Deferasirox is absorbed with oral administration, with peak plasma levels in 1.5 to 4 hours. It is highly bound to serum albumin, metabolized by glucuronidation, and reabsorbed in the intestine or excreted in bile and feces. In clinical trials, the most common adverse effects were skin rash and gastrointestinal problems (e.g., abdominal pain, vomiting, diarrhea, and constipation).

Deferasirox was approved and marketed in 2005; in 2007, the U.S. Food and Drug Administration (FDA) issued warnings that acute renal failure, blood disorders (agranulocytosis, neutropenia, and thrombocytopenia), and a few deaths had been reported in patients taking the drug.

**Deferoxamine** (Desferal) is a parenteral drug used to remove excess iron from storage sites (e.g., ferritin, hemosiderin) in the body. It combines with the iron to produce a water-soluble compound that can be excreted by the kidneys.

Table 57-4

**Drugs at a Glance: Individual Agents Used in Mineral-Electrolyte and Acid-Base Imbalances**

Drug	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Cation Exchange Resin</b>			
<b>Sodium polystyrene sulfonate</b> (Kayexalate)	Treatment of hyperkalemia	PO 15 g in 100–200 mL of water and 70% sorbitol, 1–4 times daily Rectally (retention enema) 30–50 g in 100–200 mL of water and 70% sorbitol q6h	
<b>Chelating Agents (Metal Antagonists)</b>			
<b>Deferasirox</b> (Exjade)	Chronic iron overload	PO 20 mg/kg initially, adjusted every 3–6 mo according to serum ferritin levels	Same as adults
<b>Deferoxamine</b> (Desferal)	Acute iron intoxication Hemochromatosis due to blood transfusions Hemosiderosis due to hemolytic anemia	IM 1 g initially, then 500 mg q4h for 2 doses, then 500 mg q4–12h if needed; maximum dose, 6 g/24 h IV infusion (for patients in shock) 1 g slowly (not to exceed 15 mg/kg/h), then 500 mg q4h for 2 doses, then 500 mg q4–12h if necessary; maximum dose, 6 g/24 h	Same as adults
<b>Penicillamine</b> (Cuprimine)	Wilson’s disease Rheumatoid arthritis Cystinuria	Wilson’s disease, PO 250 mg 4 times daily, increased gradually if necessary, up to 2 g daily Rheumatoid arthritis, PO 125–250 mg/d for 4 wk, increased by 125–250 mg/d at 1- to 3-mo intervals, if necessary usual maintenance dose, 500–750 mg/d; maximum dose, 1000–1500 mg/d	Older children: same as adults Infants older than 6 mo and young children: Wilson’s disease, PO 250 mg daily, dissolved in fruit juice
<b>Succimer</b> (Chemet)	Lead poisoning		PO 10 mg/kg or 350 mg/m <sup>2</sup> q8h for 5 days, then q12h for 14 days (total of 19 days of drug administration) For young children who cannot swallow capsules, the capsule contents can be sprinkled on soft food or given with a spoon.
<b>Iron Preparations</b>			
<b>Ferrous gluconate</b> (Fergon)	Iron deficiency anemia	PO 320–640 mg (40–80 mg elemental iron) 3 times daily	PO 100–300 mg (12.5–37.5 mg elemental iron) 3 times daily Infants: PO 100 mg or 30 drops of elixir initially, gradually increased to 300 mg or 5 mL (15–37.5 mg elemental iron) of elixir daily, in divided doses

(continued on page 916)

Table 57-4

### Drugs at a Glance: Individual Agents Used in Mineral-Electrolyte and Acid-Base Imbalances (continued)

Drug	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Ferrous sulfate</b> (Feosol)	Iron deficiency anemia	PO 325 mg–1.2 g (60–240 mg elemental iron) daily in 3 or 4 divided doses	6–12 y: PO 120–600 mg (24–120 mg elemental iron) daily, in divided doses  Under 6 y: 300 mg (60 mg elemental iron) daily, in divided doses
<b>Iron dextran injection</b> (InFeD)	Iron deficiency anemia	Dosage is calculated for individual clients according to hemoglobin and weight (see manufacturer's literature). A small test dose is required before therapeutic doses are given.	Dosage is calculated for individual patients according to hemoglobin and weight (see manufacturer's literature). A small test dose is required before therapeutic doses are given.
<b>Magnesium Preparations</b> <b>Magnesium oxide</b> <b>Magnesium hydroxide</b> <b>Magnesium sulfate</b>	Prevent or treat hypomagnesemia  Treat hypertension or convulsions associated with toxemia of pregnancy or acute nephritis in children	Hypomagnesemia, PO magnesium oxide 250–500 mg 3–4 times daily, milk of magnesia 5 mL 4 times daily, or a magnesium-containing antacid 15 mL 3 times daily; IM (magnesium sulfate) 1–2 g (2–4 mL of 50% solution) 1–2 times daily based on serum magnesium levels  Eclampsia, IM 1–2 g (2–4 mL of 50% solution) initially, then 1 g every 30 min until seizures stop  Convulsive seizures, IM 1 g (2 mL of 50% solution) repeated PRN  IV, do not exceed 150 mg/min (1.5 mL/min of a 10% solution, 3 mL/min of a 5% solution)	Convulsions, IM 20–40 mg/kg in a 20% solution; repeat as necessary
<b>Potassium Preparation</b> <b>Potassium chloride</b> (KCl)	Prevent or treat hypokalemia	PO 15–20 mEq 2–4 times daily IV 40–100 mEq/24 h, depending on serum potassium levels  KCl <b>must</b> be diluted in dextrose or NaCl IV solution for IV use.  <b>Maximum</b> for serum K <sup>+</sup> greater than 2.5 mEq: diluted 40 mEq/L, infused 10 mEq/h to maximum dose of 200 mEq in 24 h  <b>Maximum</b> for serum K <sup>+</sup> less than 2.5 mEq: diluted 80 mEq/L, infused 40 mEq/h to maximum dose of 400 mEq in 24 h	IV infusion up to 3 mEq/kg or 40 mEq/m <sup>2</sup> daily  Adjust amount of fluids to body size.

Drug	Indications for Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Sodium Preparation</b>			
<b>Sodium chloride (NaCl) injection</b>	Hyponatremia	IV 1500–3000 mL of 0.22% or 0.45% solution/24 h depending on the patient's fluid needs; approximately 50 mL/h to keep IV lines open	
<b>Zinc Preparation</b>			
<b>Zinc sulfate</b>	Prevent or treat zinc deficiency	PO 25–50 mg elemental zinc (e.g., zinc sulfate 110–220 mg) daily	
<b>Multiple Mineral–Electrolyte Preparations</b>			
Oral solutions (e.g., Pedialyte) IV solutions (e.g., Normosol, Plasma-Lyte 148, Ringer's solution)	Prevent or treat fluid and electrolyte deficiencies	IV 2000–3000 mL/24 h, depending on individual fluid and electrolyte needs	IV, PO, amount individualized according to fluid and electrolyte needs (i.e., estimated fluid loss), age and weight (see manufacturer's literature)

The drug can remove 10 to 50 milligrams of iron per day. The urine becomes reddish brown from the iron content.

The major indication for use of deferoxamine is acute iron intoxication. The drug may also be used in chronic conditions characterized by accumulation of iron in tissues (e.g., hemochromatosis with blood transfusions, hemosiderosis due to certain hemolytic anemias).

**Penicillamine** (Cuprimine) chelates copper, zinc, mercury, and lead to form soluble complexes that are excreted in the urine. It is used mainly to remove excess copper in patients with Wilson's disease, a rare condition characterized by accumulation of copper in vital organs. It also can be used prophylactically, before clinical manifestations occur, in patients in whom this hereditary condition is likely to develop. Penicillamine may be used to treat cystinuria, a hereditary metabolic disorder characterized by large amounts of cystine in the urine and renal calculi. It may be used in lead poisoning and in severe rheumatoid arthritis that does not respond to conventional treatment measures.

**Succimer** (Chemet) chelates lead to form water-soluble complexes that are excreted in the urine. It is used to treat lead poisoning in children. After oral administration, peak blood levels are reached in 1 to 2 hours. The drug is metabolized in the liver and excreted in urine and feces, with a half-life of 2 days. The most common adverse effects are anorexia, nausea, vomiting, and diarrhea.

## Iron Preparations

Iron preparations are used to prevent or treat iron deficiency anemia. For prevention, they are often given during periods of increased need (e.g., childhood, pregnancy). Oral ferrous salts (sulfate, gluconate, fumarate) are preferred, because they are well absorbed. Action starts in about 4 days, peaks in 7 to 10

days, and lasts 2 to 4 months. The drugs are not metabolized; a portion of a dose is lost daily in feces. Otherwise, the iron content is recycled and its half-life is unknown. Sustained-release or enteric-coated formulations are not as well absorbed as other preparations. Available ferrous salts differ in the amount of elemental iron they contain.

Adverse effects include nausea and other symptoms of GI irritation. Oral preparations also discolor feces, producing a black-green color that may be mistaken for blood in the stool. Iron preparations are contraindicated in patients with peptic ulcer disease, inflammatory intestinal disorders, anemias other than iron deficiency anemia, multiple blood transfusions, hemochromatosis, and hemosiderosis.

**Ferrous sulfate** **P** (Feosol), which contains 20% elemental iron (i.e., 65 mg per 325-mg tablet), is the prototype and often the preparation of choice. **Ferrous gluconate** (Fergon) may be less irritating to GI mucosa and therefore better tolerated than ferrous sulfate. It contains 12% elemental iron (i.e., 36 mg per 325-mg tablet). **Ferrous fumarate** (Feostat) contains 33% elemental iron (i.e., 33 mg per 100-mg tablet). As with dietary iron, only a portion is absorbed from pharmaceutical preparations and relatively large doses are needed to supply the 10 to 15 mg needed daily by most adults and children. Small amounts of iron are lost daily (about 0.5–1 mg) in urine, sweat, and sloughing of intestinal mucosal cells. Somewhat larger amounts (1–2 mg daily) are lost during menstruation. Thus, women of childbearing potential need larger amounts of iron than children, men, and postmenopausal women. Women who are pregnant have the greatest requirement and usually need an iron supplement. Although most iron products are available over-the-counter, their use should be discussed with a health care provider because of the toxicity that may occur with iron accumulation in body tissues.

**Iron dextran injection** (InFeD) is a parenteral form of iron useful in treating iron deficiency anemia when oral supplements cannot be used. One milliliter contains 50 milligrams of elemental iron. Indications for use include peptic ulcer or inflammatory bowel disease that may be aggravated by oral iron preparations, the patient's inability or unwillingness to take oral preparations, and a shortage of time for correcting the iron deficiency (e.g., late pregnancy or preoperative status). Contraindications include anemias not associated with iron deficiency and patients with hypersensitivity to the drug.

The drug is usually given IV. Drug action has a slow onset and peaks in 1 to 2 weeks. Dosage is calculated according to hemoglobin level and weight. A small IV test dose should be given before a therapeutic dose. The drug has a **BLACK BOX WARNING** about the risk of anaphylactic reactions and death.

### Magnesium Preparations

**Magnesium oxide** or **hydroxide** may be given orally for mild hypomagnesemia in asymptomatic patients. **Magnesium sulfate** is given parenterally for moderate to severe hypomagnesemia, convulsions associated with pregnancy, and prevention of hypomagnesemia in total parenteral nutrition. Therapeutic effects in these conditions are attributed to the drug's depressant effects on the central nervous system and smooth, skeletal, and cardiac muscle. Oral magnesium salts may cause diarrhea; their uses as antacids and cathartics are discussed in Chapters 59 and 60, respectively.

Magnesium preparations are contraindicated in patients who have impaired renal function or who are comatose. Oral preparations of magnesium oxide or hydroxide act in 3 to 6 hours, are minimally absorbed systemically, and are excreted in urine. With parenteral magnesium sulfate, IM injections act in 1 hour and last 3 to 4 hours; IV administration produces immediate action that lasts about 30 minutes. The products are excreted in urine.

### Potassium Preparation

**Potassium chloride** (KCl) is usually the drug of choice for preventing or treating hypokalemia because deficiencies of potassium and chloride often occur together. It may be prescribed for patients who are receiving potassium-losing diuretics (e.g., hydrochlorothiazide, furosemide), those who are receiving digoxin (hypokalemia increases risk of digoxin toxicity), and those who are receiving only IV fluids because of surgical procedures, GI disease, or other conditions. KCl also may be used to replace chloride in hypochloremic metabolic alkalosis.

It is contraindicated in patients with renal failure and in those receiving potassium-saving diuretics, such as triamterene, spironolactone, or amiloride.

KCl can be given orally or IV; *dosage must be individualized according to serum potassium levels*. Oral preparations are available in flavored powders, liquids, effervescent tablets, and controlled- or extended-release tablets. These preparations act slowly and peak in 1 to 2 hours. IV preparations act rapidly; IV KCl **must** be well diluted (usually 20 mEq in 1 L of IV fluid)

and infused slowly (usually at a maximum rate of 10 mEq/h) to prevent hyperkalemia, cardiotoxicity, and severe pain at the injection site. With severe hypokalemia (e.g., serum potassium level below 2 mEq/L), a higher concentration and a faster infusion rate may be used with continuous monitoring of the electrocardiogram and frequent measurements of serum potassium levels.

### Zinc Preparations

**Zinc sulfate** and **zinc gluconate** are available over-the-counter in various forms and strengths (e.g., tablets with 110 mg and capsules with 220 mg of zinc sulfate, equivalent to 25 or 50 mg of elemental zinc). Zinc is also an ingredient in several vitamin–mineral combination products. Zinc preparations are given orally as a dietary supplement to prevent or treat zinc deficiency. They have a slow onset of action and a delayed peak. They are metabolized in the liver and excreted in feces.

### Multiple Mineral–Electrolyte Preparations

There are numerous electrolyte solutions for IV use to maintain or replace electrolytes when the patient is unable to eat and drink.

Oral electrolyte solutions (e.g., Pedalyte) contain several electrolytes and a small amount of dextrose. They are used to supply maintenance amounts of fluids and electrolytes when oral intake is restricted. They are especially useful in children for treatment of diarrhea and may prevent severe fluid and electrolyte depletion. The amount given must be carefully calculated, prescribed, and administered to avoid excessive intake. Oral solutions should not be used in severe circumstances in which IV fluid and electrolyte therapy is indicated, and they should not be mixed with other electrolyte-containing fluids, such as milk or fruit juices. In addition, they must be cautiously used in impaired renal function.

## Nursing Process

### Assessment

Assess each patient for current or potential nutritional deficiencies. Some specific assessment factors include the following:

- What are usual eating patterns?
- Does the patient appear underweight? If so, assess for contributing factors (e.g., appetite; ability to obtain, cook, or chew food). Calculate or estimate the body mass index (BMI); a BMI under 18.5 kg/m<sup>2</sup> indicates undernutrition.
- Does the patient have symptoms, disease processes, treatments, medications, or diagnostic tests that are likely to interfere with nutrition? For example, many illnesses and oral medications cause anorexia, nausea, vomiting, and diarrhea.

With vitamins, assessment factors include the following:

- Deficiency states are more common than excess states and people with other nutritional deficiencies are likely to have vitamin deficiencies as well.
- Deficiencies of water-soluble vitamins (B complex and C) are more common than those of fat-soluble vitamins.
- Vitamin deficiencies are usually multiple and signs and symptoms often overlap, especially with B-complex deficiencies.
- Vitamin requirements are increased during infancy, pregnancy, lactation, fever, hyperthyroidism, and many illnesses. Thus, a vitamin intake that is normally adequate may be inadequate in certain circumstances.
- Vitamin deficiencies are likely to occur in people who are poor, elderly, chronically or severely ill, or alcoholic.
- Vitamin excess states are rarely caused by excessive dietary intake but may occur with use of vitamin drug preparations, especially if megadoses are taken.

With mineral–electrolytes, assessment factors include the following:

- Deficiency states are more common than excess states unless a mineral–electrolyte supplement is being taken. However, deficiencies and excesses may be equally harmful, and both must be assessed.
- Patients with other nutritional deficiencies are likely to have mineral–electrolyte deficiencies as well. Moreover, deficiencies are likely to be multiple, with overlapping signs and symptoms.
- Many drugs influence gains and losses of minerals and electrolytes, including diuretics and laxatives.
- Minerals and electrolytes are lost with gastric suction, polyuria, diarrhea, excessive perspiration, and other conditions.

Assess laboratory reports when available:

- Check the complete blood count for decreased red blood cells, hemoglobin, and hematocrit. Reduced values may indicate iron deficiency anemia, and further assessment is needed.
- Check serum electrolyte reports for abnormal values. All major minerals can be measured in clinical laboratories. The ones usually measured are sodium, chloride, and potassium; carbon dioxide content, a measure of bicarbonate, is also assessed.

### Nursing Diagnoses

- Imbalanced Nutrition: Less Than Body Requirements related to inadequate intake or impaired ability to digest nutrients
- Imbalanced Nutrition: More Than Body Requirements related to excessive intake of pharmaceutical preparations of vitamins and minerals

- Risk for Injury related to complications of tube or IV feedings
- Risk for Injury related to nutrient deficiency or overdose
- Deficient Knowledge: Nutritional needs and sources of nutrients

### Planning/Goals

The patient will

- Improve nutritional status in relation to body needs
- Maintain fluid and electrolyte balance
- Ingest appropriate amounts of vitamins and mineral–electrolytes
- Avoid complications of enteral nutrition, including aspiration, diarrhea, and infection
- Avoid complications of parenteral nutrition
- Avoid overdoses and adverse effects of vitamins and minerals
- Avoid mineral–electrolyte supplements unless recommended by a health care provider
- Take mineral–electrolyte drugs as prescribed and have appropriate laboratory tests to monitor response

### Interventions

- Promote a well-balanced diet for all patients. Five daily servings of fruits and vegetables provide adequate vitamins unless the patient has increased requirements or conditions that interfere with absorption or use of vitamins. An oral multivitamin may benefit most people, but it is not a substitute for an adequate diet. A diet that is adequate in protein and calories usually provides adequate minerals and electrolytes. Exceptions are calcium and iron, which are often needed as a dietary supplement in women and children.
- Treat symptoms or disorders that are likely to interfere with nutrition, such as pain, nausea, vomiting, or diarrhea.
- For patients who need increased protein-calorie intake, provide palatable supplements at appropriate times and encourage patients to take them.
- Promote exercise and activity. For undernourished patients, this may increase appetite, improve digestion, and aid bowel elimination.
- Minimize the use of sedative-type drugs when appropriate. Although no one should be denied pain relief, strong analgesics and other sedatives may cause drowsiness and decreased desire or ability to eat and drink as well as constipation and a feeling of fullness.
- Weigh patients at regular intervals. Calculate or estimate BMI when indicated.
- For patients receiving parenteral nutrition, monitor weight, fluid intake, urine output, vital signs, blood glucose, serum electrolytes, and complete blood count daily or weekly, according to the patient's status and whether he or she is hospitalized or at home.

- Mineral supplements are recommended only for current or potential deficiencies because all are toxic in excessive amounts.
- For patients who have nasogastric tubes to suction, irrigate the tubes with isotonic sodium chloride solution. The use of tap water is contraindicated because it is hypotonic and would pull electrolytes into the stomach. Electrolytes are then lost in the aspirated and discarded stomach contents. For the same reason, only small amounts of ice chips or water are allowed per hour. Patients often request ice chips or water in larger amounts than desirable; the nurse must explain the reason for the restrictions.

### Evaluation

- Observe undernourished patients for quantity and quality of nutrient intake, weight gain, and improvement in laboratory tests of nutritional status (e.g., serum proteins, blood sugar, electrolytes).
- Observe children for quantity and quality of food intake and appropriate increases in height and weight.
- Interview and observe for signs and symptoms of complications of enteral and parenteral nutrition.

## Principles of Therapy

### Managing Nutritional Deficiencies

When possible, oral administration of liquid formulas, vitamins, and minerals is preferred. With vitamin and mineral supplements, larger doses are needed to treat deficiencies than are needed to prevent them. Treatment of deficiency states should be cautious, to avoid excess states.

### Enteral Nutrition: Oral and Tube Feedings

When the GI tract is functional but the patient cannot ingest enough food and fluid, high-protein, high-calorie foods (e.g., milkshakes) or nutritionally complete supplements (e.g., Ensure) can be given with meals, between meals, and at bedtime. When oral feeding is contraindicated, tube feeding helps to maintain GI tract and immune system functioning. Guidelines for tube feedings include the following:

- Several tubes and placement sites are available. For short-term use (about 4 weeks), a nasogastric tube may be used. For long-term feedings, a gastrostomy or jejunostomy tube may be inserted. Percutaneous endoscopic gastrostomy (PEG) tubes are often used. Nasointestinal tubes are recommended for patients at risk of aspiration from gastric feedings or with gastric disorders. Except for gastrostomy tubes, the tubes should be soft and small bore to decrease trauma.
- When tube feedings are the patient's only source of nutrients, the feedings should be nutritionally complete and given in amounts calculated to provide adequate water, protein, calories, vitamins, and minerals.
- For feedings that enter the stomach, intermittent administration is often used. For feedings that enter the duodenum or jejunum, a continuous drip method is required because the small bowel cannot tolerate the larger volumes of intermittent feedings. Continuous feedings require an infusion pump for accurate control of the flow rate. Water can be given with, after, or between regular feedings and with medications, according to the patient's fluid needs.
- A potential complication of tube feeding is aspiration of the formula into the lungs. This is more likely to occur with unconscious patients. It can be prevented by correctly positioning patients, verifying tube placement, and giving feedings slowly.

## Patient Teaching Guidelines

### Nutritional Support Products, Vitamins, and Minerals

#### General Considerations

- Nutrition is extremely important in promoting health and recovery from illness. For people who are unable to take in enough nutrients because of poor appetite or illness, nutritional supplements can be very beneficial in improving nutritional status. For example, supplemental feedings can slow or stop weight loss; increase energy and feelings of well-being; and increase resistance to infection.
- With oral or tube-feeding supplements, choose one or more that the patient is able and willing to take when possible.
- With vitamins, supplements are often recommended because studies indicate that many adults and children do not ingest sufficient dietary vitamins. Supplements are also usually needed by pregnant women and by people who smoke, ingest large amounts of alcohol, have

impaired immune systems, or are elderly. When choosing a vitamin supplement, the following factors should be considered:

- Avoid large doses of vitamins. They will not promote health, strength, or youth. In addition, excessive amounts of B vitamins and vitamin C are eliminated in urine and some can cause adverse effects (e.g., large doses of vitamin C can cause kidney stones; niacin [B<sub>3</sub>] can cause stomach upset, flushing, skin rashes, itching, and aggravation of asthma and gout; pyridoxine [B<sub>6</sub>] may cause numbness in limbs and difficulty in walking). Excessive amounts of vitamins A, D, E, and K are stored in the body and often lead to toxic effects. For example, high doses of vitamin A can result in headaches; diarrhea; nausea; loss of appetite; dry, itching skin; and elevated blood calcium. Excessive doses during pregnancy may cause birth defects.

- Although natural vitamins are advertised as being better than synthetic vitamins, there is no evidence to support this claim. The two types are chemically identical and used in the same way by the human body. Natural vitamins are more expensive.
- Sexually active women of childbearing potential need an adequate intake of folic acid to prevent severe birth defects in infants. To help prevent birth defects from folic acid deficiency, the Food and Drug Administration requires that folic acid be added to breads and cereal-grain products. This is estimated to add about 100 mcg of folic acid to the daily diet of most people. However, the recommended daily intake for adults is 400 mcg.
- Vitamins from supplements exert the same physiologic effects as those obtained from foods.
- Multivitamin preparations often contain minerals as well, usually in smaller amounts than those recommended for daily intake. Large doses of minerals are toxic.
- With minerals, a well-balanced diet contains all the minerals needed for health in most people. Exceptions are calcium and iron, which are often needed as a dietary supplement in women and children. Note that herbal preparations of chamomile, feverfew, and St. John's wort may inhibit iron absorption. The safest action is to take mineral supplements only on a health care provider's advice, in the amounts and for the length of time prescribed. All minerals are toxic when taken in excess. Additional considerations include:
  - Keep all mineral–electrolyte substances out of reach of children to prevent accidental overdose. Acute iron intoxication is a common problem among young children and can be fatal. Also, supervise children in using fluoride supplements (e.g., remind them to spit out oral rinses and gels rather than swallow them).
  - Keep appointments with health care providers for periodic blood tests and other follow-up procedures when mineral–electrolyte supplements are prescribed (e.g., potassium chloride). This helps prevent ingestion of excessive amounts.
  - Minerals are often contained in multivitamin preparations, with percentages of the recommended dietary allowances supplied. These amounts differ in various preparations and should be included in estimations of daily intake.
- Take or give slowly, over approximately 30 to 60 minutes. Rapid administration may cause nausea and vomiting.
- With continuous feedings, change containers and tubing daily. With intermittent feedings, rinse all equipment after each use, and change at least every 24 hours. Most tube-feeding formulas are milk based and infection may occur if formulas become contaminated or equipment is not kept clean.
- Ask a health care provider about the amount of water to take or give. Most people receiving 1.5 to 2 quarts (1500–2000 mL) of tube feeding daily need approximately 1 quart (1000 mL) or more of water daily. However, patients' needs vary. Water can be mixed with the tube feeding formula, given after the tube feeding, or given between feedings. Be sure to include the amount of water used for rinsing the tube in the total daily amount.
- For giving medications by tube:
  - Give liquid preparations when available. When not available, some tablets may be crushed and some capsules may be emptied and mixed with 1 to 2 tablespoons of water. Ask a health care provider which medications can safely be crushed or altered, because some (e.g., long-acting or enteric-coated) can be harmful if crushed.
  - Do not mix medications with the tube-feeding formula because some medications may not be absorbed.
  - Do not mix medications; give each one separately.
  - Rinse the tube with water before and after each medication to get the medication through the tube and to keep the tube open.
- With supplementary vitamins, preparations differ widely in amounts and types of vitamin content. The product should not contain more than recommended amounts of vitamin D and vitamin A because of possible adverse effects.
- When choosing a vitamin supplement, compare ingredients and costs. Store brands are usually effective and less expensive than name brands.
- Vitamin C supplements are available in tablet and powder forms of various dosages, often in multivitamin and other preparations sold as antioxidants. In 2000, the recommended dietary allowance was increased from 60 mg daily to 75 mg for adult women and 90 mg for adult men. Large doses (e.g., 1000 mg or more daily) may cause adverse effects and should be avoided. An adequate amount of vitamin C can also be obtained by eating at least five servings of fruit and vegetables daily.
- Take oral niacin preparations, except for timed-release forms, with or after meals or at bedtime to decrease stomach irritation. In addition, sit or lie down for approximately 30 minutes after taking a dose. Niacin causes blood vessels to dilate and may cause facial flushing, dizziness, and falls. Facial flushing can be decreased by taking 325 mg of aspirin 30 to 60 minutes before a dose of niacin. Itching, tingling, and headache may also occur. These effects usually subside with continued use of niacin.
- Swallow extended-release products whole; do not break, crush, or chew them. Breaking the product delivers the entire dose at once and may cause adverse effects.
- Take prescribed vitamins as directed and for the appropriate time. In pernicious anemia, vitamin B<sub>12</sub> injections

### Self- or Caregiver Administration

- For oral supplemental feedings, take or give at the preferred time and temperature, when possible.
- For tube feedings:
  - Use or give with the patient in a sitting position, if possible, to decrease risks of strangling and pulling formula into the lungs.
  - Be sure the tube is placed correctly before each feeding. Ask a health care provider how to check placement with your type of tube.
  - Be sure the solution is room temperature. Cold formulas may cause abdominal cramping.
  - Do not take or give more than 1 pint (500 mL) per feeding, including 2 to 3 oz of water for rinsing the tube. This helps to avoid overfilling the stomach and possible vomiting.

## Patient Teaching Guidelines

## Nutritional Support Products, Vitamins, and Minerals (continued)

must be taken for the remainder of life. In pregnancy and lactation, vitamin supplements are usually taken only during this period of increased need.

