injections of furosemide and bumetanide over 1–2 minutes; give torsemide over 2 minutes.
- e. Give high-dose furosemide continuous IV infusions at a rate of 4 mg/min or less.

#### 2. Observe for therapeutic effects

- a. Decrease or absence of edema, increased urine output, decreased blood pressure

(1) Weigh the patient daily while edema is present and two to three times weekly thereafter. Weigh under standard conditions: early morning before eating or drinking, after urination, with the same amount of clothing, and using the same scales.

(2) Record fluid intake and output every shift for hospitalized patients.

(3) Observe and record characteristics of urine.

(4) Assess for edema daily or with each patient contact: ankles for the ambulatory patient, sacral area and posterior thighs for patients at bed rest. Also, it is often helpful to measure abdominal girth, ankles, and calves to monitor gain or loss of fluid.

(5) In patients with heart failure or acute pulmonary edema, observe for decreased dyspnea, crackles, cyanosis, and cough.

### RATIONALE/EXPLANATION

So that peak action will occur during waking hours and not interfere with sleep

Mainly to avoid falls

To decrease gastrointestinal (GI) upset

To decrease or avoid high peak serum levels, which increase risks of adverse effects, including ototoxicity

To decrease or avoid high peak serum levels, which increase risks of adverse effects, including ototoxicity

Most oral diuretics act within 2 hours; IV diuretics act within minutes. Optimal antihypertensive effects occur in approximately 2–4 weeks.

Body weight is a very good indicator of fluid gain or loss. A weight change of 2.2 lb (1 kg) may indicate a gain or loss of 1000 mL of fluid. Also, weighing assists in dosage regulation to maintain therapeutic benefit without excessive or too rapid fluid loss.

Normally, oral fluid intake approximates urinary output (1500 mL/24 h). With diuretic therapy, urinary output may exceed intake, depending on the amount of edema or fluid retention, renal function, and diuretic dosage. All sources of fluid gain, including IV fluids, must be included; all sources of fluid loss (perspiration, fever, wound drainage, GI tract drainage) are important. Patients with abnormal fluid losses have less urine output with diuretic therapy. Oliguria (decreased excretion of urine) may require stopping the drug. Output greater than 100 mL/h may indicate that side effects are more likely to occur. Dilute urine may indicate excessive fluid intake or greater likelihood of fluid and electrolyte imbalance due to rapid diuresis. Concentrated urine may mean oliguria or decreased fluid intake.

Expect a decrease in visible edema and size of measured areas. If edema reappears or worsens, a thorough reassessment of the patient is in order. Questions to be answered include:

- (1) Is the prescribed diuretic being taken correctly?
- (2) What type of diuretic and what dosage is ordered?
- (3) Is there worsening of the underlying condition(s) that led to edema formation?
- (4) Has other disease developed?

Decreased fluid in the lungs leads to improved respirations as more carbon dioxide and oxygen gas exchange takes place and greater tissue oxygenation occur.

(continued on page 857)

## Nursing Actions Diuretics (continued)

### NURSING ACTIONS

- (6) Record blood pressure 2 to 4 times daily when diuretic therapy is initiated.

#### 3. Observe for adverse effects

- a. With potassium-losing diuretics (thiazides, bumetanide, furosemide), observe for:

- (1) Hypokalemia
  - (a) Serum potassium levels below 3.5 mEq/L
  - (b) Electrocardiographic (ECG) changes (e.g., low voltage, flattened T wave, depressed ST segment)
  - (c) Cardiac dysrhythmias; weak, irregular pulse
  - (d) Hypotension
  - (e) Weak, shallow respirations
  - (f) Anorexia, nausea, vomiting
  - (g) Decreased peristalsis or paralytic ileus
  - (h) Skeletal muscle weakness
  - (i) Confusion, disorientation
- (2) Hyponatremia, hypomagnesemia, hypochloremic alkalosis, changes in serum and urinary calcium levels
- (3) Dehydration
  - (a) Poor skin turgor, dry mucous membranes
  - (b) Oliguria, urine of high specific gravity
  - (c) Thirst
  - (d) Tachycardia; hypotension
  - (e) Decreased level of consciousness
  - (f) Elevated hematocrit (above 45%)
- (4) Hyperglycemia—blood glucose above 120 mg/100 mL, polyuria, polydipsia, polyphagia, glycosuria

- (5) Hyperuricemia—serum uric acid above 7.0 mg/100 mL

- (6) Pulmonary edema (with osmotic diuretics)

- (7) Ototoxicity (with furosemide and ethacrynic acid)

- b. With potassium-sparing diuretics (spironolactone, triamterene, amiloride), observe for:

- (1) Hyperkalemia
  - (a) Serum potassium levels above 5 mEq/L

### RATIONALE/EXPLANATION

Although thiazide diuretics do not lower normal blood pressure, other diuretics may, especially with excessive or rapid diuresis.

Major adverse effects are fluid and electrolyte imbalances.

Potassium is required for normal muscle function. Thus, potassium depletion causes weakness of cardiovascular, respiratory, digestive, and skeletal muscles. Patients most likely to have hypokalemia are those who are taking large doses of diuretics, potent diuretics (e.g., furosemide), or adrenal corticosteroids; those who have decreased food and fluid intake; or those who have increased potassium losses through vomiting, diarrhea, chronic laxative or enema use, or GI suction. Clinically significant symptoms are most likely to occur with a serum potassium level below 3 mEq/L.

In addition to potassium, sodium chloride, magnesium, and bicarbonate also are lost with diuresis. Thiazides and related diuretics cause hypercalcemia and hypocalciuria. They have been used to prevent calcium nephrolithiasis (kidney stones). Furosemide and other loop diuretics tend to cause hypocalcemia and hypercalciuria.

Fluid volume depletion occurs with excessive or rapid diuresis. If it is prolonged or severe, hypovolemic shock may occur.

Hyperglycemia is more likely to occur in patients with known or latent diabetes mellitus. Larger doses of hypoglycemic agents may be required. The hyperglycemic effect may be reversible when diuretic therapy is discontinued.

Long-term use of a thiazide or loop diuretic may alter glucose metabolism. One mechanism is thought to involve diuretic-induced hypokalemia and hypomagnesemia, which then leads to decreased postprandial insulin release. Another mechanism may be development or worsening of insulin resistance.

Because glucose intolerance is an important risk factor for coronary artery disease, diuretics should be used with caution in prediabetic or diabetic hypertensive patients.

Hyperuricemia is usually asymptomatic except for patients with gout, a predisposition toward gout, or chronic renal failure. Apparently, decreased renal excretion of uric acid allows its accumulation in the blood.

Pulmonary edema is most likely to occur in patients with heart failure who cannot tolerate the increased blood volume produced by the drugs.

Reversible or transient hearing impairment, tinnitus, and dizziness are more common, although irreversible deafness may occur. Ototoxicity is more likely to occur with high serum drug levels (e.g., high doses or use in patients with severe renal impairment) or when other ototoxic drugs (e.g., aminoglycoside antibiotics) are being taken concurrently.

Hyperkalemia is most likely to occur in patients with impaired renal function or those who are ingesting additional potassium (e.g., salt substitutes).

NURSING ACTIONS	RATIONALE/EXPLANATION
(b) ECG changes (i.e., prolonged P-R interval; wide QRS complex; tall, peaked T wave; depressed ST segment) (c) Cardiac dysrhythmias, which may progress to ventricular fibrillation and asystole	
<b>4. Observe for drug interactions</b>	
a. Drugs that <i>increase</i> effects of diuretics:	Additive ototoxicity with ethacrynic acid
(1) Aminoglycoside antibiotics	Additive hypotensive effects. In addition, angiotensin-converting enzyme inhibitor therapy significantly increases risks of hyperkalemia with spironolactone.
(2) Antihypertensive agents	Additive hypokalemia
(3) Corticosteroids	
b. Drugs that <i>decrease</i> effects of diuretics:	These drugs cause retention of sodium and water.
(1) Nonsteroidal anti-inflammatory drugs (e.g., aspirin, ibuprofen, others)	
(2) Oral contraceptives	Retention of sodium and water
(3) Vasopressors (e.g., epinephrine, norepinephrine)	These drugs may antagonize hypotensive effects of diuretics by decreasing responsiveness of arterioles.

## Key Concepts

- Diuretic drugs act on the kidneys to decrease reabsorption of sodium, chloride, water, and other substances.
- A body weight change of 2.2 pounds (1 kg) may indicate a gain or loss of 1000 mL of fluid.
- Excessive table salt and salty foods (e.g., ham, packaged sandwich meats, potato chips, dill pickles, most canned soups) may aggravate edema or hypertension.
- Loop diuretics have a sodium-losing effect up to 10 times greater than that of thiazide diuretics.
- Potassium-sparing diuretics are contraindicated in patients with renal impairment because of the high risk of hyperkalemia.
- There is a known cross-sensitivity of some sulfonamide-allergic patients to a sulfonamide nonantibiotic, such as thiazides.
- Thiazides and related diuretics are the drugs of choice for most patients who require diuretic therapy, especially for long-term management of heart failure and hypertension.
- High-dose furosemide continuous IV infusions should be given at a rate of 4 mg/min or less to decrease or avoid risks of adverse effects, including ototoxicity.
- When digoxin and diuretics are given concomitantly, the risk of digoxin toxicity is increased due to diuretic-induced hypokalemia.

## Review and Application Exercises

### Short Answer Exercises

1. What are clinical indications for the use of diuretics?
2. What is the general mechanism by which diuretics act?
3. How can you assess a patient for therapeutic effects of a diuretic?
4. Compare and contrast the main groups of diuretics in terms of adverse effects.
5. Why should serum potassium levels be monitored during diuretic therapy?
6. Which prescription and over-the-counter drugs may decrease the effects of a diuretic?
7. For a patient who is starting diuretic therapy, what are important points to teach the patient about safe and effective drug usage?
8. For a patient who is taking a potassium-losing diuretic and a potassium chloride supplement, explain the possible consequences of discontinuing one drug while continuing the other.

### NCLEX-Style Questions

9. A patient receives furosemide 80 mg IV for symptoms of severe heart failure. The nurse recognizes that administering the drug slowly IV push will reduce the likelihood of which of the following adverse effects of drug therapy?
  - a. hyponatremia
  - b. hypokalemia
  - c. fluid volume deficit
  - d. ototoxicity
10. A patient who is taking an oral hypoglycemic for management of his type 2 diabetes mellitus is started on hydrochlorothiazide. The nurse should monitor for which of the following serum laboratory changes?
  - a. hypocalcemia
  - b. hypercalciuria
  - c. hyperglycemia
  - d. hypernatremia
11. A nurse is instructing a patient on dietary considerations while taking spironolactone (Aldactone). Which of the following statements made by the patient indicates that further teaching is necessary?
  - a. "I should not eat foods high in potassium while taking this medication."
  - b. "I should use a salt substitute instead of regular salt."
  - c. "I should call my nurse practitioner if I have any significant adverse effects from my medications."
  - d. "I should not take large amounts of potassium chloride supplements."
12. What assessment finding in a patient with heart failure receiving furosemide (Lasix) would indicate an improvement in her fluid volume status?
  - a. absence of crackles on auscultation of lungs
  - b. complaints of proximal nocturnal dyspnea
  - c. bounding radial pulse
  - d. decrease in hematocrit
13. Mrs. Conley, age 53, has had hypertension for 10 years and admits that she does not comply with her prescribed antihypertensive therapy. Recently, she has begun to experience shortness of breath and ankle swelling. The nurse practitioner diagnoses renal insufficiency. What classification of diuretic is the drug of choice for the nurse practitioner to first prescribe for Mrs. Conley?
  - a. thiazide
  - b. loop
  - c. osmotic
  - d. potassium-sparing

# Drugs That Affect Blood Coagulation

## KEY TERMS

- Anticoagulant
- Antiplatelet
- Embolus
- Fibrinolytic
- Hemostasis
- Plasmin
- Plasminogen
- Thrombogenesis
- Thrombolysis
- Thrombolytic
- Thrombus

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe important elements in the physiology of hemostasis and thrombosis.
2. Discuss potential consequences of blood clotting disorders.
3. Compare and contrast heparin and warfarin in terms of indications for use, onset and duration of action, route of administration, blood tests used to monitor effects, and nursing process implications.
4. Discuss antiplatelet agents in terms of indications for use and effects on blood coagulation.
5. Describe thrombolytic agents in terms of indications and contraindications for use, routes of administration, and major adverse effects.
6. Describe systemic hemostatic agents for treating overdoses of anticoagulant and thrombolytic drugs.
7. Use the nursing process in the care of patients on anticoagulant, antiplatelet, and thrombolytic agents.

## Applying Your Knowledge

Andrew Dusseau is a 45-year-old man who has suffered an acute myocardial infarction with the complication of atrial fibrillation. He is started on a heparin IV. You are the nurse providing his care.

.....

## Introduction

Anticoagulant, antiplatelet, and thrombolytic drugs are used in the prevention and management of thrombotic and thromboembolic disorders. Thrombosis involves the formation (*thrombogenesis*) or presence of a blood clot (*thrombus*) in the vascular system. Blood clotting is a normal body defense mechanism to prevent blood loss. Thus, thrombogenesis may be life saving when it occurs as a response to hemorrhage; however, it may be life threatening when it occurs at other times, because the thrombus can obstruct a blood vessel and block blood flow to tissues beyond the clot. When part of a thrombus breaks off and travels to another part of the body, it is called an *embolus*.

Atherosclerosis is the basic disease process that often leads to pathologic thrombosis. Atherosclerosis begins with accumulation of lipid-filled macrophages (i.e., foam cells) on the inner lining of arteries. Foam cells develop in response to elevated blood lipid levels and eventually become

fibrous plaques (i.e., foam cells covered by smooth muscle cells and connective tissue). Advanced atherosclerotic lesions also contain hemorrhages, ulcerations, and scar tissue.

Atherosclerosis can affect any organ or tissue but often involves the arteries supplying the heart, brain, and legs. Over time, plaque lesions become larger and extend farther into the lumen of the artery. Eventually, a thrombus may develop at plaque sites and partially or completely occlude an artery. In coronary arteries, a thrombus may precipitate myocardial ischemia (angina or infarction) (see Chap. 50); in carotid or cerebral arteries, a thrombus may precipitate a stroke; in peripheral arteries, a thrombus in peripheral circulation may cause intermittent claudication (pain in the legs with exercise) or acute occlusion. Thus, serious impairment of blood flow may occur with a large atherosclerotic plaque or a relatively small plaque with superimposed vasospasm and thrombosis. Consequences and clinical manifestations of thrombi and emboli depend primarily on their location and size.

Normally, thrombi are constantly being formed and dissolved (*thrombolysis*), but the blood remains fluid and flow is not significantly obstructed. If the balance between thrombogenesis and thrombolysis is upset, thrombotic or bleeding disorders result. Thrombotic disorders occur much more often than bleeding disorders and are emphasized in this chapter; bleeding disorders may result from excessive amounts of drugs that inhibit clotting. To aid understanding of drug therapy for thrombotic disorders, normal hemostasis, endothelial functions in relation to blood clotting, platelet functions, blood coagulation, and characteristics of arterial and venous thrombosis are described.

## Hemostasis

*Hemostasis* is prevention or stoppage of blood loss from an injured blood vessel and is the process that maintains the integrity of the vascular compartment. It involves activation of several mechanisms, including vasoconstriction, formation of a platelet plug (a cluster of aggregated platelets), sequential activation of clotting factors in the blood (Fig. 54-1), and growth of fibrous tissue (fibrin) into the blood clot to make it more stable and to repair the tear (opening) in the damaged blood vessel. Overall, normal hemostasis is a complex process involving numerous interacting activators and inhibitors, including endothelial factors, platelets, and blood coagulation factors (Box 54-1).

## Clot Lysis

When a blood clot is being formed, *plasminogen* (an inactive protein found in many body tissues and fluids) is bound to fibrin and becomes a component of the clot. After the outward blood flow is stopped and the tear in the blood vessel is repaired, plasminogen is activated by plasminogen activator (produced by endothelial cells or the coagulation cascade) to produce plasmin. *Plasmin* is an enzyme that breaks down the fibrin meshwork that stabilizes the clot; this fibrinolytic or thrombolytic action dissolves the clot.

## Thrombotic and Thromboembolic Disorders

Thrombosis may occur in both arteries and veins. Arterial thrombosis is usually associated with atherosclerotic plaque, hypertension, and turbulent blood flow. These conditions damage arterial endothelium and activate platelets to initiate the coagulation process. Arterial thrombi cause disease by obstructing blood flow. If the obstruction is incomplete or temporary, local tissue ischemia (deficient blood supply) occurs. If the obstruction is complete or prolonged, local tissue death (infarction) occurs.

Venous thrombosis is usually associated with venous stasis. When blood flows slowly, thrombin and other procoagulant substances present in the blood become concentrated in local areas and initiate the clotting process. With a normal rate of blood flow, these substances are rapidly removed from the blood, primarily by Kupffer's cells in the liver. A venous thrombus is less cohesive than an arterial thrombus, and an embolus can easily become detached and travel to other parts of the body.

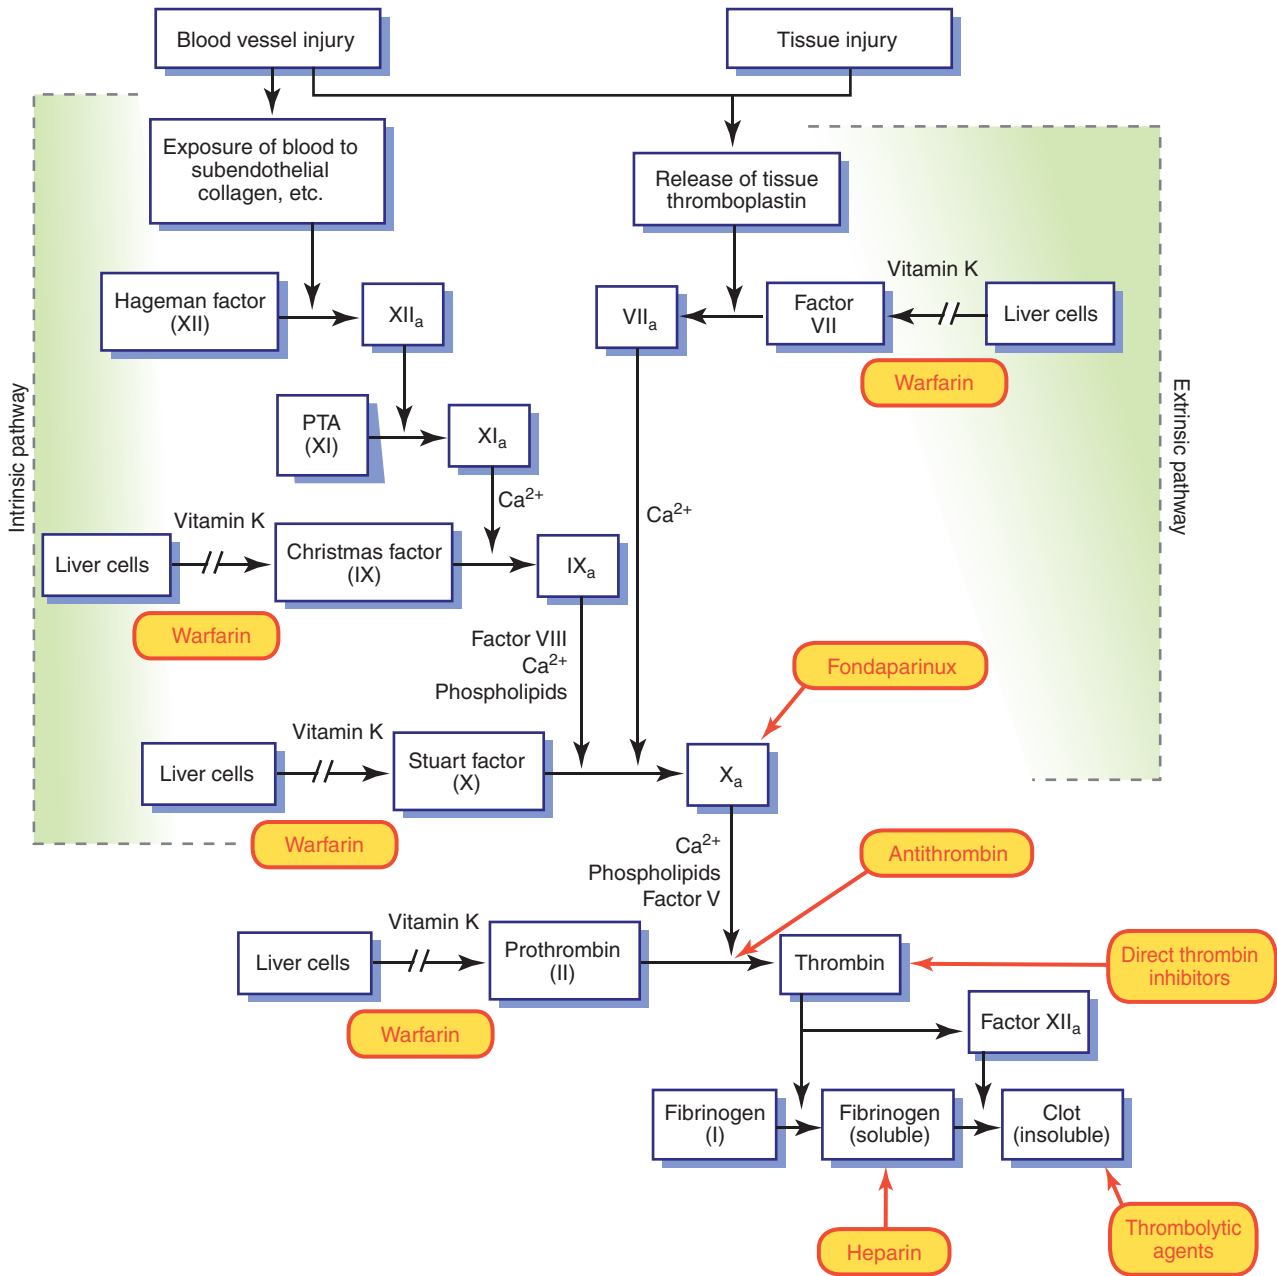

Venous thrombi cause disease by two mechanisms. First, thrombosis causes local congestion, edema, and perhaps inflammation by impairing normal outflow of venous blood (e.g., thrombophlebitis, deep vein thrombosis [DVT]). Second, embolization obstructs the blood supply when the embolus becomes lodged. The pulmonary arteries are common sites of embolization.

## Drugs Used in Thrombotic and Thromboembolic Disorders: Classifications and Individual Drugs

Drugs given to prevent or treat thrombosis alter some aspect of the blood coagulation process (see Fig. 54-1). Anticoagulants are widely used in thrombotic disorders. They are more effective in preventing venous thrombosis than arterial thrombosis. Antiplatelet drugs are used to prevent arterial thrombosis. Thrombolytic agents are used to dissolve thrombi and limit tissue damage in selected thromboembolic disorders. These drugs are described in the following sections and in Table 54-1.

### Anticoagulants

*Anticoagulant* drugs are given to prevent formation of new clots and extension of clots already present. They do not dissolve formed clots, improve blood flow in tissues around the clot, or prevent ischemic damage to tissues beyond the clot. Heparins and warfarin are commonly used anticoagulants; argatroban and lepirudin are additional agents. Clinical indications include prevention or management of thromboembolic disorders, such as thrombophlebitis, DVT, and pulmonary embolism. The main adverse effect is bleeding.

**Figure 54-1** ■ Details of the intrinsic and extrinsic clotting pathways. The sites of action of some of the drugs that can influence these processes are shown in red.

### Heparin

**Heparin** is a pharmaceutical preparation of the natural anticoagulant produced primarily by mast cells in pericapillary connective tissue. Endogenous heparin is found in various body tissues, most abundantly in the liver and lungs. Exogenous heparin is obtained from bovine lung or porcine intestinal mucosa and standardized in units of biologic activity.

Heparin combines with antithrombin III (a natural anticoagulant in the blood) to inactivate clotting factors IX, X, XI, and XII; inhibit the conversion of prothrombin to thrombin; and prevent thrombus formation (see Fig. 54-1). After thrombosis has developed, heparin can inhibit additional coagulation by inactivating thrombin, preventing the conversion of

fibrinogen to fibrin, and inhibiting factor XIII (the fibrin-stabilizing factor). Other effects include inhibiting factors V and VIII and platelet aggregation.

Heparin acts immediately after intravenous (IV) injection and within 20 to 30 minutes after subcutaneous (Sub-Q) injection. It is metabolized in the liver and excreted in the urine, primarily as inactive metabolites. Heparin does not cross the placental barrier and is not secreted in breast milk, making it the anticoagulant of choice for use during pregnancy and lactation.

Prophylactically, low doses of heparin are given to prevent DVT and pulmonary embolism in patients at risk for development of these disorders, such as the following:

## Box 54-1

## Hemostasis and Thrombosis

The blood vessels and blood normally maintain a balance between procoagulant and anticoagulant factors that favor anticoagulation and keeps the blood fluid. Injury to blood vessels and tissues causes complex reactions and interactions among vascular endothelial cells, platelets, and blood coagulation factors that shift the balance toward procoagulation and thrombosis.

### Endothelial Cells

Normal endothelium helps to prevent thrombosis by producing anticoagulant factors, inhibiting platelet reactivity, and inhibiting activation of the coagulation cascade. However, endothelium promotes thrombosis if the blood vessel wall is damaged, function is altered, or when blood flow is altered or becomes static. After a blood clot is formed, the endothelium also induces its dissolution and restoration of blood flow.

### Platelets

The only known function of platelets is hemostasis. Platelets (also called thrombocytes) are produced in the bone marrow and released into the bloodstream, where they circulate for approximately 7 to 10 days before they are removed by the spleen. They contain no nuclei and therefore cannot repair or replicate themselves.

The cell membrane of a platelet contains a coat of glycoproteins that prevents the platelet from adhering to normal endothelium but allows it to adhere to damaged areas of endothelium and collagen in the blood vessel wall. Breakdown of the cell membrane releases arachidonic acid (which can be metabolized to produce thromboxane  $A_2$ ) and allows leakage of platelet contents (e.g., thromboplastin and other clotting factors), which function to stop bleeding.