- Take iron preparations with or after meals, with approximately 8 oz of fluid, to prevent stomach upset. Do not take iron with coffee or other caffeine-containing beverages, because caffeine decreases absorption (take iron and caffeine preparations at least 2 hours apart). Do not crush or chew slow-release tablets or capsules. With liquid preparations, dilute with water, drink through a straw, and rinse the mouth afterward to avoid staining the teeth. Expect that stools will be dark green or black.
- With potassium preparations, mix oral solutions or effervescent tablets with at least 4 oz of water or juice

to improve the taste, dilute the drug, and decrease gastric irritation. Do not crush or chew slow-release preparations. Take after meals initially to decrease gastric irritation. If no nausea, vomiting, or other problems occur, the drug can be tried before meals because it is better absorbed from an empty stomach. Do not stop taking the medication without notifying the health care provider who prescribed it, especially if also taking digoxin or diuretics. Excessive amounts should also be avoided. Do not use salt substitutes unless they are recommended by a health care provider; they contain potassium chloride and may result in excessive intake. Serious problems may develop from either high or low levels of potassium in the blood.

### Parenteral Nutrition: IV Feedings

Parenteral feedings are indicated when the GI tract is non-functional, when nutritional needs cannot be met by enteral feedings, or when enteral feedings would aggravate conditions such as inflammatory bowel diseases or pancreatitis.

#### Short-Term IV Nutrition

For short-term use (e.g., 3–5 days), the goal is to provide adequate amounts of fluids and electrolytes and enough carbohydrate to minimize oxidation of body protein and fat for energy. The choice of specific solution depends on individual needs, but it should contain at least 5% dextrose. A frequently used solution is 5% dextrose in 0.22% sodium chloride, 2000 to 3000 mL in 24 hours (provides approximately 170 kcal/L, water, sodium, and chloride). KCl is often added, and vitamins may be added. These solutions are nutritionally inadequate.

#### Long-Term IV Nutrition

For long-term use (weeks to months), the goal is to provide all nutrients required for normal body functioning, including tissue repair. Basic solutions provide water, carbohydrate, protein, vitamins, and minerals; fat emulsions (e.g., Intralipid) are usually given separately to provide additional calories and essential fatty acids (500 mL of 10% emulsion provides 550 kcal). Guidelines include the following:

- Parenteral nutritional solutions can be administered through central or peripheral IV lines. Some solutions are hypertonic (from high concentrations of glucose) and must be given in a central vein so they can be diluted rapidly. Solutions that contain 5% or 10% dextrose are less hypertonic and can be given in a peripheral vein. However, they are nutritionally incomplete and used for a limited time (about 5–7 days).
- Fat emulsions are isotonic and may be given centrally or peripherally. When given peripherally, they are coinfiltrated with dextrose–protein solution to help protect the vein from phlebitis.

- Dextrose–protein solutions are given through an in-line filter. Fat emulsions should not be filtered; they are “piggy-backed” into the IV line beyond the filter.
- Solutions should be administered with an infusion pump to maintain a steady and accurate flow rate.
- Sterile technique should be used in all aspects of preparation, administration, and site care. Most agencies have specific protocols for changing solution containers, administration sets, and dressings at the venipuncture site.

### Managing Vitamin Disorders

Early recognition and treatment of vitamin disorders can prevent a mild deficiency or excess from becoming severe. For deficiency states, oral vitamin preparations are preferred when possible. Multiple deficiencies are common, and a multivitamin preparation used to treat them usually contains more than the recommended daily amount. These products should be used for limited periods. When fat-soluble vitamins are given to correct a deficiency, there is a risk of producing excess states. When water-soluble vitamins are given, excesses are less likely but may occur with large doses. For excess states, the usual treatment is to stop administration of the vitamin preparation. There are no specific antidotes or antagonists.

#### Vitamin A Disorders

With vitamin A deficiency, assist patients to increase intake of foods containing preformed vitamin A (e.g., meat, egg yolk, whole milk) or beta carotene (e.g., yellow fruits and vegetables such as cantaloupe, peaches, carrots, sweet potatoes) when feasible. If a supplement is required, vitamin A alone may be preferred over a multivitamin unless multiple deficiencies are present. Daily doses should not exceed 25,000 international units (approximately 7500 mcg RE; 1 mcg RE = 3.3 IU) daily unless a severe deficiency is present.

Vitamin A may be given IM if GI absorption is severely impaired or ocular symptoms are severe. With vitamin A excess, immediately stop known sources of the vitamin.

### Vitamin K Disorders

With vitamin K deficiency, bleeding may occur spontaneously or in response to trauma. Thus, administration of vitamin K and measures to prevent bleeding are indicated. If the deficiency is not severe, oral vitamin K may be given for a few days until serum prothrombin activity returns to a normal range. In obstructive jaundice, bile salts must be given at the same time as oral vitamin K, or vitamin K must be given parenterally. In malabsorption syndromes or diarrhea, parenteral administration is probably necessary. A single dose of vitamin K may be sufficient.

There is a **BLACK BOX WARNING** that IV administration of vitamin K may result in an anaphylactic type of reaction with risks of shock, cardiorespiratory arrest, and death, even with drug dilution and slow administration. Therefore, the IV route should be used only if other routes cannot be used and the drug is deemed necessary. With severe bleeding, transfusions of plasma or whole blood may be preferred over IV vitamin K.

### B-Complex Disorders

With B-complex vitamins, most deficiencies are multiple rather than single and treatment consists of increasing intake of foods containing B-complex vitamins (many foods, including meat, vegetables, and cereal grains) or giving multivitamin preparations. If a single deficiency seems predominant, that vitamin may be given alone or in addition to a multivitamin preparation. For example, folic acid deficiency may occur with inadequate dietary intake and intestinal disorders that inhibit absorption. In addition, folic acid is depleted by alcohol and several medications, including antibiotics containing trimethoprim (e.g., Bactrim), phenytoin, methotrexate, and oral contraceptives. Thiamine deficiency is common in alcoholics because of inadequate dietary intake and the use of large amounts of thiamine to metabolize ethanol.

### Anemias Associated With B-Complex Vitamin Deficiencies

One type of anemia occurs with pyridoxine deficiency and is relieved by administration of pyridoxine. Another type, called *megaloblastic anemia* (because it is characterized by abnormally large, immature red blood cells), occurs with deficiency of folic acid or vitamin B<sub>12</sub>. If megaloblastic anemia is severe, treatment is usually instituted with both folic acid and vitamin B<sub>12</sub>.

In pernicious anemia, vitamin B<sub>12</sub> must be given by injection because oral forms are not absorbed from the GI tract. The injections must be continued for life. Vitamin B<sub>12</sub> is also given to prevent pernicious anemia in patients who are strict vegetarians, who have had gastrectomy, or who have chronic small bowel disease. Although folic acid relieves hematologic disorders of pernicious anemia, giving folic acid alone allows continued neurologic deterioration. Thus, an accurate diagnosis is required.

In other megaloblastic anemias, vitamin B<sub>12</sub> or folic acid is indicated. Although both of these are included in many mul-

tivitamin preparations, they usually must be given separately for therapeutic purposes. With vitamin B<sub>12</sub>, doses in excess of 100 micrograms are rapidly excreted in urine. With folic acid, doses in excess of 1 milligram are excreted in the urine.

### Vitamin C Disorders

Treatment of vitamin C deficiency involves increased intake of vitamin C from dietary (e.g., fruits and vegetables) or pharmaceutical sources. Vitamin C is available alone for oral, IM, or IV administration. It is also an ingredient in most multivitamin preparations for oral or parenteral use.

In 2000, the DRI for vitamin C was increased from 60 milligrams daily to 75 milligrams for most adult women and 90 milligrams for most adult men. Some nutritionists recommend 120 milligrams per day; others recommend approximately 200 milligrams per day from five servings of fruits and vegetables or 100 milligrams per day of a vitamin C supplement. An additional recommendation is to avoid large doses (i.e., more than 1 g/day). With excessive intake of vitamin C supplements, the main concern is formation of calcium oxalate kidney stones and potential obstruction or other renal damage. There is no known benefit of such large amounts, and their use should be discouraged.

### Managing Mineral–Electrolyte Disorders

When a mineral is given to correct a deficiency state, there is a risk of producing an excess state. Because both deficiencies and excesses may be harmful, the amount of mineral supplement should be titrated closely to the amount needed by the body. Larger doses are needed to treat deficiency states than are needed to prevent deficiencies from developing. When mineral–electrolyte drug preparations are needed, oral products are preferred when possible. They are safer, less likely to produce toxicity, more convenient to administer, and less expensive than parenteral preparations.

### Potassium Disorders

#### Hypokalemia

- Assess for conditions contributing to *hypokalemia*, and attempt to eliminate them or reduce their impact.
- Assess severity by checking serum potassium levels and clinical manifestations. Serum potassium levels alone are inadequate because they may not accurately reflect depletion of body potassium or shifts of potassium into cells.
- In general, potassium supplements are indicated when serum potassium is below 3 milliequivalents per liter, when symptoms or electrocardiographic (ECG) changes indicate hypokalemia, and when patients are receiving digoxin, if necessary to maintain serum potassium above 3.5 milliequivalents per liter.
- KCl is the drug of choice in most instances. Controlled-release tablets or capsules with KCl in a wax matrix or microencapsulated form are preferred over liquids by most patients.

- IV KCl is indicated when a patient cannot take an oral preparation or has severe hypokalemia. The serum potassium level should be measured and adequate urine output established before IV potassium therapy is started.
- IV KCl must be well diluted to prevent sudden hyperkalemia, cardiotoxic effects, and phlebitis at the venipuncture site. The usual dilution is KCl 20 to 40 milliequivalents per 1000 milliliters of IV fluid.
- Dosage must be individualized. Patients receiving IV fluids only are usually given 40 to 60 milliequivalents of KCl daily (e.g., 20 mEq KCl per 1000 mL of fluids at a flow rate of 100 to 125 mL/h). An infusion pump should be used to control flow rate accurately. Also, serum potassium levels must be checked frequently and dosage adjusted if indicated.

### Hyperkalemia

- Eliminate any exogenous sources of potassium, such as potassium supplements, penicillin G potassium, salt substitutes, and blood transfusion with old blood.
- Treat acidosis, if present, because potassium leaves cells and enters the serum with acidosis.
- Use measures that antagonize the effects of potassium, that cause potassium to leave the serum and re-enter cells, and that remove potassium from the body. Appropriate measures are determined mainly by serum potassium levels and ECG changes. Continuous cardiac monitoring is required. If the following measures fail to reduce hyperkalemia, peritoneal dialysis or hemodialysis may be used.

With severe *hyperkalemia* (serum potassium above 7 mEq/L and ECG changes indicating hyperkalemia), urgent treatment is required. IV **sodium bicarbonate** 45 milliequivalents, over a 5-minute period, causes rapid movement of potassium into cells. This can be repeated in a few minutes if ECG changes persist. **Calcium gluconate** 10%, 5 to 10 milliliters IV, is also given early in treatment to decrease the cardiotoxic effects of hyperkalemia. It is contraindicated if the patient is receiving digoxin, and it cannot be added to fluids containing sodium bicarbonate because insoluble precipitates are formed. IV **glucose and insulin** may also be infused. This causes potassium to move into cells, though not as quickly as administration of sodium bicarbonate.

With less severe hyperkalemia (or when serum potassium levels have been reduced by other measures), **sodium polystyrene sulfonate**, a cation exchange resin, can be given orally or rectally to remove potassium from the body. Each gram of the resin combines with 1 milliequivalent of potassium, and both are excreted in feces. The resin is usually mixed with water and sorbitol, a poorly absorbed, osmotically active alcohol that has a laxative effect. The sorbitol offsets the constipating effect of the resin and aids in its expulsion. Oral administration is preferred, and several doses daily may be given until serum potassium is normal. When given as an enema, the solution must be retained from 1 to several hours, or repeated enemas must be given for therapeutic effect.

## Magnesium Disorders

### Hypomagnesemia

For mild hypomagnesemia, oral magnesium preparations may be given. For moderate to severe and symptomatic hypomagnesemia, parenteral (IV or IM) magnesium sulfate may be given daily as long as hypomagnesemia persists or continuing losses occur. Initial dosage may be larger, but the usual maintenance dose is approximately 8 milliequivalents daily. A 10% solution is available in 10-milliliter vials that contain 8 milliequivalents of magnesium sulfate for adding to IV solutions. A 50% solution is available in 2-milliliter vials (8 mEq) for IM administration. Serum magnesium levels should be measured daily during treatment with a magnesium preparation.

### Hypermagnesemia

- Stop any source of exogenous magnesium, such as magnesium sulfate or magnesium-containing antacids and cathartics.
- Have calcium gluconate available for IV administration. It is an antidote for the sedative effects of magnesium excess.
- Increase urine output by increasing fluid intake, if feasible. This increases removal of magnesium from the body in urine.
- Patients with chronic renal failure are the most likely to become hypermagnesemic. They may require peritoneal dialysis or hemodialysis to lower serum magnesium levels.

## Iron Deficiency and Excess

### Iron Deficiency Anemia

- Anemia is a symptom, not a disease. Therefore, the underlying cause must be identified and eliminated, if possible.
- Encourage increased dietary intake of foods with high iron content.
- Ferrous sulfate is usually the drug of choice for oral iron therapy. Slow-release or enteric-coated products decrease absorption of iron but may cause less gastric irritation.
- Dosage is calculated in terms of elemental iron. Iron preparations vary in the amount of elemental iron they contain. Ferrous sulfate, for example, contains 20% iron; thus, each 325-milligram tablet furnishes about 65 milligrams of elemental iron. With the usual regimen of one tablet three times daily, a daily dose of 195 milligrams of elemental iron is given. For most patients, probably half that amount would correct the deficiency. However, tablets are not manufactured in sizes to allow this regimen, and liquid preparations are not popular with patients. Thus, large doses are usually given, but smaller doses may be effective, especially if GI symptoms become a problem with higher dosages. Whatever the dose, only about 10% to 15% of the iron is absorbed. Most of the remainder is excreted in feces, which turn dark green or black.
- Oral iron preparations are better absorbed if taken on an empty stomach. However, because gastric irritation is a common adverse reaction, they are more often given with or immediately after meals.

- Although normal hemoglobin levels return after approximately 2 months of oral iron therapy, an additional 6-month period of drug therapy is recommended to replenish the body's iron stores.
- Reasons for failure to respond to iron therapy include continued blood loss, failure to take the drug as prescribed, or defective iron absorption. These factors must be reevaluated if no therapeutic response is evident within 3 to 4 weeks after drug therapy is begun.
- Parenteral iron is indicated when oral preparations may further irritate a diseased GI tract, when the patient is unable or unwilling to take the oral drugs, or when the anemia must be corrected rapidly.
- For severe iron deficiency anemia, blood transfusions may be most effective.

### Iron Excess

Acute iron overdosage requires treatment as soon as possible, even if overdosage is only suspected and the amount taken is unknown. It is unnecessary to wait until the serum iron level is measured.

If treatment is begun shortly after oral ingestion of iron, aspiration of stomach contents by nasogastric tube or whole bowel irrigation with a polyethylene glycol solution (e.g., CoLyte) may be performed. Gastric lavage can be followed by instillation of 1% sodium bicarbonate solution, to form insoluble iron carbonate compounds, or 5 to 8 grams of deferoxamine (Desferal) dissolved in 50 milliliters of distilled water, to bind the iron remaining in the GI tract and prevent its absorption. Deferoxamine may also be given IM or IV to bind with iron in tissues and allow its excretion in the urine. Throughout the treatment period, supportive measures may be needed for GI hemorrhage, acidosis, and shock.

For chronic iron overload or hemochromatosis, the first step in treatment is to stop the source of iron, if possible. Phlebotomy is the treatment of choice for most patients because withdrawal of 500 milliliters of blood removes about 250 milligrams of iron. Phlebotomy may be needed as often as weekly and for as long as 2 to 3 years. For patients resistant to or intolerant of phlebotomy, deferoxamine can be given. Ten to 50 milligrams of iron are excreted daily in the urine with deferoxamine administration.

## Effects of Vitamins and Minerals on Other Drugs

Folic acid decreases effects of phenytoin and may decrease absorption and effects of zinc. Niacin may increase the risk of rhabdomyolysis (a life-threatening breakdown of skeletal muscle) with statin cholesterol-lowering drugs (e.g., atorvastatin [Lipitor]). Vitamin A in large doses and vitamin E may increase the anticoagulant effect of warfarin. Vitamin C, 1000 milligrams daily or more, may decrease metabolism and increase the effects of estrogens and oral contraceptives.

Iron salts may decrease absorption of levodopa, levothyroxine, methyl dopa, penicillamine, fluoroquinolones, and

tetracyclines. Magnesium salts may decrease absorption and therapeutic effects of digoxin, fluoroquinolones, nitrofurantoin, penicillamine, and tetracyclines. Zinc salts may decrease absorption of fluoroquinolones and most tetracyclines (doxycycline is apparently not affected).

## Use in Special Populations

### Nutritional Support in Children

Children usually need sufficient water, protein, carbohydrate, and fat in proportion to their size to support growth and increased physical activity. However, reports of childhood obesity and inadequate exercise are steadily increasing. Therefore, the goal of nutritional support is to meet needs without promoting obesity.

For children with special needs in relation to nutrients, various enteral formulations are available for use. Some examples include Lofenalac for children with phenylketonuria (a disorder in which the amino acid phenylalanine cannot be metabolized normally); Nursoy and Soyolac, which contain soy protein, for children who are allergic to cow's milk; and Nutramigen and Pregestimil, which contain easily-digested nutrients for children with *malabsorption* or other GI problems.

With tube feedings, to prevent nausea and regurgitation, the recommended rate of administration is no more than 5 milliliters every 5 to 10 minutes for premature and small infants and 10 milliliters per minute for older infants and children. Preparation of formulas, positioning of children, and administration are the same as for adults to prevent aspiration and infection.

Parenteral nutrition may be indicated in infants and children who cannot eat or be fed enterally (e.g., during medical illnesses or perioperative states) to improve or maintain nutritional status. Overall, benefits include weight gain, increased height, increased liver synthesis of plasma proteins, and improved healing and recovery.

With **vitamins**, children need sufficient amounts to support growth and normal body functioning. If supplements are given, considerations include the following:

- Dosages should not exceed recommended amounts. There is a risk of overdosage by children and their parents. Because of manufacturers' marketing strategies, many supplements are available in flavors and shapes (e.g., animals, cartoon characters) designed to appeal to children. Because younger children may think of these supplements as candy and take more than recommended, they should be stored out of reach and dispensed by an adult. Because parents' desires to promote health may lead them to give unneeded supplements or to give more than recommended amounts, parents may need information about the potential hazards of vitamin overdoses.
- The content of supplements for infants and children younger than 4 years of age is regulated by the FDA; the content of preparations for older children is not regulated.
- Supplements given to children and adolescents should provide recommended amounts of vitamins. Except for single supplements of vitamin K and vitamin E in infants,

multivitamin products are commonly used. For infants, liquid formulations usually include vitamins A, D, C, and B complex. Folic acid is not included because it is unstable in liquid form. For older children, chewable tablets usually contain vitamins A, D, C, and B complex, including folic acid.

- A single IM dose of vitamin K is given to newborn infants to prevent hemorrhagic disease of newborns.
- Preterm infants need proportionately more vitamins than term infants because their growth rate is faster and their absorption of vitamins from the intestine is less complete. A multivitamin product containing the equivalent of DRIs for term infants is recommended.
- ULs have been established for some vitamins, and **these maximum daily amounts should not be exceeded**. For infants (birth to 12 months), the only UL is for vitamin D (25 mcg). For other children, ULs vary according to age, as listed in Table 57-5.

With **mineral–electrolytes**, children need sufficient amounts to support growth and normal body functioning. However, iron deficiency is common in young children and adolescent girls, and an iron supplement is often needed. Guidelines include the following:

- A combined vitamin–mineral supplement every other day may be reasonable, especially for children who eat poorly.
- If supplements are given, dosages should be discussed with a health care provider and usually should not exceed recommended amounts for particular age groups. ULs for children have been established for some minerals, and **these maximum daily amounts should not be exceeded**. They are listed in Table 57-6. The ULs for magnesium indicate maximum intake from pharmaceutical preparations; they do not include intake from food and water.
- All minerals and electrolytes are toxic in overdose and may cause life-threatening adverse effects. All such drugs should be kept out of reach of young children and should never be referred to as “candy.”

- In areas where water is not fluoridated, a vitamin–mineral supplement containing fluoride may be indicated for infants and children. Many preparations of fluoride supplements are available for oral (tablets, chewable tablets, solutions) or topical (liquid rinse solutions or gels) use. Before using a pharmaceutical supplement, though, most dental professionals recommend that a patient’s water supply be tested for fluoride. With numerous sources of fluoride available (e.g., infant formula, fruit juice, toothpaste, municipal water supplies, and supplements), however, children must also be guarded against excessive fluoride ingestion. To prevent excessive intake, all sources of fluoride should be considered, supplements used by children or adults should be kept out of the reach of children, supplements prescribed for children should be used only with adult supervision, and children using topical preparations should be reminded to spit them out and not to swallow them.
- If KCl and other electrolyte preparations are used to treat deficiency states in children, serum electrolyte levels must be monitored. In addition, doses must be carefully measured and given no more often than prescribed to avoid toxicity.
- Accidental ingestion of iron-containing medications and dietary supplements is a common cause of poisoning death in children younger than 6 years of age. To help prevent poisoning, products containing iron must be labeled with a warning and products with 30 milligrams or more of iron (e.g., prenatal products) must be packaged as individual doses. All iron-containing preparations should be stored in places that are inaccessible to young children.

### Nutritional Support in Older Adults

Older adults are at risk of under nutrition with all nutrients. Inadequate intake may result from the inability to obtain and prepare food, disease processes that interfere with the ability to digest and use nutrients, and the use of drugs that decrease absorption of nutrients. When alternative feeding methods (tube feedings, IV fluids) are used, careful assessment of nutritional status is required to avoid deficits or excesses. With the high incidence of atherosclerosis, cardiovascular disease, and

**Table 57-5**

**Vitamins: Tolerable Upper Intake Levels for Children**

VITAMIN	1–3 YEARS	4–8 YEARS	9–13 YEARS	14–18 YEARS
D	50 mg	50 mg	50 mg	50 mg
E	200 mg	300 mg	600 mg	800 mg
C	400 mg	650 mg	1200 mg	1800 mg
Folate	300 mcg	400 mcg	600 mcg	800 mcg
Niacin	10 mg	15 mg	20 mg	30 mg
Pyridoxine	30 mg	40 mg	60 mg	80 mg

Table 57-6

## Minerals: Tolerable Upper Intake Levels for Children

MINERAL	BIRTH–6 MONTHS	7–12 MONTHS	1–3 YEARS	4–8 YEARS	9–13 YEARS	14–18 YEARS
Calcium	No data	No data	2.5 g	2.5 g	2.5 g	2.5 g
Phosphorus	No data	No data	3 g	3 g	4 g	4 g
Fluoride	0.7 mg	0.9 mg	1.3 mg	2.2 mg	10 mg	10 mg
Magnesium	No data	No data	65 mg	110 mg	350 mg	350 mg
Selenium	45 mcg	60 mcg	90 mcg	150 mcg	280 mcg	400 mcg

diabetes mellitus in older adults, it is especially important that intake of animal fats and high-calorie sweets be reduced.

Vitamin requirements are the same as for younger adults, but deficiencies are common, especially of vitamins A and D, cyanocobalamin (B<sub>12</sub>), folic acid, riboflavin, and thiamine. With vitamin B<sub>12</sub>, for example, it is estimated that older adults only absorb 10% to 30% of the amount found in food. Every older adult should be assessed regarding vitamin intake (from foods and supplements) and use of drugs that interact with dietary nutrients. For most older adults, a daily multivitamin is probably desirable, even for those who seem healthy and able to eat a well-balanced diet. In addition, requirements may be increased during illnesses, especially those affecting GI function. Overdoses, especially of the fat-soluble vitamins A and D, may cause toxicity and should be avoided. ULs for older adults have been established for some vitamins (D, 50 mg; E, 1000 mg; C, 2000 mg; folate, 1000 mcg; niacin, 35 mg; pyridoxine, 100 mg), and **these amounts should not be exceeded.**

### Applying Your Knowledge 57-1

You recognize that along with being undernourished, Mrs. Farber is also most likely deficient in vitamins. You confer with the physician. What will be the likely recommendation for Mrs. Farber?

Mineral–electrolyte requirements are also the same as for younger adults, but deficiencies of calcium and iron are common. Excess states also may occur in older adults. For example, decreased renal function promotes retention of magnesium and potassium. Hyperkalemia also may occur with the use of potassium supplements or salt substitutes. All minerals and electrolytes are toxic in overdose. ULs for older adults (over 65 years of age) have been established for calcium (2.5 g), phosphorus (3–4 g), fluoride (10 mg), magnesium (350 mg), and selenium (400 mcg), and **these maximum daily amounts should not be exceeded.** In general, serum levels of minerals and electrolytes should be monitored carefully during illness and measures taken to prevent either deficiency or excess states.

### Applying Your Knowledge 57-2

It is important to assess patients for individual risk factors related to gender, health status, and age. For Mrs. Farber, what particular mineral–electrolyte deficiencies would you consider/explore?

### Nutritional Support in Patients With Renal Impairment

Patients with impaired renal function usually have multiple metabolic disorders such as hyperglycemia, accumulation of urea nitrogen (the end product of protein metabolism), and increased serum triglyceride levels from disordered fat metabolism. With *enteral nutrition*, Amin-Aid may be given to provide amino acids, carbohydrates, and a few electrolytes for patients with renal failure. With parenteral nutrition, several amino acid solutions are formulated for patients with renal failure (e.g., Aminosyn-RF). In addition, patients with acute renal failure (ARF) often have hyperkalemia, hyperphosphatemia, and hypermagnesemia, so that potassium, phosphorus, and magnesium should be omitted until serum levels return to normal. IV fat emulsions should not be given to patients with ARF if serum triglyceride levels exceed 300 milligrams per deciliter. With chronic renal failure (CRF), high-calorie, low-electrolyte enteral formulations are usually indicated. Nepro is a formulation for patients receiving dialysis; Suplena, which is lower in protein and some electrolytes than Nepro, may be used in patients who are not receiving dialysis. Serum triglyceride levels should be measured before IV fat emulsions are given. Many patients with CRF have hypertriglyceridemia, which is worsened by fat emulsions and may cause pancreatitis.

With vitamins, patients with ARF who are unable to eat an adequate diet need a vitamin supplement to meet DRIs. Large doses of vitamin C should be avoided because urinary excretion is impaired. In addition, oxalate (a product of vitamin C catabolism) may precipitate in renal tubules or form calcium oxalate stones, obstruct urine flow, and worsen renal function. Patients with CRF often have deficiencies of water-soluble vitamins because many foods that contain these

vitamins are restricted due to their potassium content. In addition, vitamin C is reabsorbed from renal tubules by a specific transport protein. When the transport protein becomes saturated, remaining vitamin C is excreted in urine. Vitamin C is removed by dialysis and patients receiving dialysis require vitamin C replacement. The optimal replacement dose is unknown but probably should not exceed 200 milligrams per day (to avoid increased oxalate and possible stones). Overall, a multivitamin with essential vitamins, including vitamin C 70 to 100 milligrams, pyridoxine 5 to 10 milligrams, and folic acid 1 milligram, is recommended for daily use.

With mineral–electrolyte products, several are contraindicated in patients with renal impairment, including magnesium and KCl, because of potential accumulation and toxicity. Frequent measurements of serum electrolyte levels may be indicated. In patients with CRF who are on hemodialysis and receiving supplemental erythropoietin therapy, sodium ferric gluconate complex (Ferrlecit) may be given IV during dialysis to treat iron deficiency anemia.

### Nutritional Support in Patients With Hepatic Impairment

The liver is extremely important in digestion and metabolism of carbohydrate, protein, and fat as well as storage of nutrients. Thus, patients with impaired hepatic function are often undernourished, with impaired metabolism of foodstuffs, vitamin deficiencies, and fluid and electrolyte imbalances. Depending on the disease process and the extent of liver impairment, these patients have special needs in relation to nutritional support.

Patients with alcoholic hepatitis or cirrhosis have a high rate of metabolism and therefore need foods to supply extra energy. However, metabolic disorders interfere with the liver's ability to process and use foodstuffs. Patients with cirrhosis often have hyperglycemia. Patients with severe hepatitis often have hypoglycemia because of impaired hepatic production of glucose and possibly impaired hepatic metabolism of insulin.

Protein restriction is usually needed in patients with cirrhosis to prevent or treat hepatic encephalopathy, which is caused by excessive protein or excessive production of ammonia (from protein breakdown in the GI tract). For patients able to tolerate enteral feedings (usually by GI tube), Hepatic Aid II is formulated for patients with liver failure. When parenteral nutrition is necessary for patients with hepatic failure and hepatic encephalopathy, HepatAmine, a special formulation of amino acids, may be used. Other amino acid preparations are contraindicated in patients with hepatic encephalopathy and coma.

Enteral and parenteral fat preparations must be used very cautiously. Medium-chain triglycerides (e.g., MCT oil), which are used to provide calories in other malnourished patients, may lead to coma in patients with advanced cirrhosis. Patients who require parenteral nutrition may develop high serum triglyceride levels and pancreatitis if given usual amounts of IV fat emulsions. Sodium and fluid restrictions are often needed to decrease edema.

Vitamin deficiencies commonly occur in patients with chronic liver disease, because of poor intake and malabsorption. With hepatic failure, hepatic stores of vitamin A, pyridoxine, folic acid, riboflavin, pantothenic acid, vitamin B<sub>12</sub>, and thiamine are depleted. Folic acid deficiency may lead to megaloblastic anemia. Thiamine deficiency may lead to Wernicke's encephalopathy. Therapeutic doses of vitamins should be given for documented deficiency states.

Niacin is contraindicated in liver disease because it may increase liver enzymes (alanine and aspartate aminotransferases, alkaline phosphatase) and bilirubin and cause further liver damage. Long-acting dosage forms may be more hepatotoxic than the fast-acting forms.

Iron dextran must be used with extreme caution in patients with impaired hepatic function. Also, overdoses of chromium and copper are hepatotoxic and should be avoided.

### Nutritional Support in Patients With Critical Illness

Critically ill patients often have organ failures that alter their ability to ingest and use essential nutrients. Thus, they may be undernourished in relation to protein-calorie, vitamin, and mineral–electrolyte needs. Some considerations include the following:

- With enteral nutrition, adequate calories and DRI-equivalent amounts of all vitamins are usually needed. Patients with respiratory impairment may need a formula that contains less carbohydrate and more fat than other products and produces less carbon dioxide (e.g., Pulmocare). Patients with cardiac or renal impairment who require fluid restriction may benefit from a more concentrated formula (e.g., 1.5 kcal/mL).
- With parenteral nutrition, adequate types and amounts of nutrients are needed. When IV fat emulsions are given, they should be infused slowly, over 24 hours. With vitamins, the Nutrition Advisory Group of the American Medical Association (NAG-AMA) has established guidelines for daily intake, and parenteral multivitamin formulations are available for adults and children. Those for adults do not contain vitamin K, which is usually injected weekly. The usual dose is 2 to 4 milligrams. Vitamin K is included in pediatric parenteral nutrition solutions.
- Electrolyte and acid–base imbalances often occur in critically ill patients and are usually treated as in other patients, with very close monitoring of serum electrolyte levels and avoiding excessive amounts of replacement products.

### Nutritional Support in Home Care

The home care nurse is involved with nutritional matters in almost any home care setting. Because nutrition is so important to health, the home care nurse should take advantage of any opportunity for health promotion in this area. Health promotion may involve assessing the nutritional status of all members of the household, especially children, older adults, and those with obvious deficiencies, and providing assistance to improve nutritional status.

For patients receiving tube feedings at home, the home care nurse may teach about the goals of treatment, administration, preparation or storage of solutions, equipment (e.g., obtaining, cleaning), and monitoring responses (e.g., weight, urine output).

For patients receiving parenteral nutrition at home, solutions, infusion pumps, and other equipment are obtained from a pharmacy, home health agency, or independent company. The home care nurse may not be involved in the initial setup but is likely to participate in ongoing patient care, monitoring of patient responses, and supporting caregivers. In addition, the home care nurse may need to coordinate activities among prescribers, IV therapy personnel, and other health care providers.

With vitamins, the home care nurse needs to assess for indications of vitamin deficiencies or use of supplements, especially megadoses. If difficulties are found, the nurse may need

to counsel household members about dietary sources of vitamins and adverse effects of excessive vitamin intake.

With mineral–electrolytes, the home care nurse needs to assess for indications of mineral–electrolyte deficiency or excess. Depending on assessment data, teaching may be needed about dietary sources of these nutrients, when mineral supplements are indicated or should be avoided, and safety factors related to iron supplements or exposure to lead in homes with small children.

 **Applying Your Knowledge 57-3**

**How Can You Avoid This Medication Error?**

Mrs. Farber is taking an iron supplement. You tell the family to give her the iron supplement with her coffee.

**Nursing Actions**

**Nutritional Products, Vitamins, and Mineral–Electrolytes**

**NURSING ACTIONS**

**RATIONALE/EXPLANATION**

**1. Administer accurately**

- a. For oral supplemental feedings, chill liquids or pour over ice and give through a straw, from a closed container, between meals.
- b. For tube feedings:
  - (1) Have the patient sitting, if possible.
  - (2) Check tube placement before each feeding.
  - (3) Give the solution at room temperature.
  - (4) If giving by intermittent instillation, do not give more than 500 mL per feeding, including water for rinsing the tube.
  - (5) Give by gravity flow (over 30–60 minutes) or infusion pump.
  - (6) With continuous feedings, change containers and tubing daily. With intermittent bolus feedings, rinse all equipment after each use, and change at least every 24 hours.
  - (7) Give additional water with, after, or between feedings.
  - (8) Rinse nasogastric tubes with at least 50–100 mL water after each bolus feeding or administration of medications through the tube.
  - (9) When medications are ordered by tube, liquid preparations are preferred over crushed tablets or powders emptied from capsules.
- c. With pancreatic enzymes, give before or with meals or food.
- d. With fat-soluble vitamins:
  - (1) Do not give oral preparations at the same time as mineral oil.
  - (2) For subcutaneous (Sub-Q) or intramuscular (IM) administration of vitamin K, aspirate carefully to avoid intravenous (IV) injection, apply gentle pressure to the injection site, and inspect the site frequently.

- Chilling (or freezing) may improve formula taste and decrease formula odor. A straw directs the formula toward the back of the throat and decreases its contact with taste buds. A closed container also decreases odor. Giving between meals may have less effect on appetite at mealtimes.
- To decrease risks of aspirating formula into lungs  
To prevent aspiration or accidental instillation of feedings into lungs  
Cold formulas may cause abdominal cramping.  
To avoid gastric distention, possible vomiting, and aspiration into lungs
- Rapid administration may cause nausea, vomiting, and other symptoms.  
Most tube-feeding formulas are milk based and provide a good culture medium for bacterial growth. Clean technique, not sterile technique, is required.
- To avoid dehydration and promote fluid balance. Most patients receiving 1500 to 2000 mL of tube-feeding formula daily will need 1000 mL or more of water daily.  
To keep the tube patent and functioning. This water is included in calculation of fluid intake.
- Tablets or powders may stick in the tube lumen. This may mean the full dose of the medication does not reach the stomach. Also, the tube is likely to become obstructed.  
To be effective, these agents must be in the small intestine when food is present.
- Mineral oil absorbs the vitamins and thus prevents their systemic absorption.  
Vitamin K is given to patients with hypoprothrombinemia, which causes bleeding tendencies. Thus, any injection may cause trauma and bleeding at the injection site.
- IV phytonadione may cause hypotension and shock from an anaphylactic type of reaction. IV administration is not recommended.

## Nursing Actions

## Nutritional Products, Vitamins, and Mineral-Electrolytes (continued)

## NURSING ACTIONS

## RATIONALE/EXPLANATION

e. With **B-complex vitamins**:

- (1) Give parenteral cyanocobalamin (vitamin B<sub>12</sub>) IM or deep Sub-Q.
- (2) Give oral niacin, except for timed-release forms, with or after meals or at bedtime. Have the patient sit or lie down for about 30 minutes after administration.
- (3) Give IM thiamine deeply into a large muscle mass. Avoid the IV route.

f. With **mineral-electrolyte preparations**, give oral drugs with food or immediately after meals; give IV preparations slowly, do not mix with any other drug in a syringe, and dilute as directed with compatible IV solutions.g. For **potassium supplements**:

- (1) For oral preparations, give with or after meals; do not crush controlled- or extended-release tablets; mix oral liquids, powders, and effervescent tablets in at least 4 oz of juice, water, or carbonated beverage.
- (2) For IV potassium chloride (KCl), **never** give undiluted drug IV; dilute 20–40 mEq in 1000 ml of IV solution, such as dextrose in water; be sure that KCl is mixed well with the IV solution; as a general rule, give potassium-containing IV solutions at a maximum rate of 10 mEq/h, for life-threatening dysrhythmias caused by hypokalemia, potassium can be replaced with 20–40 mEq/h with constant electrocardiogram (ECG) monitoring. Use an infusion pump and do not give potassium-containing IV solutions into a central venous catheter.

h. For parenteral **magnesium sulfate**

- (1) Read the drug label carefully to be sure you have the correct preparation for the intended use.
- (2) For IM use, small amounts of 50% solution are usually given (1 g magnesium sulfate = 2 mL of 50% solution).
- (3) For IV use, a 5% or 10% solution is used for direct injection, intermittent infusion, or continuous infusion. Whatever concentration is used, administer no more than 150 mg/min (1.5 mL/min of 10% solution; 3 mL/min of 5% solution).

i. For **iron preparations**:

- (1) Give tablets or capsules before meals, with 8 oz of water or juice, if tolerated. If gastric upset occurs, give with or after meals. Instruct patients not to crush or chew sustained-release preparations.
- (2) Dilute liquid iron preparations, give with a straw, and have the patient rinse the mouth afterward.
- (3) To give iron dextran IM, use a 2- to 3-inch needle and Z-track technique to inject the drug into the upper outer quadrant of the buttock.
- (4) To give iron dextran IV (either directly or diluted in sodium chloride solution and given over several hours), do not use the multidose vial.

To decrease anorexia, nausea, vomiting, diarrhea, and flatulence. Niacin causes vasodilation, which may result in dizziness, hypotension, and injury from falls. Vasodilation occurs within a few minutes and may last 1 hour.

To decrease pain at the injection site. Hypotension and anaphylactic shock have occurred with rapid IV administration and large doses.

Giving oral drugs with or after food decreases gastric irritation. Rapid IV administration may cause cardiac dysrhythmias or other serious problems. Mixing the drugs may cause drug inactivation or precipitation.

Giving with food decreases gastric irritation; crushing extended-release tablets causes the drug to be absorbed immediately rather than over several hours, as intended; mixing dilutes, disguises the taste, and decreases gastric irritation. Concentrated drug and transient hyperkalemia may cause life-threatening cardiotoxicity, severe pain, and vein sclerosis; adequate dilution decreases risks of hyperkalemia and cardiotoxicity and prevents or decreases pain at the infusion site; 10 mEq or less per hour is the safest amount and rate of potassium administration and it is usually effective; risks of hyperkalemia and life-threatening cardiotoxicity are greatly increased with high concentrations or rapid flow rates. Constant ECG monitoring can detect hyperkalemia. Infusion pumps can regulate the flow rate accurately. Administration through a central IV line can cause hyperkalemia and cardiac dysrhythmias or arrest.

Magnesium sulfate is available in concentrations of 10%, 25%, and 50% and in sizes of 2-, 10-, and 20-mL ampules, as well as a 30-mL multidose vial.

Iron preparations are absorbed better if taken on an empty stomach. If taken with meals, note that bran, eggs, tea, coffee, and dairy products decrease iron absorption. Crushing or chewing releases all the medication at once, rather than over several hours, as intended.

To prevent temporary staining of teeth

To prevent discomfort and staining of Sub-Q tissue and skin

The multidose vial contains phenol as a preservative and is not suitable for IV use. Ampules of 2 mL or 5 mL are available without preservative.

**NURSING ACTIONS**

**RATIONALE/EXPLANATION**

j. Refer to the individual drugs or package literature for instructions regarding administration of deferoxamine, penicillamine, IV sodium bicarbonate, and multiple electrolyte solutions.

**2. Observe for therapeutic effects**

a. With nutritional formulas given orally or by tube feeding, observe for weight gain and increased serum albumin. For infants and children receiving milk substitutes, observe for decreased diarrhea and weight gain.

b. With pancreatic enzymes, observe for decreased diarrhea and steatorrhea.

c. With vitamins, observe for decreased signs and symptoms of deficiency:

(1) With vitamin A, observe for improved vision, especially in dim light or at night, less dryness in eyes and conjunctiva (xerophthalmia), and improvement in skin lesions.

(2) With vitamin K, observe for decreased bleeding and more nearly normal blood coagulation tests (e.g., prothrombin time).

(3) With B-complex vitamins, observe for decreased or absent stomatitis, glossitis, seborrheic dermatitis, neurologic problems (neuritis, convulsions, mental deterioration, psychotic symptoms), cardiovascular problems (edema, heart failure), and eye problems (itching, burning, photophobia).

(4) With vitamin B<sub>12</sub> and folic acid, observe for increased appetite, strength and feeling of well-being, increased reticulocyte counts, and increased numbers of normal red blood cells, hemoglobin, and hematocrit.

(5) With vitamin C, observe for decreased or absent malaise, irritability, and bleeding tendencies (easy bruising of skin, bleeding gums, nosebleeds, and so forth).

d. With mineral–electrolyte preparations, observe for decreased signs of deficiency.

(1) With KCl or other potassium preparations, observe for decreased signs of hypokalemia and increased serum potassium levels.

(2) With magnesium sulfate, observe for decreased signs of hypomagnesemia, increased serum magnesium levels, or control of convulsions.

(3) With zinc sulfate, observe for improved wound healing.

(4) With iron preparations, observe for increased vigor and feeling of well-being, improved appetite, less fatigue, and increased red blood cells, hemoglobin, and hematocrit. With parenteral iron, observe for an average increase in hemoglobin of 1 g/wk.

**3. Observe for adverse effects**

a. With commercial nutritional formulas (except Osmolite and Isocal), observe for hypotension, tachycardia, increased urine output, dehydration, nausea, vomiting, or diarrhea.

b. With vitamin A, observe for signs of hypervitaminosis A (anorexia; vomiting; irritability; headache; skin disorders; pain in muscles, bones, and joints; other clinical manifestations; and serum levels of vitamin A above 1200 IU/dL).

c. With Sub-Q or IM vitamin K, adverse effects rarely occur.

Therapeutic effects depend on the reason for use (i.e. prevention or treatment of undernutrition).

The pancreatic enzymes function the same way as endogenous enzymes to aid digestion of carbohydrate, protein, and fat.

Night blindness is usually relieved within a few days. Skin lesions may not disappear for several weeks.

Blood coagulation tests usually improve within 4–12 hours.

Deficiencies of B-complex vitamins commonly occur together and produce many similar manifestations.

Therapeutic effects may be rapid and dramatic. The patient usually feels better within 24–48 hours, and normal red blood cells begin to appear. Anemia is decreased within approximately 2 weeks, but 4–8 weeks may be needed for complete blood count to return to normal.

Therapeutic effects are usually evident within a month unless other problems are also present (e.g., vitamin deficiency, achlorhydria, infection, malabsorption).

These adverse reactions are usually attributed to the hypertonicity of the preparations. They can be prevented or minimized by starting with small amounts of formula, given slowly.

Severity of manifestations depends largely on dose and duration of excess vitamin A intake. Very severe states produce additional clinical signs, including enlargement of liver and spleen, altered liver function, increased intracranial pressure, and other neurologic manifestations.

Vitamin K rarely produces adverse reactions. Giving IV phytonadione slowly may prevent adverse reactions.

## Nursing Actions

## Nutritional Products, Vitamins, and Mineral-Electrolytes (continued)

## NURSING ACTIONS

- d. With B-complex vitamins, observe for hypotension and anaphylactic shock with parenteral niacin, thiamine, cyanocobalamin, and folic acid; anorexia, nausea, vomiting and diarrhea, and postural hypotension with oral niacin.
- e. With vitamin C megadoses, observe for diarrhea and rebound deficiency if stopped abruptly.
- f. With mineral-electrolytes, observe for excess states.
  
- g. With potassium preparations, observe for hyperkalemia.
  
- h. With magnesium preparations, observe for hypermagnesemia.
- i. Gastrointestinal (GI) symptoms—*anorexia, nausea, vomiting, diarrhea, and abdominal discomfort from gastric irritation*
- j. Cardiovascular symptoms—*cardiac dysrhythmias, hypotension, tachycardia, other symptoms of shock*
- k. With Kayexalate, observe for hypokalemia, hypocalcemia, hypomagnesemia, and edema.

## 4. Observe for drug interactions

- a. With fat-soluble vitamins:
  - (1) Bile salts *increase* effects.
  - (2) Laxatives, especially mineral oil, *decrease* effects.
  
  - (3) Antibiotics may *decrease* effects.
- b. With B-complex vitamins:
  - (1) Isoniazid (INH) *decreases* effect.
  
  - (2) With folic acid: alcohol, cholestyramine, methotrexate, oral contraceptives, phenytoin, sulfasalazine, and triamterene *decrease* effects.
  
  - (3) With vitamin B<sub>12</sub>, omeprazole (Prilosec) *decreases* effects.
- c. Drugs that *increase* effects of minerals and electrolytes and related drugs:
  - (1) Cation exchange resin (Kayexalate): diuretics *increase* potassium loss; other sources of sodium *increase* the likelihood of edema.
  - (2) With iron salts:
    - (a) Allopurinol (Zyloprim)
  
    - (b) Ascorbic acid (vitamin C)
  - (3) With potassium salts:
    - (a) Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril)

## RATIONALE/EXPLANATION

Adverse reactions are generally rare. They are unlikely with B-complex multivitamin preparations. They are most likely to occur with large IV doses and rapid administration.

Adverse reactions are rare with usual doses and methods of administration.

These are likely to occur with excessive dosages of supplements. They can usually be prevented by using relatively low doses in nonemergency situations and by frequent monitoring of serum levels of electrolytes and iron.

This is most likely to occur with rapid IV administration, high dosages or concentrations, or in the presence of renal insufficiency and decreased urine output.

See potassium preparations, above.

Most oral preparations of minerals and electrolytes are likely to cause gastric irritation. Taking the drugs with food or 8 oz of fluid may decrease symptoms.

Potentially fatal dysrhythmias may occur with hyperkalemia or hypermagnesemia; shock may occur with deferoxamine and iron dextran injections.

Although this drug is used to treat hyperkalemia, it removes calcium and magnesium ions as well as potassium ions.

Because it acts by trading sodium for potassium, the sodium retention may lead to edema.

Increase intestinal absorption

Mineral oil combines with fat-soluble vitamins and prevents their absorption if both are taken at the same time. Excessive or chronic laxative use decreases intestinal absorption.

With vitamin K, antibiotics decrease production by decreasing intestinal bacteria. With others, antibiotics may cause diarrhea and subsequent malabsorption.

INH has an antipyridoxine effect. When INH is given for prevention or treatment of tuberculosis, pyridoxine is usually given also.

Alcohol alters liver function and leads to poor hepatic storage of folic acid. Methotrexate and phenytoin act as antagonists to folic acid and may cause folic acid deficiency. Cholestyramine, oral contraceptives, and sulfasalazine decrease absorption of folic acid.

Decreases absorption of B<sub>12</sub> from foods

Additive effects

This drug may increase the concentration of iron in the liver. It should not be given concurrently with any iron preparation. Increases absorption of iron by acidifying secretions

May increase risks of hyperkalemia

NURSING ACTIONS	RATIONALE/EXPLANATION
(b) Diuretics, potassium-saving (spironolactone, triamterene, amiloride)	These drugs should not be given with a potassium supplement because of additive risks of producing life-threatening hyperkalemia.
(c) Salt substitutes	These contain potassium rather than sodium and may cause hyperkalemia if given with potassium supplements.
(d) Penicillin G potassium	This potassium salt of penicillin contains 1.7 mEq of potassium per 1 million units and increases risks of hyperkalemia.
d. Drugs that <i>decrease</i> effects of minerals and electrolytes and related drugs:	
(1) With oral iron salts:	
(a) Antacids	Decrease absorption. Iron is best absorbed in an acidic environment and antacids increase alkalinity.
(b) Caffeine	Decreases absorption. An iron preparation and a caffeine-containing substance (e.g., coffee) should be separated by at least 2 hours.
(c) Cimetidine (Tagamet)	Decreases absorption
(d) Pancreatic extracts	Decrease absorption
(2) With potassium salts:	
(a) Calcium gluconate	Decreases cardiotoxic effects of hyperkalemia and is therefore useful in the treatment of hyperkalemia
(b) Sodium polystyrene sulfonate (Kayexalate)	Used in treatment of hyperkalemia because it removes potassium from the body

## Key Concepts

- Human nutrition for health requires sufficient water, carbohydrates, proteins, fats, vitamins, and minerals.
- Patients with other health problems often have nutritional deficiencies, such as protein-calorie undernutrition and vitamin deficiencies.
- All patients need to be assessed in terms of nutritional status. When problems are assessed, interventions to maintain or improve nutritional status are needed.
- Fat-soluble vitamins are A, D, E, and K; water-soluble vitamins are B complex and C.
- Nutrients are best obtained from foods; when they cannot be obtained from foods, they can be provided by oral, enteral (via GI tubes), or parenteral (IV) feedings to meet a patient’s nutritional needs.
- Techniques for safe administration of oral, enteral, and parenteral feedings must be consistently followed because complications and harm to patients may occur with all methods.
- Adverse effects may occur with large doses of vitamin and mineral supplements; the maximum recommended amounts should not be exceeded.
- Although most adults and children probably benefit from a daily multivitamin, large doses of single vitamins do not prevent cancer or cardiovascular disease and should be avoided.

## Review and Application Exercises

### Short Answer Exercises

1. For patients who are unable to ingest food, which nutrients can be provided with enteral or IV nutritional formulas?
2. What is the role of lipid emulsions in parenteral nutrition?
3. What roles do vitamins play in normal body functioning?
4. Identify patient populations who are at risk for vitamin deficiencies and excesses.
5. Are fat-soluble or water-soluble vitamins more toxic in overdoses? Why?
6. For a patient who asks your advice about taking a multivitamin supplement daily, how would you reply? Justify your answer.
7. How do the vitamin requirements of children, older adults, and critically ill patients differ from those of healthy young and middle-aged adults?
8. What are the major roles of minerals and electrolytes in normal body functioning?
9. When a patient is given potassium supplements for hypokalemia, how do you monitor for therapeutic and adverse drug effects?

10. List the main steps in treatment of hyperkalemia. Identify patient populations at risk for development of hyperkalemia.
  11. What are advantages and disadvantages of iron supplements?
  12. List measures an adult can take to prevent accidental iron poisoning in small children.
- NCLEX-Style Questions**
13. Mr. H develops respiratory distress while receiving continuous tube feeding. After notifying the physician and stopping the feeding, the nurse should first
    - a. Assess bowel sounds to determine if he has a paralytic ileus.
    - b. Assess breath sounds to determine if he has aspirated tube-feeding formula.
    - c. Perform nasal or tracheal suctioning.
    - d. Aspirate stomach contents.
  14. Which of the following statements by Mr. H's daughter who will care for him at home, leads you to believe that she has understood your teaching regarding tube feeding?
    - a. "I will store unopened cans of formula in the refrigerator."
    - b. "I will stop the feedings if he has more than two stools per day."
    - c. "I will place him in a sitting position for his feedings."
    - d. "I will give no more than 50 mL per hour."
  15. Which of the following is a fat-soluble vitamin that is toxic in overdose?
    - a. vitamin A
    - b. vitamin B<sub>1</sub>
    - c. vitamin C
    - d. folic acid
  16. Teaching for a patient who is being started on an iron supplement should include information that the preparation
    - a. may cause diarrhea
    - b. may cause stools to be dark green or black
    - c. should be taken with an antacid
    - d. should not be taken with fruit juice
  17. Which of the following IV electrolytes should be well diluted and never given as a bolus injection ("IV push") because it can cause fatal cardiac dysrhythmias?
    - a. sodium bicarbonate
    - b. magnesium sulfate
    - c. sodium chloride
    - d. potassium chloride

# Drugs to Aid Weight Management

## KEY TERMS

- Anorexiant
- Body mass index
- Obesity
- Overweight

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Promote healthful lifestyle measures to maintain body weight within a desirable range and avoid obesity.
2. Assess patients for risk factors and manifestations of obesity.
3. Calculate body mass index (BMI).
4. Counsel patients about the health consequences of obesity.
5. Assist overweight patients to develop and maintain a safe and realistic weight-loss program.
6. Identify reliable sources for information about nutrition, weight loss, and weight maintenance.
7. Assist patients with effective use of approved weight-loss drugs, when indicated.

## Applying Your Knowledge

Halli Vargas is a 31-year-old woman who has had a weight problem all her life. She has been on any number of diets with a yo-yo effect of weight loss followed by weight gain. She is 5 feet 5 inches tall and weighs 265 pounds. Her adult nurse practitioner starts her on orlistat and prescribes a consultation with a dietitian.

## Introduction

Carbohydrates, proteins, and fats are required for human nutrition. Either deficiencies or excesses impair health, cause illness, and impair recovery from illness or injury. Proteins are basic structural and functional components of all body cells and tissues; carbohydrates and fats serve primarily as sources of energy for cellular metabolism. Energy is measured in kilocalories (kcal, commonly called calories) per gram of food oxidized in the body. Carbohydrates and proteins supply 4 kcal per gram; fats supply 9 kcal per gram. Excessive amounts of any of these nutrients are converted to fat and stored in the body, resulting in excess weight and *obesity*. This chapter discusses obesity and treatment strategies, including drugs to aid weight loss and weight maintenance.

## Overweight and Obese Adults

Being *overweight* and obese are widespread problems and are increasing in the United States, in both children and adults. They are considered major public health problems because of their association with high rates of morbidity and mortality. Overweight is defined as a *body mass index* (BMI) of 25 to 29.9 kilograms per square meter; obese is defined as a BMI of 30 or more kilograms per square meter. The BMI reflects weight in relation to height and is a better indicator than weight alone. The desirable range for BMI is 18.5 to 24.9 kilograms per square meter, with any values below

**Box 58-1****Calculation of Body Mass Index (BMI) and Height and Weight Indicators for Overweight and Obese****BMI**

Body mass index can be calculated as weight in kilograms divided by height in meters, squared; or as weight in pounds divided by height in inches, squared, multiplied by a conversion factor of 704.5 (listed as 703 in some sources), as follows:

$$\text{BMI} = \frac{\text{Weight (pounds)}}{\text{Height (inches)}^2} \times 704.5$$

Example: A person who weighs 150 lb and is 5'5" (65 in) tall

$$\text{BMI} = \frac{150 \text{ lb}}{65 \text{ in} \times 65 \text{ in}} \times 704.5 = \frac{105,675}{422.5} = 25$$

**Weight Compared With Height as an Indicator for Being Overweight or Obese**

Height (ft/in)	Weight (lb) Indicating Overweight (BMI 25)	Weight (lb) Indicating Obesity (BMI 30)
5'2" (62 inches)	135	165
5'3"	140	170
5'4"	145	175
5'5"	150	180
5'6"	155	185
5'7"	160	190
5'8"	165	195
5'9"	170	200
5'10"	175	205
5'11"	180	210
6'0"	185	220
6'1"	190	225
6'2" (74 inches)	195	230

18.5 indicating underweight and any values of 25 or above indicating excessive weight (Box 58-1). A large waist circumference (above 35 inches for women, above 40 inches for men) is another risk factor for overweight and obesity.