When platelets come in contact with a damaged vascular surface, they become activated and aggregate at a site of injury to help plug a hole in a torn blood vessel. Aggregated platelets release substances that recruit new platelets and stimulate additional aggregation. This activity helps the platelet plug become large enough to block blood flow out of a damaged blood vessel. If the opening is small, the platelet plug can stop blood loss. If the opening is large, a platelet plug and a blood clot are both required to stop the bleeding. Platelets usually disappear from a blood clot within 24 hours and are replaced by fibrin.

### Blood Coagulation

The blood coagulation process represented in Figure 54-1 causes hemostasis within 1 to 2 minutes. It involves sequential activation of clotting factors that are normally present in blood and tissues as inactive precursors and formation of a meshwork of fibrin strands that cements blood components together to form a stable, dense clot. Major phases include release of thromboplastin by disintegrating platelets and damaged tissue; conversion of prothrombin to thrombin, which requires thromboplastin and calcium ions; and conversion of fibrinogen to fibrin by thrombin.

Blood coagulation results from activation of the intrinsic or extrinsic coagulation pathway. Both pathways, which are activated when blood passes out of a blood vessel, are needed for normal hemostasis. The intrinsic pathway occurs in the vascular system; the extrinsic pathway occurs in the tissues. Although the pathways are initially separate, the terminal steps (i.e., activation of factor X and thrombin-induced formation of fibrin) are the same leading to the formation of thrombin, which then activates fibrinogen to form fibrin, and the clot is complete.

- Patients with major illnesses (e.g., acute myocardial infarction, heart failure, serious pulmonary infections, stroke)
- Patients having major abdominal or thoracic surgery
- Patients with a history of thrombophlebitis or pulmonary embolism, including pregnant women
- Patients having gynecologic surgery, especially if they have been taking estrogens or oral contraceptives or have other risk factors for DVT
- Patients expected to be on bed rest or to have limited activity for longer than 5 days

Therapeutically, heparin is used for management of acute thromboembolic disorders (e.g., DVT, thrombophlebitis, pulmonary embolism). In these conditions, the aim of therapy is to prevent further thrombus formation and embolization. Heparin is also used in disseminated intravascular coagulation (DIC), a life-threatening condition characterized by widespread clotting, which depletes the blood of coagulation factors. The depletion of coagulation factors then produces widespread bleeding. The goal of heparin therapy in DIC is to prevent blood coagulation long enough

for clotting factors to be replenished and thus be able to control hemorrhage. Heparin is also used to prevent clotting during cardiac and vascular surgery, extracorporeal circulation, hemodialysis, and blood transfusions, and in blood samples to be used in laboratory tests.

Contraindications include GI ulcerations (e.g., peptic ulcer disease, ulcerative colitis), intracranial bleeding, dissecting aortic aneurysm, blood dyscrasias, severe kidney or liver disease, severe hypertension, polycythemia vera, and recent surgery of the eye, spinal cord, or brain. Heparin should be used with caution in patients with hypertension, renal or hepatic disease, alcoholism, history of GI ulcerations, drainage tubes (e.g., nasogastric tubes, indwelling urinary catheters), threatened abortion, endocarditis, and any occupation with high risks of traumatic injury.

Disadvantages of heparin are its short duration of action and the subsequent need for frequent administration, the necessity for parenteral injection (because it is not absorbed from the gastrointestinal [GI] tract), and local tissue reactions at injection sites.

Table 54-1

## Drugs at a Glance: Anticoagulant, Antiplatelet, and Thrombolytic Agents

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS, UNLESS SPECIFIED)
<b>Anticoagulants</b>		
<b>Heparin</b>	Prevention and management of thromboembolic disorders (e.g., DVT, pulmonary embolism, atrial fibrillation with embolization)	<p>Adults: IV injection, 5000 units initially, followed by 5000–10,000 units q4–6h, to a maximum dose of 25,000 units/d; IV infusion, 5000 units (loading dose), then 15–25 units/kg/h</p> <p>DIC, IV injection, 50–100 units/kg q4h; IV infusion, 20,000–40,000 units/d at initial rate of 0.25 units/kg/min, then adjusted according to aPTT; Sub-Q 10,000–12,000 units q8h, or 14,000–20,000 units q12h</p> <p>Low-dose prophylaxis, Sub-Q 5000 units 2 h before surgery, then q12h until discharged from hospital or fully ambulatory</p> <p>Children: DIC, IV injection, 25–50 units/kg q4h; IV infusion, 50 units/kg initially, followed by 100 units/kg q4h or 20,000 units/m<sup>2</sup> over 24 h</p>
<b>Argatroban</b> (Argatroban)	Thrombosis prophylaxis or management in heparin-induced thrombocytopenia; adjunct to PTCA	IV continuous infusion 2 mcg/kg/min
<b>Bivalirudin</b> (Angiomax)	Patients with unstable angina undergoing PTCA; acute coronary syndrome	IV bolus dose of 0.75 mg/kg followed by 4-h infusion at rate of 1.75 mg/kg/min
<b>Dalteparin</b> (Fragmin)	Prophylaxis of DVT in patients having hip replacement surgery; also patients at high risk of thromboembolic disorders who are having abdominal surgery	<p>Abdominal surgery, Sub-Q 2500 IU 1–2 h before surgery and then once daily for 5–10 days after surgery</p> <p>Hip replacement surgery, Sub-Q 2500 IU 1–2 h before surgery and the evening of surgery (at least 6 h after first dose) and then 5000 IU once daily for 5 days</p>
<b>Enoxaparin</b> (Lovenox)	Prevention and management of DVT and pulmonary embolism Management of unstable angina, to prevent myocardial infarction	<p>DVT prophylaxis in patients having hip or knee replacement surgery, Sub-Q 30 mg twice daily, with first dose within 12–24 h after surgery and continued until risk of DVT diminished or until adequately anticoagulated on warfarin</p> <p>Abdominal surgery, Sub-Q 40 mg once daily with first dose given 2 h before surgery, for 7–10 days</p> <p>DVT/pulmonary embolism management, outpatients, Sub-Q 1 mg/kg q12h; inpatients, 1 mg/kg q12h or 1.5 mg/kg q24h</p> <p>Unstable angina 1 mg/kg q12h in conjunction with oral aspirin (100–325 mg once daily)</p>
<b>Fondaparinux</b> (Arixtra)	Prevention of DVT following hip fracture surgery or knee or hip replacement	Sub-Q 2.5 mg daily, with first dose 6–8 h after surgery and continuing for a maximum of 11 days

(continued on page 866)

Table 54-1

**Drugs at a Glance: Anticoagulant, Antiplatelet, and Thrombolytic Agents** (continued)

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS, UNLESS SPECIFIED)
<b>Lepirudin</b> (Refludan)	Heparin alternative for anticoagulation in patients with heparin-induced thrombocytopenia and associated thromboembolic disorders	IV injection, 0.4 mg/kg over 15–20 sec, followed by continuous IV infusion of 0.15 mg/kg for 2–10 days or longer if needed
<b>Warfarin</b> (Coumadin)	Long-term prevention or management of venous thromboembolic disorders, including DVT, PE, and embolization associated with atrial fibrillation and prosthetic heart valves. May also be used after myocardial infarction to decrease reinfarction, stroke, venous thromboembolism, and death	PO 2–5 mg/d for 2–3 days, then adjusted according to the international normalized ratio (INR); average maintenance daily dose, 2–5 mg
<b>Antiplatelet Agents</b>		
<b>Aspirin</b>	Prevention of myocardial infarction Prevention of thromboembolic disorders in patients with prosthetic heart valves or TIAs	PO 81–325 mg daily
<b>Abciximab</b> (ReoPro)	Used with PTCA to prevent rethrombosis of treated arteries Intended for use with aspirin and heparin	IV bolus injection, 0.25 mg/kg 10–60 min before starting PTCA, then a continuous IV infusion of 10 mcg/min for 12 h
<b>Anagrelide</b> (Agrylin)	Essential thrombocythemia, to reduce the elevated platelet count, the risk of thrombosis, and associated symptoms	PO 0.5 mg 4 times daily or 1 mg twice daily initially, then titrate to lowest dose effective in maintaining platelet count <600,000/mm <sup>3</sup>
<b>Cilostazol</b> (Pletal)	Intermittent claudication, to increase walking distance (before leg pain occurs)	PO 100 mg twice daily, 30 min before or 2 h after breakfast and dinner; reduce to 50 mg twice daily with concurrent use of fluconazole, itraconazole, erythromycin, or diltiazem
<b>Clopidogrel</b> (Plavix)	Reduction of atherosclerotic events (myocardial infarction, stroke, vascular death) in patients with atherosclerosis documented by recent stroke, recent myocardial infarction, or established peripheral artery disease	PO 75 mg once daily with or without food
<b>Dipyridamole</b> (Persantine)	Prevention of thromboembolism after cardiac valve replacement, given with warfarin	PO 25–75 mg 3 times per day, 1 h before meals
<b>Dipyridamole and aspirin</b> (Aggrenox)	Reduction of stroke risk in patients with previous TIA or thrombotic event	PO 1 capsule (200 mg extended-release dipyridamole/25 mg aspirin) twice daily
<b>Eptifibatid</b> (Integrilin)	Acute coronary syndromes, including patients who are to be managed medically and those undergoing PTCA	IV bolus injection, 180 mcg/kg, followed by continuous infusion of 2 mcg/kg/min. See manufacturer's instructions for preparation and administration.
<b>Ticlopidine</b> (Ticlid)	Prevention of thrombosis in patients with coronary artery or cerebral vascular disease (e.g., patients who have had stroke precursors or a completed thrombotic stroke)	PO 250 mg twice daily with food
<b>Tirofiban</b> (Aggrastat)	Acute coronary syndromes, with heparin, for patients who are to be managed medically or those undergoing PTCA Acute myocardial infarction Pulmonary embolism	IV infusion, 0.4 mcg/kg/min for 30 min, then 0.1 mcg/kg/min. Patients with severe renal impairment (creatinine clearance <30 mL/min) should receive half the usual rate of infusion. See manufacturer's instructions for preparation and administration.

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS, UNLESS SPECIFIED)
<b>Thrombolytic Agents</b>		
<b>Alteplase</b> (Activase)	Acute ischemic stroke Acute myocardial infarction Pulmonary emboli	IV infusion, 100 mg over 3 h (first hour, 60 mg with a bolus of 6–10 mg over 1–2 min initially; second hour, 20 mg; third hour, 20 mg)
<b>Drotrecogin alfa</b> , activated (Xigris)	Reduction of mortality in severe sepsis	IV infusion of 24 mcg/kg/h for 96 h
<b>Retepase</b> , recombinant (Retavase)	Acute myocardial infarction	IV injection, 10 units over 2 min, repeated in 30 min. Inject into a flowing IV infusion line that contains no other medications.
<b>Streptokinase</b> (Streptase)	Management of acute, severe pulmonary emboli or iliofemoral thrombophlebitis Used to dissolve clots in arterial or venous cannulas or catheters May be injected into a coronary artery to dissolve a thrombus if done within 6 h of onset of symptoms	IV 250,000 units over 30 min, then 100,000 units/h for 24–72 h
<b>Tenecteplase</b> (TNKase)	Acute myocardial infarction	IV bolus dose based on weight, 30 mg (for <60 kg) not to exceed 50 mg (>90 kg)
<b>Urokinase</b> (Abbokinase)	Coronary artery thrombi Pulmonary emboli Clearance of clogged IV catheters	IV 4400 units/kg over 10 min, followed by continuous infusion of 4400 units/kg/h for 12 h For clearing IV catheters, see manufacturer's instructions.

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; DVT, deep vein thrombosis; PE, pulmonary embolism; PTCA, percutaneous transluminal coronary angioplasty or atherectomy; TIA, transient ischemic attack.

Heparin-induced thrombocytopenia (HIT) may occur in 1% to 3% of those receiving heparin and is a very serious adverse effect of heparin. HIT is an immune-mediated process that results in development of antibodies that activate platelets. The activated platelets are rapidly consumed by the reticuloendothelial system, thereby triggering a subsequent release of procoagulant microparticles that cause platelet aggregation and a hyperthrombotic state. All patients exposed to any heparin at therapeutic or prophylactic doses or minute amounts in heparin flushes or on heparin-coated catheters, as well as those receiving low-molecular-weight heparin, are at risk. All heparin administration must be discontinued and anticoagulation managed with a direct thrombin inhibitor such as argatroban.

### Low-Molecular-Weight Heparins

Standard heparin is a mixture of high- and low-molecular-weight fractions, but most anticoagulant activity is attributed to the low-molecular-weight portion. **Low-molecular-weight heparins** (LMWHs) contain the low-molecular-weight fraction and are as effective as IV heparin in treating thrombotic disorders. Indications for use include prevention or management of thromboembolic complications associated with surgery

or ischemic complications of unstable angina and myocardial infarction. Currently available LMWHs (dalteparin, enoxaparin) differ from standard heparin and each other and are not interchangeable.

LMWHs are given Sub-Q and do not require close monitoring of blood coagulation tests. These characteristics allow outpatient anticoagulant therapy, an increasing trend. The drugs are also associated with less thrombocytopenia than standard heparin. However, platelet counts should be monitored during therapy.

### Applying Your Knowledge 54-1

Before providing care for Mr. Dusseau, you review his chart (medical diagnosis and medication orders). What is the main reason for patients to receive an anticoagulant and for what adverse effect should you monitor Mr. Dusseau?

.....

### Warfarin

**Warfarin** is the most commonly used oral anticoagulant. It acts in the liver to prevent synthesis of vitamin K-dependent

clotting factors (i.e., factors II, VII, IX, and X). Warfarin is similar to vitamin K in structure and therefore acts as a competitive antagonist to hepatic use of vitamin K. Anticoagulant effects do not occur for 3 to 5 days after warfarin is started because clotting factors already in the blood follow their normal pathway of elimination. Warfarin has no effect on circulating clotting factors or on platelet function.

Warfarin is well absorbed after oral administration. It is highly bound to plasma proteins (98%), mainly albumin. It is metabolized in the liver and primarily excreted as inactive metabolites by the kidneys.

Warfarin is most useful in long-term prevention or management of venous thromboembolic disorders, including DVT, pulmonary embolism, and embolization associated with atrial fibrillation and prosthetic heart valves. In addition, warfarin therapy after myocardial infarction may decrease reinfarction, stroke, venous thromboembolism, and death. Smaller doses are being used now than formerly, with similar antithrombotic effects and decreased risks of bleeding.

Like heparin, warfarin is contraindicated in patients with GI ulcerations, blood disorders associated with bleeding, severe kidney or liver disease, severe hypertension, and recent surgery of the eye, spinal cord, or brain. It should be used cautiously in patients with mild hypertension, renal or hepatic disease, alcoholism, history of GI ulcerations, drainage tubes (e.g., nasogastric tubes, indwelling urinary catheters), and occupations with high risks of traumatic injury. In addition, warfarin is contraindicated during pregnancy. The U.S. Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** with warfarin due to its risk of causing major or fatal bleeding.

### Direct Thrombin Inhibitors

Direct thrombin inhibitors (DTIs) have benefits over agents like heparin and warfarin, including the inhibition of both circulating and clot-bound thrombin. Heparin and warfarin are indirect inhibitors of thrombin. The DTIs exert their effect by interacting directly with the thrombin molecule without the need of a cofactor, such as heparin cofactor II or antithrombin. As such, they inhibit thrombin's ability to convert soluble fibrinogen to fibrin and to activate the fibrin-generating factors V, VIII, and IX. Because thrombin also stimulates platelets, DTIs also have antiplatelet activity.

Currently, the parenteral agents **lepirudin**, **bivalirudin**, and **argatroban** are available for clinical use; others, including oral forms, are undergoing clinical trials. These drugs provide advantages over heparin, including inhibition of both circulating and clot-bound thrombin, a more predictable dose-response anticoagulant effect, inhibition of thrombin-induced platelet aggregation, and the lack of production of immune-mediated thrombocytopenia. The drugs are available for heparin-induced thrombocytopenia, acute coronary syndrome, prophylaxis and treatment of venous thromboembolism, and management of atrial fibrillation. The DTIs are less suitable for long-term treatment since they are administered by injection, lack widely available option for therapeutic drug monitoring, and have no pharmacologic antidote available to reverse their effects.

### Other Anticoagulant Drugs

**Fondaparinux** is the first of a new class of pentasaccharide antithrombotic agents that produces anticoagulant effects by directly binding to circulating and clot-bound factor Xa, accelerating the activity of antithrombin and inhibiting thrombin production. It is appreciated for its simple dosing regimen, no need for coagulation monitoring, and potentially a lower risk of heparin-induced thrombocytopenia compared with LMWH. It is used in the prevention of DVT in patients having surgery for hip fracture or joint replacement surgery of the knee or hip.

### Antiplatelet Drugs

*Antiplatelet* drugs prevent one or more steps in the prothrombotic activity of platelets. As described previously, platelet activity is very important in both physiologic hemostasis and pathologic thrombosis. Arterial thrombi, which are composed primarily of platelets, may form on top of atherosclerotic plaque and block blood flow in the artery. They may also form on heart walls and valves and embolize to other parts of the body.

Drugs used clinically for antiplatelet effects act by a variety of mechanisms to inhibit platelet activation, adhesion, aggregation, or procoagulant activity. These include drugs that block platelet receptors for thromboxane  $A_2$ , adenosine diphosphate (ADP), glycoprotein (GP) IIb/IIIa, and phosphodiesterase.

### Thromboxane $A_2$ Inhibitors

**Aspirin** is a commonly used analgesic–antipyretic–anti-inflammatory drug (see Chap. 7) with potent antiplatelet effects. Aspirin exerts pharmacologic actions by inhibiting synthesis of prostaglandins. In this instance, aspirin acetylates cyclooxygenase, the enzyme in platelets that normally synthesizes thromboxane  $A_2$ , a prostaglandin product that causes platelet aggregation. Thus, aspirin prevents formation of thromboxane  $A_2$  and thromboxane  $A_2$ -induced platelet aggregation and thrombus formation. A single dose of 300 to 600 milligrams or multiple doses of 30 milligrams (e.g., daily for several days) inhibit the cyclooxygenase in circulating platelets almost completely. These antithrombotic effects persist for the life of the platelet (7–10 days). Aspirin may be used long term for prevention of myocardial infarction or stroke and in patients with prosthetic heart valves. It is also used for the immediate treatment of suspected or actual acute myocardial infarction, for transient ischemic attacks (TIAs), and for evolving thrombotic strokes. Adverse effects are uncommon with the small doses used for antiplatelet effects. However, there is an increased risk of bleeding, including hemorrhagic stroke. Because approximately 85% of strokes are thrombotic, the benefits of aspirin or other antiplatelet agents are thought to outweigh the risks of hemorrhagic strokes (approximately 15%). No antidote exists for the effects of aspirin because it produces irreversible platelet effects; platelet transfusion may be required.

Nonsteroidal anti-inflammatory drugs (NSAIDs), including **ibuprofen** and many other aspirin-related drugs, inhibit cyclooxygenase reversibly. Their antiplatelet effects subside

when the drugs are eliminated from the circulation and the drugs usually are not used for antiplatelet effects. However, patients who take an NSAID daily (e.g., for arthritis pain) may not need to take additional aspirin for antiplatelet effects. **Acetaminophen** does not affect platelets in usual doses (see Chap. 7).

### Adenosine Diphosphate Receptor Antagonists

The adenosine diphosphate receptor antagonists, **clopidogrel** (Plavix) and **ticlopidine** (Ticlid), irreversibly block the adenosine diphosphate (ADP) receptor on platelet cell membranes. This effectively prevents platelet aggregation for the lifespan of the platelet. The drug class is indicated for reduction of myocardial infarction, stroke, and vascular death in patients with atherosclerosis; clopidogrel reportedly causes fewer or less severe adverse effects than ticlopidine.

With clopidogrel, platelet inhibition can be demonstrated 2 hours after a single dose, but the onset of action is slow, so that a loading-dose is usually administered. The FDA has recently approved a 300-milligram tablet of clopidogrel for a loading dose for appropriate patients. Clopidogrel is rapidly absorbed after oral administration with a half-life of about 8 hours, but its effect can be seen as soon as 2 hours after a 300-milligram loading dose. The most common adverse effects associated with the use of clopidogrel are pruritus, rash, purpura, and diarrhea; thrombotic thrombocytopenic purpura, hemorrhage, and severe neutropenia have also been reported.

Ticlopidine is indicated for prevention of thrombotic stroke in people who have had stroke precursor events (e.g., TIAs) or a completed thrombotic stroke. Ticlopidine is considered a second-line drug for patients who cannot take aspirin. The adverse effects (e.g., neutropenia, diarrhea, skin rashes) and greater cost make it prohibitive for use by many patients. Contraindications include active bleeding disorders (e.g., GI bleeding from peptic ulcer, intracranial bleeding), neutropenia, thrombocytopenia, severe liver disease, and hypersensitivity to the drug. No antidote exists for the effects of the adenosine diphosphate receptor antagonists as they produce irreversible platelet effects. Platelet transfusion should be considered in patients who take these drugs and have hemorrhagic complications.

### Glycoprotein IIb/IIIa Receptor Antagonists

**Abciximab** is a monoclonal antibody that prevents the binding of fibrinogen, von Willebrand factor, and other molecules to GP IIb/IIIa receptors on activated platelets. This action inhibits platelet aggregation.

Abciximab is used with percutaneous transluminal coronary angioplasty or removal of atherosclerotic plaque to prevent rethrombosis of treated arteries. It is used with aspirin and heparin and is contraindicated in patients who have recently received an oral anticoagulant or IV dextran. Other contraindications include active bleeding, thrombocytopenia, history of a serious stroke, surgery or major trauma within the previous 6 weeks, uncontrolled hypertension, or hypersensitivity to drug components.

**Eptifibatide** and **tirofiban** inhibit platelet aggregation by preventing activation of GP IIb/IIIa receptors on the platelet surface and the subsequent binding of fibrinogen and von Willebrand factor to platelets. Antiplatelet effects occur during drug infusion and stop when the drug is stopped. The drugs are indicated for acute coronary syndrome (e.g., unstable angina, myocardial infarction) in patients who are to be treated medically or by angioplasty or atherectomy.

Drug half-life is approximately 2.5 hours for eptifibatide and 2 hours for tirofiban; the drugs are cleared mainly by renal excretion. With tirofiban, plasma clearance is approximately 25% lower in older adults and approximately 50% lower in patients with severe renal impairment (creatinine clearance < 30 mL/minute).

The drugs are contraindicated in patients with hypersensitivity to any component of the products; current or previous bleeding (within previous 30 days); a history of thrombocytopenia after previous exposure to tirofiban; a history of stroke within 30 days or any history of hemorrhagic stroke; major surgery or severe physical trauma within the previous month; severe hypertension (systolic blood pressure > 180 mm Hg with tirofiban or >200 mm Hg with eptifibatide, or diastolic blood pressure > 110 mm Hg with either drug); a history of intra-cranial hemorrhage, neoplasm, arteriovenous malformation, or aneurysm; a platelet count less than 100,000 cubic millimeter; serum creatinine 2 milligrams per deciliter or above (for the 180 mcg/kg bolus and the 2 mcg/kg/min infusion) or 4 milligrams per deciliter or above (for the 135 mcg/kg bolus and the 0.5 mcg/kg/min infusion); or dependency on dialysis (eptifibatide).

Bleeding is the most common adverse effect, with most major bleeding occurring at the arterial access site for cardiac catheterization. If bleeding occurs and cannot be controlled with pressure, the drug infusion and heparin should be discontinued.

These drugs should be used cautiously if given with other drugs that affect hemostasis (e.g., warfarin, thrombolytics, other antiplatelet drugs).

### Phosphodiesterase Inhibitor

**Cilostazol** inhibits phosphodiesterase, an enzyme that metabolizes cyclic adenosine monophosphate (cAMP). This inhibition increases intracellular cAMP, which then inhibits platelet aggregation and produces vasodilation. The drug reversibly inhibits platelet aggregation induced by various stimuli (e.g., thrombin, ADP, collagen, arachidonic acid, epinephrine, shear stress). It is indicated for management of intermittent claudication. Symptoms usually improve within 2 to 4 weeks but may take as long as 12 weeks. The drug is contraindicated in patients with heart failure.

Cilostazol is highly protein bound (95%–98%), mainly to albumin; extensively metabolized by hepatic cytochrome P450 enzymes; and excreted in urine (74%) and feces. The drug and two active metabolites accumulate with chronic administration and reach steady state within a few days. The most common adverse effects are diarrhea and headache.

### Other Agents

**Anagrelide** inhibits platelet aggregation induced by cAMP phosphodiesterase, ADP, and collagen. However, it is indicated only to reduce platelet counts for patients with essential thrombocythemia (a disorder characterized by excessive numbers of platelets). Doses to reduce platelet production are smaller than those required to inhibit platelet aggregation.

**Dipyridamole** inhibits platelet adhesion, but its mechanism of action is unclear. It is used for prevention of thromboembolism after cardiac valve replacement and is given with warfarin. The combination of dipyridamole and aspirin is indicated for prevention of stroke in those who have had stroke precursors (TIAs) or a previously completed thrombotic stroke.

### Thrombolytic Agents

*Thrombolytic* agents are given to dissolve thrombi. They stimulate conversion of plasminogen to plasmin (also called *fibrinolysin*), a proteolytic enzyme that breaks down fibrin, the framework of a thrombus. The main use of thrombolytic agents is for management of acute, severe thromboembolic disease, such as myocardial infarction, pulmonary embolism, and iliofemoral thrombosis.

The goal of thrombolytic therapy is to re-establish blood flow as quickly as possible and prevent or limit tissue damage. Drugs with shorter half lives increase the risk of rethrombosis or infarction. Anticoagulant drugs, such as heparin and warfarin, and antiplatelet agents are given following thrombolytic therapy to decrease reformation of a thrombus. Thrombolytic drugs are also used to dissolve clots in arterial or venous cannulas or catheters.