Obesity may occur in anyone but is more likely to occur in women, minority groups, and poor people. It results from consistent ingestion of more calories than are used for energy, and it substantially increases risks for development of numerous health problems (Box 58-2). Most obesity-related disorders are attributed mainly to the multiple metabolic abnormalities associated with obesity. Abdominal fat out of proportion to total body fat (also called central or visceral obesity), which often occurs in men and postmenopausal women, is considered a greater risk factor for disease and death than lower body obesity. In addition to the many health problems associated with

obesity, obesity is increasingly being considered a chronic disease in its own right. Although it has been the focus of much research in recent years, no current theory adequately explains the disorder and its resistance to treatment.

**Prevalence**

The prevalence of overweight people and obesity has dramatically increased during the past 25 years. Some authorities estimate that 60% of American adults are overweight or obese. There are differences in prevalence by gender, ethnicity, and socioeconomic status. In general, more women than men are obese, whereas more men than women are overweight; African-American women and Mexican Americans of both sexes have the highest rates of overweight and obesity in the United States; and women in lower socioeconomic classes are more likely to be obese than those in higher socioeconomic classes.

**Etiology**

The etiology of excessive weight is thought to involve complex and often overlapping interactions among physiologic, genetic, environmental, psychosocial, and other factors.

**Physiologic Factors**

In general, increased weight is related to an energy imbalance in which energy intake (food/calorie consumption) exceeds energy expenditure. Total energy expenditure represents the energy expended at rest (i.e., the basal or resting metabolic rate), during physical activity, and during food consumption. When a person ingests food, about 10% of the energy content of that food is expended in the digestion, absorption, and metabolism of nutrients. Foods that contain carbohydrates and proteins stimulate energy expenditure; high-fat foods have little stimulatory effect. The energy required to metabolize and to use food reaches a maximum level about 1 hour after the food is ingested. In addition, men tend to expend more energy than women because they have proportionally more muscle mass. Energy expenditure usually decreases in older men and women of all ages because these groups have less muscle tissue and more adipose tissue. Muscle is more metabolically active (i.e., has higher energy needs and burns more calories) than adipose tissue.

Excessive weight can result from eating more calories, exercising less, or a combination of the two factors. Consuming an extra 500 calories each day for a week results in 3500 excess calories or one pound of fat. Excess calories are converted to triglycerides and stored in fat cells (adipocytes). With continued intake of excessive calories, fat cells increase in both size and number.

**Genetic Factors**

Various studies indicate that a significant portion of weight variation within a given environment is genetic in origin. For example, identical twins raised in separate environments often have similar body types. Most cases of human obesity are attributed mainly to the combination of genetic susceptibility and environmental conditions.

## Box 58-2

## Health Risks of Obesity

Obesity is associated with serious health risks. Several disease states and chronic health problems are more prevalent in obese patients, as well as increased mortality. Studies indicate that a high body mass index (BMI) is associated with an increased risk of death from all causes, among both men and women, and in all age groups. In addition, a higher death rate occurs in people who gain weight of 10 kg or more after 18 years of age. Some of the major health risks include the disorders listed below. In general, these conditions tend to worsen as the degree of obesity increases and improve with weight loss.

**Cancer**

Obesity is associated with a higher prevalence of breast, colon, and endometrial cancers. With breast cancer, risks increase in postmenopausal women with increasing body weight. Women who gain more than 20 lb from age 18 to midlife have double the risk of breast cancer compared with women who maintain a stable weight during this period of their life. In addition, central obesity apparently increases the risk of breast cancer independent of overall obesity. In women with central obesity, this additional risk factor may be related to an excess of estrogen (from conversion of androstenedione to estradiol in peripheral fatty tissue) and a deficiency of sex hormone–binding globulin to combine with the estrogen.

Colon cancer seems to be more common in obese men and women. In addition, a high BMI may be a risk factor for a higher mortality rate with colon cancer. Endometrial cancer is clearly more common in obese women, with adult weight gain again increasing risk.

**Cardiovascular Disorders**

Obesity is a major risk factor for cardiovascular disorders and increased mortality from cardiovascular disease. Studies have confirmed the relationship between obesity and increased risk of coronary heart disease (CHD) and stroke in both men and women. In addition, obesity during adolescence is associated with higher rates and greater severity of cardiovascular disease as adults.

Obesity increases risks by aggravating other risk factors such as hypertension, insulin resistance, low HDL cholesterol, and hypertriglyceridemia. In addition, obesity seems to be an independent risk factor for cardiovascular disorders, and central obesity may be more important than BMI as a risk factor for death from cardiovascular disease. The increased mortality rate is seen even with modest excess body weight.

Hypertension, dyslipidemia, insulin resistance, and glucose intolerance are known cardiac risk factors that tend to cluster in obese individuals. Hypertension often occurs in obese persons and is thought to play a major role in the increased incidence of cardiovascular disease and stroke observed in patients with obesity. Metabolic abnormalities that occur with obesity and type 2 diabetes mellitus (e.g., insulin resistance and the resultant hyperinsulinemia) aggravate hypertension and increase cardiovascular risks. The combination of obesity and

hypertension is associated with cardiac changes (e.g., thickening of the ventricular wall, ischemia, and increased heart volume) that lead to heart failure more rapidly. Weight loss of as little as 4.5 kg (10 lb) can decrease blood pressure and cardiovascular risk in many people with obesity and hypertension.

**Diabetes Mellitus**

Obesity is strongly associated with impaired glucose tolerance, insulin resistance, and diabetes mellitus. In addition, obesity during adolescence is associated with higher rates of diabetes as adults as well as more severe complications of diabetes at younger ages.

The cellular effects by which obesity causes insulin resistance are unknown. Proposed mechanisms include down-regulation of insulin receptors, abnormal postreceptor signals, and others. Whatever the mechanism, the impaired insulin response stimulates the pancreatic beta cells to increase insulin secretion, resulting in a relative excess of insulin called hyperinsulinemia, and causes impaired lipid metabolism (increased low-density lipoprotein [LDL] cholesterol and triglycerides and decreased high-density lipoprotein [HDL] cholesterol). These metabolic changes increase hypertension and other risk factors for cardiovascular disease. As with cardiovascular disease and diabetes in general, central obesity seems to increase the likelihood of serious disease. The abdominal fat of central obesity seems to be more insulin resistant than peripheral fat deposited over the buttocks and legs. Intentional weight loss significantly reduces mortality in obese individuals with diabetes.

**Dyslipidemias**

Obesity strongly contributes to abnormal and undesirable changes in lipid metabolism (e.g., increased triglycerides and LDL cholesterol; decreased HDL cholesterol) that increase risks of cardiovascular disease and other health problems.

**Gallstones**

Obesity apparently increases the risk for developing gallstones by altering production and metabolism of cholesterol and bile. The risk is higher in women, especially those who have had multiple pregnancies or who are taking oral contraceptives. However, rapid weight loss with very–low-calorie diets is also associated with gallstones.

**Metabolic Syndrome**

Metabolic syndrome is a group of risk factors and chronic conditions that occur together and greatly increase the risks of diabetes mellitus, serious cardiovascular disease, and death. The syndrome is thought to be highly prevalent in the United States. Major characteristics include many of the health problems associated with obesity (e.g., dyslipidemias, hypertension, impaired glucose tolerance, insulin resistance, central obesity). More specifically, metabolic syndrome includes three or more of the following abnormalities:

**Box 58-2****Health Risks of Obesity (continued)**

- Central obesity (waist circumference over 40 inches for men and over 35 inches for women)
- Serum triglycerides of 150 mg/dL or more
- HDL cholesterol below 40 mg/dL in men and below 50 mg/dL in women
- Blood pressure of 135/85 mm Hg or higher
- Serum glucose of 110 mg/dL or higher

**Osteoarthritis**

Obesity is associated with osteoarthritis (OA) of both weight-bearing joints, such as the hip and knee, and non-weight-bearing joints. Extra weight can stress affected bones and joints, contract muscles that normally stabilize joints, and may alter the metabolism of cartilage, collagen, and bone. In general, obese people develop OA of the knees at an earlier age and are more likely than nonobese people to require knee replacement surgery.

The important role of obesity in OA is supported by the observation that weight loss delays onset and reduces symptoms and disability. Weight reduction may also decrease infection, wound complications, and blood loss if surgery is required. Despite the benefits of weight loss, however, persons with OA have difficulty losing weight because painful joints limit exercise and activity.

**Sleep Apnea**

Sleep apnea commonly occurs in obese persons. A possible explanation is enlargement of soft tissue in the upper airways that leads to collapse of the upper airways with inspiration

during sleep. The obstructed breathing leads to apnea with hypoxemia, hypercarbia, and a stress response. Sleep apnea is associated with increased risks of hypertension, possible right heart failure, and sudden death. Weight loss leads to improvement in sleep apnea.

**Miscellaneous Effects**

Obesity is associated with numerous difficulties in addition to those described above. These may include

- Nonalcoholic fatty liver disease, which is being increasingly recognized and which may lead to liver failure
- Poor wound healing
- Poor antibody response to hepatitis B vaccine
- A negative perception of people who are obese that affects their education, socioeconomic, and employment status
- High costs associated with treatment of the medical conditions caused or aggravated by obesity as well as the costs associated with weight-loss efforts
- In women, obesity is associated with menstrual irregularities, difficulty in becoming pregnant, and increased complications of pregnancy (e.g., gestational diabetes, higher rates of labor induction and cesarean section, and increased risk of neural tube and other congenital defects in offspring of obese women).
- In men, obesity is associated with infertility.
- In children and adolescents, obesity increases risk of bone fractures and muscle and joint pain. Knee pain is commonly reported, and changes in the knee joint make movement and exercise more difficult.

**Environmental Factors**

Environmental factors contributing to the greater number of overweight and obese individuals include increased food consumption and decreased physical activity. The ready availability and relatively low cost of a wide variety of foods, in addition to large portion sizes and high-calorie foods, promote overeating. In addition, many social gatherings are associated with eating or overeating.

In relation to physical activity, usual activities of daily living for many people, including work-related activities, require relatively little energy expenditure. In addition, few Americans are thought to exercise in the optimal frequency, intensity, or duration to maintain health and prevent excessive weight gain. For both adults and children, increased time watching television, playing video or computer games, and working on computers contribute to less physical activity and are thought to promote weight gain and obesity. In general, though, it is still unknown whether less physical activity leads to obesity or the physical effects of obesity lead to minimal physical activity.

**Psychosocial Factors**

Psychosocial disorders may be either a cause or an effect of obesity. Although much is still unknown about the psychological

aspects of obesity development, depression and/or abuse may play a role. Obese people often report symptoms of depression, and some people overeat and gain weight during depressive episodes. It may be that obesity and depression commonly occur together and reinforce each other. A depressed person is less likely to take the active measures in diet and exercise that are required to lose weight, even if obesity is a prominent factor in the development of depression. In women, sexual, physical, and emotional abuse can result in obesity. Abuse during childhood and adolescence tends to produce more severe effects.

**Other Factors**

Diseases are rarely a major cause of obesity development. However, numerous disease processes may limit a person's ability to engage in calorie-burning physical activity. In addition, numerous prescription medications reportedly cause weight gain in some or most of the patients who take them (Box 58-3).

**Overweight and Obese Children**

Being overweight and obesity are common and increasing among children and adolescents, to the point of being called an "epidemic." Some studies estimate that 15% of children in the United States are overweight and that another 15% are

**Box 58-3****Effects of Selected Medications on Weight****Antidepressants**

Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine (Prozac, Sarafem) and related drugs, may promote weight loss with short-term use. However, with long-term use, they reportedly may cause as much weight gain as tricyclic antidepressants (TCAs) such as amitriptyline (Elavil). TCAs have long been associated with excessive appetite and weight gain. Mirtazapine (Remeron) and phenelzine (Nardil) are also associated with weight gain. The effects of bupropion (Wellbutrin, Zyban) on weight are unclear from clinical trials. Gain was reported when bupropion was used as a smoking deterrent, but both gain and loss occurred when used as an antidepressant. However, anorexia and weight loss occurred at a higher percentage rate than increased appetite and weight gain.

**Antidiabetic Drugs**

Although little attention is paid to the topic in most literature about diabetic drugs, weight gain apparently occurs with insulin, sulfonylureas, and the glitazones (but not with metformin, acarbose, or miglitol). Almost all patients with type 2 diabetes eventually require insulin; those who are failing on oral agents generally gain a large amount of body fat when switched to insulin therapy. Although the mechanism of weight gain is unknown, it may be related to the chronic hyperinsulinism induced by long-acting insulins and the sulfonylureas (which increase insulin secretion). Less weight is gained when oral drugs are given during the day and an intermediate- or long-acting insulin is injected at bedtime. This strategy is thought to cause less daytime hyperinsulinemia than the more traditional insulin strategies.

For near-normal-weight diabetic patients who require drug therapy, a sulfonylurea may be given. However, for obese patients, metformin is usually the initial drug of choice because it does not promote weight gain. Metformin may also be used to treat obese diabetic children, aged 10 to 16 years, who require drug therapy.

**Antiepileptic Drugs**

Weight gain commonly occurs with the use of antiepileptic drugs (AEDs). This has been observed for many years with older drugs (e.g., phenytoin, valproic acid, carbamazepine) and with newer AEDs (e.g., gabapentin, lamotrigine, tiagabine). Mechanisms by which the drugs promote weight gain are unclear but may involve stimulation of appetite and/or a slowed metabolic rate. Consequences of weight gain may include increased risks of diabetes mellitus, hypertension, and other physical health problems as well as psychological distress over appearance, especially in children and adolescents.

**Antihistamines**

Histamine<sub>1</sub> (H<sub>1</sub>) antagonists (e.g., diphenhydramine, loratadine) reportedly increase appetite and cause weight gain.

**Antihypertensives**

The main antihypertensive drugs reported to cause weight gain are the beta blockers. The drugs can cause fatigue and decrease

exercise tolerance and metabolic rate, all of which may contribute to weight gain. Other mechanisms may also be involved. As a result, some clinicians question the use of beta blockers in overweight or obese patients with uncomplicated hypertension. Alpha blockers may also cause weight gain, but apparently at a low incidence. Angiotensin-converting enzyme (ACE) inhibitors and calcium channel blockers are not reported to promote weight gain.

**Antipsychotics**

Weight gain is often reported and extensively documented with antipsychotic drugs. Although the exact mechanism is unknown, weight gain has been associated with antihistaminic effects, anticholinergic effects, and blockade of serotonin receptors. In addition, dietary factors and activity levels may also play significant roles.

Clozapine and olanzapine reportedly cause significant weight gain in 40% or more of patients. Compared with clozapine and olanzapine, risperidone causes less weight gain, and quetiapine and ziprasidone cause the least weight gain. Weight gain may lead to noncompliance with drug therapy. In addition to weight gain, clozapine and olanzapine adversely affect glucose regulation and can aggravate pre-existing diabetes or cause new-onset diabetes. The extent to which these effects are related to weight gain is unknown. For patients who are obese, diabetic, or at risk of developing diabetes, an antipsychotic drug that causes less weight gain would seem the better choice.

**Cholesterol-Lowering Agents**

Weight gain has been reported with the statin group of drugs; mechanisms and extent are unknown.

**Corticosteroids**

Systemic corticosteroids may cause increased appetite, weight gain, central obesity, and retention of sodium and fluid. Inhaled and intranasal corticosteroids have little effect on weight.

**Gastrointestinal Drugs**

Increased appetite and weight gain have been reported with the proton pump inhibitors (PPIs) such as omeprazole and others. The mechanisms and extent are unknown.

**Hormonal Contraceptives**

The weight gain associated with using hormonal contraceptives may be related more to retention of fluid and sodium than to increased body fat.

**Mood Stabilizing Agent**

Weight gain has been reported with long-term use of lithium, with approximately 20% of patients gaining 10 kg (22 lb) or more. This increased weight is attributed to fluid retention, consumption of high-calorie beverages as a result of increased thirst, or a decreased metabolic rate. Weight gain is a common reason for noncompliance with lithium therapy, and weight gain may be more common in women with lithium-induced hypothyroidism and in those who are already overweight.

at risk for becoming overweight, especially those with overweight parents. Overweight is defined as a BMI above the 85th percentile for the age group and obesity as a BMI above the 95th percentile.

Childhood obesity is a major public health concern because these children have or are at risk of developing hypertension, dyslipidemias, type 2 diabetes, and other disorders that may lead to major disability and death at younger adult ages than nonobese children. Obesity, type 2 diabetes, and other health problems are mainly attributed to poor eating habits and too little exercise. In addition, the child who is obese after 6 years of age is highly likely to be obese as an adult, especially if a parent is obese. Obesity in adults that began in childhood tends to be more severe.

In addition to major health problems, reduced energy, and less physical agility, obese children are often ridiculed or bullied by other children and may be discriminated against by adults in schools and workplaces.

## General Characteristics of Drugs for Obesity

The National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health and most other organizations generally recommend reserving drug therapy for those with a BMI of 30 kilograms per square meter or greater and health problems (e.g., hypertension, dyslipidemia, coronary heart disease, type 2 diabetes, sleep apnea) that are likely to improve with weight loss. These organizations emphasize that drug therapy for obesity should be used as part of a weight-management program that also includes a sensible diet, physical activity, and behavioral modification. Guidelines also emphasize that drug therapy should be used to decrease medical risk and improve health rather than promote cosmetic weight loss.

Drug therapy for obesity has a problematic history, mainly because of serious adverse effects and rapid weight regain when the drugs were stopped. Some drugs (fenfluramine, dexfenfluramine, phenylpropanolamine) and a component of many over-the-counter and herbal weight-loss products (ephedra, ma huang) have been taken off the market because of their adverse effects.

Older drugs include amphetamines and similar drugs. Amphetamines (see Chap. 15) are not recommended because they are controlled substances (Schedule II) with a high potential for abuse and dependence. Benzphetamine, diethylpropion, phendimetrazine, and phentermine are adrenergic drugs (see Chap. 17) that stimulate the release of norepinephrine and dopamine in the brain. This action in nerve terminals of the hypothalamic feeding center suppresses appetite. These drugs, called appetite suppressants or *anorexiant*s, are central nervous system (CNS) and cardiovascular stimulants and are contraindicated in cardiovascular disease, hyperthyroidism, glaucoma, and agitated states.

Of the adrenergic anorexiants, only phentermine is commonly used. Sibutramine and orlistat are also commonly used and are the only weight-loss drugs approved for long-term use. According to some clinicians, sibutramine and orlistat may be continued as long as they are effective and adverse effects are tolerable. The drugs are described below; dosage ranges are listed in Table 58-1.

## Individual Drugs

### Phentermine

**Phentermine** (Adipex-P) is the most frequently prescribed adrenergic anorexiants. It is a Schedule IV drug and recommended only for short-term use (3 months or less). Its use is contraindicated in patients with hypertension or other cardiovascular disease and in those with a history of drug abuse. Because it increases blood pressure, phentermine should be used with caution even in patients with mild hypertension. The drug should also be used cautiously in patients with anxiety or agitation because of CNS stimulant effects. The most commonly reported adverse effects are nervousness, dry mouth, constipation, and hypertension.

### Sibutramine

**Sibutramine** (Meridia) is a Schedule IV drug and the most commonly prescribed anti-obesity drug. It inhibits the reuptake of serotonin and norepinephrine in the brain, thereby increasing the amounts of these neurotransmitters. Clinical effects include increased satiety, decreased food intake, and a

Table 58-1

Drugs at a Glance: Drugs for Obesity

#### GENERIC/TRADE NAME

#### ROUTE AND DOSAGE RANGES

##### Appetite Suppressants

**Phentermine hydrochloride** (Adipex-P, Ionamin, Pro-Fast)

PO 8 mg 3 times daily, 30 min before meals, or 15–37.5 mg daily in the morning

**Sibutramine** (Meridia)

PO 10–15 mg once daily, in the morning, with or without food

##### Fat Blocker

**Orlistat** (Xenical, Alli)

PO 120 mg with each main meal, up to 3 capsules daily

faster metabolism rate. Sibutramine is approved by the U.S. Food and Drug Administration (FDA) for long-term use, but effects are mostly unknown beyond 1 to 2 years. The drug increases blood pressure and heart rate and is contraindicated in patients with cardiovascular disorders (e.g., coronary heart disease, dysrhythmias, heart failure, hypertension). It should be used cautiously in patients who take other medications that increase blood pressure and heart rate. It should also be used cautiously in patients with impaired hepatic function, narrow-angle glaucoma (may cause mydriasis), or a history of substance abuse or dependency. Sibutramine is not approved for use in children less than 16 years of age and is not recommended for women who are pregnant or lactating. The drug is contraindicated in people with severe renal or hepatic dysfunction.

Oral sibutramine is rapidly absorbed from the intestine and undergoes first-pass metabolism, during which time active metabolites are formed. Peak plasma levels of the active metabolites occur within 3 to 4 hours, and drug half-life is 14 to 16 hours. The long half-lives of the active metabolites allow for once-daily dosing. The drug is highly bound to plasma proteins and rapidly distributed to most body tissues, with the highest concentrations in the liver and kidneys. It is metabolized in the liver, mainly by the cytochrome P450 3A4 enzymes. The active metabolites produced by first-pass metabolism are further metabolized to inactive metabolites, which are then excreted in urine and feces.

Common adverse effects of sibutramine include dry mouth, headache, insomnia, nervousness, and constipation; cardiovascular effects include hypertension, tachycardia, and palpitations. Potentially serious drug interactions may occur if sibutramine is taken with other cardiovascular stimulants (increased risk of hypertension and dysrhythmias), CNS stimulants (increased anxiety and insomnia), and serotonergic drugs (serotonin syndrome). Other drugs that increase serotonin include the selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac] and related drugs), the triptan antimigraine drugs (e.g., sumatriptan [Imitrex]), dextromethorphan (a common ingredient in cough syrups), and lithium. The combination of sibutramine with any of these drugs may cause serotonin syndrome, a condition characterized by agitation, confusion, hypomania, impaired coordination, loss of consciousness, nausea, tachycardia, and other symptoms.

In clinical trials, people lost the most weight during the first 6 months of sibutramine therapy. However, continued drug therapy helped to maintain weight loss for 12 to 24 months. Most of the clinical trials included diet and behavioral modification techniques in addition to sibutramine therapy. As with other weight-loss drugs, studies indicate that sibutramine therapy is more effective when it is combined with lifestyle modification and diet than when used alone.

## Orlistat

**Orlistat** (Xenical, Alli) differs from phentermine and sibutramine because it decreases absorption of dietary fat from the intestine (by binding to gastric and pancreatic lipases in the gastrointestinal [GI] tract lumen and making them unavailable

to break down dietary fats into absorbable free fatty acids and monoglycerides). The drug blocks absorption of approximately 30% of the fat ingested in a meal; increasing dosage does not increase this percentage. Decreased fat absorption leads to decreased caloric intake, resulting in weight loss and improved serum cholesterol values (e.g., decreased total and low-density lipoprotein [LDL] cholesterol levels). The improvement in cholesterol levels is thought to be independent of weight-loss effects.

Orlistat is not absorbed systemically, and its action occurs in the GI tract. Consequently, it does not cause systemic adverse effects or drug interactions as phentermine and sibutramine do. Its main disadvantages are frequent administration (3 times daily) and GI symptoms (abdominal pain, oily spotting, fecal urgency, flatulence with discharge, fatty stools, fecal incontinence, and increased defecation). Adverse GI effects occur in almost all orlistat users but usually subside after a few weeks of continued drug usage. The drug also prevents absorption of the fat-soluble vitamins, A, D, E, and K. As a result, people taking orlistat should also take a multivitamin containing these vitamins daily. The multivitamin should be taken 2 hours before or after the orlistat dose. If taken at the same time, the orlistat prevents absorption of the fat-soluble vitamins.

Orlistat is intended for people who are clinically obese, not those wanting to lose a few pounds. In addition, high-fat foods still need to be decreased because total caloric intake is a major determinant of weight, and adverse effects (e.g., diarrhea; fatty, malodorous stools) worsen with high fat consumption. Long-term effects of orlistat are unknown. In addition to weight loss and reduced cholesterol levels, clinical trials found reduced severity and improved management of other health problems associated with obesity, such as diabetes and hypertension. In general, the addition of orlistat therapy to diet and other lifestyle changes produced greater weight loss than addition of a placebo. In some patients with impaired glucose tolerance, weight loss with orlistat and lifestyle changes prevented or delayed the occurrence of diabetes mellitus. After the medication was stopped, most patients regained weight.

### Applying Your Knowledge 58-1

Ms. Vargas asks how orlistat will help her when nothing else in the past has been successful. How would you respond?

## Herbal and Dietary Supplements

Many people use herbal or dietary supplements for weight loss, even though reliable evidence of safety and effectiveness are lacking. Some herbal products claim to decrease appetite and increase the rate at which the body burns calories. However, in most cases, there is no scientific evidence that they work at all. Some supplements for weight loss contain cardiovascular and

CNS stimulants that may cause serious, even life-threatening, adverse effects.

In general, many consumers do not seem to appreciate the benefits of proven weight-management techniques (e.g., appropriate diet and exercise) or the potential risks of taking unproven weight-loss products. Selected products are described below.

**Glucomannan** expands on contact with body fluids. It is included in weight-loss regimens because of its supposed ability to produce feelings of stomach fullness, thereby causing a person to eat less. It also has a laxative effect. There is little evidence to support its use as a weight-loss aid. Products containing glucomannan should not be used by people with diabetes; glucomannan may cause hypoglycemia alone and increases hypoglycemic effects of antidiabetic medications.

**Guarana**, a major source of commercial caffeine, is found in weight-loss products as well as caffeine-containing soft drinks, “energy” drinks, bodybuilding supplements, smoking-cessation products, vitamin supplements, candies, and chewing gums. Caffeine is the active ingredient; the amount varies among products, and caffeine content of any particular product cannot be accurately predicted. Guarana is promoted to decrease appetite and increase energy and mental alertness. It is contraindicated in patients with dysrhythmias and may aggravate gastroesophageal reflux disease (GERD) and peptic ulcer disease.

Adverse effects include diuresis, cardiovascular symptoms (premature ventricular contractions, tachycardia), CNS symptoms (agitation, anxiety, insomnia, seizures, tremors), and GI symptoms (nausea, vomiting, diarrhea). Such effects are more likely to occur with higher doses or concomitant use of guarana and other sources of caffeine. Adverse drug–drug interactions include additive CNS and cardiovascular stimulation with beta-adrenergic agonists (e.g., epinephrine, albuterol and related drugs, pseudoephedrine) and theophylline. In addition, concurrent use of cimetidine, fluoroquinolones, or oral contraceptives may increase or prolong serum caffeine levels and subsequent adverse effects.

**Guar gum** is a dietary fiber included in weight-loss products because it is bulk forming and produces feelings of fullness. Several small studies indicated it is no more effective than placebo for weight loss. It may cause esophageal or intestinal obstruction if not taken with an adequate amount of water and may interfere with the absorption of other drugs if taken at the same time. Adverse effects include nausea, diarrhea, flatulence, and abdominal discomfort.

**Hydroxycitric acid** (in Citrimax and other supplements) apparently suppresses appetite in animals, but there are no reliable studies that indicate its effectiveness in humans. One 12-week study did not show weight loss.

**Laxative and diuretic herbs** (e.g., aloe, rhubarb root, buckthorn, cascara, senna, parsley, juniper, dandelion leaves) are found in several products such as Super Dieter’s Tea, Trim-Maxx Tea, and Water Pill. These products cause a significant loss of body fluids and electrolytes, not fat. Adverse effects may

include low serum potassium levels, with subsequent cardiac dysrhythmias and other heart problems. In addition, long-term use of laxatives may lead to loss of normal bowel function and the necessity for continued use (i.e., laxative dependency).

## Nursing Process

### Assessment

Assess each overweight or obese patient for factors contributing to overweight and health risks related to excess weight, regardless of the reason for the contact. Some specific assessment factors include the following:

- Assess usual drinking and eating patterns, including healthful (e.g., whole-grain breads and cereals, fruits, vegetables, low-fat dairy products) and unhealthful (e.g., sugar-containing beverages and desserts, fried foods, saturated fat, fast foods, high-calorie snack foods) intake. The best way is to ask the patient to keep a food diary for 2 or 3 days. If food intake is not written down, people tend to underestimate the amount and caloric content. (If available, consult a nutritionist to assess a patient’s diet and work with the patient to improve health and weight status.)
- Assess any obviously overweight person for health problems caused or aggravated by excessive weight (e.g., elevated blood pressure, other cardiovascular problems, diabetes mellitus, sleep apnea, osteoarthritis and other musculoskeletal disorders).
- Calculate the body mass index (see Box 58-1) and measure waist circumference.
- Check available reports of laboratory tests. Overweight patients may have abnormally high values for total and LDL cholesterol, triglycerides, and blood sugar and low values for high-density lipoprotein (HDL) cholesterol. If no laboratory reports are available, ask patients if a health care provider has ever told them they have high cholesterol or blood sugar.
- List all prescription and nonprescription medications being taken and ask about vitamins, herbals, and other dietary supplements. Review the list for drugs used to treat health problems associated with obesity, drugs that may promote weight gain, and any products that may be used to promote weight loss.
- Assess usual patterns of physical activity and exercise, including work and recreational activities.
- Assess motivation to develop and adhere to a weight-management plan. Ask if there are concerns about weight; if there is interest in a weight-management program to improve health; and what methods, over-the-counter products, or herbal or dietary supplements have been previously used to reduce weight, if any. The nurse must be very tactful in eliciting information and assessing whether

a patient would like assistance with weight management. If the nurse–patient contact stems from a health problem caused or aggravated by excessive weight, the nurse may use this information to help motivate the patient to lose weight and improve health.

## Nursing Diagnoses

- Imbalanced Nutrition: More Than Body Requirements related to excessive caloric intake
- Disturbed Body Image related to excessive weight gain
- Deficient Knowledge: Weight management

## Planning/Goals

The patient will

- Reduce the impact of excessive weight on chronic health problems
- Modify lifestyle behaviors toward weight loss and weight maintenance at a more healthful level
- Avoid overuse of anorexiants
- Avoid unproven weight-loss dietary supplements

## Interventions

- Support programs/efforts to help promote a healthful lifestyle and prevent obesity (e.g., in families and schools).
- Serve as a role model by maintaining a healthful lifestyle and weight.
- Serve as a reliable source of information about weight loss and weight-loss products and programs.
- For an obese patient who reports interest and motivation in losing weight, assist to formulate realistic goals. Patients often expect to rapidly lose large amounts of weight with little or no effort. Most treatment programs result in a weight loss of 10% of body weight or less.
- Discuss health risks of obesity and anticipated benefits of achieving and maintaining a healthier weight. Emphasize that losing 5% to 10% of body weight is a reasonable goal and can significantly reduce the medical problems associated with being overweight.
- Assist patients to identify factors that support weight-loss efforts (e.g., family and friend encouragement) and factors that sabotage weight-loss efforts (e.g., having high-calorie foods readily available, frequently eating at fast-food restaurants).
- Promote exercise and activity. For overweight and obese patients, exercise may decrease appetite and distract from eating behaviors as well as increase calorie expenditure. For very sedentary, physically unfit patients, emphasize that any exercise can be beneficial and to start slowly, increasing the amount and intensity as physical condition improves.
- Encourage any efforts toward improving diet and increasing exercise to improve health.

- Weigh patients at regular intervals and measure waist circumference periodically.
- Refer patients to a nutritionist when indicated.
- Be alert for the psychological consequences of obesity and refer patients for counseling if indicated.
- Refer overweight and obese children to pediatric obesity specialists when possible.

## Evaluation

- Observe overweight or obese patients for food intake, weight loss, decreased waist circumference, and appropriate use of exercise and anorexiants.

## Applying Your Knowledge 58-2

In addition to proper administration of her medication, what strategies should you review with Ms. Vargas to assist her in being successful with weight loss?

## Principles of Therapy

### Strategies to Prevent Becoming Overweight and Obese

Preventing excessive weight gain is a major struggle for many Americans as they fight the “battle of the bulge” daily. Many people want to lose weight, often more for appearance than for health. However, many are also unwilling or unable to adapt their lifestyles toward more healthful eating, exercising, and weight-controlling habits. As a result, millions of dollars are spent annually on weight-loss diets, products, and programs in an effort to find an easy way to lose weight. Health care providers need to promote efforts to prevent overweight and obesity when possible. When prevention is not possible, efforts should be aimed toward early recognition and treatment, before obesity and major health problems develop. Some strategies include the following:

- Personally practice a healthful lifestyle, primarily for one’s own health and well-being, but also to serve as a role model and proponent for healthful practices in daily life.
- Provide or assist others to obtain reliable information about healthful lifestyle habits. For example, the U.S. Department of Health and Human Services and the Department of Agriculture publish *Dietary Guidelines for Americans* every 5 years. The 2005 update is available online at [www.healthier.us.gov/dietaryguidelines](http://www.healthier.us.gov/dietaryguidelines). Selected recommendations are listed in Patient Teaching Guidelines.
- Use reliable resources for information about nutrition and weight management (Box 58-4).
- Read labels on food products and minimize the use of high-calorie products.
- Reduce fat, sugar, and salt when preparing meals.

## Patient Teaching Guidelines

## Weight Management and Drugs That Aid Weight Loss

### General Considerations

- Because of the extensive health problems associated with overweight and obesity, individuals whose weight is within a normal range should try to prevent excessive weight gain by practicing a healthful lifestyle in terms of diet and exercise. Following are selected recommendations from the *Dietary Guidelines for Americans 2005*, published by the U.S. Department of Health and Human Services and the Department of Agriculture in January 2005 (updated every 5 years; available online at [www.healthierus.gov/dietaryguidelines](http://www.healthierus.gov/dietaryguidelines)).
  1. Eat a variety of foods daily (e.g., 6–11 servings of whole-grain bread and cereals, 2 cups of fruit, 2 1/2 cups of vegetables, three or more servings of low-fat milk or other dairy products). Also limit intake of saturated fat (e.g., in meats and whole-milk dairy products), trans fats (e.g., hydrogenated oils in many commercial baked goods and other products), cholesterol, added sugars, salt, and alcohol. With trans fats, the amount in commercial products must be listed on the Nutrition Facts label. In addition, many restaurants have reduced or eliminated trans fats in their cooking oils. Canola oil and olive oil are healthy fats, but they have a high calorie content (120 calories per tablespoon), which must be considered in weight control efforts.
  2. To maintain body weight in a healthy range, balance diet (i.e., calories gained) with exercise (i.e., calories used). To prevent gradual weight gain over time, make small decreases in food and beverage calories and increase physical activity. Engage in regular physical activity and reduce sedentary activities to promote health, psychological well-being, and a healthy body weight. To reduce the risk of chronic disease, engage in at least 30 to 60 minutes of moderate-intensity physical activity, above usual activity, at work or home on most days of the week. For most people, greater health benefits can be obtained by engaging in physical activity of more vigorous intensity or longer duration.
  3. Physical fitness can be developed or improved by including cardiovascular conditioning, stretching exercises for flexibility, and resistance exercises or calisthenics for muscle strength and endurance.
- Individuals who are already overweight or obese should try to lose weight and maintain a lower weight because the likelihood of serious health problems and early death increases as weight increases. However, try to emphasize goals for improvement in health status rather than losing a large amount of weight. Remember that even a modest weight loss of 10 to 30 lbs can benefit your health. Most people are unlikely to achieve their “ideal” weight, and having unrealistic expectations sets one up for failure in any weight-loss program.
- Obesity is considered a chronic disease that requires long-term treatment, much like the treatment of diabetes and hypertension. Weight loss can be induced by severe calorie restriction, but without lifestyle changes (e.g., in eating and activity behavior), body fat is invariably regained. The safest and most effective way to lose weight and keep it off is permanent lifestyle changes that involve eating less and exercising more. Reducing caloric intake by 500 to 1000 calories per day allows the loss of 1 to 2 lb of fat per week, respectively. Higher levels of physical activity can help with weight loss and prevent weight regain. Additional health benefits include lower rates of cardiovascular disease and death.
- Use available resources. For example, if unable to implement needed changes alone, consult a nutritionist, qualified obesity expert, or behavioral therapist. Such clinicians can help modify the eating, activity, and thinking habits that predispose to obesity.
- In addition to feeling better, health benefits of weight loss may include reduced blood pressure, reduced blood fats, less likelihood of having a heart attack or stroke, and less risk for development of diabetes mellitus.
- Any weight loss program should include a nutritionally adequate diet with decreased calories and increased exercise.
- Regular physical examinations and follow-up care are needed during weight loss programs.
- Although many weight-loss supplements are available and heavily advertised in newspapers, magazines, and television, none is considered safe and effective and none is recommended for use. If you do choose to use any of these products, notify your primary health care provider. Depending on your condition (i.e., whether you have chronic health problems such as diabetes mellitus, hypertension, or others), the medications you take, and so forth, some weight-loss supplements can be harmful to your health.
- Diet and exercise are recommended for people who want to lose a few pounds. Medications to aid weight loss are usually recommended only for people whose health is endangered (i.e., those who are overweight and have other risk factors for heart disease, and those who are obese).
- Read package inserts and other available information about the drug being taken, who should not take the drug, instructions and precautions for safe usage, and so forth. Keep the material for later reference if questions arise. If unclear about any aspect of the information, consult a health care provider before taking the drug.
- Appetite-suppressant drugs must be used correctly to avoid potentially serious adverse effects. Because most of these drugs stimulate the heart and the brain, adverse effects may include increased blood pressure, fast heartbeat, irregular heartbeat, heart attack, stroke, dizziness, nervousness, insomnia (if taken late in the day), and mental confusion. In addition, prolonged use of prescription drugs may lead to psychological dependence.
- Avoid over-the-counter decongestants and allergy, asthma, cold remedies, and weight-loss herbal or dietary supplements when taking a prescription appetite suppressant. The combination can cause serious adverse effects from excessive heart and brain stimulation.
- Inform health care providers when taking an appetite suppressant, mainly to avoid other drugs with similar effects.
- Orlistat (Xenical) is not an appetite suppressant and does not cause heart or brain stimulation. It works in the intestines to keep fats in foods from being absorbed. It should be taken with a low-fat diet. Adverse effects include fatty stools and bloating. It is available over-

the-counter as Alli, with the recommended dosage one-half that of prescription Xenical.

#### Self-Administration

- Take appetite suppressants in the morning to decrease appetite during the day and avoid interference with sleep at night.
- Do not crush or chew sustained-release products.
- With sibutramine (Meridia):
  - Take once daily, with or without food.
  - Have blood pressure and heart rate checked at regular intervals (the drug increases them).
- Notify a health care provider if a skin rash, hives, or other allergic reaction occurs.
- With orlistat (Xenical, Alli):
  - Take one capsule with each main meal or up to 1 hour after a meal, up to three capsules daily. If you miss a meal or eat a meal with no fat, you may omit a dose of orlistat.
  - Take a multivitamin containing fat-soluble vitamins (A, D, E, and K) daily, at least 2 hours before or after taking orlistat. Orlistat prevents absorption of fat-soluble vitamins from food or multivitamin preparations if taken at the same time.

## Management of Overweight and Obese Patients

Treatment options for obesity include diet, exercise, behavioral modification, drug therapy, and, if these options fail, possibly referring a patient for bariatric (weight-loss) surgery. The safest and most effective treatment for most people usually includes a combination of diet, exercise, and behavioral modification. Drug therapy and bariatric surgery are recommended only for seriously overweight people with major medical problems that can be improved by weight loss. In addition, neither of these treatments is a substitute for the necessary changes in eating and physical activity patterns.

The NHLBI issued a report entitled “Clinical Guidelines on the Identification, Evaluation and Treatment of Over-

weight and Obesity in Adults,” which is available at [www.nhlbi.nih.gov/guidelines/obesity/ob\\_gdlns.htm](http://www.nhlbi.nih.gov/guidelines/obesity/ob_gdlns.htm); its recommendations are summarized in Box 58-5.

In addition to the NHLBI guidelines, additional recommendations and comments include the following:

- Emphasize health benefits of weight reduction. There is strong evidence that weight loss reduces risk factors for cardiovascular disease, including blood pressure, serum triglycerides, and total and LDL cholesterol. It also increases HDL cholesterol. In addition, in overweight and obese people without diabetes, weight loss reduces blood glucose levels and the risk for development of type 2 diabetes.
- For people who already have type 2 diabetes, weight loss reduces blood levels of glucose and glycosylated ( $A_{1c}$ ) hemoglobin. These effects make the diabetes easier to manage, reduce complications of diabetes, and may allow smaller doses of antidiabetic medications. For people who already have hypertension, losing excess weight reduces blood pressure and may reduce the number or amount of antihypertensive drugs. For people who already have dyslipidemias, blood lipid profiles improve with weight loss.
- Weight-loss diets wax and wane in popularity with the American public (Box 58-6). Although all of them can lead to weight loss if adhered to long enough, some are healthier than others and most are discarded before significant weight loss is achieved. Actually, any diet that reduces caloric intake in relation to caloric expenditure can lead to weight loss, and adherence is probably more important than the particular diet. Regardless of what some diet gurus and others say, total caloric intake must be considered because it is a major determinant of weight loss, gain, or maintenance.
- Various formula diets or meal-replacement programs are available. The good ones contain high-quality protein, sugar as fructose, and a moderate amount of monounsaturated fat. The usual recommendation is to replace two meals daily for weight loss and one meal for weight maintenance. They can also be used as single meal replacements.
- Although both calorie-reduced diets and sufficient exercise can lead to weight loss and maintenance, the NHLBI guide-

## Box 58-5

## NHLBI Report: “Clinical Guidelines on the Identification, Evaluation and Treatment of Overweight and Obesity in Adults”

- Weight loss reduces health problems of individuals: decrease blood pressure if hypertensive; lower elevated levels of total cholesterol, LDL cholesterol, and triglycerides and raise low levels of HDL cholesterol if dyslipidemic; lower elevated blood glucose levels in persons with type 2 diabetes.
- BMI is used to assess overweight and obesity and to estimate disease risks. Measure waist circumference initially and periodically to assess abdominal fat content. Weigh regularly to monitor body weight for gain, loss, or maintenance.
- The initial goal of weight-loss therapy should be to reduce body weight by about 10% from baseline, at a rate of 1 to 2 pounds per week for a period of 6 months. Steady weight loss over a longer period reduces fat stores in the body, limits the loss of vital protein tissues, and avoids the sharp decline in metabolic rate that accompanies rapid weight loss. After weight loss, weight maintenance should be the priority goal, because weight regain is a problem with all weight-loss programs. In some cases, after a period of weight maintenance, additional losses may be desirable.
- Dietary recommendations include low-calorie diets for weight loss, mainly reducing caloric intake by 500 to 1000 calories daily. Reducing dietary fat can reduce calories. However, reducing dietary fat without reducing total caloric intake does not produce weight loss. Vitamin and mineral supplements that meet age-related requirements are usually recommended with weight-loss programs that provide less than 1200 kcal for women or 1800 kcal for men.
- Physical activity recommendations should be part of any weight-management program because physical activity contributes to weight loss, may decrease abdominal fat, increases cardiorespiratory fitness, and helps with weight maintenance. Initially, physical activity for 30 to 45 minutes, 3 to 5 days a week, is encouraged. Long-term, adults should try to accumulate at least 30 minutes or more of moderate-intensity physical activity on most days of the week.
- In general, weight-loss and weight-maintenance programs should combine reduced-calorie diets, increased physical activity, and behavior therapy. After weight loss, weight-loss maintenance with dietary therapy, physical activity, and behavior therapy should be continued indefinitely. Drug therapy can also be used. However, drug safety and efficacy beyond 1 to 2 years of total treatment have not been established.
- Behavioral modification can be helpful in a weight-loss program. The goals are to help patients modify their eating, activity, and thinking habits that predispose to obesity. Techniques include identifying triggers that promote overeating and barriers that keep one from adopting a more healthful lifestyle. One strategy is keeping an accurate record of food/calorie intake and physical activity (most people tend to underestimate food intake and overestimate activity). In addition, stress management, stimulus control, and social support are helpful. Patients who eat more when stressed can learn to manage stress more healthfully. Counseling by a behavioral therapist may be needed. Stimulus control has to do with avoiding or minimizing circumstances that promote overeating (e.g., cooking calorie-dense foods; having high-calorie snacks and “junk food” readily available; eating high-fat, high-calorie foods at fast-food restaurants). Social support involves family, friends, co-workers, and fellow dieters who encourage weight-loss efforts rather than sabotage them by urging one to eat high-calorie foods. In general, weight-loss regimens that use several of these strategies are more effective.

lines are based on studies indicating that a combination of the two strategies is more effective than either alone. However, many overweight and obese people may be physically unfit and unable or unwilling to increase activity. Thus, activity should be started slowly and gradually increased, with the goal of exercise becoming part of the daily routine. Aerobic exercise increases the metabolic rate during and for approximately 1 hour after activity. Consistent adherence to a reduced-calorie diet and exercise routine is a major factor in achieving weight control and health benefits.

- For any patients following a weight-loss regimen, provide psychological support and positive reinforcement for efforts toward weight management. Programs or support groups involving supervision or regular participation within a social group appear to be more successful over time.

However, a systematic review that evaluated major commercial weight-loss programs found few high-quality studies. In general, there was more evidence of success with the Weight Watchers program than with Health Management Resources, OPTIFAST, Jenny Craig, or L.A. Weight Loss.

- There seems to be increasing support for the long-term use of weight-loss medications in treatment of obesity. When drug therapy is indicated, a single drug in the lowest effective dose is recommended. As with most other drugs, low doses decrease risks of adverse drug effects. In addition, the National Institutes of Health do not recommend combining weight-loss medications except in the context of clinical trials. Thus far, studies indicate that combining sibutramine and orlistat has no additional benefit over using one of the drugs alone.

## Box 58-6

## Characteristics of Selected Diets

Various diets all work if total caloric intake is less than energy expenditure. Many diets are quite restrictive, however, and most people soon drop out and rapidly regain the weight they lost. As a result, the best “diet” is nutritionally adequate except for calories and is one the person can follow long term.

**Low calorie.** These diets provide 1200 to 1600 kcal per day.

The usual recommendation is to reduce caloric intake by 500 to 1000 calories daily, to allow weight loss of 1 to 2 lb weekly. This rate of loss is likely to be more successful in terms of weight loss, and continuing a reduced-calorie diet promotes weight maintenance rather than weight regain.

*Note that losing weight through diet alone, without increased physical activity, is unlikely to improve cardiovascular health.*

**Very-low calorie.** These diets usually consist of 800 calories or fewer per day. Numerous commercial products that promise “magical” results have been marketed. These diets result in rapid initial weight losses due mainly to diuresis and loss of sodium and water. Multiple health risks accompany such diets, including abnormalities in electrolytes, trace elements, and vitamins; gout; gallstones; cold intolerance; fatigue; lightheadedness; anemia; menstrual irregularities; and other problems.

The National Institutes of Health (NIH) recommends against using diets that provide fewer than 800 calories daily. If used at all, very-low-calorie diets should be used intermittently, for short periods, with a diet that maintains weight and is more nutritionally adequate.

**Low fat.** These diets do not cause significant weight loss unless caloric intake is reduced. Because fats are energy dense (9 cal/g), reducing fat is a practical way to reduce caloric intake. For both health and weight loss, current recommendations emphasize reducing intake of “bad” fats (e.g., saturated and trans fats) but including healthy mono- and polyunsaturated fats (e.g., olive and canola oil) within the caloric allotment.

**Low carbohydrate.** The weight loss that occurs with these diets (e.g., Atkins and South Beach) is attributed to caloric reduction or water loss rather than to the carbohydrate restriction. There have been no studies evaluating the long-term safety of these diets. In addition, numerous adverse effects may occur (e.g., constipation, dehydration, dyslipidemia, electrolyte imbalance, headache, aggravation of renal impairment, and hyperuricemia leading to gout).

## Applying Your Knowledge 58-3

Ms. Vargas says she needs to lose 140 pounds and would like to accomplish this by her next birthday. How should you respond?

## Management of Obesity in Special Populations

### Managing Obesity in Children

Children in general need increased amounts of protein, carbohydrate, and fat in proportion to their size to support growth and increased physical activity. However, reports of childhood obesity have greatly increased over recent years, and childhood obesity has become a major public health concern. Therefore, the goal of nutrition is to meet needs without promoting obesity. When possible, specialists in childhood obesity should design and supervise treatment programs.

Efforts are needed toward both prevention and treatment of childhood obesity. Prevention should focus on identifying at-risk and overweight children and adolescents at an early stage, educating families about the health consequences of being overweight, and encouraging weight-control measures (e.g., a more active lifestyle, a low-fat diet, regular meals, avoidance of high-calorie snacks, drinking water instead of calorie-containing beverages, decreasing the time spent watch-

ing television and playing computer games). These measures are implemented successfully mainly within a family unit, and family support is needed to assist the child in weight control and a more healthful lifestyle. In addition, schools should teach children the basic principles of good nutrition and why eating a balanced diet is important to health.

Pediatric clinicians recommend treatment for children and adolescents who are overweight and have complications of obesity and for all children who are obese. Treatment of childhood obesity should focus on healthy eating and increasing physical activity. In general, children should not be put on “diets.” For a child who is overweight, the recommended goal is to maintain weight or slow the rate of weight gain so that weight and BMI gradually decline as the child grows in height. If the child has already reached his or her anticipated adult weight, maintenance of that weight and prevention of additional gain should be the long-term treatment goal. If the child already exceeds the optimal adult weight, the goal of treatment should be a slow weight loss of 10 to 12 pounds per year until the optimal adult weight is reached. As with adults, increased activity is required for successful weight loss or management in children.

Family involvement and support are vital to children’s weight management. Actually, the goal beyond weight control for a child is to develop healthier eating and exercise habits for long-term health benefits for the entire family. Studies indicate that children who eat adequate amounts of fruits, vegetables, and dairy products tend to continue these healthy eating

habits. In general, young children who learn to eat a healthy diet are likely to reap the benefits throughout their lives. Improved diets and increased activity are unlikely to occur without active participation of parents and other caregivers.

Although drug therapy has not been generally recommended for treatment of childhood obesity, orlistat is approved for use in children aged 12 to 16 years and is considered safe and effective for weight reduction in overweight adolescents. As with adults, common adverse effects in clinical trials were gastrointestinal (e.g., diarrhea, flatulence) and reduced concentrations of fat-soluble vitamins. Sibutramine has not been studied in children under 16 years of age but is effective in reducing weight in adolescents. However, the drug may cause severe adverse effects (e.g., elevated blood pressure, tachycardia, depression, and suicidal ideations) and must be used cautiously. Metformin is undergoing investigation as a weight-loss drug in obese adolescents, both in nondiabetics and in those who have developed insulin resistance or type 2 diabetes.

### Managing Obesity in Older Adults

Overweight and obesity are common among older adults. Although caloric needs are usually decreased, primarily because of slowed metabolism and decreased physical activity, most people continue usual eating patterns. With the high incidence of atherosclerosis and cardiovascular disease in older adults, it is especially important that intake of saturated and trans fats be reduced. Anorexiants should be used very cautiously, if at all, because older adults often have cardiovascular, renal, or hepatic impairments that increase risks of adverse drug effects. With orlistat, the manufacturer recommends conservative use and dosage because older adults often have decreased renal, cardiac, and hepatic function.

### Managing Obesity in Patients With Renal Impairment

In relation to drugs for obesity, little information is available about their use in patients with renal impairment. With sibutramine, dosage reductions are not recommended with mild to

moderate impairment because the drug and its active metabolites are eliminated by the liver. However, some inactive metabolites are also formed and these are excreted renally. The drug is contraindicated in patients with severe renal impairment.

### Managing Obesity in Patients With Hepatic Impairment

In relation to drugs for obesity, little information is available about their use in patients with hepatic impairment. Because sibutramine is metabolized in the liver, it is contraindicated in patients with severe hepatic impairment.

### Managing Obesity in Home Care

The home care nurse may be involved with weight-management issues in almost any home care setting. Because nutrition, exercise, and weight control are so important to health, the home care nurse should take advantage of any opportunity for health promotion in this area. Health promotion may involve assessing the nutritional and fitness status of all members of the household and providing counseling or other assistance to improve health status. Those who are obviously overweight or who have obesity-related health problems must be approached with diplomacy and tact; they have probably tried repeatedly to lose weight and been told by previous health care providers that they need to lose weight. The home care nurse should be able to provide accurate information about realistic and successful techniques for losing weight and keeping it off; health benefits of even modest weight loss; and reasons to avoid “fad” diets, weight-loss herbal and dietary supplements, and programs that promise rapid and easy weight loss with little effort.

### Applying Your Knowledge 58-4

#### How Can You Avoid This Medication Error?

Ms. Vargas' prescription is for orlistat three times a day. She takes the dose with breakfast, lunch, and dinner. She has a meeting today that runs through lunch and so she skips lunch but takes her pill on time.

## Nursing Actions Drugs for Weight Loss and Maintenance

### NURSING ACTIONS

#### 1. Administer accurately

- a. With phentermine:
  - (1) Give single-dose drugs in the early morning.
  - (2) Give multiple-dose preparations 30 minutes before meals and the last dose of the day about 6 hours before bedtime.
- b. With sibutramine, give once daily, in the morning.
- c. With orlistat, give one capsule with each main meal or up to 1 hour after a meal, up to three capsules daily. If a meal is missed or contains no fat, the dose can be omitted.

### RATIONALE/EXPLANATION

For maximum appetite-suppressant effects during the day  
For maximum appetite-suppressant effects at mealtime and to avoid interference with sleep from the drug's stimulating effects on the central nervous system (CNS)

The drug needs to be in the gastrointestinal tract when fat-containing foods are eaten, to prevent fat absorption.