**Streptokinase** and **urokinase** are enzymes that break down fibrin. They are used mainly to lyse coronary artery clots in acute myocardial infarction. Streptokinase may also be used

to dissolve clots in vascular catheters and to treat acute, severe pulmonary emboli or iliofemoral thrombophlebitis. Urokinase is recommended for use in patients allergic to streptokinase. As with other anticoagulants and thrombolytic agents, bleeding is the main adverse effect.

**Alteplase**, **reteplase**, and **tenecteplase** are tissue plasminogen activators used mainly in acute myocardial infarction to dissolve clots obstructing coronary arteries and re-establish perfusion of tissues beyond the thrombotic area. The drugs bind to fibrin in a clot and act locally to dissolve the clot. The most common adverse effect is bleeding, which may be internal (e.g., intracranial, GI, genitourinary) or external (e.g., venous or arterial puncture sites, surgical incisions). The drugs are contraindicated in the presence of bleeding, a history of stroke, central nervous system surgery or trauma within the previous 2 months, and severe hypertension.

**Drotrecogin alfa** is a recombinant version of human activated protein C that is approved for use in severe sepsis or septic shock. Severe sepsis is characterized by an excessive inflammatory reaction to infection, inappropriate blood clot formation, and impaired breakdown of clots. Drotrecogin alfa is given for its thrombolytic effects, along with other therapies for inflammation and infection. The major adverse effect is bleeding.

### Drugs Used to Control Bleeding

Anticoagulant, antiplatelet, and thrombolytic drugs profoundly affect hemostasis, and their major adverse effect is bleeding. As a result, systemic hemostatic agents (antidotes) may be needed to prevent or treat bleeding episodes. Antidotes should be used cautiously because overuse can increase risks of recurrent thrombotic disorders. These drugs are described in this section and in Table 54-2.

Table 54-2

### Drugs at a Glance: Systemic Hemostatic Drugs

GENERIC/TRADE NAME	INDICATIONS FOR USE	DOSAGE (ADULTS, UNLESS SPECIFIED)
<b>Aminocaproic acid</b> (Amicar)	Control bleeding caused by overdoses of thrombolytic agents or bleeding disorders caused by hyperfibrinolysis (e.g., cardiac surgery, blood disorders, hepatic cirrhosis, prostatectomy, neoplastic disorders)	PO, IV infusion, 5 g initially, followed by 1.0 to 1.25 g/h for 8 h or until bleeding is controlled; maximum dose, 30 g/24 h
<b>Protamine sulfate</b>	Treatment of heparin overdosage	Depends on the amount of heparin given within the previous 4 h
<b>Tranexamic acid</b> (Cyklokapron)	Control bleeding caused by overdoses of thrombolytic agents Prevent or decrease bleeding from tooth extraction in patients with hemophilia	PO 25 mg/kg 3 to 4 times daily, starting 1 d before surgery, or IV 10 mg/kg immediately before surgery, followed by 25 mg/kg PO 3 to 4 times daily for 2–8 d
<b>Vitamin K</b> (Mephyton)	Antidote for warfarin overdosage	PO 10–20 mg in a single dose

**Aminocaproic acid** and **tranexamic acid** are used to stop bleeding caused by overdoses of thrombolytic agents. Aminocaproic acid also may be used in other bleeding disorders caused by hyperfibrinolysis (e.g., in cardiac surgery, blood disorders, hepatic cirrhosis, prostatectomy, neoplastic disorders). Tranexamic acid also is used for short periods (2–8 days) in patients with hemophilia to prevent or decrease bleeding from tooth extraction. Dosage of tranexamic acid should be reduced in the presence of moderate or severe renal impairment.

**Protamine sulfate** is an antidote for standard heparin and LMWHs. Because heparin is an acid and protamine sulfate is a base, protamine neutralizes heparin activity. Protamine dosage depends on the amount of heparin administered during the previous 4 hours. Each milligram of protamine neutralizes approximately 100 units of heparin or dalteparin and 1 milligram of enoxaparin. A single dose should not exceed 50 milligrams. The FDA has issued a **BLACK BOX WARNING** with the use of protamine sulfate due to the risk of severe hypotension, cardiovascular collapse, noncardiogenic pulmonary edema, catastrophic pulmonary vasoconstriction, and pulmonary hypertension with its use.

The drug is given by slow IV infusion over at least 10 minutes (to prevent or minimize adverse effects of hypotension, bradycardia, and dyspnea). Protamine effects occur immediately and last for approximately 2 hours. A second dose may be required because heparin activity lasts approximately 4 hours.

Protamine sulfate can cause severe hypotensive and anaphylactoid reactions. Thus, it should be given in settings with equipment and personnel for resuscitation and management of anaphylactic shock.

**Vitamin K** is the antidote for warfarin overdose. An oral dose of 10 to 20 milligrams usually stops minor bleeding and returns the international normalized ratio (INR; see “Drug Dosage and Administration: Regulation of Heparin and Warfarin Dosage,” below) to a normal range within 24 hours.

## Nursing Process

### Assessment

Assess the patient’s status in relation to thrombotic and thromboembolic disorders.

- Risk factors for thromboembolism include
  - Immobility (e.g., limited activity or bed rest for more than 5 days)
  - Obesity
  - Cigarette smoking
  - History of thrombophlebitis, DVT, or pulmonary emboli
  - Congestive heart failure
  - Pedal edema
  - Lower limb trauma

- Myocardial infarction
- Atrial fibrillation
- Mitral or aortic stenosis
- Prosthetic heart valves
- Abdominal, thoracic, pelvic, or major orthopedic surgery
- Atherosclerotic heart disease or peripheral vascular disease
- Use of oral contraceptives
- Signs and symptoms of thrombotic and thromboembolic disorders depend on the location and size of the thrombus.
  - DVT and thrombophlebitis usually occur in the legs. The conditions may be manifested by edema (the affected leg is often measurably larger than the other) and pain, especially in the calf when the foot is dorsiflexed (Homans’ sign). If thrombophlebitis is superficial, it may be visible as a red, warm, tender area following the path of a vein.
  - Pulmonary embolism, if severe enough to produce symptoms, is manifested by chest pain, cough, hemoptysis, tachypnea, and tachycardia. Massive emboli cause hypotension, shock, cyanosis, and death.
  - DIC is usually manifested by bleeding, which may range from petechiae or oozing from a venipuncture site to massive internal bleeding or bleeding from all body orifices.

### Nursing Diagnoses

- Ineffective Tissue Perfusion related to thrombus or embolus or drug-induced bleeding
- Acute Pain related to tissue ischemia
- Impaired Physical Mobility related to bed rest and pain
- Ineffective Coping related to the need for long-term prophylaxis of thromboembolic disorders or fear of excessive bleeding
- Anxiety related to fear of myocardial infarction or stroke
- Deficient Knowledge related to anticoagulant or antiplatelet drug therapy
- Risk for Injury related to drug-induced impairment of blood coagulation

### Planning/Goals

#### The patient will

- Receive or take anticoagulant and antiplatelet drugs correctly
- Be monitored closely for therapeutic and adverse drug effects, especially when drug therapy is started and when changes are made in drugs or dosages
- Use nondrug measures to decrease venous stasis and prevent thromboembolic disorders

*Nursing Process continues on page 872*

- Act to prevent trauma from falls and other injuries
- Inform any health care provider when taking an anticoagulant or antiplatelet drug
- Avoid or report adverse drug reactions
- Verbalize or demonstrate knowledge of safe management of anticoagulant drug therapy
- Keep follow-up appointments for tests of blood coagulation and drug dosage regulation
- Avoid preventable bleeding episodes

## Interventions

Use measures to prevent thrombotic and thromboembolic disorders.

- Have the patient ambulate and exercise legs regularly, especially after surgery.
- For patients who cannot ambulate or do leg exercises, do passive range-of-motion and other leg exercises several times daily when changing the patient's position or performing other care.
- Have the patient wear elastic stockings. Elastic stockings should be removed every 8 hours and replaced after inspecting the skin. Improperly applied elastic stockings can impair circulation rather than aid it. For patients on bed rest, intermittent pneumatic compression devices can also be used.
- Avoid trauma to lower extremities.
- Maintain adequate fluid intake (1500–3000 mL/day) to avoid dehydration and hemoconcentration.
- Assist patients to promote good blood circulation (e.g., exercise) and avoid situations that impair circulation (e.g., wearing tight clothing, crossing the legs at the knees, prolonged sitting or standing, bed rest, placing pillows under the knees when in bed).

For the patient receiving anticoagulant therapy, implement safety measures to prevent trauma and bleeding.

- For patients who cannot ambulate safely because of weakness, sedation, or other conditions, keep the call light within reach, keep bed rails elevated, and assist in ambulation.
- Provide an electric razor for shaving.
- Avoid intramuscular injections, venipunctures, and arterial punctures when possible.
- Avoid intubations when possible (e.g., nasogastric tubes, indwelling urinary catheters).

For the patient receiving tirofiban or eptifibatid:

- Monitor the femoral artery access site closely. This is the most common site of bleeding.
- Avoid invasive procedures as much as possible (e.g., arterial and venous punctures, intramuscular injections,

urinary catheters, nasotracheal suction, nasogastric tubes). If venipuncture must be done, avoid sites where pressure cannot be applied (e.g., subclavian or jugular veins).

- While the vascular sheath is in place, keep patients on complete bed rest with the head of the bed elevated 30 degrees and the affected limb restrained in a straight position.
- Discontinue heparin for 3 to 4 hours and be sure the activated clotting time is less than 180 seconds or the activated partial thromboplastin time (aPTT) is less than 45 seconds before removing the vascular sheath.
- After the vascular sheath is removed, apply pressure to the site and observe closely. For outpatients, be sure there is no bleeding for at least 4 hours before hospital discharge.

For the patient receiving a thrombolytic drug or a revascularization procedure for acute myocardial infarction:

- Monitor closely for bleeding.
- Assist the patient and family to understand the importance of diligent efforts to reverse risk factors contributing to coronary artery disease (e.g., diet and perhaps medication to lower serum cholesterol to less than 200 mg/dL and low-density lipoprotein cholesterol to less than 130 mg/dL; weight reduction if overweight; control of blood pressure if hypertensive; avoidance of smoking; stress-reduction techniques; exercise program designed and supervised by a health care provider).
- Assist the patient and family to understand the importance of complying with medication orders to prevent reinfarction and other complications, and continued medical supervision (see accompanying Patient Teaching Guidelines).

## Evaluation

- Observe for signs and symptoms of thromboembolic disorders or bleeding.
- Check blood coagulation tests for therapeutic ranges.
- Observe and interview regarding compliance with instructions about drug therapy.
- Observe and interview regarding adverse drug effects.

## Principles of Therapy

### Drug Selection

Choices of anticoagulant and antiplatelet drugs depend on the reason for use and other drug and patient characteristics.

- Heparin is the anticoagulant of choice in acute venous thromboembolic disorders because the anticoagulant effect begins immediately with IV administration.

- Warfarin is the anticoagulant of choice for long-term maintenance therapy (i.e., several weeks or months) because it can be given orally.
- Aspirin has long been the most widely used antiplatelet drug for prevention of myocardial reinfarction and arterial thrombosis in patients with TIAs and prosthetic heart valves. However, clopidogrel may be more effective than aspirin.
- When anticoagulation is required during pregnancy, heparin is used because it does not cross the placenta. Warfarin is contraindicated during pregnancy as it crosses the placenta and may produce fatal fetal hemorrhage.

- Various combinations of antithrombotic drugs are used concomitantly or sequentially (e.g., abciximab is used with aspirin and heparin; thrombolytic drugs are usually followed with heparin and warfarin).

### Drug Dosage and Administration: Regulation of Heparin and Warfarin Dosage

Heparin dosage is regulated by the activated partial thromboplastin time (aPTT), which is sensitive to changes in blood clotting factors, except factor VII. Thus, normal or control values indicate normal blood coagulation; therapeutic values

## Patient Teaching Guidelines

## Drugs to Prevent or Treat Blood Clots

### General Considerations

- Antiplatelet and anticoagulant drugs are given to people who have had, or who are at risk of having, a heart attack, stroke, or other problems from blood clots. For prevention of a heart attack or stroke, you are most likely to be given an antiplatelet drug (e.g., aspirin, clopidogrel) or warfarin (Coumadin). For home management of deep vein thrombosis, which usually occurs in the legs, you are likely to be given heparin injections for a few days, followed by warfarin for long-term therapy. These medications help to prevent the blood clot from getting larger, traveling to your lungs, or recurring later.
- All of these drugs can increase your risk of bleeding, so you need to take safety precautions to prevent injury.
- To help prevent blood clots from forming and decreasing blood flow through your arteries, you need to reduce risk factors that contribute to cardiovascular disease. This can be done by a low-fat, low-cholesterol diet (and medication if needed) to lower total cholesterol to below 200 mg/dL and low-density lipoprotein cholesterol to below 130 mg/dL; weight reduction if overweight; control of blood pressure if hypertensive; avoidance of smoking; stress-reduction techniques; and regular exercise.
- To help prevent blood clots from forming in your leg veins, avoid or minimize situations that slow blood circulation, such as wearing tight clothing; crossing the legs at the knees; prolonged sitting or standing; and bed rest. For example, on automobile trips, stop and walk around every 1 to 2 hours; on long plane trips, exercise your feet and legs at your seat and walk around when you can.
- Following instructions regarding these medications is extremely important. Too little medication increases your risk of problems from blood clot formation; too much medication can cause bleeding.
- While taking any of these medications, you need regular medical supervision and periodic blood tests. The blood tests can help your health care provider regulate drug dosage and maintain your safety.
- You need to take the drugs as directed; avoid taking other drugs without the health care provider's knowledge and consent; inform any health care provider (including dentists) that you are taking an antiplatelet or anticoagulant drug before any invasive diagnostic tests or treatments are begun; and keep all appointments for continuing care.

- With warfarin therapy, you need to avoid walking barefoot; avoid contact sports; use an electric razor; avoid injections when possible; and carry an identification card, necklace, or bracelet (e.g., MedicAlert) stating the name of the drug and the health care provider's name and telephone number. Also, avoid large amounts of certain vegetables (e.g., broccoli, brussels sprouts, cabbage, cauliflower, chives, collard greens, kale, lettuce, mustard greens, peppers, spinach, turnips, and watercress), tomatoes, bananas, or fish; these foods contain vitamin K and may decrease anticoagulant effects.
- For home management of deep vein thrombosis, both warfarin and enoxaparin (Lovenox) are given for 3 months or longer. With Lovenox, you need an injection, usually every 12 hours. You or someone close to you may be instructed in injecting the medication, or a visiting nurse may do the injections, if necessary.
 

Even if a nurse is not needed to give the injections, one will usually visit your home each day to perform a finger stick blood test. The results of this test determine your daily dose of warfarin. After the blood test and the warfarin dose stabilize, the blood tests are done less often (e.g., every 2 weeks).
- Report any sign of bleeding (e.g., excessive bruising of the skin; blood in urine or stool). If superficial bleeding occurs, apply direct pressure to the site for 3 to 5 minutes or longer if necessary.

### Self-Administration

- Take aspirin with food or after meals, with 8 oz of water, to decrease stomach irritation. However, stomach upset is uncommon with the small doses used for antiplatelet effects. Do not crush or chew coated tablets (long-acting preparations).
- Take cilostazol (Pletal) 30 minutes before or 2 hours after morning and evening meals for better absorption and effectiveness.
- Take ticlopidine (Ticlid) with food or after meals to decrease GI upset. Clopidogrel (Plavix) may be taken with or without food.
- With Lovenox, wash hands and cleanse skin to prevent infection; inject deep under the skin, around the navel, upper thigh, or buttocks; and change the injection site daily. If excessive bruising occurs at the injection site, rubbing an ice cube over an area before the injection may be helpful.

indicate low levels of clotting factors and delayed blood coagulation. During heparin therapy, the aPTT should be maintained at approximately 1.5 to 2.5 times the control or baseline value. The normal control value is 25 to 35 seconds; therefore, therapeutic values are 45 to 70 seconds, approximately. With continuous IV infusion, blood for the aPTT may be drawn at any time; with intermittent administration, blood for the aPTT should be drawn approximately 1 hour before a dose of heparin is scheduled. Monitoring of aPTT is not necessary with low-dose standard heparin given Sub-Q for prophylaxis of thromboembolism or with the LMWHs (e.g., enoxaparin).

### Applying Your Knowledge 54-2

Mr. Dusseau's aPTT is measured to regulate the amount of heparin he receives. What is the aPTT goal for a therapeutic value?

Warfarin dosage is regulated according to the INR, for which therapeutic values are 2.0 to 3.0 in most conditions. An average daily dose of 4 to 5 milligrams maintains a therapeutic INR; stopping warfarin returns an elevated INR to normal in approximately 4 days in most patients.

The INR is based on prothrombin time (PT). PT is sensitive to changes in three of the four vitamin K–dependent coagulation factors. Thus, normal or control values indicate normal levels of these factors; therapeutic values indicate low levels of the factors and delayed blood coagulation. A normal baseline or control PT is approximately 12 seconds; a therapeutic value is approximately 1.5 times the control, or 18 seconds.

When warfarin is started, PT and INR should be assessed daily until a stable daily dose is reached (the dose that maintains PT and INR within therapeutic ranges and does not cause bleeding). Thereafter, PT and INR are determined every 2 to 4 weeks for the duration of oral anticoagulant drug therapy. If the warfarin dose is changed, PT and INR measurements are needed more often until a stable daily dose is again established.

For many years, PT was used to regulate warfarin dosage. PT is determined by adding a mixture of thromboplastin and calcium to citrated plasma and measuring the time (in seconds) it takes for the blood to clot. However, values vary among laboratories according to the type of thromboplastin and the instrument used to measure PT. The INR system standardizes PT by comparing a particular thromboplastin with a standard thromboplastin designated by the World Health Organization. Advantages of the INR include consistent values among laboratories, more consistent warfarin dosage with less risk of bleeding or thrombosis, and more consistent reports of clinical trials and other research studies. Some laboratories report both PT and INR.

Warfarin dosage may need to be reduced in patients with biliary tract disorders (e.g., obstructive jaundice), liver disease (e.g., hepatitis, cirrhosis), malabsorption syndromes (e.g., steatorrhea), hyperthyroidism, or fever. These conditions increase

anticoagulant drug effects by reducing absorption of vitamin K, decreasing hepatic synthesis of blood clotting factors, or increasing the breakdown of clotting factors. Despite these influencing factors, however, the primary determinant of dosage is the PT and INR.

Warfarin interacts with many other drugs to cause increased, decreased, or unpredictable anticoagulant effects (see Nursing Actions). Thus, warfarin dosage may need to be increased or decreased when other drugs are given concomitantly. Most drugs can be given if warfarin dosage is titrated according to the PT or INR and altered appropriately when an interacting drug is added or stopped. INR or PT measurements and vigilant observation are needed whenever a drug is added to or removed from a drug therapy regimen containing warfarin.

### Applying Your Knowledge 54-3

#### How Can You Avoid This Medication Error?

In anticipation of Mr. Dusseau's discharge from the hospital, the physician changes his medication from heparin to warfarin. The order is for warfarin 5 mg PO daily and for evaluation of baseline PT and INR. You administer the warfarin and order the blood work for the next morning.

## Thrombolytic Therapy

- Thrombolytic therapy should be performed only by experienced personnel in an intensive care or diagnostic/interventional setting with cardiac and other monitoring devices in place.
- All of the available agents are effective with recommended uses. Thus, the choice of a thrombolytic agent depends mainly on risks of adverse effects and costs. All of the drugs may cause bleeding. Alteplase may act more specifically on the fibrin in a clot and cause less systemic depletion of fibrinogen, but this agent is very expensive. Streptokinase, the least expensive agent, may cause allergic reactions because it is a foreign protein. Combination therapy (e.g., with alteplase and streptokinase) may also be used.
- Before a thrombolytic agent is begun, INR, aPTT, platelet count, and fibrinogen should be checked to establish baseline values and to determine if a blood coagulation disorder is present. Two or 3 hours after thrombolytic therapy is started, the fibrinogen level can be measured to determine that fibrinolysis is occurring. Alternatively, INR or aPTT can be checked for increased values because the breakdown products of fibrin exert anticoagulant effects.
- Major factors in decreasing risks of bleeding are selecting recipients carefully, avoiding invasive procedures when possible, and omitting anticoagulant or antiplatelet drugs while thrombolytics are being given. If bleeding does occur, it is most likely from a venipuncture or invasive procedure site, and local pressure may control it. If bleeding cannot be controlled or involves a vital organ, the thrombolytic drug

should be stopped and fibrinogen replaced with whole blood plasma or cryoprecipitate. Aminocaproic acid or tranexamic acid may also be given.

- When the drugs are used in acute myocardial infarction, cardiac dysrhythmias may occur when blood flow is re-established. Therefore, antidysrhythmic drugs should be readily available.

## Use in Special Populations

### Use in Children

Little information is available about the use of anticoagulants in children. Heparin solutions containing benzyl alcohol as a preservative should not be given to premature infants because fatal reactions have been reported. When given for systemic anticoagulation, heparin dosage should be based on the child's weight (approximately 50 units/kg). Extreme caution should be used to ensure that the vial concentration of heparin is correct. Fatalities in infants have been reported with overdosing of heparin. Safety and effectiveness of LMWHs (e.g., enoxaparin) have not been established in children.

Warfarin is given to children after cardiac surgery to prevent thromboembolism, but doses and guidelines for safe, effective use have not been developed. Accurate drug administration, close monitoring of blood coagulation tests, safety measures to prevent trauma and bleeding, avoiding interacting drugs, and informing others in the child's environment (e.g., teachers, baby-sitters, health care providers) are necessary.

Antiplatelet and thrombolytic drugs have no established indications for use in children.

### Use in Older Adults

Older adults often have atherosclerosis and thrombotic disorders, including myocardial infarction, thrombotic stroke, and peripheral arterial insufficiency, for which they receive an anticoagulant or an antiplatelet drug. They are more likely than younger adults to experience bleeding and other complications of anticoagulant and antiplatelet drugs. For example, aspirin or clopidogrel is commonly used to prevent thrombotic stroke, but both drugs increase risks of hemorrhagic stroke.

With standard heparin, general principles for safe and effective use apply. With LMWHs, elimination may be delayed in older adults with renal impairment and the drugs should be used cautiously. They should also be used with caution in patients taking a platelet inhibitor (e.g., aspirin, clopidogrel) to prevent myocardial infarction or thrombotic stroke or an NSAID for arthritis pain. NSAIDs, which are commonly used by older adults, also have antiplatelet effects. Patients who take an NSAID daily may not need low-dose aspirin for antithrombotic effects.

With warfarin, dosage should be reduced because impaired liver function and decreased plasma proteins increase the risks of bleeding. Also, many drugs interact with warfarin to increase or decrease its effect, and older adults often take multiple drugs. Starting or stopping any drug may require that warfarin dosage be adjusted.

### Use in Patients With Renal Impairment

Most anticoagulant, antiplatelet, and thrombolytic drugs may be used in patients with impaired renal function. For example, heparin and warfarin can be used in usual dosages, and thrombolytic agents (e.g., streptokinase, urokinase) may be used to dissolve clots in IV catheters or vascular access sites for hemodialysis. Dosage of LMWHs should be reduced in patients with severe renal impairment (creatinine clearance < 30 mL/minute) because they are excreted by the kidneys and elimination is slowed. In addition, home management of DVT with LMWHs and warfarin is contraindicated in patients with severe renal impairment. Guidelines for the use of other drugs include the following:

- Anagrelide may be given to patients with renal impairment (e.g., serum creatinine < 2 mg/dL) if potential benefits outweigh risks. Patients receiving this medication should be monitored closely for signs of renal toxicity.
- Cilostazol is probably safe to use in patients with mild or moderate renal impairment. However, severe renal impairment alters drug protein binding and increases blood levels of metabolites.
- Clopidogrel does not need dosage reduction in patients with renal impairment.
- Eptifibatid does not need dosage reduction in patients with mild to moderate renal impairment. No data are available for patients with severe impairment or those on hemodialysis.
- Lepirudin is excreted by the kidneys and may accumulate in patients with impaired renal function. Dosage should be reduced.
- Ticlopidine may be more likely to cause bleeding in patients with renal impairment because the plasma drug concentration is increased and elimination is slower.
- Tirofiban clearance from plasma is decreased approximately 50% in patients with severe renal impairment (e.g., creatinine clearance < 30 mL/minute), including those receiving hemodialysis. Dosage must be reduced by approximately 50%.

### Use in Patients With Hepatic Impairment

Little information is available about the use of most anticoagulant, antiplatelet, and thrombolytic drugs in patients with impaired liver function. However, such drugs should be used very cautiously because these patients may already be predisposed to bleeding due to decreased hepatic synthesis of clotting factors. Additional considerations include the following:

- Warfarin is more likely to cause bleeding in patients with liver disease, because of decreased synthesis of vitamin K. In addition, warfarin is eliminated only by hepatic metabolism and may accumulate with liver impairment.
- LMWHs are contraindicated for home management of DVT in patients with severe liver disease because of high risks of excessive bleeding.

- Anagrelide is metabolized in the liver and may accumulate with hepatic impairment. Patients with evidence of impairment (e.g., bilirubin or aspartate aminotransferase more than 1.5 times the upper limit of normal) should receive anagrelide only if potential benefits outweigh potential risks. When anagrelide is given, patients should be closely monitored for signs of hepatotoxicity.
- Clopidogrel is metabolized in the liver and may accumulate with hepatic impairment. It should be used cautiously.
- Dipyridamole is metabolized in the liver and excreted in bile.

### Use in Home Care

Antiplatelet agents and warfarin are used for long-term prevention or management of thromboembolism and are often taken at home. For prevention, antiplatelet agents and warfarin are usually self-administered at home, with periodic office or clinic visits for blood tests and other follow-up care.

For home management of DVT, warfarin may be self-administered, but a nurse usually visits, performs a fingerstick INR, and notifies the prescriber, who then prescribes the appropriate dose of warfarin. Precautions are needed to decrease risks of bleeding. The risk of bleeding has lessened in recent years because of the lower doses of warfarin being used. In addition, bleeding during warfarin therapy may be caused by medical conditions other than anticoagulation.