NURSING ACTIONS	RATIONALE/EXPLANATION
<p><b>2. Observe for therapeutic effects</b></p> <p>a. With phentermine and sibutramine, observe for decreased caloric intake and weight loss.</p> <p>b. With orlistat, observe for weight loss and improvements in health status (e.g., reduced LDL cholesterol, elevated HDL cholesterol, improved glycemic control, and reduced blood pressure).</p>	<p>The recommended rate of weight loss is 1–2 lb weekly.</p> <p>Most weight loss occurs in the first 6 months of therapy, but the reduced weight can be maintained as long as orlistat is continued. The metabolic improvements are very beneficial for people with obesity-related health problems such as diabetes, dyslipidemia, hypertension, and metabolic syndrome.</p>
<p><b>3. Observe for adverse effects</b></p> <p>a. With phentermine and sibutramine, observe for:</p> <p>(1) Nervousness, insomnia, hyperactivity</p> <p>(2) Hypertension</p> <p>(3) Development of tolerance to appetite-suppressant effects</p> <p>b. With orlistat, observe for abdominal cramping, gas pains, diarrhea, and fatty stools.</p>	<p>These effects result from excessive stimulation of the CNS. They are more likely to occur with large doses or too-frequent administration.</p> <p>Anorexiants stimulate the sympathetic nervous system and may cause or aggravate hypertension. This usually occurs within 4–6 weeks and is an indication for discontinuing drug administration. Continued administration and/or large doses do not maintain appetite-suppressant effects. Instead, they increase the incidence of adverse effects. These effects commonly occur. They usually improve within a few weeks of continued drug use, but worsen with a high intake of dietary fat, which should be avoided.</p>
<p><b>4. Observe for drug interactions</b></p> <p>a. Drugs that increase effects of phentermine and sibutramine:</p> <p>(1) Antidepressants, tricyclic</p> <p>(2) Other CNS stimulants</p> <p>(3) Other sympathomimetic drugs (e.g., epinephrine)</p> <p>b. Drugs that decrease effects of phentermine and sibutramine:</p> <p>(1) Antihypertensive drugs</p> <p>(2) CNS depressants (e.g., alcohol)</p> <p>c. Drugs that increase effects of sibutramine:</p> <p>(1) Adrenergics (e.g., epinephrine, pseudoephedrine)</p> <p>(2) Antidepressants (tricyclic antidepressants [TCAs; e.g., amitriptyline], selective serotonin reuptake inhibitors [SSRIs; e.g., fluoxetine])</p> <p>(3) Antifungals (e.g., itraconazole and related azoles)</p> <p>(4) Antimigraine triptans (e.g., sumatriptan)</p> <p>(5) Lithium</p>	<p>May increase hypertensive effects</p> <p>Additive stimulant effects</p> <p>Additive hypertensive and other cardiovascular effects</p> <p>Decrease blood pressure-raising effects of anorexiant</p> <p>Antagonize or decrease effects</p> <p>Additive increases in blood pressure</p> <p>TCAs and sibutramine increase levels of norepinephrine and serotonin in the brain; SSRIs increase serotonin levels. Concurrent use of these drugs may cause excessive CNS stimulation, hypertension, and serotonin syndrome and should be avoided.</p> <p>Decrease metabolism and may increase adverse effects and toxicity of sibutramine</p> <p>Additive serotonin effects</p> <p>Additive serotonin effect</p>

## Key Concepts

- Overweight and obesity are major concerns because of their association with numerous health problems, including diabetes, hypertension, other cardiovascular disorders, and muscle and joint disorders.
- Ingesting 500 calories more per day than those used in exercise and physical activity leads to a weight gain of one pound in 1 week; decreasing caloric intake or increasing caloric output of 500 calories per day for 1 week leads to a weight loss of one pound.
- Reducing caloric intake and increasing caloric expenditure are part of any successful weight-loss program.

- Weight-loss drugs are generally recommended only for people who are seriously overweight or have health problems associated with or aggravated by obesity.
- Many people lose weight but regain it within a few months if they do not change their lifestyle habits toward eating more healthfully and exercising more.

## Review and Application Exercises

### Short Answer Exercises

1. Calculate the BMI for yourself, one or more members of your family, or a patient.
2. Assess eating and physical activity habits of yourself, one or more members of your family, or a patient. In general, do these habits promote health or obesity?
3. If you, the family member, or the patient has health problems related to overweight and obesity, list at least three things that can be done to improve health.
4. Debate whether or not it is important that health care providers demonstrate healthful practices in diet, exercise, and weight control to the general public.
5. With an overweight or obese patient who wants to lose weight, what are some nursing interventions to assist and support the patient?
6. List advantages and disadvantages of drug therapy for weight loss or maintenance.
  - c. is required for weight loss.
  - d. focuses on high-fat, high-carbohydrate foods
8. Drug therapy for weight management may be prescribed for patients with which of the following?
  - a. BMI of 22 and a desire to lose 10 pounds
  - b. BMI of 24.5 and physically fit
  - c. BMI of 27 or more with weight-related health problems
  - d. BMI of 25–29 and healthy
9. Sibutramine (Meridia) may be contraindicated for patients with which of the following disorders?
  - a. cardiovascular disease
  - b. diabetes mellitus
  - c. chronic fatigue syndrome
  - d. gastroesophageal reflux disease
10. Orlistat (Xenical) aids weight loss by
  - a. decreasing appetite
  - b. increasing satiety and feelings of fullness
  - c. increasing metabolism
  - d. decreasing absorption of dietary fat
11. To decrease diarrhea with orlistat (Xenical), a patient should be instructed to
  - a. avoid large amounts of fatty foods.
  - b. drink eight glasses of water daily.
  - c. avoid caffeine-containing beverages.
  - d. increase physical activity.

### NCLEX-Style Questions

7. In counseling a patient about weight loss diets, the nurse knows that a recommended low-calorie or reduced-calorie diet
  - a. provides about 500 to 800 kcal per day.
  - b. reduces daily intake to about 1800 kcal per day.

# Drugs Used for Peptic Ulcer and Acid Reflux Disorders

## KEY TERMS

- Antacids
- Duodenal ulcers
- Gastric ulcers
- Gastritis
- Gastroesophageal reflux disease (GERD)
- *Helicobacter pylori*
- Histamine<sub>2</sub> receptor antagonists (H<sub>2</sub>RAs)
- Hydrogen, potassium adenosine triphosphatase
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Peptic ulcer disease
- Proton pump inhibitors (PPIs)
- Stress ulcers
- Zollinger-Ellison syndrome

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the main elements of peptic ulcer disease and gastroesophageal reflux disease (GERD).
2. Differentiate the types of drugs used to treat peptic ulcers and acid reflux disorders.
3. Discuss the advantages and disadvantages of proton pump inhibitors.
4. Differentiate between prescription and over-the-counter uses of histamine<sub>2</sub> receptor blocking agents.
5. Discuss significant drug–drug interactions with cimetidine.
6. Describe characteristics, uses, and effects of selected antacids.
7. Discuss the rationale for using combination antacid products.
8. Teach patients nonpharmacologic measures to manage peptic ulcers and GERD.

## Apply Your Knowledge

Kathleen Daniels is a 54-year-old woman who has chronic GERD. She is prescribed rabeprazole 20 mg PO daily. She also takes OTC famotidine 10 mg twice a day as needed to control her heartburn. When needed, she also takes Mylanta 5 mL.

## Introduction

Drugs to prevent or treat peptic ulcer and acid reflux disorders consist of several groups of drugs, most of which alter gastric acid and its effects on the mucosa of the upper gastrointestinal (UGI) tract. To aid understanding of drug effects, peptic ulcer disease and gastroesophageal reflux disease (GERD) are described below; related UGI disorders are described in Box 59-1.

## Peptic Ulcer Disease

*Peptic ulcer disease* is characterized by ulcer formation in the esophagus, stomach, or duodenum, areas of the gastrointestinal (GI) mucosa that are exposed to gastric acid and pepsin. *Gastric and duodenal ulcers* are more common than esophageal ulcers.

Peptic ulcers are attributed to an imbalance between cell-destructive and cell-protective effects (i.e., presence of increased destructive mechanisms or presence of decreased protective mechanisms). Cell-destructive effects include those of gastric acid (hydrochloric acid), pepsin, *Helicobacter pylori* (*H. pylori*) infection, and ingestion of *nonsteroidal anti-inflammatory drugs* (NSAIDs). Gastric acid, a strong acid that can digest the stomach wall, is secreted by parietal cells in the mucosa of the stomach antrum, near the pylorus. The parietal cells contain receptors for acetyl-

## Box 59-1

## Selected Upper Gastrointestinal Disorders

**Gastritis**

Gastritis, a common disorder, is an acute or chronic inflammatory reaction of gastric mucosa. Patients with gastric or duodenal ulcers usually also have gastritis. *Acute gastritis* (also called *gastropathy*) usually results from irritation of the gastric mucosa by such substances as alcohol, aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs), and others. *Chronic gastritis* is usually caused by *Helicobacter pylori* infection and it persists unless the infection is treated effectively. *H. pylori* organisms may cause gastritis and ulceration by producing enzymes (e.g., urease, others) that break down mucosa; they also alter secretion of gastric acid.

**Nonsteroidal Anti-Inflammatory Drug Gastropathy**

NSAID gastropathy indicates damage to gastroduodenal mucosa by aspirin and other NSAIDs. The damage may range from minor superficial erosions to ulceration and bleeding. NSAID gastropathy is one of the most common causes of gastric ulcers, and it may cause duodenal ulcers as well. Many people take NSAIDs daily for pain, arthritis, and other conditions. Chronic ingestion of NSAIDs causes local irritation of gastroduodenal mucosa; inhibits the synthesis of prostaglandins (which normally protect gastric mucosa by inhibiting acid secretion, stimulating secretion of bicarbonate and mucus, and maintaining mucosal blood flow); and increases the synthesis of leukotrienes and possibly other inflammatory substances that may contribute to mucosal injury.

**Stress Ulcers**

Stress ulcers indicate gastric mucosal lesions that develop in patients who are critically ill from trauma, shock, hemorrhage,

sepsis, burns, acute respiratory distress syndrome, major surgical procedures, or other severe illnesses. The lesions may be single or multiple ulcers or erosions. Stress ulcers are usually manifested by painless upper gastrointestinal (GI) bleeding. The frequency of occurrence has decreased, possibly because of improved management of sepsis, hypovolemia, and other disorders associated with critical illness and the prophylactic use of antiulcer drugs. However there is concern about inappropriate use of stress ulcer prophylaxis (See Evidence Based Practice Box).

Although the exact mechanisms of stress ulcer formation are unknown, several factors are thought to play a role, including mucosal ischemia, reflux of bile salts into the stomach, reduced GI-tract motility, and systemic acidosis. Acidosis increases severity of lesions, and correction of acidosis decreases their formation. In addition, lesions do not form if the pH of gastric fluids is kept at about 3.5 or above and lesions apparently form only when mucosal blood flow is diminished.

**Zollinger-Ellison Syndrome**

Zollinger-Ellison syndrome is a rare condition characterized by excessive secretion of gastric acid and a high incidence of ulcers. It is caused by gastrin-secreting tumors in the pancreas, stomach, or duodenum. Approximately two thirds of the gastrinomas are malignant. Symptoms are those of peptic ulcer disease, and diagnosis is based on high levels of serum gastrin and gastric acid. Treatment may involve long-term use of a proton pump inhibitor to diminish gastric acid, or surgical excision.

choline, gastrin, and histamine, substances that stimulate gastric acid production. Acetylcholine is released by vagus nerve endings in response to stimuli, such as thinking about or ingesting food. Gastrin is a hormone released by cells in the stomach and duodenum in response to food ingestion and stretching of the stomach wall. It is secreted into the bloodstream and eventually circulated to the parietal cells. Histamine is released from cells in the gastric mucosa and diffuses into nearby parietal cells. An enzyme system (*hydrogen, potassium adenosine triphosphatase*, or  $H^+$ ,  $K^+$ -ATPase) catalyzes the production of gastric acid and acts as a gastric acid (proton) pump to move gastric acid from parietal cells in the mucosal lining of the stomach into the stomach lumen.

Pepsin is a proteolytic enzyme that helps digest protein foods and also can digest the stomach wall. Pepsin is derived from a precursor called pepsinogen, which is secreted by chief cells in the gastric mucosa. Pepsinogen is converted to pepsin only in a highly acidic environment (i.e., when the pH of gastric juices is 3 or less).

*H. pylori* is a gram-negative bacterium found in the gastric mucosa of most patients with chronic *gastritis*, about 75% of patients with gastric ulcers, and more than 90% of patients with duodenal ulcers. It is spread mainly by the fecal-oral route. However, iatrogenic spread by contaminated endoscopes, biopsy forceps, and nasogastric tubes has also occurred. After it moves into the body, the organism colonizes the mucus-secreting epithelial cells of the stomach mucosa and is thought to produce gastritis and ulceration by impairing mucosal function. Eradication of the organism accelerates ulcer healing and significantly decreases the rate of ulcer recurrence.

Cell-protective effects (e.g., secretion of mucus and bicarbonate, dilution of gastric acid by food and secretions, prevention of diffusion of hydrochloric acid from the stomach lumen back into the gastric mucosal lining, the presence of prostaglandin E, alkalinization of gastric secretions by pancreatic juices and bile, perhaps other mechanisms) normally prevent autodigestion of stomach and duodenal tissues and ulcer formation.

A gastric or duodenal ulcer may penetrate only the mucosal surface or it may extend into the smooth muscle layers. When superficial lesions heal, no defects remain. When smooth muscle heals, however, scar tissue remains and the mucosa that regenerates to cover the scarred muscle tissue may be defective. These defects contribute to repeated episodes of ulceration.

Although there is considerable overlap in etiology, clinical manifestations, and treatment of gastric and duodenal ulcers, there are differences as well. Gastric ulcers (which may be preceded by less severe mucosal defects such as erosions or gastritis) are often associated with stress (e.g., major trauma, severe medical illness), NSAID ingestion, or *H. pylori* infection of the stomach. They are often manifested by painless bleeding and take longer to heal than duodenal ulcers. Gastric ulcers associated with stress may occur in any age group and are usually acute in nature; those associated with *H. pylori* infection or NSAID ingestion are more likely to occur in older adults, especially in the sixth and seventh decades, and to be chronic in nature. Duodenal ulcers are strongly associated with *H. pylori* infection and NSAID ingestion, may occur at any age, occur about equally in men and women, are often manifested by abdominal pain, and are usually chronic in nature. They are also associated with cigarette smoking. Compared with nonsmokers, smokers are more likely to develop duodenal ulcers, their ulcers heal more slowly with treatment, and the ulcers recur more rapidly.

## Gastroesophageal Reflux Disease

*Gastroesophageal reflux disease (GERD)*, the most common disorder of the esophagus, is characterized by regurgitation of gastric contents into the esophagus and exposure of esophageal mucosa to gastric acid and pepsin. The same amount of acid-pepsin exposure may lead to different amounts of mucosal damage, possibly related to individual variations in esophageal mucosal resistance.

Acid reflux often occurs after the evening meal and decreases during sleep. The main symptom is heartburn (pyrosis), which increases with a recumbent position or bending over. Effortless regurgitation of acidic fluid into the mouth, especially after a meal and at night, is often indicative of GERD. Depending on the frequency and extent of acid-pepsin reflux, GERD may result in mild to severe esophagitis or esophageal ulceration. Pain on swallowing usually means erosive or ulcerative esophagitis.

The main cause of GERD is thought to be an incompetent lower esophageal sphincter (LES). Normally, the LES is contracted or closed and prevents the reflux of gastric contents. It opens or relaxes on swallowing to allow passage of food or fluid, then contracts again. Several circumstances contribute to impaired contraction of the LES and the resulting reflux, including foods (e.g., fats, chocolate), fluids (e.g., alcohol, caffeinated beverages), medications (e.g., beta adrenergics, calcium channel blockers, nitrates), gastric distention, cigarette smoking, and recumbent posture.

GERD occurs in men, women, and children but is especially common during pregnancy and after 40 years of age.

## Classifications and Individual Drugs

Drugs used in the treatment of acid-peptic disorders promote healing of lesions and prevent recurrence of lesions by decreasing cell-destructive effects or increasing cell-protective effects. Several types of drugs are used, alone and in various combinations. *Antacids* neutralize gastric acid and decrease pepsin production, antimicrobials and bismuth can eliminate *H. pylori* infection, *histamine<sub>2</sub> receptor antagonists (H<sub>2</sub>RAs)* and *proton pump inhibitors (PPIs)* decrease gastric acid secretion, sucralfate provides a barrier between mucosal erosions or ulcers and gastric secretions, and misoprostol restores prostaglandin activity. Types of drugs and individual agents are described in the following sections; dosages are listed in the Drugs at a Glance tables.

### Antacids

Antacids are alkaline substances that neutralize acids. They react with hydrochloric acid in the stomach to produce neutral, less acidic, or poorly absorbed salts and to raise the pH (alkalinity) of gastric secretions. Raising the pH to approximately 3.5 neutralizes more than 90% of gastric acid and inhibits conversion of pepsinogen to pepsin. Commonly used antacids are aluminum, magnesium, and calcium compounds. Table 59-1 provides information for representative antacid products.

Antacids differ in the amounts needed to neutralize gastric acid (50–80 mEq of acid is produced hourly), in onset of action, and in adverse effects. Aluminum compounds have a low neutralizing capacity (i.e., relatively large doses are required) and a slow onset of action. They can cause constipation. In people who ingest large amounts of aluminum-based antacids over a long period, hypophosphatemia and osteomalacia may develop because aluminum combines with phosphates in the GI tract and prevents phosphate absorption. Aluminum compounds are rarely used alone for acid-peptic disorders. Magnesium-based antacids have a high neutralizing capacity and a rapid onset of action. They may cause diarrhea and hypermagnesemia. Calcium compounds have a rapid onset of action but may cause hypercalcemia and hypersecretion of gastric acid (“acid rebound”) due to stimulation of gastrin release, if large doses are used. Consequently, calcium compounds are rarely used in peptic ulcer disease.

Commonly used antacids are mixtures of aluminum hydroxide and magnesium hydroxide (e.g., Gelusil, Mylanta, Maalox). Some antacid mixtures contain other ingredients, such as simethicone (contained in Mylanta) or alginic acid. **Simethicone** is an antiflatulent drug available alone as Mylicon. When added to antacids, simethicone does not affect gastric acidity. It reportedly decreases gas bubbles, thereby reducing GI distention and abdominal discomfort. Alginic acid (e.g., in Gaviscon) produces a foamy, viscous layer on top of gastric acid and thereby decreases backflow of gastric acid onto esophageal mucosa while the person is in an upright position.

Table 59-1

Drugs at a Glance: Representative Antacid Products

Trade Name	COMPONENTS				Route and Dosage Ranges (Adults)
	Magnesium Oxide or Hydroxide	Aluminum Hydroxide	Calcium Carbonate	Other	
Amphojel		300 or 600 mg/tab			PO 600 mg 5 or 6 times daily
Gelusil	200 mg/tab	200 mg/tab		Simethicone 25 mg/tab	PO 10 or more mL or 2 or more tablets after meals and at bedtime or as directed by physician to a maximum of 12 tablets or tsp/24 h
Maalox suspension	200 mg/5 mL	225 mg/5 mL			PO 30 mL 4 times daily, after meals and at bedtime or as directed by physician; maximal dose, 16 tsp/24 h
Mylanta	200 mg/tab, 200 mg/5 mL	200 mg/tab, 200 mg/5 mL		Simethicone 25 mg/tab, 20 mg/5 mL	PO 5–10 mL or 1–2 tablets q2–4h, between meals and at bedtime or as directed by physician.
Mylanta Double strength	400 mg/tab, 400 mg/5 mL	400 mg/tab, 400 mg/5 mL		Simethicone 30 mg/tab, 30 mg/5 mL	Same as Mylanta
Titralac			420 mg/tab, 1 g/5 mL	Glycine 180 mg/tab, 300 mg/5 mL	PO 1 tsp or 2 tablets, after meals or as directed by physician, to maximal dose of 19 tablets or 8 tsp/24 h

Antacids act primarily in the stomach and are used to prevent or treat peptic ulcer disease, GERD, esophagitis, heartburn, gastritis, GI bleeding, and *stress ulcers*. Aluminum-based antacids also are given to patients with chronic renal failure and hyperphosphatemia to decrease absorption of phosphates in food.

Magnesium-based antacids are contraindicated in patients with renal failure.

**Helicobacter pylori Agents**

Multiple drugs are required to eradicate *H. pylori* organisms and heal related ulcers. Effective combinations include two antimicrobials and a PPI or an H<sub>2</sub>RA. For the antimicrobial component, two of the following drugs—**amoxicillin**, **clarithromycin**, **metronidazole**, or **tetracycline**—are used. A single antimicrobial agent is not used because of concern about emergence of drug-resistant *H. pylori* organisms. For patients with an active ulcer, adding an antisecretory drug (e.g., H<sub>2</sub>RA or PPI) to an antimicrobial regimen accelerates symptom relief and ulcer healing. In addition, antimicrobial–antisecretory combinations are associated with low ulcer-recurrence rates.

A bismuth preparation is added to some regimens. Bismuth exerts antibacterial effects against *H. pylori* by disrupting bacterial cell walls, preventing the organism from adhering to gastric epithelium, and inhibiting bacterial enzymatic and proteolytic activity. It also increases secretion of mucus and bicar-

bonate, inhibits pepsin activity, and accumulates in ulcer craters.

Although several regimens are effective in *H. pylori* infection, a recent international consensus conference recommended a three-drug regimen with a PPI plus clarithromycin and either amoxicillin or metronidazole twice daily as the first treatment choice. An alternative regimen using metronidazole, a bismuth compound, tetracycline, and an antisecretory drug is very effective in healing ulcers. However, this regimen is not well tolerated, partly because of the multiple daily doses required. Because patient compliance is difficult with all the *H. pylori* eradication regimens, some drug combinations are packaged as individual doses to increase convenience. For example, Helidac contains bismuth subsalicylate, metronidazole, and tetracycline (taken with an H<sub>2</sub>RA); Prevpac contains amoxicillin, clarithromycin, and lansoprazole. The newest combination product, Pylera, contains metronidazole, tetracycline, and bismuth subcitrate potassium. Bismuth subcitrate potassium has similar effects as bismuth subsalicylate without the risks associated with a salicylate. Table 59-2 provides further information.

**Histamine<sub>2</sub> Receptor Antagonists (H<sub>2</sub>RAs)**

Histamine is a substance found in almost every body tissue and released in response to certain stimuli (e.g., allergic reactions,

Table 59-2

## Drugs at a Glance: Drugs for Acid-Peptic Disorders

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS)
<b>Histamine<sub>2</sub> Receptor Antagonists</b>	<p>Treatment of peptic ulcers and GERD to promote healing, then maintenance to prevent recurrence</p> <p>Prevention of stress ulcers, GI bleeding, and aspiration pneumonia</p> <p>Treatment of Zollinger-Ellison syndrome</p> <p>Treatment of heartburn</p>	
<b>Cimetidine</b> (Tagamet)		<p><i>Duodenal or gastric ulcer</i>, PO 800 mg once daily at bedtime or 300 mg 4 times daily or 400 mg twice daily</p> <p><i>Maintenance</i>, PO 400 mg at bedtime</p> <p><i>IV injection</i>, 300 mg diluted in 20 mL of 0.9% NaCl solution q6–8h</p> <p><i>IV intermittent infusion</i>, 300 mg diluted in 50 mL of dextrose or saline solution q6h</p> <p><i>Impaired renal function</i> (creatinine clearance &lt; 30ml/min). Give 25 mg/h IV for prevention of GI bleeding. PO or IV 300 mg q12h, may increase to every 8h if tolerated.</p> <p><i>IM</i> 300 mg q6–8h</p> <p><i>GERD</i>, PO 800 mg twice daily or 400 mg 4 times daily</p> <p><i>Prevention of upper GI bleeding</i>, IV continuous infusion, 50 mg/h</p> <p><i>Heartburn</i>, PO 200 mg once or twice daily as needed</p> <p><i>Impaired renal function</i>, PO, IV 300 mg q8–12h</p>
<b>Famotidine</b> (Pepcid, Pepcid RPD)		<p><i>Duodenal or gastric ulcer</i>, PO or IV 40 mg once daily at bedtime or 20 mg twice daily for 4–8 wk; maintenance, PO or IV 20 mg once daily at bedtime</p> <p><i>Zollinger-Ellison syndrome</i>, PO 20 mg q6h, increased if necessary</p> <p><i>IV injection</i>, 20 mg q12h, diluted to 5 or 10 mL with 5% dextrose or 0.9% sodium chloride</p> <p><i>IV infusion</i>, 20 mg q12h, diluted with 100 mL of 5% dextrose or 0.9% sodium chloride</p> <p><i>Impaired renal function</i> (creatinine clearance &lt;50 mL/min), PO, IV 20 mg q24–48h</p> <p><i>GERD</i>, PO 20 mg twice daily for 6–12 wk</p> <p><i>Heartburn</i>, (Pepcid Complete) PO 1–2 tablets, chewed, daily as needed</p>
<b>Famotidine 10 mg, calcium carbonate 800 mg, &amp; magnesium hydroxide 165 mg</b> (Pepcid Complete)		
<b>Nizatidine</b> (Axid)		<p><i>Duodenal or gastric ulcer</i>, PO 300 mg once daily at bedtime or 150 mg twice daily; maintenance, PO 150 mg once daily at bedtime</p> <p><i>GERD</i>, PO 150 mg twice daily</p> <p><i>Heartburn</i>, PO 75 mg 30–60 min before meals.</p> <p><i>Impaired renal function</i> (creatinine clearance [CrCl] 20–50 mL/min), PO 150 mg daily; CrCl &lt;20 mL/min, PO 150 mg q48h</p>

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS)
<b>Ranitidine</b> (Zantac)		<p><i>Duodenal ulcer</i>, PO 300 mg once daily at bedtime or 150 mg twice daily, maintenance 150 mg PO at bedtime.</p> <p>IM 50 mg q6–8h</p> <p>IV injection, 50 mg diluted to 100 mL in 5% dextrose or 0.9% sodium chloride solution q6–8h</p> <p>IV intermittent infusion, 50 mg diluted in 100 mL of 5% dextrose or 0.9% sodium chloride solution</p> <p><i>Gastric ulcer or GERD</i>, PO 150 mg twice daily</p> <p><i>Impaired renal function (CrCl &lt;50 mL/min)</i>, PO 150 mg q24h; IV, IM 50 mg q18–24h</p> <p><i>Heartburn</i>, PO 75 mg as needed</p> <p><i>H. Pyloric infection</i>, PO 400 mg twice daily for 4 weeks in combination with clarithromycin.</p>
<b>Proton Pump Inhibitors</b>	<p>Treatment of gastric and duodenal ulcers, for 4–8 wk</p> <p>Treatment of GERD with erosive esophagitis for 4–8 wk to promote healing, then maintenance to prevent recurrence</p> <p>Treatment of Zollinger-Ellison syndrome</p>	
<b>Esomeprazole</b> (Nexium, Nexium IV, Nexium delayed-release capsules)		<p><i>GERD with erosive esophagitis</i>, PO 20–40 mg once daily for 4–8 wk; maintenance, 20 mg once daily, IV 20–40 mg daily up to 10 d</p>
<b>Lansoprazole</b> (Prevacid, Prevacid IV)		<p><i>Duodenal ulcer</i>, PO 15 mg daily for healing and maintenance</p> <p><i>Gastric ulcer</i>, PO 30 mg once daily, up to 8 wk</p> <p><i>Erosive esophagitis</i>, PO 30 mg daily up to 8 wk; maintenance, 15 mg daily, IV 30 mg daily up to 7 d</p> <p><i>H. pylori infection</i>, PO 30 mg (with amoxicillin and clarithromycin) twice daily for 14 d</p> <p><i>Hypersecretory conditions</i>, PO 60–90 mg daily</p>
<b>Omeprazole</b> (Prilosec, Prilosec OTC)		<p><i>Gastric ulcer</i>, PO 40 mg once daily for 4–8 wk</p> <p><i>Duodenal ulcer</i>, PO 20 mg once daily for 4–8 wk</p> <p><i>GERD, with erosive esophagitis</i>, PO 20 mg once daily</p> <p><i>Zollinger-Ellison syndrome</i>, PO 60 mg once daily</p> <p><i>Heartburn</i>, PO 20 mg for 14 days. May repeat treatment every 4 months if needed.</p> <p><i>H. Pylori infection</i>, PO 40 mg daily for 14 days then 20 mg daily for 14 days, with clarithromycin.</p>
<b>Pantoprazole</b> (Protonix, Protonix IV)		<p><i>GERD with erosive esophagitis</i>, PO, IV 40 mg once daily</p> <p><i>Zollinger-Ellison syndrome</i>, PO, IV 40–80 mg q12h</p>
<b>Rabeprazole</b> (Aciphex)		<p><i>Duodenal ulcer</i>, PO 20 mg once daily up to 4 wk</p> <p><i>GERD</i>, PO 20 mg once daily for healing and maintenance</p> <p><i>Zollinger-Ellison syndrome</i>, PO 60 mg once or twice daily</p>
<b>Miscellaneous Agents</b>		
<b>Misoprostol</b> (Cytotec)	<p>Prevention of aspirin and NSAID-induced gastric ulcers in selected clients</p>	<p>PO 100–200 mg 4 times daily with meals and at bedtime</p>

Table 59-2

## Drugs at a Glance: Drugs for Acid-Peptic Disorders (continued)

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES (ADULTS)
<b>Sucralfate</b> (Carafate)	Treatment of active duodenal ulcer to promote healing, then maintenance to prevent recurrence	<i>Treatment of active ulcer</i> , PO 1 g 4 times daily before meals and at bedtime <i>Maintenance therapy</i> , PO 1 g 2 times daily
<b>Helicobacter pylori Agents</b>		
<b>Antimicrobials</b>		
<b>Amoxicillin</b>	<i>H. pylori</i> infection causing gastric or duodenal ulcers	1g 2–3 times daily
<b>Clarithromycin</b>		PO 500 mg 3 times daily
<b>Metronidazole</b>		PO 250 mg 4 times daily
<b>Tetracycline</b>		PO 500 mg 4 times daily
<b>Bismuth Subsalicylate</b>	<i>H. pylori</i> eradication and GI upset (abdominal cramping, indigestion, nausea, diarrhea)	<i>Adults</i> : PO 525 mg (2 tabs or 30 mL) 4 times daily <i>Children</i> : 9–12 y, PO 1 tab or 15 mL; 6–9 y, PO 2/3 tab or 10 mL; 3–6 y, PO 1/3 tab or 5 mL; <3 y, consult physician. Dosage may be repeated every 30–60 min, if needed, up to 8 doses in 24 h.
<b>Combination Regimens</b>		
<b>Bismuth Subcitrate, metronidazole, tetracycline</b> (Pylera)		PO bismuth subcitrate 140 mg, metronidazole 125 mg, tetracycline 125 mg. 3 caps 4 times daily with 8 oz water after meals and at bedtime for 10 days.
<b>Bismuth Subsalicylate, metronidazole, and tetracycline</b> (Helidac)		PO bismuth 525 mg (2 tabs), metronidazole 250 mg (1 tab), tetracycline 500 mg (1 capsule) 4 times daily for 14 d
<b>Amoxicillin, clarithromycin, and lansoprazole</b> (Prevpac)		PO amoxicillin 1 g, clarithromycin 500 mg, lansoprazole 30 mg twice daily, morning and evening, for 14 d

GERD, gastroesophageal reflux disease, including erosive esophagitis; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

tissue injury). After it is released, histamine causes contraction of smooth muscle in the bronchi, GI tract, and uterus; dilation and increased permeability of capillaries; dilation of cerebral blood vessels; and stimulation of sensory nerve endings to produce pain and itching.