Heparin may also be taken at home. Standard heparin may be taken Sub-Q, but use of LMWHs for home management of venous thrombosis has become standard practice. Enoxaparin is approved by the Food and Drug Administration for outpatient use. Daily visits by a home care nurse may be needed if the patient or a family member is unable or unwilling to inject the medication. Platelet counts should be done before and every 2 to 3 days during heparin therapy. Heparin should be discontinued if the platelet count falls below 100,000 or to less than half the baseline value.

Most home management regimens involve a structured protocol. Patients and family members should be educated about the disorder (usually DVT), including the potential consequences of either overcoagulation or undercoagulation and the need for blood tests.

The home care nurse needs to assess patients in relation to knowledge about prescribed drugs and ability and willingness to comply with instructions for taking the drugs, obtaining blood tests when indicated, and taking safety precautions. In addition, assess the environment for risk factors for injury. Interventions vary with patients, environments, and assessment data but may include reinforcing instructions for safe use of the drugs, assisting patients to obtain laboratory tests, and teaching how to observe for signs and symptoms of bleeding.

### Use of Herbal and Dietary Supplements

Many commonly used herbs and supplements have a profound effect on drugs used for anticoagulation. Multivitamin supplements may contain 25 to 28 micrograms of vitamin K and should be taken consistently to avoid fluctuating vitamin K levels. Doses of vitamin C in excess of 500 milligrams per day may lower INR, and vitamin E in excess of 400 international units per day may increase warfarin effects. Herbs commonly used that may increase the effects of warfarin include alfalfa, celery, clove, feverfew, garlic, ginger, ginkgo, ginseng, and licorice. Patients taking warfarin should be questioned carefully about their use of herbs as well as vitamin or mineral supplements.

### Applying Your Knowledge 54-4

After 6 months of treatment with warfarin, the physician orders Mr. Dusseau to change to aspirin therapy. What is the purpose of aspirin therapy?

.....

## Nursing Actions

## Drugs That Affect Blood Coagulation

### NURSING ACTIONS

#### 1. Administer accurately

##### a. With standard heparin:

- (1) When handwriting a heparin dose, write out “units” rather than using the abbreviation “U.”
- (2) Check dosage and vial label carefully.

##### (3) For subcutaneous (Sub-Q) heparin:

- (a) Use a 26-gauge, 1/2-inch needle.
- (b) Leave a small air bubble in the syringe to follow dose.

### RATIONALE/EXPLANATION

This is a safety precaution to avoid erroneous dosage. For example, 1000 U (1000 units) may be misread as 10,000 units. Underdosage may cause thromboembolism, and overdosage may cause bleeding. In addition, heparin is available in several concentrations (1000, 2500, 5000, 10,000, 15,000, 20,000, and 40,000 units/mL).

To minimize trauma and risk of bleeding  
Locks drug into subcutaneous space and minimizes trauma

**NURSING ACTIONS**

**RATIONALE/EXPLANATION**

<p>(c) Grasp a skinfold and inject the heparin into it, at a 90-degree angle, without aspirating.</p> <p>(d) Do not massage site after injection.</p> <p>(4) For intermittent intravenous (IV) administration:</p> <p>(a) Give by direct injection into a heparin lock or tubing injection site.</p> <p>(b) Dilute the dose in 50–100 mL of any IV fluid (usually 5% dextrose in water).</p> <p>(5) For continuous IV administration:</p> <p>(a) Use a volume-control device and an infusion-control device.</p> <p>(b) Add only enough heparin for a few hours. One effective method is to fill the volume-control set (e.g., Volutrol) with 100 mL of 5% dextrose in water and add 5000 units of heparin to yield a concentration of 50 units/mL. Dosage is regulated by varying the flow rate. For example, administration of 1000 units/h requires a flow rate of 20 mL/h. Another method is to add 25,000 units of heparin to 500 mL of IV solution.</p> <p>b. With low-molecular-weight heparins:</p> <p>(1) Give by deep Sub-Q injection, into an abdominal skin fold, with the patient lying down, using the same technique as standard heparin. Do not rub the injection site.</p> <p>(2) Rotate sites.</p> <p>c. After the initial dose of warfarin, check the international normalized ratio (INR) before giving a subsequent dose. Do not give the dose if the INR is above 3.0. Notify the health care provider.</p> <p>d. Give ticlopidine with food or after meals; give cilostazol 30 minutes before or 2 hours after morning and evening meals; give clopidogrel with or without food.</p> <p>e. With eptifibatide, tirofiban, and thrombolytic agents, follow manufacturers' instructions for reconstitution and administration.</p> <p><b>2. Observe for therapeutic effects</b></p> <p>a. With prophylactic heparins and warfarin, observe for the absence of signs and symptoms of thrombotic disorders.</p> <p>b. With therapeutic heparins and warfarin, observe for decrease or improvement in signs and symptoms (e.g., less edema and pain with deep vein thrombosis, less chest pain and respiratory difficulty with pulmonary embolism).</p> <p>c. With prophylactic or therapeutic warfarin, observe for an INR between 2.0 and 3.0.</p> <p>d. With therapeutic heparin, observe for an activated partial thromboplastin time of 1.5 to 2 times the control value.</p> <p>e. With anagrelide, observe for a decrease in platelet count.</p> <p>f. With aspirin, clopidogrel, and other antiplatelet drugs, observe for the absence of thrombotic disorders (e.g., myocardial infarction, stroke).</p> <p>g. With cilostazol, observe for ability to walk farther without leg pain (intermittent claudication).</p> <p><b>3. Observe for adverse effects</b></p> <p>a. Bleeding:</p> <p>(1) Record vital signs regularly.</p>	<p>To give the drug in a deep subcutaneous or fat layer, with minimal trauma</p> <p>These methods prevent repeated venipunctures.</p> <p>This is usually the preferred method because it maintains consistent serum drug levels and decreases risks of bleeding. To regulate dosage and flow rate accurately</p> <p>To avoid inadvertent administration of large amounts. Whatever method is used, it is desirable to standardize concentration of heparin solutions within an institution. Standardization is safer, because it reduces risks of errors in dosage.</p> <p>To decrease bruising</p> <p>The INR is measured daily until a maintenance dose is established, then periodically throughout warfarin therapy. An elevated INR indicates a high risk of bleeding.</p> <p>These drugs require special preparation and administration techniques.</p> <p>Frequency of INR determinations varies, but the test should be done periodically in all patients taking warfarin.</p> <p>Platelet counts should be done every 2 days during the first week of management and weekly until a maintenance dose is reached. Counts usually begin to decrease within the first 2 weeks of therapy. Improvement may occur within 2–4 weeks or take as long as 12 weeks.</p> <p>Bleeding is the major adverse effect of anticoagulant drugs. It may occur anywhere in the body, spontaneously or in response to minor trauma. With eptifibatide and tirofiban, most major bleeding occurs at the arterial access site for cardiac catheterization. Hypotension and tachycardia may indicate internal bleeding.</p>
---	---

## Nursing Actions Drugs That Affect Blood Coagulation (continued)

### NURSING ACTIONS

- (2) Check stools for blood (melena).
- (3) Check urine for blood (hematuria).
- (4) Inspect the skin and mucous membranes daily.
- (5) Assess for excessive menstrual flow.
- b. Other adverse effects:
  - (1) With heparin, tissue irritation at injection sites, transient alopecia, reversible thrombocytopenia, paresthesias, and hypersensitivity
  - (2) With warfarin, dermatitis, diarrhea, and alopecia
  - (3) With anagrelide, adverse cardiovascular effects (e.g., tachycardia, vasodilation, heart failure)
  - (4) With clopidogrel and ticlopidine, GI upset, skin rash, neutropenia, and thrombocytopenia
- c. With thrombolytic drugs, observe for bleeding with all uses and reperfusion dysrhythmias when used for acute myocardial infarction.

#### 4. Observe for drug interactions

- a. Drugs that *increase* risks of bleeding with anticoagulant, antiplatelet, and thrombolytic agents:
  - (1) Any one of these drugs in combination with any other drug that affects hemostasis
  - (2) A combination of these drugs
- b. Drugs that *increase* effects of heparins:
  - (1) Antiplatelet drugs (e.g., aspirin, clopidogrel, others)
  - (2) Warfarin
  - (3) Parenteral penicillins and cephalosporins
- c. Drugs that *decrease* effects of heparins:
  - (1) Antihistamines, digoxin, tetracyclines
  - (2) Protamine sulfate
- d. Drugs that *increase* effects of warfarin:
  - (1) Analgesics (e.g., acetaminophen, aspirin and other nonsteroidal anti-inflammatory drugs)
  - (2) Androgens and anabolic steroids
  - (3) Antibacterial drugs (e.g., aminoglycosides, erythromycin, fluoroquinolones, isoniazid, metronidazole, penicillins, cephalosporins, rimethoprim-sulfamethoxazole, tetracyclines)
  - (4) Antifungal drugs (e.g., fluconazole, ketoconazole, miconazole), including intravaginal use
  - (5) Antiseizure drugs (e.g., phenytoin)
  - (6) Cardiovascular drugs (e.g., amiodarone, beta blockers, loop diuretics, gemfibrozil, lovastatin, propafenone, quinidine)
  - (7) Gastrointestinal drugs (e.g., cimetidine, omeprazole)
  - (8) Thyroid preparations (e.g., levothyroxine)

### RATIONALE/EXPLANATION

- Gastrointestinal (GI) bleeding is fairly common; risks are increased with intubation. Blood in stools may be bright red, tarry (blood that has been digested by GI secretions), or occult (hidden to the naked eye but present with a guaiac test). Hematemesis also may occur.
- Genitourinary bleeding also is fairly common; risks are increased with catheterization or instrumentation. Urine may be red (indicating fresh bleeding) or brownish or smoky gray (indicating old blood). Or bleeding may be microscopic (red blood cells are visible only on microscopic examination during urinalysis).
- Bleeding may occur in the skin as petechiae, purpura, or ecchymoses. Surgical wounds, skin lesions, parenteral injection sites, the nose, and gums may be bleeding sites.
- These effects are uncommon. They are more likely to occur with large doses or prolonged administration.
- These effects occur only occasionally. Warfarin has been given for prolonged periods without toxicity. These effects are most likely to occur in patients with known heart disease.
- Neutropenia and thrombocytopenia are more likely to occur with ticlopidine than clopidogrel.
- Bleeding is most likely to occur at sites of venipuncture or other invasive procedures. Reperfusion dysrhythmias may occur when blood supply is restored to previously ischemic myocardium.

These drugs are often used concurrently or sequentially to decrease risks of myocardial infarction or stroke.

Additive anticoagulant effects and increased risks of bleeding. Some may affect blood coagulation and increase risks of bleeding.

These drugs antagonize the anticoagulant effects of heparin. Mechanisms are not clear.

The antidote for heparin overdose. Mechanisms by which drugs may increase effects of warfarin include inhibiting warfarin metabolism, displacing warfarin from binding sites on serum albumin, causing antiplatelet effects, inhibiting bacterial synthesis of vitamin K in the intestinal tract, and others.

**NURSING ACTIONS**

- e. Drugs that *decrease* effects of warfarin:
- (1) Antacids and griseofulvin
  - (2) Carbamazepine, disulfiram, rifampin
  
  - (3) Cholestyramine
  - (4) Diuretics
  - (5) Estrogens, including oral contraceptives
  
  - (6) Vitamin K
- f. Drug that may *increase* or *decrease* effects of warfarin:
- (1) Alcohol
- 
- g. Drugs that *increase* effects of cilostazol:
- (1) Diltiazem
  - (2) Erythromycin
  - (3) Itraconazole, ketoconazole

**RATIONALE/EXPLANATION**

May decrease GI absorption  
 These drugs activate liver metabolizing enzymes, which accelerate the rate of metabolism of warfarin.

Decreases absorption  
 Increase synthesis and concentration of blood clotting factors  
 Increase synthesis of clotting factors and have thromboembolic effect  
 Restores prothrombin and other vitamin K-dependent clotting factors in the blood. Antidote for overdose of warfarin.

Alcohol may induce liver enzymes, which decrease effects by accelerating the rate of metabolism of the anticoagulant drug. However, with alcohol-induced liver disease (i.e., cirrhosis), effects may be increased owing to impaired metabolism of warfarin.

These drugs inhibit the main cytochrome P450 enzyme (CYP3A4) that metabolizes cilostazol. Grapefruit juice also inhibits drug metabolism and should be avoided.

## Key Concepts

- Anticoagulant drugs are given to prevent formation of new clots and extension of clots already present.
- Antiplatelet drugs are used to prevent arterial thrombosis.
- Thrombolytic agents are used to dissolve thrombi and limit tissue damage in selected thromboembolic disorders.
- No antidote exists for the effects of aspirin or the adenosine diphosphate receptor antagonists because both produce irreversible platelet effects; platelet transfusion may be required.
- Warfarin dosage is regulated according to the INR (derived from prothrombin time [PT]), for which a therapeutic value is between 2.0 to 3.0 in most conditions; a therapeutic PT value is approximately 1.5 times the control, or 18 seconds.
- Herbs commonly used that may increase the effects of warfarin include alfalfa, celery, clove, feverfew, garlic, ginger, ginkgo, ginseng, and licorice.
- Vitamin K (Mephyton) is the antidote for warfarin.
- The FDA has issued a **BLACK BOX WARNING** with warfarin due to its risk of causing major or fatal bleeding.
- Currently available LMWHs (dalteparin, enoxaparin) differ from standard heparin and each other and are not interchangeable.
- During heparin therapy, the aPTT should be maintained at approximately 1.5 to 2.5 times the control or baseline value.
- Monitoring of aPTT is not necessary with low-dose standard heparin given Sub-Q for prophylaxis of thromboembolism or with the LMWHs.
- Protamine sulfate is the antidote for standard heparin and LMWHs.
- The FDA has issued a **BLACK BOX WARNING** with the use of protamine sulfate due to the risk of severe hypotension, cardiovascular collapse, noncardiogenic pulmonary edema, catastrophic pulmonary vasoconstriction, and pulmonary hypertension with its use.
- When the thrombolytic agents are used in acute myocardial infarction, cardiac dysrhythmias may occur when blood flow is re-established; antidysrhythmic drugs should be readily available.

## Review and Application Exercises

### Short Answer Exercises

1. What are the major functions of the endothelium, platelets, and coagulation factors in hemostasis and thrombosis?
2. What are the indications for use of heparin and warfarin?
3. How do heparin and warfarin differ in mechanism of action, onset and duration of action, and method of administration?

4. List interventions to protect patients from anticoagulant-induced bleeding.
5. When is it appropriate to use protamine sulfate as an antidote for heparin?
6. When is it appropriate to use vitamin K as an antidote for warfarin?
7. How do antiplatelet drugs differ from heparin and warfarin?
8. For what conditions are antiplatelet drugs indicated?
9. When is it appropriate to use a thrombolytic drug?
10. How do aminocaproic acid and tranexamic acid stop bleeding induced by thrombolytics?
11. Compare and contrast nursing care needs of patients receiving anticoagulant therapy in hospital and home settings.
12. In explaining the use of warfarin to a patient, the nurse is correct in telling her all of the following, except
  - a. Warfarin is a vitamin K antagonist.
  - b. Warfarin does not cross the placenta.
  - c. Warfarin is used for long-term anticoagulation therapy.
  - d. Warfarin is metabolized by the liver.
13. The nurse is reviewing the laboratory results of a hospitalized patient receiving IV heparin therapy for pulmonary embolism. The aPTT is 38 seconds. The nurse should
  - a. not give the next dose because the level is too high
  - b. continue the present order because the level is appropriate
  - c. notify the provider that the aPTT is low and the dose should be increased
  - d. request an order for warfarin now that the patient is heparinized
14. The nurse explains to a patient that aspirin suppresses blood clotting by
  - a. inactivating thrombin
  - b. promoting fibrin degradation
  - c. decreasing synthesis of clotting factors
  - d. decreasing platelet aggregation
15. A patient's Port-a-Cath has become occluded with thrombus. The nurse expects which agent will likely be used to lyse the clot?
  - a. protamine sulfate
  - b. tirofiban
  - c. streptokinase
  - d. enoxaparin
16. Clopidogrel is indicated for
  - a. reduction of myocardial infarction, stroke, and vascular death in patients with atherosclerosis
  - b. adjunctive therapy to warfarin for DVT
  - c. heparin-induced thrombocytopenia
  - d. patients in whom bleeding is a consideration

# Drugs for Dyslipidemia

## KEY TERMS

- Central adiposity
- Cholesterol
- Dyslipidemia
- Hyperlipoproteinemias
- Lipoproteins
- Metabolic syndrome

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Recognize the role of dyslipidemia in the metabolic syndrome.
2. Identify sources and functions of cholesterol and triglycerides.
3. Describe dyslipidemic drugs in terms of mechanism of action, indications for use, major adverse effects, and nursing process implications.
4. Educate patients about pharmacologic and nonpharmacologic measures to prevent or reduce dyslipidemia.
5. Use the nursing process in the care of patients with dyslipidemia.

## Applying Your Knowledge

Lewis Watkins is a 62-year-old man who has had elevated cholesterol and triglyceride levels during his two previous visits to the physician. He has tried diet modification and increasing exercise; however, his lipid levels remain elevated. His physician decides to prescribe atorvastatin 10 mg PO daily and gemfibrozil 600 mg PO bid. You are the home care nurse assigned to his care.

## Introduction

Dyslipidemic drugs are used in the management of patients with elevated blood lipids, a major risk factor for atherosclerosis and vascular disorders such as coronary artery disease, strokes, and peripheral arterial insufficiency. These drugs have proven efficacy and are being used increasingly to reduce morbidity and mortality from coronary heart disease and other atherosclerosis-related cardiovascular disorders. To understand clinical use of these drugs, it is necessary to understand characteristics of blood lipids, metabolic syndrome, and types of blood lipid disorders.

### Blood Lipids

Blood lipids, which include cholesterol, phospholipids, and triglycerides, are derived from the diet or synthesized by the liver and intestine. Most *cholesterol* is found in body cells, where it is a component of cell membranes and performs other essential functions. In cells of the adrenal glands, ovaries, and testes, cholesterol is required for the synthesis of steroid hormones (e.g., cortisol, estrogen, progesterone, testosterone). In liver cells, cholesterol is used to form cholic acid which is conjugated with other substances to form bile salts; bile salts promote absorption and digestion of fats. In addition, a small amount of cholesterol is found in blood serum. Serum cholesterol is the portion of total body cholesterol involved in formation of atherosclerotic plaques. Unless a person has a genetic disorder of lipid metabolism, the amount of cholesterol in the blood is strongly related to dietary intake of saturated fat. Phospholipids are essential components of cell membranes, and triglycerides provide energy for cellular metabolism.

Blood lipids are transported in plasma by specific proteins called *lipoproteins*. Each lipoprotein contains cholesterol, phospholipid, and triglyceride bound to protein. The lipoproteins vary in density and amounts of lipid and protein. Density is determined mainly by the amount of protein, which is more dense than fat. Thus, density increases as the proportion of protein increases. The lipoproteins are differentiated according to these properties, which can be measured in the laboratory. For example, high-density lipoprotein (HDL) cholesterol contains larger amounts of protein and smaller amounts of lipid; low-density lipoprotein (LDL) cholesterol contains less protein and larger amounts of lipid. Other plasma lipoproteins are chylomicrons and very-low-density lipoproteins (VLDL).

Additional characteristics of lipoproteins are described in Box 55-1.

## Metabolic Syndrome

*Metabolic syndrome* is a group of cardiovascular risk factors linked with obesity. *The Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults* (NCEP III) clustered several elements of metabolic syndrome: elevated waist circumference (*central adiposity*), elevated triglycerides, reduced high-density lipoprotein cholesterol, elevated blood pressure, and elevated fasting glucose. These risk factors frequently produce an additive effect on cardiovascular,

### Box 55-1

### Types of Lipoproteins

**Chylomicrons**, the largest lipoprotein molecules, are synthesized in the wall of the small intestine. They carry recently ingested dietary cholesterol and triglycerides that have been absorbed from the gastrointestinal tract. Hyperchylomicronemia normally occurs after a fatty meal, reaches peak levels in 3 to 4 hours, and subsides within 12 to 14 hours. Chylomicrons carry triglycerides to fat and muscle cells, where the enzyme lipoprotein lipase breaks down the molecule and releases fatty acids to be used for energy or stored as fat. This process leaves a remnant containing cholesterol, which is then transported to the liver. Thus, chylomicrons transport triglycerides to peripheral tissues and cholesterol to the liver.

**Low-density lipoprotein (LDL) cholesterol**, sometimes called “bad cholesterol,” transports approximately 75% of serum cholesterol and carries it to peripheral tissues and the liver. LDL cholesterol is removed from the circulation by receptor and nonreceptor mechanisms. The receptor mechanism involves the binding of LDL cholesterol to receptors on cell surface membranes. The bound LDL molecule is then engulfed into the cell, where it is broken down by enzymes and releases free cholesterol into the cytoplasm.

Most LDL cholesterol receptors are located in the liver. However, nonhepatic tissues (e.g., adrenal glands, smooth muscle cells, endothelial cells, and lymphoid cells) also have receptors by which they obtain the cholesterol needed for building cell membranes and synthesizing hormones. These cells can regulate their cholesterol intake by adding or removing LDL receptors.

Approximately two thirds of the LDL cholesterol is removed from the bloodstream by the receptor-dependent mechanism. The number of LDL receptors on cell membranes determines the amount of LDL degradation (i.e., the more receptors on cells, the more LDL is broken down). Conditions that decrease the number or function of receptors (e.g., high dietary intake of cholesterol, saturated fat, or calories), increase blood levels of LDL.

The remaining one third is removed by mechanisms that do not involve receptors. Nonreceptor uptake occurs in various cells, especially when levels of circulating LDL cholesterol are high. For example, macrophage cells in arterial walls can

attach LDL, thereby promoting accumulation of cholesterol and the development of atherosclerosis. The amount of LDL cholesterol removed by nonreceptor mechanisms is increased with inadequate numbers of receptors or excessive amounts of LDL cholesterol.

A high serum level of LDL cholesterol is atherogenic and a strong risk factor for coronary heart disease. The body normally attempts to compensate for high serum levels by inhibiting hepatic synthesis of cholesterol and cellular synthesis of new LDL receptors.

**Very-low-density lipoprotein (VLDL)** contains approximately 75% triglycerides and 25% cholesterol. It transports endogenous triglycerides (those synthesized in the liver and intestine, not those derived exogenously, from food) to fat and muscle cells. There, as with chylomicrons, lipoprotein lipase breaks down the molecule and releases fatty acids to be used for energy or stored as fat. The removal of triglycerides from VLDL leaves a cholesterol-rich remnant, which returns to the liver. Then the cholesterol is secreted into the intestine, mostly as bile acids, or it is used to form more VLDL and recirculated.

**High-density lipoprotein (HDL) cholesterol**, often referred to as “good cholesterol,” is a small but very important lipoprotein. It is synthesized in the liver and intestine and some is derived from the enzymatic breakdown of chylomicrons and VLDL. It contains moderate amounts of cholesterol. However, this cholesterol is transported from blood vessel walls to the liver for catabolism and excretion. This reverse transport of cholesterol has protective effects against coronary heart disease.

The mechanisms by which HDL cholesterol exerts protective effects are unknown. Possible mechanisms include clearing cholesterol from atheromatous plaque; increasing excretion of cholesterol so less is available for reuse in the formation of LDL cholesterol; and inhibiting cellular uptake of LDL cholesterol. Regular exercise and moderate alcohol consumption are associated with increased levels of HDL cholesterol; obesity, diabetes mellitus, genetic factors, smoking, and some medications (e.g., steroids and beta blockers) are associated with decreased levels. HDL cholesterol levels are not directly affected by diet.

## Box 55-2

## Types of Dyslipidemias

**Type I** is characterized by elevated or normal serum cholesterol, elevated triglycerides, and chylomicronemia. This rare condition may occur in infancy and childhood.

**Type IIa** (familial hypercholesterolemia) is characterized by a high level of low-density lipoprotein (LDL) cholesterol, a normal level of very-low-density lipoprotein (VLDL), and a normal or slightly increased level of triglycerides. It occurs in children and is a definite risk factor for development of atherosclerosis and coronary artery disease.

**Type IIb** (combined familial hyperlipoproteinemia) is characterized by increased levels of LDL, VLDL, cholesterol, and triglycerides and lipid deposits (xanthomas) in the feet, knees, and elbows. It occurs in adults.

**Type III** is characterized by elevations of cholesterol and triglycerides plus abnormal levels of LDL and VLDL. This type usually occurs in middle-aged adults (40–60 years) and

is associated with accelerated coronary and peripheral vascular disease.

**Type IV** is characterized by normal or elevated cholesterol levels, elevated triglycerides, and increased levels of VLDL. This type usually occurs in adults and may be the most common form of hyperlipoproteinemia. Type IV is often secondary to obesity, excessive intake of alcohol, or other diseases. Ischemic heart disease may occur at 40 to 50 years of age.

**Type V** is characterized by elevated cholesterol and triglyceride levels with an increased level of VLDL and chylomicronemia. This uncommon type usually occurs in adults. Type V is not associated with ischemic heart disease. Instead, it is associated with fat and carbohydrate intolerance, abdominal pain, and pancreatitis, which are relieved by lowering triglyceride levels.

cerebrovascular, and peripheral vascular disease and are principal contributors to the significant morbidity and mortality of these conditions. Improvements in insulin resistance and lipid profiles are essential lifestyle modifications and constitute first-line treatment of metabolic syndrome. This chapter specifically addresses management of components of metabolic syndrome related to dyslipidemia; additional discussion of other factors is found in Chapters 26 and 50.

## Dyslipidemia

*Dyslipidemia* (also called hyperlipidemia) is associated with atherosclerosis and its many pathophysiologic effects (e.g., myocardial ischemia and infarction, stroke, peripheral arterial occlusive disease). Ischemic heart disease has a high rate of morbidity and mortality. Elevated total cholesterol and LDL cholesterol and reduced HDL cholesterol are the abnormalities that are major risk factors for coronary artery disease. Elevated triglycerides also play a role in cardiovascular disease. For example, high blood levels reflect excessive caloric intake (excessive dietary fats are stored in adipose tissue; excessive proteins and carbohydrates are converted to triglycerides and also stored in adipose tissue) and obesity. High caloric intake also increases the conversion of VLDL to LDL cholesterol, and high dietary intake of triglycerides and saturated fat decreases the activity of LDL receptors and increases synthesis of cholesterol. Very high triglyceride levels are associated with acute pancreatitis.

Dyslipidemia may be primary (i.e., genetic or familial) or secondary to dietary habits, other diseases (e.g., diabetes mellitus, alcoholism, hypothyroidism, obesity, obstructive liver disease), and medications (e.g., beta blockers, cyclosporine, oral estrogens, glucocorticoids, sertraline, thiazide diuretics, anti-human immunodeficiency virus protease inhibitors). Types of dyslipidemia (also called *hyperlipoproteinemias* because increased blood levels of lipoproteins accompany increased

blood lipid levels) are described in Box 55-2. Although hypercholesterolemia is usually emphasized, hypertriglyceridemia is also associated with most types of hyperlipoproteinemia.

## Initial Management of Dyslipidemia

Overall, the most effective blood lipid profile for prevention or management of metabolic syndrome and its sequelae is high HDL cholesterol, low LDL cholesterol, and low total cholesterol. A low triglyceride level is also desirable. NCEP III classified blood lipid levels and proposed the following guidelines as treatment goals for patients with lipid abnormalities:

### Total serum cholesterol (mg/dL)

Normal or desirable = less than 200

Borderline high = 200 to 239

High = 240 or above

### LDL cholesterol (mg/dL)

Optimal = less than 100

Near or above optimal = 100 to 129

Borderline high = 130 to 159

High = 160 to 189

Very high = 190 or above

### HDL cholesterol (mg/dL)

High = more than 60

Low = less than 40

### Triglycerides (mg/dL)

Normal or desirable = less than 150

Borderline high = 150 to 199

High = 200 to 499

Very high = 500 or above

For accurate interpretation of a patient's lipid profile, blood samples for laboratory testing of triglycerides should be drawn after the patient has fasted for 12 hours. Fasting is not required for cholesterol testing.

NCEP III recommends treatment of patients according to their blood levels of total and LDL cholesterol and their risk factors for cardiovascular disease (Table 55-1). Note that therapeutic lifestyle changes (TLC), including exercise, smoking cessation, changes in diet, and drug therapy, are recommended at lower serum cholesterol levels in patients who already have cardiovascular disease or diabetes mellitus. Also, the target LDL serum level is lower in these patients.

Guidelines include the following:

- Assess for, and treat, if present, conditions known to increase blood lipids (e.g., diabetes mellitus, hypothyroidism).
- Stop medications known to increase blood lipids, if possible.
- Start a low-fat diet. A Step I diet contains no more than 30% of calories from fat, less than 10% of calories from saturated fats (e.g., meat, dairy products), and less than 300 mg of cholesterol per day. A Step II diet contains no more than 30% of calories from fat, less than 7% of calories from saturated fat, and less than 200 mg of cholesterol per day. The Step II diet is more stringent and may be used initially in patients with more severe dyslipidemia, cardiovascular disease, or diabetes mellitus. It can decrease LDL cholesterol levels by 8% to 15%. Diets with more stringent fat restrictions than the Step II diet are not recommended because they produce little additional reduction in LDL cholesterol; raise serum triglyceride levels; and lower HDL cholesterol concentrations.
- Use the “Mediterranean diet,” which includes moderate amounts of monounsaturated fats (e.g., canola, olive oils) and polyunsaturated fats (e.g., safflower, corn, cottonseed, sesame, soybean, sunflower oils) to also decrease risks of cardiovascular disease.
- Increase dietary intake of soluble fiber (e.g., psyllium preparations, oat bran, pectin, fruits and vegetables). This diet lowers serum LDL cholesterol by 5% to 10%.
- Dietary supplements (e.g., Cholestin) and cholesterol lowering margarines (e.g., Benecol, Take Control) can help reduce cholesterol levels. These products are considered to be foods, not drugs, and are costly.
- Start a weight-reduction diet if the patient is overweight or obese. Weight loss can increase HDL and decrease LDL.
- Emphasize regular aerobic exercise (usually 30 minutes at least three times weekly). This strategy increases blood levels of HDL.
- If the patient smokes, assist to develop a cessation plan. In addition to numerous other benefits, HDL levels are higher in nonsmokers.
- If the patient is postmenopausal, hormone replacement therapy can raise HDL and lower LDL.
- If the patient has elevated serum triglycerides, initial management includes efforts to achieve desirable body weight, ingest low amounts of saturated fat and cholesterol, exercise regularly, stop smoking, and reduce alcohol intake, if indicated. The goal is to reduce serum triglyceride levels to 200 mg/dL or less.
- Unless lipid levels are severely elevated, 6 months of intensive diet therapy and lifestyle modification may be undertaken before drug therapy is considered. It is essential that TLC continue during drug therapy because the benefits of diet, exercise, and drug therapy are additive.

Since the publication of the NCEP III in 2001, numerous clinical trials of statin therapy have been published. In 2004, more intensive treatment recommendations were established for those in the category of “very high” risk. Factors contributing to the increased risk include the presence of established cardiovascular disease or an acute coronary syndrome, with multiple major risk factors such as diabetes,

Table 55-1

### National Cholesterol Education Program Recommendations for Treatment of Dyslipidemia

Patient's Cardiovascular Disease Status	THERAPEUTIC LIFESTYLE CHANGES (TLC)	DRUG THERAPY	GOAL OF THERAPY
	LDL Cholesterol (mg/dL)	LDL Cholesterol (mg/dL)	LDL Cholesterol (mg/dL)
No or one risk factor	≥160	≥190	<160
More than two risk factors	≥130	≥160	<130
Has cardiovascular disease	≥100	≥130	<100

*LDL, low-density lipoprotein.*

obesity, hypertension (evidence of metabolic syndrome), high triglycerides, low HDL, and severe or poorly controlled risk factors such as continued cigarette smoking. These recommendations included consideration of treatment goals for LDL cholesterol to less than 70 milligrams per deciliter and earlier initiation of drug therapy in the presence of elevated triglyceride and low HDL levels. As current trials are continuing, the lower levels of LDL should be considered a therapeutic option for those at increased risk, with the goal of less than 100 milligrams per deciliter remaining as a strong recommendation for those not at high risk.

## General Characteristics of Drugs Used for Management of Dyslipidemia

Dyslipidemic drugs are used to decrease blood lipids, prevent or delay the development of atherosclerotic plaque, promote the regression of existing atherosclerotic plaque, and reduce morbidity and mortality from cardiovascular disease. Clinical data

suggest that drug therapy may be efficacious even for those with mild to moderate elevations of LDL cholesterol. The drugs act by altering the production, absorption, metabolism, or removal of lipids and lipoproteins. Drug therapy is initiated when 6 months of dietary and other lifestyle changes fail to decrease dyslipidemia to an acceptable level. It is also recommended for patients with signs and symptoms of coronary heart disease, a strong family history of coronary heart disease or dyslipidemia, or other risk factors for atherosclerotic vascular disease (e.g., hypertension, diabetes mellitus, cigarette smoking). Although several dyslipidemic drugs are available, none is effective in all types of dyslipidemia.

## Dyslipidemic Drugs: Classifications and Individual Drugs

Categories of drugs are described in this section; individual drugs are listed in Table 55-2. The sites of action of dyslipidemic drugs are found in Figure 55.1.

Table 55-2

Drugs at a Glance: Dyslipidemic Agents

Generic/Trade Name	Clinical Indications (Type of Dyslipidemia)	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>HMG-CoA Reductase Inhibitors (Statins)</b>			
<b>Atorvastatin</b> (Lipitor)	Types IIa and IIb	PO 10–80 mg daily in a single dose	10–17y: 10 mg once daily to maximum of 20 mg/d
<b>Fluvastatin</b> (Lescol, Lescol XL)	Types IIa and IIb	PO 20–80 mg daily in 1 or 2 doses	10–16y: 20 mg once daily to maximum of 80 mg in 1 or 2 doses
<b>Lovastatin</b> (Mevacor, Altacor)	Types IIa and IIb	PO 20 mg daily with evening meal to 80 mg/d	10–17 y: 10–40 mg once daily with evening meal
<b>Pravastatin</b> (Pravachol)	Types IIa and IIb	PO 40–80 mg once daily Elderly, PO 10 mg once daily initially	8–13 y: 20 mg/d 14–18 y: 40 mg/d
<b>Rosuvastatin</b> (Crestor)	Types IIa and IIb, IV	PO 10–40 mg once daily	<18 y: not recommended
<b>Simvastatin</b> (Zocor)	Types IIa, IIb, IV, V	PO 5–80 mg once daily in the evening Elderly, PO 5–20 mg once daily in the evening	10–17 y: 10 mg once daily in the evening to maximum of 40 mg/d
<b>Fibrates</b>			
<b>Fenofibrate</b> (TriCor)	Types IV, V (hypertriglyceridemia)	PO 48 mg once daily with meals increased if necessary to a maximum dose of 201 mg daily	

(continued on page 886)

Table 55-2

## Drugs at a Glance: Dyslipidemic Agents (continued)

Generic/Trade Name	Clinical Indications (Type of Dyslipidemia)	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Gemfibrozil</b> (Lopid)	Types IV, V (hypertriglyceridemia)	PO 1200 mg daily, in 2 divided doses, 30 min before morning and evening meals	
<b>Bile Acid Sequestrants</b> <b>Cholestyramine</b> (Prevalite, Questran)	Type IIa	PO tablets, 4 g once or twice daily initially, gradually increased at monthly intervals to 8–16 g daily in 2 divided doses. Maximum daily dose, 24 g PO powder, 4 g 1–6 times daily	240 mg/kg/d in 3 divided doses
<b>Colesevelam</b> (WelChol)	Type IIa	PO 3.75 g daily in 1 or 2 doses with meals. Maximum daily dose, 4.375 g	
<b>Colestipol</b> (Colestid)	Type IIa	PO tablets, 2 g once or twice daily initially, gradually increased at 1- to 2-mo intervals, up to 16 g daily PO granules, 5 g daily initially, gradually increased at 1- to 2-mo intervals, up to 30 g daily in single or divided doses	
<b>Cholesterol Absorption Inhibitor</b> <b>Ezetimibe</b> (Zetia)	Types IIa and IIb	PO 10 mg once daily	<10 y: not recommended ≥10 y: PO 10 mg once daily
<b>Miscellaneous</b> <b>Niacin</b> (immediate-release)	Types II, III, IV, V	PO 2–6 g daily, in 3 or 4 divided doses, with or just after meals	PO 55–87 mg/kg/d, in 3 or 4 divided doses, with or just after meals
<b>Niacin</b> (extended-release)	Types IIa and IIb	PO 500–2000 mg daily	

## HMG-CoA Reductase Inhibitors

The HMG-CoA reductase inhibitors or statins (e.g., **atorvastatin**) inhibit an enzyme (hydroxymethylglutaryl-coenzyme A reductase) required for hepatic synthesis of cholesterol. By decreasing production of cholesterol, these drugs decrease total serum cholesterol, LDL cholesterol, VLDL cholesterol, and triglycerides. They reduce LDL cholesterol within 2 weeks and reach maximal effects in approximately 4 to 6 weeks. HDL cholesterol levels remain unchanged or may increase.

These drugs are useful in treating most of the major types of dyslipidemia and are the most widely used dyslipidemic drugs. Studies indicate that these drugs can reduce the blood levels of C-reactive protein, which is associated with severe arterial inflammation that leads to heart attacks and strokes. The incidence of coronary artery disease is reduced by 25% to 60% and the risk of death from any cause by approxi-

mately 30%. Statins also reduce the risk of angina pectoris and peripheral arterial disease as well as the need for angioplasty and coronary artery grafting to increase or restore blood flow to the myocardium.

### Applying Your Knowledge 55-1

You are counseling Mr. Watkins about his medication. He asks when he will need to have his laboratory work completed. How do you respond?

.....

**Atorvastatin** is currently the most widely used statin and one of the most widely used drugs in the United States. There is indication that pravastatin may be preferred in patients who have had a transplant or who are receiving immunosuppres-

Figure 55-1 ■ Sites of dyslipidemic drugs.

sants, because it interacts less with immunosuppressant agents than other statins. There is controversy regarding clinical and subclinical effects of individual agents. Several studies have suggested that atorvastatin and **rosuvastatin** may possess some benefits that other statins do not. Multiple outcomes including intimal thickness, results of imaging studies, mortality, incidence of stroke, and progression of lesions have been studied, but there continue to be questions about the benefit profiles of individual drugs.

Absorption following oral administration varies by drug. **Lovastatin** and **pravastatin** are poorly absorbed; **fluvastatin** has the highest rate of absorption. Most of the statins undergo extensive first-pass metabolism by the liver, which results in low levels of drug available for general circulation. Metabolism occurs in the liver, with 80% to 85% of drug metabolites excreted in feces and the remaining excreted in urine.

Statins are usually well tolerated; the most common adverse effects (nausea, constipation, diarrhea, abdominal cramps or pain, headache, skin rash) are usually mild and transient. More serious reactions include rare occurrences of hepatotoxicity and myopathy. Liver function studies should be monitored before onset of therapy, after 6 and 12 weeks of therapy, and intermittently during the course of therapy to detect any elevation or change. Statins can injure muscle tissue, resulting in muscle ache or weakness. Rarely is there progression to myositis and subsequent rhabdomyolysis, defined as muscle disintegration or dissociation. Factors that increase risk of myopathy include advanced age, frail or small body frame, high dosage of statins, concomitant use with fibrates, hypothyroidism, and multiple systemic diseases such as renal insufficiency secondary to diabetic nephropathy. Patients should be advised to notify their health care provider if unexplained muscle pain or tenderness occurs.

Statins are potentially teratogenic medications (pregnancy category D). Women of childbearing age should have contraceptive counseling to enhance awareness of the risks associated with statin use. Careful consideration should be given if potential benefits warrant use of the drug class in pregnant women despite potential risks.

### Applying Your Knowledge 55-2

When educating Mr. Watkins about his new medication, you teach him about common adverse effects. What would be included in your teaching about the adverse effects of atorvastatin? What signs and symptoms of complications would you discuss with him?

## Bile Acid Sequestrants

Bile acid sequestrants (e.g., **cholestyramine**) bind bile acids in the intestinal lumen. This causes the bile acids to be excreted in feces and prevents their being recirculated to the liver. Loss of bile acids stimulates hepatic synthesis of more bile acids from cholesterol. As more hepatic cholesterol is used to produce bile acids, more serum cholesterol moves into the liver to replenish the supply, thereby lowering serum cholesterol (primarily LDL). LDL cholesterol levels decrease within a week of starting these drugs and reach maximal reductions within a month. When the drugs are stopped, pretreatment LDL cholesterol levels return within a month.

These drugs are used mainly to reduce LDL cholesterol further in patients who are already taking a statin drug. The inhibition of cholesterol synthesis by a statin drug makes bile acid-binding drugs more effective. In addition, the combination increases HDL cholesterol and can further reduce the risk of cardiovascular disorders.

These drugs are not absorbed systemically, and their main adverse effects are abdominal fullness, flatulence, and constipation. They may decrease absorption of many oral medications (e.g., digoxin, folic acid, glipizide, propranolol, tetracyclines, thiazide diuretics, thyroid hormones, fat-soluble vitamins, warfarin). Other drugs should be taken at least 1 hour before or 4 hours after bile acid sequestrants. In addition, dosage of the interactive drug may need to be changed when a bile acid sequestrant is added or withdrawn.

## Fibrates

Fibrates are derivatives of fibric acid (e.g., **gemfibrozil**, **fenofibrate**) and are similar to endogenous fatty acids. The drugs increase the oxidation of fatty acids in liver and muscle tissue and thereby decrease hepatic production of triglycerides, decrease VLDL cholesterol, and increase HDL cholesterol. These are the most effective drugs for reducing serum triglyceride levels, and their main indication for use is high serum triglyceride levels (>500 mg/dL). They are also useful for patients with low HDL cholesterol levels. In patients with

coronary artery disease, management with gemfibrozil is associated with regression of atherosclerotic lesions on angiography.

These drugs are well absorbed following oral administration. Metabolism occurs in the liver and excretion is by urinary elimination. The main adverse effects are gastrointestinal discomfort and diarrhea, which may occur less often with fenofibrate than with gemfibrozil. The drugs may also increase cholesterol concentration in the biliary tract and formation of gallstones. For patients receiving warfarin, the warfarin dosage should be substantially decreased because fibrates displace warfarin from binding sites on serum albumin.

## Niacin

**Niacin** (nicotinic acid) decreases both cholesterol and triglycerides. It inhibits mobilization of free fatty acids from peripheral tissues, thereby reducing hepatic synthesis of triglycerides and secretion of VLDL, which leads to decreased production of LDL cholesterol. Niacin is the most effective drug for increasing the concentration of HDL cholesterol. Disadvantages of niacin are the high doses required for dyslipidemic effects and the subsequent adverse effects. Niacin commonly causes skin flushing, pruritus, and gastric irritation and may cause hyperglycemia, hyperuricemia, elevated hepatic aminotransferase enzymes, and hepatitis. Flushing can be reduced by starting with small doses, gradually increasing doses, taking doses with meals, and taking 325 milligrams of aspirin about 30 minutes before niacin doses.

Niacin is rapidly absorbed from the gastrointestinal tract. Minimal metabolism occurs by the liver and the majority of the drug is excreted unchanged in the urine. Tablet strengths are not interchangeable; do not substitute immediate-release forms with long-acting ones.

Niacin is most effective in preventing heart disease when used in combination with another dyslipidemic drug such as a bile acid sequestrant or a fibrate. Its use with a statin lowers serum LDL cholesterol more than either drug alone, but the combination has not been studied in relation to preventing cardiovascular disease.

## Cholesterol Absorption Inhibitor

The cholesterol absorption inhibitor (e.g., **ezetimibe**), the newest class of dyslipidemic drugs, acts in the small intestine to inhibit absorption of cholesterol and decrease the delivery of intestinal cholesterol to the liver, resulting in reduced hepatic cholesterol stores and increased clearance of cholesterol from the blood. This distinct mechanism is complementary to that of HMG-CoA reductase inhibitors.

This drug reduces total cholesterol and triglycerides and increases HDL. The drug is indicated as an adjunctive therapy to dietary management of hyperlipidemia. Administration may be with or without food, but it should be taken 2 hours before or 4 hours after a bile acid sequestrant. Therapeutic response is achieved within 2 weeks of initiation of therapy and maintained with continued use. The most common adverse effects include hypersensitivity reactions such as rash and nausea. This drug is contraindicated in pregnancy.

## Nursing Process

### Assessment

Assess the patient's status in relation to atherosclerotic vascular disease.

- Identify risk factors:
  - Hypertension
  - Diabetes mellitus
  - High intake of dietary fat and refined sugars
  - Obesity
  - Inadequate exercise
  - Cigarette smoking
  - Family history of atherosclerotic disorders
  - Dyslipidemia
- Signs and symptoms depend on the specific problem:
  - Dyslipidemia is manifested by elevated serum cholesterol ( $>200$  mg/100 mL), triglycerides ( $>150$  mg/100 mL), or both.
  - Coronary artery atherosclerosis is manifested by myocardial ischemia (angina pectoris, myocardial infarction).
  - Cerebrovascular insufficiency may be manifested by syncope, memory loss, transient ischemic attacks (TIAs), or strokes. Impairment of blood flow to the brain is caused primarily by atherosclerosis in the carotid, vertebral, or cerebral arteries.
  - Peripheral arterial insufficiency is manifested by impaired blood flow in the legs (weak or absent pulses; cool, pale extremities; intermittent claudication; leg pain at rest; and development of gangrene, usually in the toes because they are most distal to blood supply). This condition results from atherosclerosis in the distal abdominal aorta, the iliac arteries, and the femoral and smaller arteries in the legs.

### Nursing Diagnoses

- Ineffective Tissue Perfusion related to interruption of arterial blood flow
- Imbalanced Nutrition: More Than Body Requirements of fats and calories
- Anxiety related to risks of atherosclerotic cardiovascular disease
- Disturbed Body Image related to the need for lifestyle changes
- Noncompliance related to dietary restrictions and adverse drug reactions
- Deficient Knowledge related to drug and diet therapy of dyslipidemia

### Planning/Goals

The patient will

- Take lipid-lowering drugs as prescribed
- Decrease dietary intake of saturated fats and cholesterol
- Lose weight if obese and maintain the lower weight
- Have periodic measurements of blood lipids
- Avoid preventable adverse drug effects
- Receive positive reinforcement for efforts to lower blood lipid levels
- Feel less anxious and more in control as risks of atherosclerotic cardiovascular disease are decreased

### Interventions

Use measures to prevent, delay, or minimize atherosclerosis.

- Help patients control risk factors. Ideally, primary prevention begins in childhood with healthful eating habits (e.g., avoiding excessive fats, meat, and dairy products; obtaining adequate amounts of all nutrients, including dietary fiber; avoiding obesity), exercise, and avoiding cigarette smoking. However, changing habits to a more healthful lifestyle is helpful at any time, before or after disease manifestations appear. Weight loss often reduces blood lipids and lipoproteins to a normal range. Changing habits is difficult for most people, even those with severe symptoms.
- Use measures to increase blood flow to tissues:
  - Exercise is helpful in developing collateral circulation in the heart and legs. Collateral circulation involves use of secondary vessels in response to tissue ischemia related to obstruction of the principal vessels. Patients with angina pectoris or previous myocardial infarction require a carefully planned and supervised program of progressive exercise. Those with peripheral arterial insufficiency usually can increase exercise tolerance by walking regularly. Distances should be determined by occurrence of pain and must be individualized.
  - Posture and position may be altered to increase blood flow to the legs in patients with peripheral arterial insufficiency. Elevating the head of the bed and having the legs horizontal or dependent may help. Elevating the feet is usually contraindicated unless edema is present or likely to develop.
- Although drug therapy is being increasingly used to prevent or manage atherosclerotic disorders, a major therapeutic option for management of occlusive vascular disease is surgical removal of atherosclerotic plaque or revascularization procedures. Thus, severe angina pectoris may be relieved by a coronary artery bypass procedure that detours blood flow around occluded vessels. This procedure also may be done after a myocardial infarction. The goal is to

*Nursing Process continues on page 890*

prevent infarction or reinfarction. TIAs may be relieved by carotid endarterectomy; the goal is to prevent a stroke. Peripheral arterial insufficiency may be relieved by aortofemoral, femoropopliteal, or other bypass grafts that detour around occluded vessels. Although these procedures increase blood flow to ischemic tissues, they do not halt progression of atherosclerosis.

The nursing role in relation to these procedures is to provide excellent preoperative and postoperative nursing care to promote healing, prevent infection, maintain patency of grafts, and help the patient to achieve optimum function.

- Provide appropriate teaching related to drug therapy (see accompanying display).
- Any dyslipidemic drug therapy must be accompanied by an appropriate diet; refer patients to a nutritionist. Overeating or gaining weight may decrease or cancel the lipid-lowering effects of the drugs.
- Encourage adult patients to have their serum cholesterol level measured at least once every 5 years. Adults and children with a personal or family history of dyslipidemia or other risk factors should be tested more often.
- The most effective measures for preventing dyslipidemia and atherosclerosis are those related to a healthful lifestyle (e.g., diet low in cholesterol and saturated fats, weight control, exercise).
- Help patients and family members understand the desirability of lowering high blood lipid levels before serious cardiovascular diseases develop.

### Evaluation

- Observe for decreased blood levels of total and LDL cholesterol and triglycerides; observe for increased levels of HDL cholesterol.
- Observe and interview regarding compliance with instructions for drug, diet, and other therapeutic measures.
- Observe and interview regarding adverse drug effects.
- Validate the patient's ability to identify foods high and low in cholesterol and saturated fats.

### Applying Your Knowledge 55-3

#### How Can You Avoid This Medication Error?

You arrive at Mr. Watkins' home at 8:45 A.M. Mr. Watkins greets you and asks if you mind waiting a moment while he finishes his breakfast. While you are waiting, you prepare the correct doses of both his atorvastatin and gemfibrozil, which he receives routinely at 9:00 A.M. You then administer his medication.

.....

## Principles of Therapy

### Drug Selection

Drug selection is based on the type of dyslipidemia and its severity. For single-drug therapy to lower cholesterol, a statin is preferred. To lower cholesterol and triglycerides, a statin, a cholesterol absorption inhibitor, gemfibrozil, or niacin may be used. To lower triglycerides, gemfibrozil, a cholesterol absorption inhibitor, or niacin may be used. Gemfibrozil, rather than niacin, is usually preferred for people with diabetes because niacin increases blood sugar.

When monotherapy is not effective, combination therapy is rational because the drugs act by different mechanisms. In general, a statin combined with a cholesterol absorption inhibitor or a bile acid sequestrant or niacin combined with a bile acid sequestrant are the most effective combinations in reducing total and LDL cholesterol. A fibrate, a cholesterol absorption inhibitor, or niacin may be used when a goal of therapy is to increase the level of HDL cholesterol. However, a fibrate–statin combination should be avoided because of increased risks of severe myopathy, and a niacin–statin combination increases the risks of hepatotoxicity. Adverse reactions from combination statin and cholesterol absorption inhibitor therapy are reported to be similar to those from statins alone.

### Use in Special Populations

#### Use in Various Ethnic Groups

Little information has been reported on racial or ethnic differences for lipid-lowering drugs. Members of minority populations (e.g., African Americans, Mexican Americans) are less likely to be treated than Caucasians. Despite an increased prevalence of diabetes and obesity, Native Americans appear to have lower cholesterol levels than the United States population as a whole. This suggests that diet and exercises may be more useful than lipid-lowering drugs for this group.