Histamine also causes strong stimulation of gastric acid secretion. Vagal stimulation causes release of histamine from cells in the gastric mucosa. The histamine then acts on receptors located on the parietal cells to increase production of hydrochloric acid. These receptors are called the H<sub>2</sub> receptors.

Traditional antihistamines or H<sub>1</sub> receptor antagonists prevent or reduce other effects of histamine but do not block histamine effects on gastric acid production. The H<sub>2</sub>RA inhibit both basal secretion of gastric acid and the secretion stimulated by histamine, acetylcholine, and gastrin. They decrease the amount, acidity, and pepsin content of gastric juices. A single dose of an H<sub>2</sub>RA can inhibit acid secretion for 6 to 12 hours, and a continuous intravenous (IV) infusion can inhibit secretion for prolonged periods.

Clinical indications for use include prevention and treatment of peptic ulcer disease, GERD, esophagitis, GI bleeding due to acute stress ulcers, and *Zollinger-Ellison syndrome*. With gastric or duodenal ulcers, healing occurs within 6 to 8 weeks; with esophagitis, healing occurs in about 12 weeks. Over-the-counter (OTC) oral preparations, at lower dosage strengths, are approved for the treatment of heartburn.

There are no known contraindications, but the drugs should be used with caution in children, pregnant women, older adults, and patients with impaired renal or hepatic function. Dosage should be reduced in the presence of impaired renal function.

Adverse effects occur infrequently with usual doses and duration of treatment. They are more likely to occur with prolonged use of high doses and in older adults or those with impaired renal or hepatic function.

Cimetidine, ranitidine, famotidine, and nizatidine are the four available H<sub>2</sub>RA (see Table 59-2). **Cimetidine** was the first, and it is still widely used. It is well absorbed after oral administration. After a single dose, peak blood level is

reached in 1 to 1.5 hours, and an effective concentration is maintained about 6 hours. The drug is distributed in almost all body tissues. Cimetidine should be used with caution during pregnancy because it crosses the placenta, and it should not be taken during lactation because it is excreted in breast milk. Most of an oral dose is excreted unchanged in the urine within 24 hours; some is excreted in bile and eliminated in feces. For acutely ill patients, cimetidine is given IV. A major disadvantage of cimetidine is that it inhibits the hepatic metabolism of numerous other drugs, thereby increasing blood levels and risks of toxicity with the inhibited drug.

**Ranitidine** is more potent than cimetidine on a weight basis, and smaller doses can be given less frequently. In addition, ranitidine causes fewer drug interactions than cimetidine. Oral ranitidine reaches peak blood levels 1 to 3 hours after administration and is metabolized in the liver; approximately 30% is excreted unchanged in the urine. Parenteral ranitidine reaches peak blood levels in about 15 minutes; 65% to 80% is excreted unchanged in the urine. **Famotidine** and **nizatidine** are similar to cimetidine and ranitidine.

Compared with cimetidine, the other drugs cause similar effects except they are less likely to cause mental confusion and gynecomastia (antiandrogenic effects). In addition, they do not affect the cytochrome P450 drug-metabolizing system in the liver and therefore do not interfere with the metabolism of other drugs.

## Proton Pump Inhibitors (PPIs)

PPIs are strong inhibitors of gastric acid secretion. These drugs bind irreversibly to the gastric proton pump (e.g., the enzyme  $H^+$ ,  $K^+$ -ATPase) to prevent the “pumping” or release of gastric acid from parietal cells into the stomach lumen, thereby blocking the final step of acid production. Inhibition of the proton pump suppresses gastric acid secretion in response to all primary stimuli, histamine, gastrin, and acetylcholine. Thus, the drugs inhibit both daytime (including meal-stimulated) and nocturnal (unstimulated) acid secretion.

Indications for use include treatment of peptic ulcer disease, erosive gastritis, GERD, and Zollinger-Ellison syndrome. PPIs are usually the drugs of choice for treatment of duodenal and gastric ulcers, GERD with erosive esophagitis, and Zollinger-Ellison syndrome. Compared with  $H_2$ RAs, PPIs suppress gastric acid more strongly and for a longer time. This effect provides faster symptom relief and faster healing in acid-related diseases. For example, healing of duodenal and gastric ulcers after 2 weeks is similar to the healing after 4 weeks of  $H_2$ RA therapy. The PPIs and  $H_2$ RAs are similarly effective in maintenance therapy of peptic ulcer disorders, with similar rates of ulcer recurrence. In patients with GERD, PPIs usually abolish symptoms within 1 to 2 weeks and heal esophagitis within 8 weeks. The drugs are also effective in maintenance therapy to prevent recurrence of esophagitis. In patients with *H. pylori*-associated ulcers, eradication of the organism with antimicrobial drugs is preferable to long-term maintenance therapy with antisecretory drugs.

The drugs usually are well tolerated; adverse effects are minimal with both short- and long-term use. Nausea, diarrhea, and headache are the most frequently reported adverse effects. However, long-term consequences of profound gastric acid suppression are unknown.

**Omeprazole**, **esomeprazole**, **lansoprazole**, **pantoprazole**, and **rabeprazole** are the available PPIs (see Table 59-2). Omeprazole was the first and is still widely used. It is well absorbed after oral administration, highly bound to plasma proteins (about 95%), metabolized in the liver, and excreted in the urine (about 75%) and bile or feces. Acid-inhibiting effects occur within 2 hours and last 72 hours or longer. When the drug is discontinued, effects persist for 48 to 72 hours or longer, until the gastric parietal cells can synthesize additional  $H^+$ ,  $K^+$ -ATPase. The other drugs are very similar to omeprazole. Omeprazole (Prilosec OTC) has been approved for OTC sales for treating heartburn. If heartburn is not improved within 14 days of treatment, patients should be evaluated by their health care provider. A 2-week treatment with Prilosec OTC can be repeated every 4 months if needed to control heartburn.

## Prostaglandin

Naturally occurring prostaglandin E, which is produced in mucosal cells of the stomach and duodenum, inhibits gastric acid secretion and increases mucus and bicarbonate secretion, mucosal blood flow, and perhaps mucosal repair. It also inhibits the mucosal damage produced by gastric acid, aspirin, and NSAIDs. When synthesis of prostaglandin E is inhibited, erosion and ulceration of gastric mucosa may occur. This is the mechanism by which aspirin and other NSAIDs are thought to cause gastric and duodenal ulcers (see Chap. 7).

**Misoprostol** (see Table 59-2) is a synthetic form of prostaglandin E approved for concurrent use with NSAIDs to protect gastric mucosa from NSAID-induced erosion and ulceration. It is indicated for patients at high risk of GI ulceration and bleeding, such as those taking high doses of NSAIDs for arthritis and older adults. The U.S. Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** to alert health care professionals that misoprostol is contraindicated in women of childbearing potential, unless effective contraceptive methods are being used, and during pregnancy, because it may induce abortion, premature birth, or birth defects. The most common adverse effects are diarrhea (occurs in 10%–40% of recipients) and abdominal cramping. Older adults may be unable to tolerate misoprostol-induced diarrhea and abdominal discomfort.

## Sucralfate

**Sucralfate** is a preparation of sulfated sucrose and aluminum hydroxide that binds to normal and ulcerated mucosa. It is used to prevent and treat peptic ulcer disease. It is effective even though it does not inhibit secretion of gastric acid or pepsin, and it has little neutralizing effect on gastric acid. Its mechanism of action is unclear, but it is thought to act locally on the gastric and duodenal mucosa. Possible mechanisms include binding to the ulcer and forming a protective barrier between

the mucosa and gastric acid, pepsin, and bile salts; neutralizing pepsin; stimulating prostaglandin synthesis in the mucosa; and exerting healing effects through the aluminum component. Sucralfate is effective in healing duodenal ulcers and in maintenance therapy to prevent ulcer recurrence. In general, the rates of ulcer healing with sucralfate are similar to the rates with H<sub>2</sub>RAs.

Adverse effects are low in incidence and severity because sucralfate is not absorbed systemically. Constipation and dry mouth are most often reported. The main disadvantages of using sucralfate are that the tablet is large; it must be given at least twice daily; it requires an acid pH for activation and should not be given with an antacid, H<sub>2</sub>RA, or PPI; and it may bind to other drugs and prevent their absorption. In general, sucralfate should be given 2 hours before or after other drugs.

## Herbal and Dietary Supplements

Several herbal supplements are promoted as aiding heartburn, gastritis, and peptic ulcer disease. Most have not been studied in humans, and there is little, if any, evidence that they are either safe or effective for the proposed uses. Given the known safety and effectiveness of available drugs and the possible consequences of delaying effective treatment, the use of herbal supplements for any acid-peptic disorder should be discouraged.

## Nursing Process

### Assessment

Assess the patient's status in relation to peptic ulcer disease, GERD, and other conditions in which antiulcer drugs are used.

- Identify risk factors for peptic ulcer disease.
  - Cigarette smoking. Effects are thought to include stimulation of gastric acid secretion and decreased blood supply to gastric mucosa. (Nicotine constricts blood vessels.) Moreover, patients with peptic ulcers who continue to smoke heal more slowly and have more recurrent ulcers, despite usually adequate treatment, than those who stop smoking.
  - Stress, including physiologic stress (e.g., shock, sepsis, burns, surgery, head injury, severe trauma, medical illness) and psychological stress. One mechanism may be that stress activates the sympathetic nervous system, which then causes vasoconstriction in organs not needed for “fight or flight.” Thus, stress may lead to ischemia in gastric mucosa, with ulceration if ischemia is severe or prolonged.
  - Drug therapy with aspirin and other NSAIDs, corticosteroids, and antineoplastics.

- Signs and symptoms depend on the type and location of the ulcer.
  - Periodic epigastric pain, which occurs 1 to 4 hours after eating or during the night and is often described as “burning” or “gnawing,” is a symptom of a chronic duodenal ulcer.
  - GI bleeding occurs with acute or chronic ulcers when the ulcer erodes into a blood vessel. Clinical manifestations may range from mild (e.g., occult blood in feces, eventual anemia) to severe (e.g., hematemesis, melena, hypotension, shock).
  - GERD produces heartburn (a substernal burning sensation).

## Nursing Diagnoses

- Pain related to effects of gastric acid on peptic ulcers or inflamed esophageal tissues
- Imbalanced Nutrition: Less Than Body Requirements related to anorexia and abdominal discomfort
- Constipation related to aluminum- or calcium-containing antacids and sucralfate
- Diarrhea related to magnesium-containing antacids and misoprostol
- Deficient Knowledge related to drug therapy and nonpharmacologic management of GERD and peptic ulcer disease

## Planning/Goals

### The patient will

- Take or receive antiulcer, anti-heartburn drugs accurately
- Experience relief of symptoms
- Avoid situations that cause or exacerbate symptoms, when possible
- Be observed for GI bleeding and other complications of peptic ulcer disease and GERD
- Maintain normal patterns of bowel function
- Avoid preventable adverse effects of drug therapy

## Interventions

Use measures to prevent or minimize peptic ulcer disease and gastric acid–induced esophageal disorders.

- With peptic ulcer disease, helpful interventions may include the following:
  - General health measures such as a well-balanced diet, adequate rest, and regular exercise
  - Avoiding cigarette smoking and gastric irritants (e.g., alcohol, aspirin and NSAIDs, caffeine)
  - Reducing psychological stress (e.g., by changing environments) or learning healthful strategies of stress management (e.g., relaxation techniques, physical exercise). There is no practical way to avoid psychological stress because it is part of everyday life.

- Long-term drug therapy with small doses of H<sub>2</sub>RAs, antacids, or sucralfate. With “active” peptic ulcer disease, helping the patient follow the prescribed therapeutic regimen helps to promote healing and prevent complications (see accompanying Patient Teaching Guidelines).
- Diet therapy is of minor importance in prevention or treatment of peptic ulcer disease. Some physicians prescribe no dietary restrictions, whereas others suggest avoiding or minimizing highly spiced foods, gas-forming foods, and caffeine-containing beverages.
- With heartburn and esophagitis, helpful measures are those that prevent or decrease gastroesophageal reflux of gastric contents (e.g., avoiding irritant, highly spiced, or fatty foods; eating small meals; not lying down for 1 to 2 hours after eating; elevating the head of the bed; avoiding obesity, constipation, or other conditions that increase intra-abdominal pressure).

### Evaluation

- Observe and interview regarding drug use.
- Observe and interview regarding relief of symptoms.
- Observe for signs and symptoms of complications.
- Observe and interview regarding adverse drug effects.

### Applying Your Knowledge 59-1

In addition to taking her medication properly, you should instruct Ms. Daniels to take measures to avoid gastric irritation. What content would be included in this teaching plan?

.....

### Applying Your Knowledge 59-2

Ms. Daniels suffers from acid reflux. She should be taught measures that can help reduce the pain associated with heartburn. What should you teach her with regard to minimizing the symptoms of acid reflux?

.....

## Principles of Therapy

### Drug Selection

All of the drugs used for acid-peptic disorders are effective for indicated uses; the choice of drugs may depend on etiology, acuity, severity of symptoms, cost, and convenience. General guidelines include the following:

## Patient Teaching Guidelines

### Antiulcer and Anti-Heartburn Drugs

#### General Considerations

- These drugs are commonly used to prevent and treat peptic ulcers and heartburn. Peptic ulcers usually form in the stomach or first part of the small bowel (duodenum), where tissues are exposed to stomach acid. Two common causes of peptic ulcer disease are stomach infection with a bacterium called *Helicobacter pylori* and taking nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and many others. Heartburn (also called gastroesophageal reflux disease) is caused by stomach acid splashing back onto the esophagus.
 

Peptic ulcer disease and heartburn are chronic conditions that are usually managed on an outpatient basis. Complications such as bleeding require hospitalization. Overall, these conditions can range from mild to serious, and it is important to seek information about the disease process, ways to prevent or minimize symptoms, and drug therapy.
- With heartburn, try to minimize acid reflux by elevating the head of the bed; avoiding stomach distention by eating small meals; not lying down for 1 to 2 hours after eating; minimizing intake of fats, chocolate, citric juices, coffee, and alcohol; avoiding smoking (stimulates gastric acid production); and avoiding obesity, constipation, or other conditions that increase intra-abdominal pressure.

In addition, take tablets and capsules with 8 oz of water and do not take medications at bedtime unless instructed to do so. Some medications (e.g., tetracycline, potassium chloride tablets, iron supplements, nonsteroidal anti-inflammatory drugs [NSAIDs]) may cause “pill-induced” irritation of the esophagus (esophagitis) if not taken with enough liquid.

- Most medications for peptic ulcer disease and heartburn decrease stomach acid. An exception is the antibiotics used to treat ulcers caused by *H. pylori* infection. The strongest acid reducers are omeprazole (Prilosec), esomeprazole (Nexium), lansoprazole (Prevacid), pantoprazole (Protonix), and rabeprazole (Aciphex). These are prescription drugs, except for omeprazole, which is approved for nonprescription use. Histamine-blocking drugs such as cimetidine (Tagamet), famotidine (Pepcid), and others are available as both prescription and over-the-counter (OTC) preparations. OTC products are indicated for heartburn, and smaller doses are taken than for peptic ulcer disease. These drugs usually should not be taken longer than 2 weeks without the advice of a health care provider. The concern is that OTC drugs may delay diagnosis and treatment of potentially serious illness. In addition, cimetidine can increase toxic effects of numerous drugs and should be avoided if you are taking other medications.

## Patient Teaching Guidelines

## Antiulcer and Anti-Heartburn Drugs (cont'd)

Misoprostol (Cytotec) is given to prevent ulcers from NSAIDs, which are commonly used to relieve pain and inflammation with arthritis and other conditions. This drug should be taken only while taking a traditional NSAID such as ibuprofen. A related drug, celecoxib (Celebrex) is less likely to cause peptic ulcer disease. Do not take misoprostol if pregnant and do not become pregnant while taking the drug. If pregnancy occurs during misoprostol therapy, stop the drug and notify your health care provider immediately. Misoprostol can cause abdominal cramps and miscarriage.

Numerous antacid preparations are available, but they are not equally safe in all people and should be selected carefully. For example, products that contain magnesium have a laxative effect and may cause diarrhea; those that contain aluminum or calcium may cause constipation. Some commonly used antacids (e.g., Maalox, Mylanta) are a mixture of magnesium and aluminum preparations, an attempt to avoid both constipation and diarrhea. People with kidney disease should not take products that contain magnesium because magnesium can accumulate in the body and cause serious adverse effects. Thus, it is important to read product labels and, if you have a chronic illness or take other medications, ask your physician or pharmacist to help you select an antacid and an appropriate dose.

### Self- or Caregiver Administration

- Take antiulcer drugs as directed. Underuse decreases therapeutic effectiveness; overuse increases adverse effects. For acute peptic ulcer disease or esophagitis, drugs are given in relatively high doses for 4 to 8 weeks to promote

healing. For long-term maintenance therapy, dosage is reduced.

- With Prilosec, Aciphex, Nexium, and Protonix, swallow the capsule whole; do not open, chew, or crush. With Prevacid, the capsule can be opened and the granules sprinkled on applesauce for patients who are unable to swallow capsules. Also, the granules are available in a packet for preparing a liquid suspension. Follow instructions for mixing the granules exactly. The granules should not be crushed or chewed.
- Take cimetidine with meals or at bedtime. Take famotidine, nizatidine, and ranitidine with or without food. Do not take an antacid for 1 hour before or after taking one of these drugs.
- Take sucralfate on an empty stomach at least 1 hour before meals and at bedtime. Also, do not take an antacid for 1 hour before or after taking sucralfate.
- Take misoprostol with food.
- For treatment of peptic ulcer disease, take antacids 1 and 3 hours after meals and at bedtime (4 to 7 doses daily), 1 to 2 hours before or after other medications. Antacids decrease absorption of many medications if taken at the same time. Also, chew chewable tablets thoroughly before swallowing, then drink a glass of water; allow effervescent tablets to dissolve completely and almost stop bubbling before drinking; and shake liquids well before measuring the dose.
- Take Pepcid RPD orally disintegrating tablets by placing on tongue and allowing to dissolve with saliva. Taking with liquids not necessary.

- PPIs are the drugs of first choice in most situations. They heal gastric and duodenal ulcers more rapidly and may be more effective in treating erosive esophagitis due to GERD, erosive gastritis, and Zollinger-Ellison syndrome than H<sub>2</sub>RAs. They are also effective in eradicating *H. pylori* infection when combined with two antibacterial drugs. Omeprazole and rabeprazole are given only orally; esomeprazole, lansoprazole, and pantoprazole may be given orally or IV. PPIs are more expensive than H<sub>2</sub>RAs. Many patients with GERD will experience a reoccurrence of symptoms when PPIs are discontinued; therefore, long-term maintenance therapy may be required.
- H. pylori* infection should be considered in most cases of peptic ulcer disease. If infection is confirmed by appropriate diagnostic tests, agents to eradicate the organisms should be drugs of first choice. The most-recommended drug regimen is a combination of a PPI and clarithromycin plus amoxicillin or metronidazole.
- H. pylori* eradication is helpful but insufficient as sole treatment to prevent NSAID-related ulcer disease in patients taking chronic NSAIDs. However, initial *H. pylori* eradication before beginning chronic NSAID therapy use may be helpful in preventing peptic ulcer formation. *H. pylori* infec-

tion should be considered in patients taking long-term aspirin or other NSAID therapy who experience bleeding. In patients on long-term NSAID therapy with peptic ulcers and bleeding ulcers, PPI treatment is more effective than *H. pylori* eradication in preventing reoccurrence of ulcers and bleeding.

- H<sub>2</sub>RAs have been replaced as first-choice drugs by the PPIs for most indications but are still widely used. Cimetidine may be less expensive, but it may cause confusion and antiandrogenic effects. It also increases the risks of toxicity with several commonly used drugs. Compared with cimetidine, other H<sub>2</sub>RAs are more potent on a weight basis and have a longer duration of action, so they can be given in smaller, less frequent doses. In addition, they do not alter the hepatic metabolism of other drugs. OTC H<sub>2</sub>RAs are indicated for the treatment of heartburn. In some cases, patients may depend on self-medication with OTC drugs and delay seeking treatment for peptic ulcer disease or GERD. For prescription or nonprescription uses, cimetidine is preferably taken by patients who are taking no other medications.
- Antacids are often used as needed to relieve heartburn and abdominal discomfort. If used to treat acid-peptic disorders, they are more often used with other agents than alone and

require a regular dosing schedule. The choice of antacid should be individualized to find a preparation that is acceptable to the patient in terms of taste, dosage, and convenience of administration. Some guidelines include the following:

- Most commonly used antacids combine aluminum hydroxide and magnesium hydroxide. The combination decreases the adverse effects of diarrhea (with magnesium products) and constipation (with aluminum products). Calcium carbonate is effective in relieving heartburn, but it is infrequently used to treat peptic ulcers or GERD.
- Antacids may be used more often now that low doses (e.g., two antacid tablets four times a day) have been shown to be effective in healing gastric and duodenal ulcers. All of the low-dose regimens contained aluminum, and the aluminum rather than acid neutralization may be the important therapeutic factor. Compared with other drugs for acid-peptic disorders, low-dose antacids are inexpensive and cause few adverse effects. In addition, tablets are as effective as liquids and usually more convenient to use.
- Antacids with magnesium are contraindicated in renal disease because hypermagnesemia may result; those with high sugar content are contraindicated in diabetes mellitus.
- Additional ingredients may be helpful to some patients. Simethicone has no effect on intragastric pH but may be useful in relieving flatulence or gastroesophageal reflux. Alginic acid may be useful in patients with daytime acid reflux and heartburn.
- Sucralfate must be taken before meals, and this is inconvenient for some patients.

### Applying Your Knowledge 59-3

#### How Can You Avoid This Medication Error?

Ms. Daniels finds that Maalox is less expensive than Mylanta so she switches her antacid brand. She complains that her heartburn is getting worse.

.....

### Guidelines for Therapy With Proton Pump Inhibitors

- Recommended doses of PPIs heal most gastric and duodenal ulcers in about 4 weeks. Large gastric ulcers may require 8 weeks.
- The drugs may be used to maintain healing of gastric and duodenal ulcers and decrease risks of ulcer recurrence.
- A PPI and two antimicrobial drugs is the most effective regimen for eradication of *H. pylori* organisms.

- With GERD, higher doses or longer therapy may be needed for severe disease and esophagitis. Lower doses can maintain symptom relief and esophageal healing.

### Guidelines for Therapy With Histamine<sub>2</sub> Receptor Antagonists

- For an acute ulcer, full dosage may be given up to 8 weeks. When the ulcer heals, dosage may be reduced by 50% for maintenance therapy to prevent recurrence.
- For duodenal ulcers, a single evening or bedtime dose produces the same healing effects as multiple doses. Commonly used nocturnal doses are cimetidine 800 milligrams, ranitidine 300 milligrams, nizatidine 300 milligrams, or famotidine 40 milligrams.
- For gastric ulcers, the optimal H<sub>2</sub>RA dosage schedule has not been established. Gastric ulcers heal more slowly than duodenal ulcers and most authorities prescribe 6 to 8 weeks of drug therapy.
- To maintain ulcer healing and prevent recurrence, long-term H<sub>2</sub>RA therapy is often used. The drug is usually given as a single bedtime dose, but the amount is reduced by 50% (i.e., cimetidine 400 mg, ranitidine 150 mg, nizatidine 150 mg, or famotidine 20 mg).
- For Zollinger-Ellison syndrome, high doses as often as every 4 hours may be required.
- For severe reflux esophagitis, multiple daily doses may be required for adequate symptom control.
- Dosage of all these drugs should be reduced in the presence of impaired renal function.
- Antacids are often given concurrently with H<sub>2</sub>RAs to relieve pain. They should not be given at the same time (except for Pepcid Complete) because the antacid reduces absorption of the other drug. H<sub>2</sub>RAs usually relieve pain after 1 week of administration.
- H<sub>2</sub>RAs are available in a wide array of products. Precautions must be taken to ensure the correct formulation, dosage strength, and method of administration for the intended use. For example, cimetidine is available in tablets of 200, 300, 400, and 800 milligrams; an oral liquid with 300 milligrams per 5 milliliters; and injectable solutions. Ranitidine is available in tablets of 75 milligrams, capsules (Zantac GELdose) of 150 and 300 milligrams, liquid syrup with 15 milligrams per milliliter, effervescent granules of 150 milligrams, and injectable solutions of 1 milligram per milliliter and 25 milligrams per milliliter. Nizatidine is available in tablets of 75 milligrams and capsules of 150 and 300 milligrams; famotidine is available in tablets of 10, 20, and 40 milligrams; chewable tablets of 10 milligrams; orally disintegrating tablets (Pepcid RPD) of 20 and 40 milligrams; a powder for oral suspension that contains 40

milligram per 5 milliliters when reconstituted; and injection solutions of 10 milligrams per milliliter and 20 milligrams per 50 milliliters.

- All H<sub>2</sub>RAs are available by prescription and OTC. When prescriptions are given, patients should be advised to avoid concomitant use of OTC versions of the same or similar drugs.

### Guidelines for Therapy With Sucralfate

- When sucralfate is used to treat an ulcer, it should be administered for 4 to 8 weeks unless healing is confirmed by radiologic or endoscopic examination.
- When used long term to prevent ulcer recurrence, dosage should be reduced.

### Guidelines for Therapy With Antacids

- To prevent stress ulcers in critically ill patients and to treat acute GI bleeding, nearly continuous neutralization of gastric acid is desirable. Dose and frequency of administration must be sufficient to neutralize approximately 50 to 80 milliequivalents of gastric acid each hour. This can be accomplished by a continuous intragastric drip through a nasogastric tube or by hourly administration.
- When a patient has a nasogastric tube in place, antacid dosage may be titrated by aspirating stomach contents, determining pH, and then basing the dose on the pH. (Most gastric acid is neutralized and most pepsin activity is eliminated at a pH above 3.5.)
- When prescribing antacids to treat active ulcers, it has long been recommended to take them 1 hour and 3 hours after meals and at bedtime for greater acid neutralization. This schedule is effective but inconvenient for many patients. More recently, lower doses taken less often have been found effective in healing duodenal or gastric ulcers even though less acid neutralization occurs.
- It was formerly thought that liquid antacid preparations were more effective. Now, tablets are considered as effective as liquids.
- When antacids are used to relieve pain, they usually may be taken as needed. However, they should not be taken in high doses or for prolonged periods because of potential adverse effects.