#### Use in Children

Definitive evidence indicates that the development of atherosclerotic cardiovascular disease begins in early childhood and the rate of progression is greatly increased by lipid abnormalities. The frequency of dyslipidemia in children is on the rise, predominately associated with the concurrent epidemic of obesity and the metabolic syndrome. Therefore, a primary goal is to identify and manage dyslipidemia in at-risk children and adolescents to reduce the lipoprotein profile component on the risk burden of atherosclerosis. As with adults, initial management consists of diet therapy and management of any secondary causes, especially with younger children. Experts are calling for revisions of the existing 1992 guidelines for screening and managing dyslipidemia in children and adolescents. Since the initial publication of the guidelines, interventional studies in children with familial hyperlipidemia have shown statins to be the preferred pharmacological treatment in children and adolescents and supplementation with antioxidant vitamins and omega-3 fatty acids. Randomized clinical drug trials are ongoing in the pediatric age groups with primary high-risk lipid

## Patient Teaching Guidelines Dyslipidemic Drugs

### General Considerations

- Heart and blood vessel disease causes a great deal of illness and many deaths. The basic problem is usually atherosclerosis, in which the arteries are partly blocked by cholesterol deposits. Cholesterol, a waxy substance made in the liver, is necessary for normal body functioning. However, excessive amounts in the blood increase the likelihood of having a heart attack, stroke, or leg pain from inadequate blood flow. One type of cholesterol (low-density lipoprotein [LDL] or “bad”) attaches to artery walls, where it can enlarge over time and block blood flow. The other type (high-density lipoprotein [HDL] or “good”) carries cholesterol away from the artery and back to the liver, where it can be broken down. Thus, the healthiest blood cholesterol levels are low total cholesterol (<200 mg/dL), low LDL (<130 mg/dL), and high HDL (>35 mg/dL). High levels of blood triglycerides, another type of fat, are also unhealthy.
- Dyslipidemic drugs are given to lower high concentrations of fats (total cholesterol, LDL cholesterol, and triglycerides) in your blood. The goal of management is to prevent heart attack, stroke, and peripheral arterial disease. If you already have heart and blood vessel disease, the drugs can improve your symptoms, activity level, and quality of life.
- A low-fat diet is needed. This is often the first step in treating high cholesterol or triglyceride levels, and may be prescribed for 6 months or longer before drug therapy is begun. When drug therapy is prescribed, the diet should be continued. An important part is reducing the amount of saturated fat (from meats, dairy products). In addition, eating a bowl of oat cereal daily can help lower cholesterol by 5% to 10%. Diet counseling by a dietitian or nutritionist can be helpful in developing guidelines that fit your needs and lifestyle. Overeating or gaining weight may decrease or cancel the lipid-lowering effects of the drugs.
- Other lifestyle changes that can help improve cholesterol levels include regular aerobic exercise (raises HDL); losing weight (raises HDL, lowers LDL, lowers triglycerides); and not smoking (HDL levels are higher in nonsmokers).
- Adults should have measurements of total cholesterol and HDL cholesterol at least once every 5 years. People with a personal or family history of dyslipidemia or other risk factors for cardiovascular disease should be tested more often.
- Techniques for home monitoring of cholesterol levels are improving and are more available for self-use. Patients may be instructed to perform self-monitoring and report their results to their health care provider. At present, equipment and supplies can be expensive, and most are not reimbursed by insurance companies.
- Atorvastatin and other statin-type dyslipidemic drugs may increase sensitivity to sunlight. Avoid prolonged exposure to the sun, use sunscreens, and wear protective clothing.
- Gemfibrozil may cause dizziness or blurred vision and should be used cautiously while driving or performing other tasks that require alertness, coordination, or physical dexterity. It also may cause abdominal pain, diarrhea, nausea, or vomiting. Notify a health care provider if these symptoms become severe.
- Skin flushing may occur with niacin. If it is distressing, taking one regular aspirin tablet (325 mg) 30 to 60 minutes before the niacin dose may decrease this reaction. Flushing usually decreases in a few days, but may recur when niacin dosage is increased. Ask your health care provider if there is any reason you should not take aspirin.
- Cholestyramine and colestipol can cause constipation. Increasing intake of dietary fiber can help prevent this adverse effect.

### Self-Administration

- Take lovastatin with food; take fluvastatin, pravastatin, or simvastatin in the evening, with or without food. Food decreases stomach upset associated with lovastatin. All of these drugs may be more effective if taken in the evening or at bedtime, probably because more cholesterol is produced at nighttime and the drugs block cholesterol production.
- Take atorvastatin with or without food and without regard to time of day.
- Take fenofibrate with food; food increases drug absorption.
- Take gemfibrozil on an empty stomach, 30 minutes before morning and evening meals.
- Take immediate-release niacin with meals to decrease stomach upset; take timed-release niacin without regard to meals. Do not substitute immediate release forms with long-acting ones.
- Mix cholestyramine powder and colestipol granules with water or other fluids, soups, cereals, or fruits such as applesauce and follow with more fluid. These drug forms should not be taken dry.
- Do not take cholestyramine, colestipol, or colestipol with other drugs because they may prevent absorption of the other drugs. If taking other drugs, take them 1 hour before or 4 to 6 hours after cholestyramine or colestipol.
- Swallow colestipol tablets whole; do not cut, crush, or chew.
- Take ezetimibe with or without food at the same time each day. If taken in combination with a statin, take it at the same time (usually in the evening).

abnormalities to determine the safety and effectiveness of currently available lipid-lowering drugs. Recommended levels at which to initiate drug therapy for dyslipidemia have not been established in children.

### Use in Older Adults

As with younger adults, diet, exercise, and weight control should be tried first. When drug therapy is required, statins are

effective for lowering LDL cholesterol and usually are well tolerated by older adults. However, they are expensive. Niacin and bile acid sequestrants are effective, but older adults do not tolerate their adverse effects very well. In postmenopausal women, estrogen replacement therapy increases HDL cholesterol.

Older adults often have diabetes, impaired liver function, or other conditions that raise blood lipid levels. Thus, man-

agement of secondary causes is especially important. The older adult is also likely to have cardiovascular and other disorders that increase the adverse effects of dyslipidemic drugs. Overall, use of dyslipidemic drugs should be cautious, with close monitoring for therapeutic and adverse effects. Lower starting dosages are recommended for fenofibrate (67 mg/day), pravastatin (10 mg/day), and simvastatin (5 mg/day). Cholesterol absorption inhibitor as monotherapy (without statins) does not require dosage reduction in geriatric patients.

### Use in Patients With Renal Impairment

Statins are metabolized by the liver and excreted partly through the kidneys (their main route of excretion is through bile). Drug plasma concentrations may be increased in patients with renal impairment and these drugs should be used cautiously; some need reduced dosage.

- With atorvastatin, plasma levels are not affected and dosage reductions are not needed.
- With fluvastatin, because it is cleared hepatically and less than 6% of the dose is excreted in urine, dosage reduction for mild to moderate renal impairment is unnecessary. Use caution with severe impairment. Recent randomized controlled clinical trials have demonstrated the drug's safety in kidney transplant recipients.
- With lovastatin, plasma concentrations are increased in patients with severe renal impairment (creatinine clearance < 30 mL/minute), and doses above 20 mg/day should be used with caution.
- With pravastatin, initiate therapy with 10 mg/day.
- With simvastatin, initiate therapy with 5 mg/day and monitor closely.

Cholesterol absorption inhibitors as monotherapy (without statins) do not require dosage reduction in renal insufficiency.

Fibrates are excreted mainly by the kidneys and therefore accumulate in the serum of patients with renal impairment. With gemfibrozil, there have been reports of worsening renal impairment in patients whose baseline serum creatinine levels were higher than 2 milligrams per deciliter. A different type of dyslipidemic drug may be preferred in these patients. Fenofibrate is contraindicated in patients with severe renal impairment, and the recommended starting dose is 67 milligrams per day in patients with a creatinine clearance of less than 50 milliliters per minute. Drug and dose effects on renal function and triglyceride levels should be evaluated before dosage is increased.

### Use in Patients With Hepatic Impairment

Statins are metabolized in the liver and may accumulate in patients with impaired hepatic function. They are contraindicated in patients with active liver disease or unexplained elevations of serum aspartate or alanine aminotransferase. They should be used cautiously, in reduced dosages, for patients who ingest substantial amounts of alcohol or who have a history of liver disease.

Liver function tests are recommended before starting a statin, at 6 and 12 weeks after starting the drug or increasing the dose, then every 6 months. Monitor patients who have increased serum aminotransferases until the abnormal values resolve. If the increases are more than three times the upper limit of normal levels and persist, the dose should be reduced or the drug discontinued.

Cholesterol absorption inhibitors as monotherapy (without statins) do not require dosage reduction in mild hepatic insufficiency. Fibrates may cause hepatotoxicity. Abnormal elevations of serum aminotransferases have occurred with both gemfibrozil and fenofibrate, but they usually subside when the drug is discontinued. Fenofibrate is contraindicated in severe hepatic impairment, including patients with primary biliary cirrhosis, pre-existing gallbladder disease, and persistent elevations in liver function test results. In addition, hepatitis (hepatocellular, chronic active, and cholestatic) has been reported after use of fenofibrate from a few weeks to several years. Liver function tests should be monitored during the first year of drug administration. The drug should be discontinued if elevated enzyme levels persist at more than three times the normal limit.

Niacin may cause hepatotoxicity, especially with doses above 2 grams daily, with timed-release preparations, and if given in combination with a statin or a fibrate.

### Use in Home Care

For a patient with dyslipidemia, the home care nurse should reinforce teaching about the role of blood lipids in causing myocardial infarction, stroke, and peripheral arterial insufficiency; the prescribed management regimen and its goals; and the importance of improving dyslipidemia in preventing or improving cardiovascular disorders. In addition, the patient may need assistance in obtaining blood tests (e.g., lipids, liver function tests) and dietary counseling. Increasing availability of home cholesterol-monitoring devices will require additional patient teaching about technique and interpretation of the results.

## Use of Herbal and Dietary Supplements

There is little evidence outlining the efficacy and safety of herbal and dietary supplements for reduction of cholesterol and the prevention of CAD. Concerns about drug interaction make the use of these agents potentially dangerous if taken in conjunction with standard lipid-lowering drug therapy. Therefore, a careful medication history should be taken on all patients, including over-the-counter, herbal, and supplemental medications.

Flax or flax seed is used internally as a laxative and a dyslipidemic agent. Absorption of all medications may be decreased when taken with flax, resulting in a less than therapeutic effect. Garlic is reportedly used as a dyslipidemic agent and as a possible antihypertensive, but there is little scientific

support for such use. Bleeding may be increased when garlic is used with anticoagulants, and insulin doses may need to be decreased as a result of the hypoglycemic effect of garlic. Green tea is commonly used for its dyslipidemic effect and the caffeinated product can be a central nervous system stimulant. Soy

is used as a food source and has been researched extensively. Use of soy to lower cholesterol (LDL and total cholesterol) has been documented. Significant interactions with other herbs or drugs have not been reported. Red yeast rice has been shown to lower cholesterol; however, dosage standardization is a concern.

## Nursing Actions Drugs for Dyslipidemia

### NURSING ACTIONS

#### 1. Administer accurately

- Give lovastatin with food; give fluvastatin on an empty stomach or at bedtime. Atorvastatin, pravastatin, or simvastatin may be given with or without food in the evening. Atorvastatin can be given without regard to time of day. Avoid giving with grapefruit juice.
- Give fenofibrate with food.
- Give gemfibrozil on an empty stomach, about 30 minutes before morning and evening meals.
- Give immediate-release niacin with meals; give timed-release niacin without regard to meals.
- Mix cholestyramine powder and colestipol granules with water or other fluids, soups, cereals, or fruits such as applesauce and follow with more fluid.
- Do not give cholestyramine or colestipol with other drugs; give them 1 hour before or 4–6 hours after cholestyramine or colestipol.
- Instruct patients to swallow colestipol tablets whole; do not cut, crush, or chew.
- Give ezetimibe with or without food at the same time each day; give at night if used in combination with a statin.
- Give ezetimibe 2 hours before or 4 hours after bile sequestrants.

#### 2. Observe for therapeutic effects

- Decreased levels of total serum cholesterol, low-density lipoprotein cholesterol, and triglycerides, and increased levels of high-density lipoprotein cholesterol.

#### 3. Observe for adverse effects

- GI problems—nausea, vomiting, flatulence, constipation or diarrhea, abdominal discomfort
- With lovastatin and related drugs, observe for GI upset (see 2a), skin rash, pruritus, and myopathy.
- With niacin, flushing of the face and neck, pruritus, and skin rash may occur, as well as tachycardia, hypotension, and dizziness.

#### 4. Observe for drug interactions

- Drugs that increase effects of lovastatin and related drugs:
  - Azole antifungals (e.g., fluconazole, itraconazole)
  - Cyclosporine
  - Erythromycin

### RATIONALE/EXPLANATION

Food decreases gastrointestinal (GI) upset associated with lovastatin. These drugs are more effective if taken in the evening or at bedtime, because more cholesterol is produced by the liver at night and the drugs block cholesterol production. Grapefruit juice increases serum drug levels.  
Food increases drug absorption.

The immediate-release formulation may cause gastric irritation.

These drug forms should not be taken dry.

Cholestyramine and colestipol prevent absorption of many drugs.

Food does not affect absorption.

Cholestyramine and colestipol prevent absorption of many drugs.

With statins, effects occur in 1–2 wk, with maximum effects in 4–6 wk. With fibrates and niacin, effects occur in approximately 1 mo. With cholestyramine and colestipol, maximum effects occur in approximately 1 mo.

GI symptoms are the most common adverse effects of dyslipidemic drugs. Constipation is especially common with cholestyramine and colestipol.

Adverse effects are usually mild and of short duration. A less common but potentially serious effect is liver dysfunction, usually manifested by increased levels of serum aminotransferases. Serum aminotransferases (aspartate and alanine aminotransferase) should be measured before starting the drug, every 4–6 weeks during the first 3 months, then every 6–12 weeks or after dosage increases for 1 year, then every 6 months.

These symptoms may be prominent when nicotinic acid is used to lower blood lipids because relatively high doses are required. Aspirin 325 mg, 30 minutes before nicotinic acid, decreases the flushing reaction.

Risk of myopathy is increased. It is recommended that statin therapy be interrupted temporarily if systemic azole antifungals are needed.

Risk of severe myopathy or rhabdomyolysis is increased.

Risk of severe myopathy or rhabdomyolysis is increased.

## Nursing Actions Drugs for Dyslipidemia (continued)

### NURSING ACTIONS

- (4) Fibrate dyslipidemics (e.g., fenofibrate, gemfibrozil)
- (5) Niacin
- (6) Drugs that *increase* effects of fluvastatin:
  - (a) Alcohol, cimetidine, ranitidine, omeprazole
- (7) Drugs that *increase* effects of ezetimibe:
  - (a) Cyclosporine
- b. Drugs that *decrease* effects of lovastatin and related drugs:
  - (1) Bile acid sequestrant dyslipidemics
  - (2) Antacids
  - (3) Isradipine
  - (4) Rifampin
  - (5) St. John's wort
- c. Drugs that *decrease* effects of fibrate dyslipidemic drugs:
  - (1) Bile acid sequestrant dyslipidemic drugs

### RATIONALE/EXPLANATION

- Risk of severe myopathy or rhabdomyolysis is increased.
- Risk of severe myopathy or rhabdomyolysis is increased.
- Increased blood levels
- Increased blood levels
- Decreased blood levels unless the drugs are taken 1–4 hours apart
- Decrease absorption of atorvastatin
- This calcium channel blocker may decrease blood levels of lovastatin and its metabolites by increasing their hepatic metabolism.
- Decreases blood levels of fluvastatin
- Decreases blood levels of atorvastatin
- Decrease absorption unless the fibrate is taken about 1 hour before or 4–6 hours after the bile acid sequestrant

## Key Concepts

- Unless a person has a genetic disorder of lipid metabolism, the amount of cholesterol in the blood is strongly related to dietary intake of saturated fat.
- For accurate interpretation of a patient's lipid profile, blood samples for laboratory testing of triglycerides should be drawn after the patient has fasted for 12 hours. Fasting is not required for cholesterol testing.
- Metabolic syndrome is a group of cardiovascular risk factors linked with obesity that include elevated waist circumference (central adiposity), elevated triglycerides, reduced high-density lipoprotein cholesterol, elevated blood pressure, and elevated fasting glucose.
- Lifestyle changes that can help improve cholesterol levels include a low-fat diet, regular aerobic exercise, losing weight, and not smoking.
- Take lovastatin with food; take fluvastatin, pravastatin, or simvastatin in the evening, with or without food; atorvastatin can be taken with or without food and without regard to time of day.
- Skin flushing may occur with niacin.
- Fibrates are the most effective drugs for reducing serum triglyceride levels.

## Review and Application Exercises

### Short Answer Exercises

1. How would you describe dyslipidemia to a patient?
2. What is the goal of management of dyslipidemia?
3. Differentiate lipid-lowering drugs according to their mechanisms of action.
4. What are the main nonpharmacologic measures to decrease total and LDL cholesterol and increase HDL cholesterol?
5. What are the main nonpharmacologic measures to decrease serum triglyceride levels?

### NCLEX-Style Questions

6. The primary focus for prevention and management of metabolic syndrome and its sequelae is
  - a. high HDL cholesterol, low LDL cholesterol, low total cholesterol
  - b. low HDL cholesterol, low LDL cholesterol, low total cholesterol
  - c. low triglycerides
  - d. high HDL cholesterol, low LDL cholesterol, low triglycerides

7. Your patient, Mr. John Samuels, has not been able to decrease his LDL levels with lifestyle management, and his nurse practitioner has prescribed an HMG-CoA reductase inhibitor. You explain to him that these drugs, commonly called statins, are best administered
  - a. with breakfast
  - b. at noon
  - c. with a snack in the early afternoon
  - d. at night or bedtime
8. Your patient is on niacin (nicotinic acid) to decrease both her cholesterol and her triglycerides. In counseling her about taking this medication, you explain that flushing, a common adverse effect of niacin therapy, can be decreased by
  - a. taking half the dose in the morning and half the dose at night
  - b. taking 325 mg aspirin 30 minutes before the niacin
  - c. taking the drug on an empty stomach
  - d. taking niacin as monotherapy for dyslipidemia
9. A 48-year-old man visits the health care provider for his annual checkup. He is otherwise in good health, but assessment findings reveal a new onset of a slight increase in blood pressure and a total serum cholesterol of 240 mg/dL. What can the nurse anticipate as the preferred treatment for this patient?
  - a. a low-lipid diet and an exercise program
  - b. a low-lipid diet and a cholesterol synthesis inhibitor
  - c. an exercise program and a fibrate
  - d. a low-lipid diet, an exercise program, and niacin
10. A 36-year-old female patient has been taking lovastatin 40 mg PO daily for 6 months to treat mild dyslipidemia. At a clinic appointment, she tells the nurse she is 6 weeks' pregnant. The nurse counsels the patient to understand that it is likely that her midwife will counsel her
  - a. to increase the dose of prenatal vitamins
  - b. to reduce the dosage of her lovastatin to 20 mg PO daily
  - c. to increase the dosage to 40 mg PO twice daily
  - d. about discontinuing the drug during pregnancy

# Drugs Affecting the Digestive System

## Chapter Outline

- 56** ■ Physiology of the Digestive System
- 57** ■ Nutritional Support Products, Vitamins, and Mineral-Electrolytes
- 58** ■ Drugs to Aid Weight Management
- 59** ■ Drugs Used for Peptic Ulcer and Acid Reflux Disorders
- 60** ■ Laxative and Cathartics
- 61** ■ Antidiarrheals
- 62** ■ Antiemetics

# Physiology of the Digestive System

## KEY TERMS

- Alimentary canal
- Bile
- Digestion
- Elimination
- Esophagus
- Gallbladder
- Gastric juice
- Large intestine
- Liver
- Mucus
- Oral cavity
- Pancreas
- Pancreatic juices
- Peristalsis
- Saliva
- Small intestine
- Stomach

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review roles of the main digestive tract structures.
2. List common signs and symptoms affecting gastrointestinal functions.
3. Identify general categories of drugs used to treat gastrointestinal disorders.
4. Discuss the effects of nongastrointestinal drugs on gastrointestinal functioning.

## Introduction

The digestive system (Figure 56-1) consists of the *alimentary canal* (a tube extending from the *oral cavity* to the anus, approximately 25 to 30 feet [7.5–9 m] long) and the accessory organs (salivary glands, gallbladder, liver, and pancreas). The main function of the system is to provide the body with fluids, nutrients, and electrolytes in a form that can be used at the cellular level. The system also disposes of waste products that result from the digestive process (*elimination*).

The alimentary canal has the same basic structure throughout. The layers of the wall are mucosa, connective tissue, and muscle. *Peristalsis* propels food through the tract and mixes the food bolus with digestive juices. Stimulation of the parasympathetic nervous system (by vagus nerves) increases motility and secretions. Sympathetic stimulation promotes sphincter function and inhibits motility. The tract has an abundant blood supply, which increases cell regeneration and healing. Blood flow increases during *digestion* and absorption. Blood flow decreases with strenuous exercise, sympathetic nervous system stimulation (i.e., “fight or flight”), aging (secondary to decreased cardiac output and atherosclerosis), and conditions that shunt blood away from the digestive tract (e.g., heart failure, atherosclerosis).

## Structures of the Digestive System

### Oral Cavity

In the oral cavity, chewing mechanically breaks food into smaller particles, which can be swallowed more easily and provide a larger surface area for enzyme action. Food is also mixed with *saliva*, which lubricates the food bolus for swallowing and initiates the digestion of starch.

### Esophagus

The *esophagus* is a musculofibrous tube about 10 inches (25 cm) long; its main function is to convey food from the pharynx to the stomach. It secretes a small amount of *mucus* and has some peristaltic movement. Each end of the esophagus functions as a sphincter. The upper esophageal sphincter prevents air from entering the esophagus during inspiration. The last 2 centimeters of the esophagus is the lower esophageal sphincter (LES). The function of the LES is to prevent reflux of acidic gastric contents into the esophagus.

**Figure 56-1** ■ The digestive system.

## Stomach

The *stomach* is a dilated area that serves as a reservoir. It churns and mixes the food with digestive juices; secretes mucus, hydrochloric acid, and enzymes; starts protein breakdown; and secretes intrinsic factor, which is necessary for absorption of vitamin B<sub>12</sub> from the ileum. Although there is much diffusion of water and electrolytes through the gastric mucosa in both directions, there is little absorption of these substances. Carbohydrates and amino acids are also poorly absorbed. Only a few highly lipid-soluble substances, such as alcohol and some drugs, are absorbed in moderate quantities from the stomach.

The inlet of the stomach, the cardiac orifice, is at the terminal end of the esophagus. The stomach outlet is the pylorus, a ring-like muscle that opens into the beginning of the duodenum. The stomach normally holds about 1000 milliliters comfortably and empties in about 4 hours. Numerous factors influence the rate of gastric emptying, including the size of the pylorus, gastric motility, type of food, fluidity and composition of the chyme (the material produced by gastric digestion of food), and the state of the duodenum. Factors that cause rapid emptying include carbohydrate foods, increased motility, fluid chyme, and an empty duodenum. The stomach empties more slowly with decreased gastric tone and motility, fatty foods, and excessively acidic chyme. Cholecystokinin and gastric inhibitory peptide are released by the duodenum in response to an acidic pH, increased osmolality, or fatty acid composition of

the chyme, delaying gastric emptying. When the chyme in the duodenum contains fats, the duodenal mucosa also produces a hormone, enterogastrone, which inhibits gastric secretion and motility. This allows a longer time for the digestion of fats in the small intestine.

## Small Intestine

The *small intestine* consists of the duodenum, jejunum, and ileum and is approximately 20 feet (6 m) long. The duodenum makes up the first 10 to 12 inches (25–30 cm) of the small intestine. The pancreatic and bile ducts empty into the duodenum at the papilla of Vater. The small intestine contains numerous glands that secrete digestive enzymes, hormones, and mucus. For the most part, digestion and absorption occur in the small intestine, including absorption of most orally administered drugs.

## Large Intestine

The *large intestine* consists of the cecum, colon, rectum, and anus. The ileum opens into the cecum. The colon secretes mucus and absorbs water.

## Pancreas

The *pancreas* secretes enzymes required for the digestion of carbohydrates, proteins, and fats. It also secretes insulin, glucagon and somatostatin, hormones that regulate glucose metabolism and blood sugar levels.

## Gallbladder

The *gallbladder* is a small pouch attached to the underside of the liver that stores and concentrates *bile*. It has a capacity of 50 to 60 milliliters. The gallbladder releases bile when fats are present in the duodenum.

## Liver

The *liver* is a vital organ that performs numerous functions. It receives about 1500 milliliters per minute, or 25% to 30%, of the total cardiac output. About three fourths of the blood flow is venous blood from the stomach, intestines, spleen, and pancreas (portal circulation); the remainder is arterial blood through the hepatic artery. The hepatic artery carries blood to the connective tissue of the liver and bile ducts, then empties into the hepatic sinuses. Arterial blood mixes with blood from the portal circulation. Venous blood from the liver flows into the inferior vena cava for return to the systemic circulation. The ample blood flow facilitates the many functions of the liver, which are described below.

The liver serves as a blood reservoir for the body. The liver can eject 500 to 1000 milliliters of blood into the general circulation in response to stress, decreased blood volume, and sympathetic nervous system stimulation (e.g., hemorrhagic or hypovolemic shock).

The liver serves as a blood filter and detoxifier. Kupffer's cells in the liver phagocytize bacteria carried from the intestines by the portal vein. They also break down worn-out erythrocytes, saving iron for reuse in hemoglobin synthesis, and

form bilirubin, a waste product excreted in bile. The liver metabolizes many body secretions and most drugs to prevent accumulation and harmful effects on body tissues.

Most drugs are active as the parent compound and are metabolized in the liver to an inactive metabolite, which is then excreted by the kidneys. However, some drugs become active only after formation of a metabolite in the liver.

The liver detoxifies or alters substances by oxidation, hydrolysis, or conjugation. Conjugation involves combining a chemical substance with an endogenous substance to produce an inactive or harmless compound. Essentially all steroid hormones, including adrenal corticosteroids and sex hormones, are at least partially conjugated in the liver and secreted into the bile. When the liver is damaged, these hormones may accumulate in body fluids and cause symptoms of hormone excess.

The liver plays a role in the metabolism of carbohydrate, fat, and protein. In carbohydrate metabolism, the liver converts glucose to glycogen for storage and reconverts glycogen to glucose when needed to maintain an adequate blood sugar concentration. Excess glucose that cannot be converted to glycogen is converted to fat. The liver also changes fructose and galactose, which cannot be used by body cells, to glucose, which provides energy for cellular metabolism. Fats are synthesized and catabolized by the liver. Amino acids from protein breakdown may be used to form glycogen, plasma proteins, and enzymes. In addition to glycogen, the liver also stores fat-soluble vitamins (i.e., vitamins A, D, E, K), vitamin B<sub>12</sub>, iron, phospholipids, cholesterol, and small amounts of protein and fat.

The liver synthesizes bile; serum albumin and globulin; prothrombin; fibrinogen; blood coagulation factors V, VII, VIII, IX, XI, and XII; and urea. Formation of urea removes ammonia from body fluids. Large amounts of ammonia are formed by intestinal bacteria and absorbed into the blood. If the ammonia is not converted to urea by the liver, plasma ammonia concentrations rise to toxic levels and cause hepatic coma and death.

A final function of the liver is production of body heat by continuous cellular metabolism. The liver is the body organ with the highest rate of chemical activity during basal conditions, and it produces about 20% of total body heat.

## Secretions of the Digestive System

### Mucus

Mucus is secreted by mucous glands in every part of the gastrointestinal (GI) tract. The functions of mucus are to protect the lining of the tract from digestive juices, lubricate the food bolus for easier passage, promote adherence of the fecal mass, and neutralize acids and bases. Prostaglandins aid in protecting the gastrointestinal mucosa from injury.

### Saliva

Saliva consists of mucus, ptyalin, and salivary amylase. It is produced by the salivary glands and totals about 1000 milliliters daily. Saliva has a slightly acidic to neutral pH (6–7); it lubricates the food bolus and begins starch digestion.

### Gastric Juice

*Gastric juice* consists of mucus, digestive enzymes, hydrochloric acid, and electrolytes. The gastric glands secrete about 2000 milliliters of highly acidic (pH of 1–3) gastric juice daily. Secretion varies according to time of day, the time and type of food intake, psychological states, and other metabolic activities of the body. It is highest in the evening and lowest in the early morning. Secretion is stimulated by the parasympathetic nervous system (by the vagus nerve); the hormone gastrin; the presence of food in the mouth; and seeing, smelling, or thinking about food.

The major digestive enzyme in gastric juice is pepsin, a proteolytic enzyme (named before the “ase” system of naming enzymes) that functions best at a pH of 2 to 3. Hydrochloric acid provides the acid medium to promote pepsin activity. Gastrin, acetylcholine and histamine stimulate mechanisms that result in increased production of gastric acid from the gastric glands. The major function of gastric juice is to begin digestion of proteins. There is also a weak action on fats by gastric lipase and on carbohydrates by gastric amylase. A large amount of mucus is secreted in the stomach to protect the stomach wall from the proteolytic action of pepsin. When mucus is not secreted, gastric ulceration occurs within hours.

### Pancreatic Juices

*Pancreatic juices* are alkaline (pH of 8 or above) secretions that contain amylase for carbohydrate digestion, lipase for fat digestion, and trypsin and chymotrypsin for protein digestion. They also contain large amounts of sodium bicarbonate, a base (alkali) that neutralizes the acid chyme from the stomach by reacting with hydrochloric acid. This protects the mucosa of the small intestine from the digestive properties of gastric juice. The daily amount of pancreatic secretion is about 1200 milliliters. The hormone cholecystokinin stimulates secretion of enzyme-rich pancreatic juices. Secretin stimulates increased production of bicarbonate-rich pancreatic juices.

### Bile

Bile is an alkaline (pH of about 8) secretion that is formed continuously in the liver, carried to the gallbladder by the bile ducts, and stored there. The hormone cholecystokinin causes the gallbladder to contract and release bile into the small intestine when fats are present in intestinal contents. The liver secretes about 600 milliliters of bile daily. This amount is concentrated to the 50- to 60-milliliter capacity of the gallbladder. Bile contains bile salts, cholesterol, bilirubin, fatty acids, and electrolytes. Bile salts are required for digestion and absorption of fats, including fat-soluble vitamins. Most of the bile salts are reabsorbed and reused by the liver (enterohepatic recirculation); some are excreted in feces.

## Effects of Drugs on the Digestive System

The digestive system and drug therapy have a reciprocal relationship. Many common symptoms (i.e., nausea, vomiting, constipation, diarrhea, abdominal pain) relate to GI dysfunction. These symptoms may result from a disorder in the digestive system, disorders in other body systems, or drug therapy. Many GI symptoms and disorders alter the ingestion, dissolution, absorption, and metabolism of drugs. Drugs may be administered to relieve these symptoms and disorders, but

drugs administered for conditions unrelated to the digestive system may cause such symptoms and disorders. GI conditions may alter responses to drug therapy.

Drugs used in digestive disorders primarily alter GI secretion, absorption, or motility. They may act systemically or locally in the GI tract. The drug groups included in this section are laxatives, antidiarrheals, antiemetics, and drugs used for acid-peptic disorders. Other drug groups used in GI disorders include cholinergics (see Chap. 19), anticholinergics (see Chap. 20), corticosteroids (see Chap. 23), and anti-infective drugs (see Section 5).

## Key Concepts

- The main functions of the digestive system are to provide the body with useable nutrition and dispose of waste products that result from the digestive process.
- Peristalsis propels food through the digestive tract and mixes the food bolus with digestive juices.
- Parasympathetic stimulation increases GI motility and secretions.
- Sympathetic stimulation promotes sphincter function and inhibits motility.
- Digestion begins in the oral cavity with mastication and digestion of starches.
- The esophagus is bordered by sphincters at each end and serves to convey food to the stomach.
- Failure of the lower esophageal sphincter results in reflux of gastric contents into the esophagus.
- Food is mixed with gastric juice, containing mucus, digestive enzymes such as pepsin, and hydrochloric acid in the stomach.
- Pepsin requires an acidic pH to effectively digest proteins.
- Gastrin, acetylcholine, and histamine stimulate secretion of gastric acid.
- Mucus and prostaglandins protect the stomach from the acidic pH of the gastric secretions.
- Most nutrients and drugs are absorbed in the small intestine.
- Pancreatic juices are rich in bicarbonate and digestive enzymes.
- The gallbladder stores and releases bile into the small intestine when fats are present in the duodenum.
- The liver plays numerous roles in digestion, including metabolism of carbohydrates, fats, and proteins; storage of fat-soluble vitamins, vitamin B<sub>12</sub>, iron, phospholipids, cholesterol, and a small amount of protein and fat; and synthesis of bile.

## Review and Application Exercises

### Short Answer Exercises

1. What is the main function of the GI system?
2. What is the role of the parasympathetic nervous system in GI function?
3. List factors affecting GI motility and secretions.

4. Describe important GI secretions and their functions.
5. What factors stimulate or inhibit GI secretions?
6. How does the GI tract affect oral medications?
7. How do oral medications affect the GI tract?

# Nutritional Support Products, Vitamins, and Mineral–Electrolytes

## KEY TERMS

- Chelating agent
- Electrolytes
- Enteral nutrition
- Fat-soluble vitamins
- Hyperkalemia
- Hypokalemia
- Malabsorption
- Megaloblastic anemia
- Megavitamins
- Parenteral nutrition
- Water-soluble vitamins

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Assess patients for risk factors and manifestations of protein-calorie undernutrition.
2. Identify patients at risk for development of vitamin and/or mineral–electrolyte deficiency or excess.
3. Describe adverse effects associated with overdoses of vitamins.
4. Discuss the rationale for administering vitamin K to newborns.
5. Describe signs, symptoms, and treatment of sodium, potassium, magnesium, and chloride imbalances.
6. Describe signs, symptoms, and treatment of iron deficiency anemia.
7. Discuss the chelating agents used to remove excessive copper, iron, and lead from body tissues.
8. Apply nursing process skills to prevent, recognize, or treat nutritional imbalances.
9. Monitor laboratory reports that indicate nutritional status.

## Applying Your Knowledge

Jane Farber is a 91-year-old woman who suffers from heart failure, osteoarthritis, and Parkinson's disease. Upon evaluation, you find that Mrs. Farber is undernourished and slightly dehydrated.

## Introduction

Water, carbohydrates, proteins, fats, vitamins, and minerals are required to promote or maintain health, to prevent illness, and to promote recovery from illness or injury. Water is required for cellular metabolism and excretion of metabolic waste products; 2000 to 3000 milliliters are needed daily. Proteins are structural and functional components of all body tissues; the recommended amount for adults is 50 to 60 grams daily. Carbohydrates and fats mainly provide energy for cellular metabolism. Energy is measured in kilocalories (kcal) per gram of food oxidized in the body. Carbohydrates and proteins supply 4 kcal per gram; fats supply 9 kcal per gram.

Vitamins are required for normal body metabolism, growth, and development. They are components of enzyme systems that release energy from ingested carbohydrates, proteins, and fats. They also are required for formation of red blood cells, nerve cells, hormones, genetic material, and bone and other tissues. Minerals and electrolytes are essential constituents of bone, teeth, cell membranes, connective tissue, and many essential enzymes. They function to maintain fluid,

electrolyte, and acid–base balance; maintain osmotic pressure; maintain nerve and muscle function; assist in transfer of compounds across cell membranes; and influence the growth process.

For all of these nutrients, patients' requirements vary widely, depending on age, sex, size, health or illness status, and other factors. This chapter discusses products to improve nutritional status in patients with deficiency states and excess states of selected vitamins and mineral–electrolytes.

## Nutritional Deficiency States

Nurses encounter many patients who are unable to ingest, digest, absorb, or use sufficient nutrients to improve or maintain health. Debilitating illnesses such as cancer; acquired immunodeficiency syndrome; and chronic lung, kidney, or cardiovascular disorders often interfere with appetite and gastrointestinal (GI) function. Therapeutic drugs often cause anorexia, nausea, vomiting, diarrhea, or constipation. Nutritional deficiencies may impair the function of essentially every body organ. Signs and symptoms include unintended weight loss, increased susceptibility to infection, weakness and fatigability, impaired wound healing, impaired growth and development in children, edema, and decreased hemoglobin.

## Nutritional Products

Various products are available to supplement or substitute for dietary intake. These may consist of liquid enteral formulas, intravenous (IV) fluids, pancreatic enzymes, vitamins, and minerals.

### Liquid Enteral Products

Numerous liquid enteral formulas are available over-the-counter or in health care settings for oral or tube feedings. Many are nutritionally complete, except for water, when given in sufficient amounts (e.g., Ensure, Isocal, Sustacal, Resource).

Additional water must be given to meet fluid needs. Most oral products are available in a variety of flavors and contain 1 kcal per milliliter. Additional products are formulated for patients with special conditions (e.g., renal or hepatic failure, malabsorption syndromes) or needs (e.g., high protein, increased calories).

### Intravenous Fluids

IV fluids are used when oral or tube feedings are contraindicated. Most are nutritionally incomplete and are used short term to supply fluids, electrolytes, and a few calories. Dextrose or dextrose and sodium chloride solutions are often used. When nutrients must be provided intravenously for more than a few days, a special *parenteral nutrition* formula can be designed to meet all nutritional needs or to supplement other feeding methods.

### Pancreatic Enzymes

Pancreatic enzymes (amylase, protease, lipase) are required for absorption of carbohydrates, protein, and fat. Pancrelipase and others are commercial preparations used as replacement therapy in deficiency states, including cystic fibrosis, chronic pancreatitis, pancreatectomy, and pancreatic obstruction. Dosage is 1 to 3 capsules or tablets with each meal or snack.

### Vitamins

Vitamins are obtained from foods or supplements. Although foods are considered the best source, studies indicate that most adults and children do not consume enough fruits, vegetables, cereal grains, dairy products, and other foods to consistently meet their vitamin requirements. In addition, some conditions increase requirements above the usual recommended amounts (e.g., pregnancy, lactation, various illnesses).

Historically, the major concern about vitamins was sufficient intake to promote health and prevent deficiency diseases. To this end, the Food and Nutrition Board of the National Academy of Sciences established recommendations for daily vitamin intake (Dietary Reference Intakes [DRIs]; see Box 57-1).

#### Box 57-1

#### Dietary Reference Intakes (DRIs)

Dietary Reference Intakes are the recommended amounts of vitamins (see Table 57-1) and some minerals (see Table 57-3). The current DRIs were established in 1997, 1998, and 2000 by the Food and Nutrition Board of the National Academy of Sciences and are intended to replace the Recommended Dietary Allowances (RDAs) used since 1989. DRIs consist of four subtypes of nutrient recommendations, as follows:

1. **Estimated Average Requirement (EAR)** is the amount estimated to provide adequate intake in 50% of healthy persons in a specific group.
2. **Recommended Dietary Allowance (RDA)** is the amount estimated to meet the needs of approximately 98% of

healthy children and adults in a specific age and gender group. The RDA is used to advise various groups about nutrient intake. It should be noted, however, that RDAs were established to prevent deficiencies and that they were extrapolated from studies of healthy adults. Thus, they may not be appropriate for all groups, such as young children and older adults.

3. **Adequate Intake (AI)** is the amount thought to be sufficient when there is not enough reliable, scientific information to estimate an average requirement. The AI is derived from data that show an average intake that appears to maintain health.

(continued on page 904)

## Box 57-1

## Dietary Reference Intakes (DRIs) (continued)

4. **Tolerable Upper Intake Level (UL)** is the maximum intake considered unlikely to pose a health risk in almost all healthy persons in a specified group; it is not intended to be a recommended level of intake.

With **vitamins**, the ULs for adults (19–70 years and older) are D, 50 mg; E, 1000 mg; C, 2000 mg; folate, 1000 mcg; niacin, 35 mg; and pyridoxine, 100 mg. With vitamins C and D and pyridoxine, the UL refers to the total intake from food, fortified food, and supplements. With niacin and folate, the UL applies to synthetic forms obtained from supplements, fortified foods, or a combination of the two. With vitamin E, the UL applies to any form of supplemental alpha-tocopherol. These ULs should not be exceeded.

Currently, concern extends to excessive vitamin intake, which may also be detrimental to health. Vitamin supplements are widely promoted to increase health and prevent or treat illness. However, the supplements can be harmful if overused. As a result, the DRIs include the maximum Tolerable Upper Intake Levels (ULs) of some vitamins. **These amounts should not be exceeded.**

Vitamins are classified as fat soluble (A, D, E, K) and water soluble (B complex, C). *Fat-soluble vitamins* are absorbed from the intestine with dietary fat, and absorption requires the presence of bile salts and pancreatic lipase. Vitamin D is discussed mainly in Chapter 25 because of its major role in bone metabolism. Vitamin deficiencies occur with inadequate intake or disease processes that interfere with absorption or use of vitamins. Excess states occur with excessive intake of fat-soluble vitamins because these vitamins accumulate in the body. Excess states do not occur with dietary intake of water-soluble vitamins but may occur with vitamin supplements that exceed recommended amounts. Vitamins are described further in Table 57-1, and recommended dosages of vitamin preparations are listed in Table 57-2.

### Vitamin Supplements

Vitamin supplements may be prescribed by health care providers, but most are self-prescribed. Because vitamins are essential nutrients, some people believe that large amounts (megadoses) promote health and provide other beneficial effects. However, excessive intake may cause harmful effects, and *megavitamins* should never be self-prescribed. Additional characteristics include the following:

- Vitamins from supplements exert the same physiologic effects as those obtained from foods.
- Vitamin supplements do not require a prescription.
- Vitamin products vary widely in number, type, and amount of specific ingredients.
- Preparations should not contain more than recommended amounts of vitamin D, folic acid, and vitamin A.

There are inadequate data for establishing ULs for biotin, cyanocobalamin (B<sub>12</sub>), pantothenic acid, riboflavin, and thiamine. As a result, consuming more than the recommended amounts of these vitamins should generally be avoided.

With **minerals**, ULs have been established for calcium (2.5 g), phosphorus (3–4 g), magnesium (350 mg), fluoride (10 mg), and selenium (400 mcg). The UL should not be exceeded for any mineral–electrolyte because all minerals are toxic in overdose. Except for magnesium, which is set for supplements only and excludes food and water sources, the stated UL amounts include those from both foods and supplements.

- Synthetic vitamins have the same structure and function as natural vitamins derived from plant and animal sources and are less expensive.
- Multivitamin preparations often contain minerals as well. **Large doses of all minerals are toxic.**
- Vitamins are often marketed in combination products with each other (e.g., antioxidant vitamins) and with herbal products (e.g., B-complex vitamins with ginseng, for “energy”). There is no reliable evidence to support the use of such products.
- Some vitamins (e.g., C; E; beta carotene, a precursor of vitamin A) have been thought to prevent heart disease, cancer, and other illnesses by their antioxidant effects. Antioxidants inactivate oxygen free radicals, potentially toxic substances formed during normal cell metabolism, and inhibit them from damaging body cells. However, the results of most research studies with antioxidant vitamin supplements have been disappointing and inconclusive. The consensus view seems to be that dietary vitamins from several daily servings of grains, fruits, and vegetables and a daily multivitamin supplement are beneficial for most children and adults, but vitamin supplements to prevent various chronic illnesses cannot be recommended with current evidence.

### Mineral–Electrolytes

There are 22 minerals considered necessary for human nutrition. Some (calcium, phosphorus, sodium, potassium, magnesium, chlorine, sulfur) are required in relatively large amounts. Calcium and phosphorus are discussed mainly in Chapter 25 because of their major roles in bone metabolism. Sulfur is a component of cellular proteins, several amino acids, B vitamins, insulin, and other essential body substances. No recommended intake has been established; it is obtained from protein foods.

Other minerals are required in small amounts and are often called trace elements. Eight of these (chromium, cobalt,

Table 57-1

Vitamins

VITAMIN/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
<b>Fat-Soluble Vitamins</b>				
<p><b>Vitamin A</b> (retinol)</p> <p>Required for normal vision, growth, bone development, skin, and mucous membranes</p>	<p>DRIs*</p> <p><i>Females:</i> 14 y and older, 700 mcg; in pregnancy, 750–770 mcg; lactation, 1200–1300 mcg</p> <p><i>Males:</i> 14 y and older, 900 mcg</p> <p><i>Children:</i> 1–3 y, 300 mcg; 4–8 y, 400 mcg; 9–13 y, 600 mcg</p> <p><i>Infants (AIs):</i> 0–6 mo, 400 mcg; 6–12 mo, 500 mcg</p>	<p>Preformed vitamin A: meat, butter and fortified margarine, egg yolk, whole milk, cheese made from whole milk</p> <p>Carotenoids: turnip and collard greens, carrots, sweet potatoes, squash, apricots, peaches, cantaloupe</p>	<p>Night blindness; xerophthalmia, which may progress to corneal ulceration and blindness; changes in skin and mucous membranes that lead to skin lesions and infections, respiratory tract infections, and urinary calculi</p>	<p>Anorexia, vomiting, irritability, skin changes (itching, desquamation, dermatitis); pain in muscles, bones, and joints; gingivitis; enlargement of spleen and liver; increased intracranial pressure; other neurologic signs.</p> <p>Congenital abnormalities in newborns whose mothers took excessive vitamin A during pregnancy.</p> <p>Acute toxicity, with increased intracranial pressure, bulging fontanel, and vomiting, may occur in infants who are given vitamin A.</p>
<p><b>Vitamin E</b></p> <p>Antioxidant in preventing destruction of certain fats, including the lipid portion of cell membranes; may increase absorption, hepatic storage, and use of vitamin A</p>	<p>RDAs†</p> <p><i>Females:</i> 14 y and older, 15 mg; in pregnancy, 15 mg (22.5 IU); lactation, 19 mg (28.5 IU)</p> <p><i>Males:</i> 14 y and older, 15 mg</p> <p><i>Children:</i> 1–3 y, 6 mg; 4–8 y, 7 mg; 9–13 y, 11 mg</p> <p><i>Infants (AIs):</i> 0–6 mo, 4 mg; 7–12 mo, 6 mg</p>	<p>Cereals, green leafy vegetables, egg yolk, milk fat, butter, meat, vegetable oils</p>	<p>Deficiency is rare.</p>	<p>Fatigue; nausea; headache; blurred vision; diarrhea</p>
<p><b>Vitamin K</b></p> <p>Essential for normal blood clotting. Activates precursor proteins, found in the liver, into clotting factors II, VII, IX, and X</p>	<p>1 mcg/kg</p>	<p>Green leafy vegetables (spinach, kale, cabbage, lettuce), cauliflower, tomatoes, wheat bran, cheese, egg yolk, liver</p>	<p>Abnormal bleeding (melena, hematemesis, hematuria, epistaxis, petechiae, ecchymoses, hypovolemic shock)</p>	<p>Clinical manifestations rarely occur. However, when vitamin K is given to someone who is receiving warfarin (Coumadin), the client can be made “warfarin-resistant” for 2–3 wk.</p>
<b>Vitamin D</b> (see Chap. 25)				
<b>Water-Soluble Vitamins</b>				
<b>B-Complex</b>				
<p><b>Biotin</b></p> <p>Essential in fat and carbohydrate metabolism</p>	<p>AIs</p> <p><i>Females:</i> 14–18 y, 25 mcg; 19 y and older, 30 mcg; in pregnancy, 30 mcg; lactation, 35 mcg</p>	<p>Meat, egg yolk, nuts, cereals, most vegetables</p>	<p>Anorexia, nausea, depression, muscle pain, dermatitis</p>	<p>Not established</p>

(continued on page 906)

Table 57-1

Vitamins (continued)

VITAMIN/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
	<p>Males: 4–18 y, 25 mcg; 19 y and older, 30 mcg</p> <p>Children: 1–3 y, 8 mcg; 4–8 y, 12 mcg; 9–13 y, 20 mcg</p> <p>Infants: 0–6 mo, 5 mcg; 7–12 mo, 6 mcg</p>			
<p><b>Cyanocobalamin (B<sub>12</sub>)</b></p> <p>Essential for normal metabolism of all body cells; normal red blood cells; normal nerve cells; growth; and metabolism of carbohydrate, protein, and fat</p>	<p>RDAs</p> <p>Females: 14 y and older, 2.4 mcg; in pregnancy, 2.6 mcg; lactation, 2.8 mcg</p> <p>Males: 14 y and older, 2.4 mcg</p> <p>Children: 1–3 y, 0.9 mcg; 4–8 y, 1.2 mcg; 9–13 y, 1.8 mcg</p> <p>Infants (AIs): 0–6 mo, 0.4 mcg; 7–12 mo, 0.5 mcg</p>	<p>Meat, eggs, fish, cheese</p>	<p>Pernicious anemia: decreased numbers of RBCs; large, immature RBCs; fatigue; dyspnea</p> <p>Severe deficiency: leukopenia, infection, thrombocytopenia, cardiac dysrhythmias, heart failure</p> <p>Neurologic signs and symptoms: paresthesias in hands and feet; unsteady gait; depressed deep-tendon reflexes; loss of memory; confusion; delusions; hallucinations; psychosis. Nerve damage may be irreversible.</p>	<p>Not established</p>
<p><b>Folic acid (folate)</b></p> <p>Essential for normal metabolism of all body cells; normal red blood cells; and growth</p>	<p>RDAs</p> <p>Females: 14 y and older, 400 mcg; in pregnancy, 600 mcg; lactation, 500 mcg</p> <p>Males: 14 y and older, 400 mcg</p> <p>Children: 1–3 y, 150 mcg; 4–8 y, 200 mcg; 9–13 y, 300 mcg</p> <p>Infants (AIs): 0–6 mo, 65 mcg; 7–12 mo, 80 mcg</p>	<p>Liver, kidney beans, fresh green vegetables (spinach, broccoli, asparagus), fortified grain products (e.g., breads, cereals, rice)</p>	<p>Megaloblastic anemia that cannot be distinguished from the anemia produced by B<sub>12</sub> deficiency; impaired growth in children; glossitis; GI problems</p>	<p>Not established</p>
<p><b>Niacin (B<sub>3</sub>)</b></p> <p>Essential for glycolysis, fat synthesis, and tissue respiration. It functions as a coenzyme in many metabolic processes (after conversion to nicotinamide, the physiologically active form).</p>	<p>DRIs</p> <p>Females: 14 y and older, 14 mg; in pregnancy, 18 mg; lactation, 17 mg</p> <p>Males: 14 y and older, 16 mg</p> <p>Children: 1–3 y, 6 mg; 4–8 y, 8 mg; 9–13 y, 12 mg</p>	<p>Meat, poultry, fish, peanuts</p>	<p>Pellagra: erythematous skin lesions, GI problems (stomatitis, glossitis, enteritis, diarrhea), central nervous system problems (headache, dizziness, insomnia, depression, memory loss)</p> <p>Severe deficiency: delusions,</p>	<p>Flushing; pruritus; hyperglycemia; hyperuricemia; increased liver enzymes</p>

VITAMIN/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
	Infants (AIs): 0–6 mo, 2 mg; 7–12 mo, 4 mg		hallucinations, impairment of peripheral motor and sensory nerves	
<b>Pantothenic acid (B<sub>5</sub>)</b> Essential for metabolism of carbohydrate, fat, and protein (e.g., release of energy from carbohydrate; fatty acid metabolism; synthesis of cholesterol, steroid hormones, and phospholipids)	AIs Females: 14 y and older, 5 mg; in pregnancy, 6 mg; lactation, 7 mg Males: 14 y and older, 5 mg Children: 1–3 y, 2 mg; 4–8 y, 3 mg; 9–13 y, 4 mg Infants: 0–6 mo, 1.7 mg; 7–12 mo, 1.8 mg	Eggs, liver, salmon, yeast, cauliflower, broccoli, lean beef, potatoes, tomatoes	No deficiency state established	Not established
<b>Pyridoxine (B<sub>6</sub>)</b> A coenzyme in metabolism of carbohydrate, protein, and fat; required for formation of tryptophan and conversion of tryptophan to niacin; helps release glycogen from the liver and muscle tissue; functions in metabolism of the central nervous system; helps maintain cellular immunity	DRIs Females: 14–18 y, 1.2 mg; 19–50 y, 1.3 mg; 51–70 and older, 1.5 mg; in pregnancy, 1.9 mg; lactation, 2.0 mg Males: 14–50 y, 1.3 mg; 51–70 y and older, 1.7 mg Children: 1–3 y, 0.5 mg; 4–8 y, 0.6 mg; 9–13 y, 1.0 mg Infants (AIs): 0–6 mo, 0.1 mg; 7–12 mo, 0.3 mg	Yeast, wheat germ, liver and other glandular meats, whole grain cereals, potatoes, legumes	Skin and mucous membrane lesions (seborrheic dermatitis, intertrigo, glossitis, stomatitis), neurologic problems (convulsions, peripheral neuritis, mental depression)	Not established
<b>Riboflavin (B<sub>2</sub>)</b> A coenzyme in metabolism; necessary for growth; may function in production of corticosteroids and red blood cells and gluconeogenesis	DRIs Females: 14–18 y, 1.0 mg; 19 y and older, 1.1 mg; in pregnancy, 1.4 mg; lactation, 1.6 mg Males: 14 y and older, 1.3 mg Children: 1–3 y, 0.5 mg; 4–8 y, 0.6 mg; 9–13 y, 0.9 mg Infants (AIs): 0–6 mo, 0.3 mg; 7–12 mo, 0.4 mg	Milk, cheddar and cottage cheeses, meat, eggs, green leafy vegetables	Glossitis, stomatitis, seborrheic dermatitis, eye disorders (burning, itching, lacrimation, photophobia, vascularization of the cornea)	Not established
<b>Thiamine (B<sub>1</sub>)</b> A coenzyme in carbohydrate metabolism; essential for energy production	DRIs Females: 14–18 y, 1.0 mg; 19 y and older, 1.1 mg; in pregnancy, 1.4 mg; lactation, 1.4 mg Males: 14 y and older, 1.2 mg	Meat, poultry, fish, egg yolk, dried beans, whole-grain cereal products, peanuts	Mild deficiency: fatigue, anorexia, retarded growth, mental depression, irritability, apathy, lethargy Severe deficiency (beriberi): peripheral neuritis; personality	Not established

(continued on page 908)

Table 57-1

Vitamins (continued)

VITAMIN/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
	Children: 1–3 y, 0.5 mg; 4–8 y, 0.6 mg; 9–13 y, 0.9 mg Infants (AIs): 0–6 mo, 0.2 mg; 7–12 mo, 0.3 mg		disturbances; heart failure; edema; Wernicke-Korsakoff syndrome in alcoholics	
<b>Vitamin C (ascorbic acid)</b> Essential for formation of skin, ligaments, cartilage, bone, and teeth; required for wound healing and tissue repair, metabolism of iron and folic acid, synthesis of fats and proteins, preservation of blood vessel integrity, and resistance to infection	DRIs Females: 14–18 y, 65 mg; 19 y and older, 75 mg; in pregnancy, 80–85 mg; lactation, 115–120 mg Males: 14–18 y, 75 mg; 19 y and older, 90 mg Children: 1–3 y, 15 mg; 4–8 y, 25 mg; 9–13 y, 45 mg Infants (AIs): 0–6 mo, 40 mg; 7–12 mo, 50 mg	Fruits and vegetables, especially citrus fruits and juices	Mild deficiency: irritability, malaise, arthralgia, increased tendency to bleed Severe deficiency: scurvy and adverse effects on most body tissues (gingivitis; bleeding of gums, skin, joints, and other areas; disturbances of bone growth; anemia; and loosening of teeth). If not treated, coma and death may occur.	Renal calculi

\*DRIs for vitamin A are expressed in retinol activity equivalents (RAEs), which include both preformed vitamin A and carotenoids. 1 RAE = 1 mcg retinol or 12 mcg beta carotene.

†Vitamin E activity is expressed in milligrams of alpha-tocopherol equivalents (alpha TE).

AIs, Adequate Intakes; DRIs, Dietary Reference Intakes; GI, gastrointestinal; RBCs, red blood cells; RDAs, Recommended Dietary Allowances.

Table 57-2

Drugs at a Glance: Vitamin Drug Preparations

Generic/Trade Name	ROUTES AND DOSAGE RANGES		Comments
	Adults	Children	
<b>Fat-Soluble Vitamins</b> Vitamin A (also called retinol)	Deficiency, PO, IM 100,000 IU daily for 3 d, then 50,000 IU daily for 2 wk, then 10,000–20,000 IU daily for another 2 mo	Kwashiorkor, Retinol 30 mg IM followed by intermittent oral therapy Xerophthalmia (over 1 y old), retinyl palmitate 110 mg PO or 55 mg IM plus another 110 mg PO at 1 and 3 or 4 d later	IM administration indicated when oral not feasible, as in anorexia, nausea, vomiting, preoperative and postoperative conditions, or malabsorption syndromes With xerophthalmia, vitamin E 40 IU should be coadministered to increase effectiveness of the retinol.
Vitamin E	PO 100–400 IU daily	PO 15–30 IU daily	Should not be given IV because IV use has been associated with 38 infant deaths

Generic/Trade Name	ROUTES AND DOSAGE RANGES		Comments
	Adults	Children	
Vitamin K Phytonadione (Mephyton)	Anticoagulant-induced prothrombin deficiency, PO, Sub-Q, IM 2.5–10 mg initially, repeat after 6–8 h (injected dose) or 12–48 h (oral dose) if needed (i.e., if prothrombin time still prolonged) Hypoprothrombinemia due to other causes, PO, Sub-Q, IM 2.5–25 mg	Older children, same as adults Newborns, prevention of hemorrhagic disease, IM 0.5–1 mg within 1 h after birth; may be repeated after 2–3 wk if mother received anticoagulant, anticonvulsant, antitubercular, or recent antibiotic drug therapy during pregnancy Treatment of hemorrhagic disease, Sub-Q, IM 1 mg	Do not give IV; unless necessary serious, anaphylaxis-like reactions have occurred.
<b>Water-Soluble Vitamins</b>			
<b>B-COMPLEX VITAMINS</b>			
Calcium pantothenate (B <sub>5</sub> )	Total parenteral nutrition, IV 15 mg daily	Total parenteral nutrition, over 11 y, IV 15 mg daily; 1–11 y, IV 5 mg daily	Deficiency states seen only with severe, multiple B-complex deficiency states
Cyanocobalamin (B <sub>12</sub> )	PO 100–250 mcg daily IM 30 mcg daily for 5–10 d, then 100–200 mcg monthly	PO, IM, Sub-Q 10–100 mcg daily for 5–15 d, then 100–200 mcg monthly	Oral drug, alone or in multivitamin preparations, is given for nutritional deficiencies.
Nascobal	Intranasal gel, 1 spray (500 mcg) in one nostril, once per wk		Parenteral B <sub>12</sub> should be given for pernicious anemia. Intranasal drug should not be used if rhinitis, nasal congestion, or upper respiratory infection is present.
Folic acid	Deficiency, megaloblastic anemia, PO, Sub-Q, IM, IV up to 1 mg daily until symptoms decrease and blood tests are normal, then maintenance dose of 0.4 mg daily	PO, Sub-Q, IM, IV up to 1 mg daily until symptoms decrease and blood tests are normal, then a daily maintenance dose as follows: infants, 0.1 mg; under 4 y, up to 0.3 mg; over 4 y, 0.4 mg	Oral administration preferred unless severe intestinal malabsorption is present
Niacin (nicotinic acid) Niacinamide (nicotinamide)	Deficiency, PO 50–100 mg daily Pellagra, PO Up to 500 mg daily Hyperlipidemia, PO 2–6 g daily (maximum dose, 6 g/d)	Safety and effectiveness not established for amounts exceeding the RDA	To reduce flushing with larger doses, start with smaller doses and gradually increase them.
Pyridoxine (B <sub>6</sub> )	Deficiency, PO, IM, IV 2–5 mg daily Anemia, peripheral neuritis, 50–200 mg daily	Safety and effectiveness not established for amounts exceeding the RDA	Usually given with isoniazid, an antitubercular drug, to prevent peripheral neuropathy
Riboflavin	Deficiency, PO 5–10 mg daily In total parenteral nutrition, 3.6 mg/d	In total parenteral nutrition, IV over 11 y, 3.6 mg/d; 1–11 y, 1.4 mg/d	Deficiency rarely occurs alone; more likely with other vitamin deficiency states

(continued on page 910)

Table 57-2

### Drugs at a Glance: Vitamin Drug Preparations (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES		Comments
	Adults	Children	
Thiamine (B <sub>1</sub> )	Deficiency, PO 10–30 mg daily; IM 10–20 mg 3 times daily for 2 wk, supplemented with 5–10 mg orally; IV 50–100 mg/d until able to take orally	Safety and effectiveness not established for amounts exceeding the RDA	Deficiency is common in alcoholics.
<b>VITAMIN C</b>			
Vitamin C (ascorbic acid)	Deficiency, PO, IM, IV 100–500 mg daily Urinary acidification, 2 g daily in divided doses Prophylaxis, 50–100 mg daily	Infants receiving formula, 35–50 mg daily for first few weeks of life	Excessive doses (e.g., 2000 mg or more daily) cause adverse effects and should be avoided.

*IU, international units.*

copper, fluoride, iodine, iron, selenium, and zinc) have relatively well-defined roles in human nutrition. Others (manganese, molybdenum, nickel, silicon, tin, and vanadium) are present in many body tissues and may be necessary for normal growth, structure, and function of connective tissue. However, requirements are unknown, and states of deficiency or excess have not been identified in humans.

Minerals occur in the body and foods mainly in ionic form. Ions are electrically charged particles. Metals (e.g., sodium, potassium, calcium, magnesium) form positive ions or cations; nonmetals (e.g., chlorine, phosphorus, sulfur) form negative ions or anions. These cations and anions combine to form compounds that are physiologically inactive and electrically neutral. When placed in solution, such as a body fluid, the components separate into electrically charged particles called *electrolytes*. At any given time, the body must maintain an equal number of positive and negative charges. Therefore, the ions are constantly combining and separating to maintain electrical neutrality or electrolyte balance.

These electrolytes also maintain the acid–base balance of body fluids. When foods are digested, they produce mineral residues that react chemically as acids or bases. Acids are usually anions (e.g., chloride, bicarbonate, sulfate, phosphate). Bases are usually cations (e.g., sodium, potassium, calcium, magnesium). If approximately equal amounts of cations and anions are present in the mineral residue, the residue is essentially neutral, and the pH of body fluids does not require adjustment. If there is an excess of cations (base), the body must draw on its anions (acid) to combine with the cations, render them physiologically inactive, and restore the normal pH of the blood. Excess cations combine with anions (e.g., phosphate) and are excreted in the urine; excess anions combine with hydrogen ions or other cations and are excreted in the urine.

Mineral–electrolytes are obtained from foods or supplements. Although most minerals are supplied by a well-

balanced diet, studies indicate that most adults and children do not ingest sufficient dietary calcium and that iron deficiency anemia is common in some populations. In addition, some conditions increase requirements (e.g., pregnancy, lactation, various illnesses), and some drug–drug interactions decrease absorption or use of minerals.

As with vitamins, goals for daily mineral intake have been established as DRIs. Thus far, DRIs and ULs have been established for calcium, phosphorus, magnesium, iron, fluoride, and selenium. **The UL should not be exceeded for any mineral–electrolyte.** Except for magnesium, which is set for supplements only and excludes food and water sources, the stated amounts include those from both foods and supplements. Mineral–electrolytes are described further in Table 57-3.

### Mineral Supplements

Many people take mineral preparations as dietary supplements, usually in a multivitamin–mineral combination. Health care providers and patients should consider the following factors in relation to mineral supplements.

- Nutritionists usually recommend dietary intake of nutrients rather than pharmaceutical supplements and emphasize that supplements do not compensate for an inadequate diet.
- In general, **recommended daily doses should not be exceeded because all minerals are toxic at high doses.**
- Multivitamin–mineral combinations recommended for age and gender groups contain different amounts of some minerals (e.g., postmenopausal women need less iron than younger women). This should be considered in choosing a product.
- Iron supplements other than those in multivitamin–mineral combinations are usually intended for temporary use in the presence of deficiency or a period of increased need (e.g., pregnancy). They should not be taken otherwise because of the risk of accumulation and toxicity.

Table 57-3

Minerals and Electrolytes

MINERAL/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
<b>Macro Minerals</b>				
<b>Sodium</b>				
<p>Assists in regulating osmotic pressure, water balance, conduction of electrical impulses in nerves and muscles, and electrolyte and acid–base balance</p> <p>Influences permeability of cell membranes and assists in movement of substances across cell membranes</p> <p>Participates in many intracellular chemical reactions</p>	Approximately 2 g	<p>In most foods. Proteins contain large amounts, vegetables and cereals contain moderate to small amounts, fruits contain little or no sodium.</p> <p>Major source in the diet is table salt added to food in cooking, processing, or seasoning. One teaspoon contains 2.3 g of sodium.</p> <p>Water in some areas may contain significant amounts of sodium.</p>	<p>Serum sodium less than 135 mEq/L; anorexia, nausea, and vomiting; ataxia; confusion; delirium; hypotension and tachycardia; muscle tremors; oliguria and increased BUN; seizures; weakness</p>	<p>Serum sodium greater than 145 mEq/L; disorientation; dry skin and mucous membranes; fever; hyperactive reflexes; hypotension; muscle rigidity; tremors and spasms; irritability; cerebral hemorrhage; coma; oliguria, concentrated urine, increased BUN</p>
<b>Potassium</b>				
<p>Within cells, helps maintain osmotic pressure, fluid and electrolyte balance, and acid–base balance</p> <p>In extracellular fluid, is required for conduction of nerve impulses and contraction of muscle</p> <p>Helps transport glucose into cells and is required for glycogen formation and storage</p> <p>Required for synthesis of muscle proteins</p>	Approximately 40 mEq	<p>Present in most foods, including meat, whole-grain breads or cereals, bananas, citrus fruits, tomatoes, and broccoli</p>	<p>Serum potassium less than 3.5 mEq/L; dysrhythmias and electrocardiographic changes; cardiac arrest; confusion; delirium; hyperglycemia; postural hypotension; muscle weakness; abdominal distention, constipation, paralytic ileus; polyuria, polydipsia, nocturia.</p> <p>Prolonged deficiency may increase serum creatinine and BUN.</p>	<p>Serum potassium greater than 5 mEq/L; muscle weakness; cardiotoxicity, with dysrhythmias or cardiac arrest</p> <p>Cardiac effects are not usually severe until serum levels are 7 mEq/L or above.</p>
<b>Magnesium</b>				
<p>Required for conduction of nerve impulses and contraction of muscle (especially important in functions of cardiac and skeletal muscles)</p> <p>Serves as a component of many enzymes</p> <p>Essential for metabolism of carbohydrate and protein</p>	<p>Adults (DRIs): Males 19–30 y, 400 mg; 31–70 y and older, 420 mg; females 19–30 y, 310 mg; 31–70 y and older, 320 mg; in pregnancy, 350–360 mg; lactation, 310–320 mg</p> <p>Upper Level (UL) or maximum intake from pharmaceutical preparations, 350 mg (does not include intake from food and water)</p>	<p>Present in many foods; diet that is adequate in other respects contains adequate magnesium. Good food sources include nuts, cereal grains, dark green vegetables, and seafoods.</p>	<p>Serum magnesium less than 1.5 mEq/L; ataxia; confusion; dizziness; irritability; muscle tremors, carpopedal spasm, nystagmus, generalized spasticity; seizures; tachycardia, hypotension, premature atrial and ventricular beats</p>	<p>Serum magnesium greater than 2.5 mEq/L; skeletal muscle weakness; cardiac dysrhythmias, hypotension; respiratory insufficiency; coma</p>

Table 57-3

## Minerals and Electrolytes (continued)

MINERAL/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
	<p>Children (RDAs): 1–3 y, 80 mg; 4–8 y, 130 mg; 9–13 y, 240 mg; 14–18 y, 410 mg</p> <p>Infants (AIs): 0–6 mo, 30 mg; 7–12 mo, 75 mg</p>			
<p><b>Chloride</b></p> <p>Helps maintain osmotic pressure and electrolyte, acid–base, and water balance</p> <p>Forms hydrochloric acid (HCl) in gastric mucosal cells</p>	80–110 mEq	Most dietary chloride is ingested as sodium chloride (NaCl), and foods high in sodium are also high in chloride.	Serum chloride less than 95 mEq/L; arterial blood pH greater than 7.45; dehydration; hypotension; low, shallow respirations; paresthesias of face and extremities; muscle spasms and tetany, which cannot be distinguished from the tetany produced by hypocalcemia	Serum chloride greater than 103 mEq/L; arterial blood pH less than 7.35; increased rate and depth of respiration; lethargy, stupor, disorientation, and coma if acidosis is not treated
<p><b>Trace Elements</b></p> <p><b>Chromium</b></p> <p>Aids glucose use by increasing effectiveness of insulin and facilitating transport of glucose across cell membranes</p>	Not established	Brewer's yeast and whole-wheat products.	Impaired glucose tolerance (hyperglycemia, glycosuria); impaired growth and reproduction; decreased life span	Not established
<p><b>Cobalt</b></p> <p>A component of vitamin B<sub>12</sub> that is required for normal function of all body cells and for maturation of red blood cells</p>	Approximately 1 mg in the form of vitamin B <sub>12</sub>	Animal foods, including liver, muscle meats, and shellfish. Fruits, vegetables, and cereals contain no cobalt as vitamin B <sub>12</sub> .	Deficiency of vitamin B <sub>12</sub> produces pernicious anemia.	Not established
<p><b>Copper</b></p> <p>A component of many enzymes</p> <p>Essential for correct functioning of the central nervous, cardiovascular, and skeletal systems</p> <p>Important in formation of red blood cells, apparently by regulating storage and release of iron for hemoglobin</p>	Approximately 2 mg	Many foods, including liver, shellfish, nuts, cereals, poultry, dried fruits	Decreased serum levels; decreased iron absorption; anemia from impaired erythropoiesis; leukopenia. Death can occur.  In infants, anemia, chronic malnutrition and diarrhea, or Menke's syndrome (retarded growth and progressive mental deterioration) can occur.	Increased serum levels; Wilson's disease (a rare disorder characterized by accumulation of copper in brain, liver, and kidneys). Signs and symptoms vary according to affected organs.

MINERAL/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
<p><b>Fluoride</b></p> <p>A component of tooth enamel</p> <p>Strengthens bones</p> <p>Adequate intake before ages 50–60 years may decrease osteoporosis and fractures during later years.</p>	<p><i>Adults (AIs):</i> males 19–70 y and older, 4 mg; females 19–70 y and older, 3 mg; in pregnancy and lactation, 5 mg</p> <p><i>Children (AIs):</i> 1–3 y, 0.7 mg; 4–8 y, 1 mg; 9–13 y, 2 mg; 14–18 y, 3 mg</p> <p><i>Infants (AIs):</i> 0–6 mo, 0.01 mg; 7–12 mo, 0.5 mg</p>	<p>Beef, canned salmon, eggs. Very little in milk, cereal grains, fruits, and vegetables. Fluoride content of foods depends on fluoride content of soil where they are grown.</p>	<p>Dental caries and possibly a greater incidence of osteoporosis</p>	<p>Mottling of teeth and osteosclerosis.</p>
<p><b>Iodine</b></p> <p>Essential component of thyroid hormones</p>	<p><i>Adults (RDAs):</i> males and females 19–51 y and older, 150 mcg; in pregnancy, 175 mcg; lactation, 200 mcg</p> <p><i>Children:</i> 1–10 y, 10 mg; males 11–18 y, 12 mg; females 11–18 y, 15 mg</p> <p><i>Infants:</i> 0–6 mo, 40 mcg; 6–12 mo, 50 mcg</p>	<p>Seafood is the best source. In vegetables, iodine content varies with the amount of iodine in soil where grown. In milk and eggs, content depends on the amount present in animal feed.</p>	<p>Thyroid gland enlargement; possible hypothyroidism</p>	<p>Iodism, with coryza, edema, fever, conjunctivitis, lymphadenopathy, stomatitis, vomiting</p>
<p><b>Iron</b></p> <p>Essential component of hemoglobin, myoglobin, and several enzymes: hemoglobin is required for transport and use of oxygen by body cells; myoglobin aids oxygen transport and use by muscle cells; enzymes are important for cellular metabolism.</p>	<p><i>Adults (RDAs):</i> males 19–51 y and older, 10 mg; females 19–50, 15 mg; 51 y and older, 10 mg; in pregnancy, 30 mg; lactation, 15 mg</p> <p><i>Children:</i> 1–10 y, 10 mg; males 11–18 y, 12 mg; females 11–18 y, 15 mg</p> <p><i>Infants:</i> 0–6 mo, 6 mg; 6–12 mo, 10 mg</p>	<p>Liver and other organ meats, lean meat, shellfish, dried beans and vegetables, egg yolks, dried fruits, molasses, whole-grain and enriched breads. Milk and milk products contain essentially no iron.</p>	<p>Iron deficiency anemia: with gradual development of anemia, minimal symptoms occur; with rapid development or severe anemia, dyspnea, fatigue, tachycardia, malaise and drowsiness occur.</p>	<p>Acute iron intoxication: vomiting, diarrhea, melena, abdominal pain, shock, convulsions, and metabolic acidosis. Death may occur within 24 h if treatment is not prompt.</p> <p>Chronic iron overload (hemochromatosis): cardiac dysrhythmias, heart failure, diabetes mellitus, bronze pigmentation of skin, liver enlargement, arthropathy, and others</p>
<p><b>Selenium</b></p> <p>Important for function of myocardium and probably other muscles</p>	<p><i>Adults (RDAs):</i> males and females 19–70 y and older, 55 mcg; in pregnancy, 60 mcg; lactation, 70 mcg</p> <p><i>Children (RDAs):</i> 1–3 y, 20 mcg; 4–8 y, 30 mcg; 9–13 y, 40 mcg; 14–18 y, 55 mcg</p> <p><i>Infants (AIs):</i> 0–6 mo, 15 mcg; 7–12 mo, 20 mcg</p>	<p>Fish, meat, breads, and cereals.</p>	<p>Deficiency most likely with long-term IV therapy. Signs and symptoms include myocardial abnormalities and other muscle discomfort and weakness.</p>	<p>Highly toxic in excessive amounts. Signs and symptoms include fatigue, peripheral neuropathy, nausea, diarrhea, and alopecia.</p>

Table 57-3

## Minerals and Electrolytes (continued)

MINERAL/FUNCTION	RECOMMENDED DAILY INTAKE	FOOD SOURCES	SIGNS & SYMPTOMS OF DEFICIENCY	SIGNS & SYMPTOMS OF EXCESS
<b>Zinc</b> A component of many enzymes that are essential for normal metabolism (e.g., carbonic anhydrase, lactic dehydrogenase, alkaline phosphatase). Necessary for normal cell growth, synthesis of nucleic acids (RNA and DNA), and synthesis of carbohydrates and proteins. May be essential for use of vitamin A	<i>Adults (RDAs):</i> males 19–51 y and older, 15 mg; females, 19–51 y and older, 12 mg; in pregnancy, 15 mg; lactation, 16–19 mg <i>Children:</i> 1–10 y, 10 mg; males 11–18 y, 12 mg; females 11–18 y, 15 mg <i>Infants:</i> 0–6 mo, 40 mcg; 6–12 mo, 50 mcg	Animal proteins, such as meat, liver, eggs, and seafood. Wheat germ is also a good source.	Most evident in growing children and include impaired growth, hypogonadism in boys, anorexia, and sensory impairment (loss of taste and smell). Also, if the client has had surgery, wound healing may be delayed.	Unlikely with dietary intake but may develop with excessive ingestion or inhalation of zinc. Ingestion may cause nausea, vomiting, and diarrhea; inhalation may cause vomiting, headache, and fever.

*Als, Adequate Intakes; BUN, blood urea nitrogen; DRIs, Dietary Reference Intakes; RDAs, Recommended Dietary Allowances.*

- Most adolescent and adult females probably benefit from a calcium supplement to achieve the recommended amount (1000–1300 mg daily). The amounts consumed in dairy products and other foods should be considered, and the UL of 2500 milligrams daily should not be exceeded.
- Although zinc is promoted for treatment of the common cold and to promote wound healing, there is insufficient evidence to support such uses. With colds, zinc reportedly helps some people and does not help others. With wounds, zinc is reportedly beneficial only if the patient has a zinc deficiency. More studies are needed before supplemental zinc can be recommended for general use.

## Agents Used in Mineral–Electrolyte Imbalances

Mineral–electrolyte imbalances include both deficiency states and excess states. Most deficiency states occur with inadequate intake or excessive losses (e.g., vomiting, gastric suction, diarrhea, overuse of laxatives). Most excess states occur with excessive intake or impaired renal excretion.

Several pharmacologic agents are used to prevent or treat mineral–electrolyte imbalances. Usually, neutral salts of minerals (e.g., potassium chloride) are used in deficiency states, and nonmineral drug preparations are used in excess states. These agents are described below; routes and dosage ranges are listed in Table 57-4.

### Cation Exchange Resin

**Sodium polystyrene sulfonate** (Kayexalate) is used to treat hyperkalemia. Given orally or rectally, the resin combines with

potassium in the colon. Potassium is then eliminated from the body in the feces. Each gram of resin removes about 1 milliequivalent of potassium. Because the resin requires several hours to lower serum potassium levels, it may be used after other measures (e.g., IV insulin and glucose infusions) have lowered serum levels. Insulin and glucose lower serum potassium levels by driving potassium into the cells; they do not remove potassium from the body.

### Chelating Agents (Metal Antagonists)

**Deferasirox** (Exjade) is an oral iron *chelating agent* (drug) that is used to treat chronic iron overload in children and adults who require frequent blood transfusions for severe, chronic anemia. Untreated iron accumulation from the transfusions can lead to heart and liver failure.