### Effects of Acid-Suppressant Drugs on Other Drugs

Antacids may prevent absorption of most drugs taken at the same time, including benzodiazepine antianxiety drugs, corticosteroids, digoxin, H<sub>2</sub>RAs (e.g., cimetidine), iron supplements, phenothiazine antipsychotic drugs, phenytoin,

fluoroquinolone antibacterials, and tetracyclines. Antacids increase absorption of a few drugs, including levodopa, quinidine, and valproic acid. These interactions can be avoided or minimized by separating administration times by 1 to 2 hours.

H<sub>2</sub>RAs may alter the effects of several drugs. Most significant effects occur with cimetidine, which interferes with the metabolism of many commonly used drugs. Consequently, the affected drugs are eliminated more slowly, their serum levels are increased, and they are more likely to cause adverse effects and toxicity unless dosage is reduced.

Interacting drugs include antidysrhythmics (lidocaine, propafenone, quinidine), the anticoagulant warfarin, anticonvulsants (carbamazepine, phenytoin), benzodiazepine antianxiety or hypnotic agents (alprazolam, diazepam, flurazepam, triazolam), beta-adrenergic blocking agents (labetalol, metoprolol, propranolol), the bronchodilator theophylline, calcium channel blocking agents (e.g., verapamil), tricyclic antidepressants (e.g., amitriptyline), and sulfonylurea antidiabetic drugs. In addition, cimetidine may increase serum levels (e.g., fluorouracil, procainamide and its active metabolite) and pharmacologic effects of other drugs (e.g., respiratory depression with opioid analgesics) by unidentified mechanisms. Cimetidine also may decrease effects of several drugs, including drugs that require an acidic environment for absorption (e.g., iron salts, indomethacin, fluconazole, tetracyclines) and miscellaneous drugs (e.g., digoxin, tocinide) by unknown mechanisms.

Ranitidine, famotidine, and nizatidine do not inhibit the cytochrome P450 metabolizing enzymes. Ranitidine decreases absorption of diazepam if given at the same time and increases hypoglycemic effects of glipizide. Nizatidine increases serum salicylate levels in people taking high doses of aspirin.

PPIs have relatively few effects on other drugs. Omeprazole increases blood levels of some benzodiazepines (diazepam, flurazepam, triazolam), phenytoin, and warfarin, probably by inhibiting hepatic metabolism. These interactions have not been reported with the other PPIs.

Sucralfate decreases absorption of ciprofloxacin and other fluoroquinolones, digoxin, phenytoin, and warfarin. Sucralfate binds to these drugs when both are present in the GI tract. This interaction can be avoided or minimized by giving the interacting drug 2 hours before sucralfate.

### Effects of Acid-Suppressant Drugs on Nutrients

Dietary folate, iron, and vitamin B<sub>12</sub> are better absorbed from an acidic environment. When gastric fluids are made less acidic by antacids, H<sub>2</sub>RAs, or PPIs, deficiencies of these nutrients may occur. In addition, sucralfate interferes with absorption of fat-soluble vitamins, and magnesium-containing antacids interfere with absorption of vitamin A.

## Use in Special Populations

### Use in Children

Antacids may be given to ambulatory children in doses of 5 to 15 milliliters every 3 to 6 hours or after meals and at bedtime, as for adults with acid-peptic disorders. For prevention of GI bleeding in critically ill children, 2 to 5 milliliters may be given to infants and 5 to 15 milliliters to children every 1 to 2 hours. Safety and effectiveness of other antiulcer drugs have not been established for children.

Although most PPIs are not approved by the FDA for use in children, they are widely used in the treatment of peptic ulcer and gastroesophageal disease. They are also used to eradicate *H. pylori* organisms. Omeprazole is the only PPI approved by the FDA for children 2 years or older for the treatment of GERD or other acid related disorders. For children weighing less than 20 kilograms, the recommended dosage is 10 milligrams. For children weighing at least 20 kilograms, a dosage of 20 milligrams is recommended.

### Use in Older Adults

All of the antiulcer, anti-heartburn drugs may be used in older adults. With antacids, smaller doses may be effective because older adults usually secrete less gastric acid than younger adults. Also, with decreased renal function, older adults are more likely to have adverse effects, such as neuromuscular effects with magnesium-containing antacids. Many physicians recommend calcium carbonate antacids (e.g., Tums) as a calcium supplement to prevent or treat osteoporosis in older women.

With H<sub>2</sub>RAs, older adults are more likely to experience adverse effects, especially confusion, agitation, and disorientation with cimetidine. In addition, older adults often have decreased renal function, and doses need to be reduced.

Older adults often take large doses of NSAIDs for arthritis and therefore are at risk for development of acute gastric ulcers and GI bleeding. Thus, they may be candidates for treatment with misoprostol. Dosage of misoprostol may need to be reduced to prevent severe diarrhea and abdominal cramping.

Sucralfate is well tolerated by older adults. PPIs are also well tolerated; however, long-term use (>1 year) is associated with increased risk of hip fractures in adults older than 50 years. The risk of fractures increases the longer the medications are taken. This study also demonstrated that the risk of hip fractures is greater in those taking higher dosages of PPIs. The increased risk of fractures may be due to decreased calcium absorption due to achlorhydria resulting from PPI therapy. PPIs are probably the drug of choice for treating symptomatic GERD because evidence suggests that patients 60 years of age and older require stronger antisecretory effects than younger adults; however, appropriate dose and duration of therapy should be considered when treating GERD in older adults. H<sub>2</sub>RAs are not associated with increased risk of hip fractures in older adult.

### Use in Patients With Renal Impairment

Antacids containing magnesium are contraindicated in patients with impaired renal function (creatinine clearance < 30 mL/minute) because 5% to 10% of the magnesium may be absorbed and accumulate to cause hypermagnesemia. Antacids containing aluminum hydroxide have historically been used in patients with chronic renal failure because aluminum binds with phosphate in the GI tract, preventing phosphate absorption and hyperphosphatemia that commonly occurs in renal failure. However, aluminum may accumulate in patients with renal failure leading to encephalopathy, erythropoietin-resistant anemia, and osteomalacia. Antacids containing calcium carbonate are currently recommended for the purpose of controlling phosphate levels in patients with end-stage renal failure. Antacids with calcium carbonate can cause alkalosis and raise urine pH, and chronic use may cause renal stones and hypercalcemia.

With PPIs, no special precautions or dosage reductions are required in patients with renal impairment.

All of the available H<sub>2</sub>RAs are eliminated through the kidneys, and dosage needs to be substantially reduced in patients with renal impairment to avoid adverse effects. Cimetidine may cause mental confusion in patients with renal impairment. It also blocks secretion of creatinine in renal tubules, thereby decreasing creatinine clearance and increasing serum creatinine level. With moderate to severe renal impairment, recommended dosages include cimetidine 300 milligrams every 12 hours, ranitidine 150 milligrams orally once daily or IV every 18 to 24 hours, and famotidine 20 milligrams at bedtime or every 36 to 48 hours if indicated. Dosage may be cautiously increased if necessary and if renal function is closely monitored. For patients on hemodialysis, an H<sub>2</sub>RA should be given at the end of dialysis.

### Use in Patients With Hepatic Impairment

PPIs are metabolized in the liver and may cause transient elevations in liver function tests. With omeprazole, bioavailability is increased because of decreased first-pass metabolism, and plasma half-life is increased. However, dosage adjustments are not recommended. Lansoprazole and rabeprazole should be used cautiously, and dosage should be reduced in patients with severe liver impairment.

H<sub>2</sub>RAs are partly metabolized in the liver and may be eliminated more slowly in patients with impaired liver function. A major concern with cimetidine is that it can inhibit hepatic metabolism of many other drugs.

### Use in Patients With Critical Illness

Gastric acid-suppressant drugs (e.g., PPIs, H<sub>2</sub>RAs) and sucralfate are commonly used in critically ill patients. The PPIs are the strongest gastric acid suppressants and are usually well tolerated. For patients who cannot take drugs orally, a PPI can be given IV. The H<sub>2</sub>RAs are used to prevent stress-induced gastric ulceration in adults and children. Except for patients with

renal impairment, in whom dosage must be reduced, information about the pharmacokinetics of these drugs in critically ill patients is limited, and only cimetidine and ranitidine have been studied. Compared with healthy people, critically ill patients had a longer half-life and lower clearance rate for H<sub>2</sub>RAs. The drugs are usually given by intermittent IV infusion. Ranitidine or famotidine is preferred because critically ill patients often require numerous other drugs with which cimetidine may interact and alter effects. Nizatidine is not available in a parenteral formulation.

### Use in Home Care

All of the antiulcer, anti-heartburn drugs are commonly taken in the home setting, usually by self-administration. The home care nurse can assist patients by providing information about taking the drugs correctly and monitoring responses. If cimetidine is being taken, the home care nurse needs to assess for potential drug–drug interactions. With OTC H<sub>2</sub>RAs, patients should be instructed to avoid daily use of maximum doses for longer than 2 weeks. If use of antacids or OTC H<sub>2</sub>RAs seems to be excessive or prolonged, the patient should be assessed for peptic ulcer disease or GERD.

## Evidence-Based Practice

### 59-1 Appropriate Use of Stress Ulcer Prophylaxis

PPIs or H<sub>2</sub>RAs are often prescribed in both intensive care and nonintensive care settings in an effort to reduce the morbidity and mortality associated with gastrointestinal bleeding due to stress ulcers. It is estimated that between 27% and 50% of all hospitalized patients are prescribed medications for stress ulcer prophylaxis and about one-half of these patients are discharged with a prescription to continue taking these drugs. Although these medications have reduced the incidence of GI bleeding due to stress ulcers, several studies have examined the impact of inappropriate use of these medications. Increased health care costs and increased risk of adverse drug effects are the most commonly cited concerns. Guidelines for appropriate use of stress ulcer prophylaxis released by the American Society of Health Systems Pharmacists (1999) recommend preventative therapy in the presence of mechanical ventilation for more than 48 hours or when there is presence of coagulopathy (e.g., INR > 1.5, PTT > 2 times normal, or platelet count < 50,000). Research has shown that education regarding appropriate use of stress ulcer prophylaxis is effective in reducing the inappropriate use of these drugs.

## Nursing Actions Antiulcer Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. With proton pump inhibitors:
  - (1) Give most of the drugs before food intake; give oral pantoprazole with or without food.
  - (2) Ask patients to swallow the tablets or capsules whole, without crushing or chewing.
  - (3) For patients who are unable to swallow capsules, the lansoprazole capsule can be opened and the granules mixed with 60 mL of orange or tomato juice or sprinkled on 1 tablespoon of applesauce, Ensure pudding, cottage cheese, or yogurt, and swallowed immediately, without chewing. Esomeprazole capsules can be mixed with applesauce and swallowed without chewing.
  - (4) To give lansoprazole granules as a liquid suspension, mix 1 packet with 30 mL of water (use no other liquids), stir well, and ask the patient to swallow immediately, without chewing the granules. Esomeprazole capsules can be opened, mixed with 50 mL of water, and swallowed or administered via nasogastric tube. Flush tube with water after administration.
  - (5) With omeprazole, Do not substitute two 20-mg oral capsules or suspension packets for one 40-mg dose.
  
- (6) Give intravenous (IV) pantoprazole over 15 minutes, injected into a dedicated line or the Y-site of an IV infusion. Use the in-line filter provided; if injecting in a Y-site, the filter should be placed below the Y-site closest to the patient. Flush the IV line with 5% dextrose, 0.9% NaCl, or lactated Ringer's solution before and after pantoprazole administration. IV esomeprazole can be injected over no less than 3 minutes or infused over 10–30 minutes into a dedicated IV line. Flush the IV line with 5% dextrose or lactated Ringer's solution before and after esomeprazole administration.

### RATIONALE/EXPLANATION

Manufacturer's recommendations

Drug formulations are delayed-release and long-acting. Opening, crushing, or chewing destroys these effects. Manufacturer's recommendations. Enteric-coated, delayed-release granules are in oral capsules or separate packets. Chewing or crushing destroys the coating; mixing the granules with applesauce or other acidic substances preserves the coating of the granules, allowing them to remain intact until they reach the small intestine.

The 20-mg and 40-mg dosage contains the same amount of sodium bicarbonate. Substituting two 20-mg doses for one 40-mg dose results in administration of too much sodium bicarbonate.

**NURSING ACTIONS**

- b. With histamine ( $H_2$ ) blockers:
- (1) Give single oral doses at bedtime; give multiple oral doses of cimetidine with meals and at bedtime and other drugs without regard to food intake.
  - (2) To give oral disintegrating tablets (Pepcid RPD), open blister package with dry hands immediately before use, place on tongue, and allow to dissolve with saliva to swallow. Administration with liquids not necessary.
  - (3) To give cimetidine or ranitidine IV, dilute in 20 mL of 5% dextrose or normal saline solution, and inject over at least 2 minutes. For intermittent infusion, dilute in at least 50 mL of 5% dextrose or 0.9% sodium chloride solution, and infuse over 15–20 minutes.
  - (4) To give famotidine IV, dilute with 5–10 mL of 0.9% sodium chloride injection, and inject over at least 2 minutes. For intermittent infusion, dilute in 100 mL of 5% dextrose or 0.9% sodium chloride, and infuse over 15–30 minutes.
- c. With antacids:
- (1) Do not give doses within approximately 1 hour of oral  $H_2$  antagonists or sucralfate.
  - (2) Shake liquids well before measuring the dose.
  - (3) Instruct clients to chew antacid tablets thoroughly and follow with a glass of water.
- d. Give sucralfate 1 hour before meals and at bedtime.
- e. Give misoprostol with food.
- f. Follow package instructions for administering combination drug regimens for *Helicobacter pylori* infection (e.g., Prevpac, Helidac) and instruct patient to avoid alcohol during and 72 hours after therapy.

**2. Observe for therapeutic effects**

- a. Decreased epigastric pain with gastric and duodenal ulcers; decreased heartburn with gastroesophageal reflux disorders
- b. Decreased gastrointestinal (GI) bleeding (e.g., absence of visible or occult blood in vomitus, gastric secretions, or feces)
- c. Higher pH of gastric contents
- d. Radiologic or endoscopic reports of ulcer healing

**3. Observe for adverse effects**

- a. With proton pump inhibitors, observe for headache, diarrhea, abdominal pain, nausea, and vomiting.
- b. With  $H_2$  antagonists, observe for diarrhea or constipation, headache, dizziness, muscle aches, fatigue, skin rashes, mental confusion, delirium, coma, depression, fever.
- c. With antacids containing magnesium, observe for diarrhea and hypermagnesemia.
- d. With antacids containing aluminum or calcium, observe for constipation.

**RATIONALE/EXPLANATION**

The drugs are effective and convenient in a single oral dose at bedtime.

Antacids decrease absorption and therapeutic effectiveness of the other drugs.

These preparations are suspensions and must be mixed thoroughly to give the correct dose.

To increase the surface area of drug available to neutralize gastric acid

To allow the drug to form its protective coating over the ulcer before high levels of gastric acidity. Sucralfate requires an acidic environment. After it has adhered to the ulcer, antacids and food do not affect drug action.

Metronidazole may precipitate a disulfiram-like reaction if alcohol ingestion occurs with use.

Therapeutic effects depend on the reason for use.

Antacids should relieve pain within a few minutes. Proton pump inhibitors and  $H_2$  antagonists relieve pain in 7–10 days by healing effects on peptic ulcers or esophagitis.

The minimum acceptable pH with antacid therapy is 3.5. Healing usually occurs within 4 to 8 weeks.

These effects occur infrequently and are usually well tolerated.

Adverse effects are uncommon and usually mild with recommended doses. Central nervous system effects have been associated with high doses in elderly patients or those with impaired renal function. With long-term administration of cimetidine, other adverse effects have been observed. These include decreased sperm count and gynecomastia in men, and galactorrhea in women.

Diarrhea may be prevented by combining these antacids with other antacids containing aluminum or calcium. Hypermagnesemia may occur in patients with impaired renal function. These antacids should not be given to patients with renal failure.

Constipation may be prevented by combining these antacids with other antacids containing magnesium. A high-fiber diet, adequate fluid intake (2000–3000 mL daily), and exercise also help prevent constipation.

## Nursing Actions Antiulcer Drugs (continued)

### NURSING ACTIONS

- e. With sucralfate, observe for constipation.
- f. With misoprostol, observe for diarrhea, abdominal pain, nausea and vomiting, headache, uterine cramping, vaginal bleeding.
- g. With bismuth, observe for black stools.

### 4. Observe for drug interactions

- a. Drugs that *alter* effects of proton pump inhibitors:
  - (1) Clarithromycin *increases* effects of omeprazole.
  - (2) Sucralfate *decreases* effects of lansoprazole.
- b. Drugs that *decrease* effects of H<sub>2</sub> antagonists:
  - (1) Antacids
- c. Drugs that *alter* effects of antacids:
  - (1) Anticholinergic drugs (e.g., atropine) *increase* effects.
  - (2) Cholinergic drugs (e.g., dextpanthenol [Ilopan]) *decrease* effects.
- d. Drugs that *decrease* effects of sucralfate:
  - (1) Antacids

### RATIONALE/EXPLANATION

- The drug is not absorbed systemically and constipation is the most commonly reported adverse effect. Diarrhea commonly occurs and may be severe enough to lead to dosage reduction or stopping the drug.
- This is a harmless discoloration of feces; it does not indicate GI bleeding.
- Most significant drug interactions alter the effect of the other drug rather than that of the antiulcer or anti-gastroesophageal reflux disease (GERD) drug.
- May increase blood levels  
Decreases absorption of lansoprazole, which should be given about 30 minutes before sucralfate if both are used.
- Antacids decrease absorption of cimetidine and probably ranitidine. The drugs should not be given at the same time.
- May increase effects by delaying gastric emptying and by decreasing acid secretion themselves  
May decrease effects by increasing GI motility and rate of gastric emptying
- Antacids should not be given within 30 minutes before or after administration of sucralfate.

## Key Concepts

- Peptic ulcers are attributed to an imbalance between cell-destructive and cell-protective effects. The most common location for a peptic ulcer is the duodenum followed by the stomach and esophagus.
- Cell-destructive effects include gastric acid (hydrochloric acid), pepsin, *Helicobacter pylori* infection, and ingestion of NSAIDs.
- Cell-protective effects include secretion of mucus and bicarbonate, dilution of hydrochloric acid by food and secretions, prevention of diffusion of hydrochloric acid from the stomach back into the gastric mucosal lining, the presence of prostaglandin E, and alkalization of gastric secretions by pancreatic juices and bile.
- Gastroesophageal reflux disease (GERD) is characterized by regurgitation of acidic gastric contents into the esophagus, resulting in esophagitis or esophageal ulceration.
- Antacids are alkaline substances that neutralize acids.
- Aluminum antacids have low neutralizing capacity and often cause constipation.
- Magnesium antacids have high neutralizing capacity and may cause diarrhea and hypermagnesemia.
- Calcium antacids have high neutralizing capacity and rapid onset. They may cause rebound acidity and hypercalcemia.
- The treatment of choice for *Helicobacter pylori* infection is a PPI and clarithromycin plus either amoxicillin or metronidazole.
- The H<sub>2</sub>RAs (e.g., cimetidine, famotidine, nizatidine, and ranitidine) inhibit secretion of gastric acid, decreasing the acidity of gastric juices. They are indicated for prevention and treatment of heartburn, peptic ulcer disease, GERD, esophagitis, GI bleeding due to stress ulcers, and hypersecretory syndromes such as Zollinger-Ellison syndrome.
- The PPIs (e.g., esomeprazole, lansoprazole, omeprazole, pantoprazole, rabeprazole) bind irreversibly to the gastric proton pump to prevent the release of gastric acid from parietal cells into the stomach lumen. They are considered drugs of choice for treatment of heartburn, gastric and duodenal ulcers, GERD, esophagitis, and hypersecretory syndromes such as Zollinger-Ellison syndrome.

- Misoprostol is a synthetic form of prostaglandin E approved for concurrent use with NSAIDs to protect the gastric mucosa from NSAID-induced erosion and ulceration.
- Sucralfate forms a protective barrier over mucosal ulcerations, protecting from exposure to gastric juices. It requires an acid pH to be effective.

## Review and Application Exercises

### Short Answer Exercises

1. What are risk factors for peptic ulcer disease?
2. What roles do gastric acid, pepsin, *H. pylori* organisms, prostaglandins, and mucus play in peptic ulcer occurrence?
3. How do the various drug groups heal ulcers or prevent their recurrence?
4. Compare H<sub>2</sub>RAs and PPIs in indications for use and effectiveness.
5. What is the rationale for taking H<sub>2</sub> blockers at bedtime, sucralfate before meals, and antacids after meals?
6. Why are aluminum and magnesium salts often combined in antacid preparations?
7. For a patient who smokes cigarettes and is newly diagnosed with peptic ulcer disease, how would you explain that smoking cessation aids ulcer healing?
8. Compare and contrast peptic ulcer disease and GERD in terms of risk factors, drug therapy, and patient teaching needs.

### NCLEX-Style Questions

9. When taking a patient's history, the nurse notes that the patient is taking warfarin and cimetidine, an H<sub>2</sub>RA, concurrently. The nurse should anticipate that the
  - a. warfarin effects would be increased
  - b. cimetidine effects would be increased
  - c. warfarin effects would be decreased
  - d. cimetidine effects would be decreased
10. The nurse explains to the patient being discharged who is taking sucralfate that the medication should be administered
  - a. at the same time as an antacid
  - b. after meals
  - c. with meals
  - d. 2 hours before other drugs
11. A patient with *H. pylori* develops a related ulcer. He is placed on ranitidine and Helidac, a drug combination that contains bismuth, metronidazole, and tetracycline. The patient had been instructed not to consume alcohol, ignored the teaching, and drank beer. The patient presents to the emergency department with tachycardia, headache, diaphoresis, and nausea and vomiting. This disulfiram-like reaction occurred because of the interaction between the alcohol and which drug in the combination?
  - a. ranitidine
  - b. bismuth
  - c. metronidazole
  - d. tetracycline
12. A patient asks the nurse how sucralfate (Carafate) works. The nurse replies that sucralfate
  - a. inhibits gastric acid secretion
  - b. increases mucus and bicarbonate secretion
  - c. binds to normal and ulcerated mucosa, creating a protective barrier
  - d. enhances prostaglandin synthesis
13. One of the most common adverse effects of misoprostol that makes the drug difficult to tolerate in older adults is
  - a. headache
  - b. constipation
  - c. hyperphosphatemia
  - d. diarrhea

# Laxatives and Cathartics

## KEY TERMS

- Cathartic
- Constipation
- Defecation
- Flatulence
- Impaction
- Laxative

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Differentiate the major types of laxatives according to effects on the gastrointestinal tract.
2. Differentiate the consequences of occasional use from those of chronic use.
3. Discuss rational choices of laxatives for selected patient populations or purposes.
4. Discuss bulk-forming laxatives as the most physiologic agents.
5. Discuss possible reasons for and hazards of overuse and abuse of laxatives.

## Applying Your Knowledge

Mia Campbell is an 84-year-old woman. Her past health history includes arthritis, osteoporosis, hemorrhoids, and peptic ulcer disease. She is complaining about being constipated. You are her home care nurse.

## Introduction

Laxatives and cathartics are drugs used to promote bowel elimination (*defecation*). The term *laxative* implies mild effects and elimination of soft, formed stool. The term *cathartic* implies strong effects and elimination of liquid or semiliquid stool. Because the different effects depend more on the dose than on the particular drug used, the terms often are used interchangeably.

## Defecation

Defecation is normally stimulated by movements and reflexes in the gastrointestinal (GI) tract. When the stomach and duodenum are distended with food or fluids, gastrocolic and duodenocolic reflexes cause propulsive movements in the colon, which move feces into the rectum and arouse the urge to defecate. When sensory nerve fibers in the rectum are stimulated by the fecal mass, the defecation reflex causes strong peristalsis, deep breathing, closure of the glottis, contraction of abdominal muscles, contraction of the rectum, relaxation of anal sphincters, and expulsion of the fecal mass.

The cerebral cortex normally controls the defecation reflex so that defecation can occur at acceptable times and places. Voluntary control inhibits the external anal sphincter to allow defecation or contracts the sphincter to prevent defecation. When the external sphincter remains contracted, the defecation reflex dissipates, and the urge to defecate usually does not recur until additional feces enter the rectum or several hours later.

In people who often inhibit the defecation reflex or fail to respond to the urge to defecate, constipation develops as the reflex weakens. *Constipation* is the infrequent and painful expulsion of hard, dry stools. Although there is no “normal” number of stools because of variations in diet and other factors, most people report more than three bowel movements per week. Normal bowel elimination should produce a soft, formed stool without pain.

## General Characteristics of Laxatives and Cathartics

### Indications for Use

There are several rational indications for use:

- To relieve constipation in pregnant women, elderly patients whose abdominal and perineal muscles have become weak and atrophied, children with megacolon, and patients receiving drugs that decrease intestinal motility (e.g., opioid analgesics, drugs with anticholinergic effects)
- To prevent straining at stool in patients with coronary artery disease (e.g., post–myocardial infarction), hypertension, cerebrovascular disease, and hemorrhoids and other rectal conditions
- To empty the bowel in preparation for bowel surgery or diagnostic procedures (e.g., colonoscopy, barium enema)
- To accelerate elimination of potentially toxic substances from the GI tract (e.g., orally ingested drugs or toxic compounds)
- To prevent absorption of intestinal ammonia in patients with hepatic encephalopathy
- To obtain a stool specimen for parasitologic examination
- To accelerate excretion of parasites after anthelmintic drugs have been administered
- To reduce serum cholesterol levels (psyllium products)

### Contraindications to Use

Laxatives and cathartics should not be used in the presence of undiagnosed abdominal pain. The danger is that the drugs may cause an inflamed organ (e.g., the appendix) to rupture and spill GI contents into the abdominal cavity with subsequent peritonitis, a life-threatening condition. Oral drugs also are contraindicated with intestinal obstruction and fecal *impaction*.

## Classifications and Individual Drugs

Laxatives and cathartics are somewhat arbitrarily classified as bulk-forming laxatives, surfactant laxatives or stool softeners, saline cathartics, stimulant cathartics, lubricant or emollient laxatives, and miscellaneous. Individual drugs are listed in Table 60-1.

### Bulk-Forming Laxatives

Bulk-forming laxatives (e.g., **polycarbophil**, **psyllium seed**) are substances that are largely unabsorbed from the intestine. When water is added, these substances swell and become gel-like. The added bulk or size of the fecal mass stimulates peristalsis and defecation. The substances also may act by pulling water into the intestinal lumen. Bulk-forming laxatives are the most physiologic laxatives because their effect is similar to that of increased intake of dietary fiber. They usually act within 12 to 24 hours but may take as long as 2 to 3 days to exert their full effects.

### Surfactant Laxatives (Stool Softeners)

Surfactant laxatives (e.g., **docusate calcium**, **potassium**, or **sodium**) decrease the surface tension of the fecal mass to allow water to penetrate into the stool. They also act as a detergent to facilitate admixing of fat and water in the stool. As a result, stools are softer and easier to expel. These agents have little if any laxative effect. Their main value is to prevent straining while expelling stool. They usually act within 1 to 3 days and should be taken daily.

### Saline Laxatives

Saline laxatives (e.g., **magnesium citrate**, **milk of magnesia**) are not well absorbed from the intestine. Consequently, they increase osmotic pressure in the intestinal lumen and cause water to be retained. Distention of the bowel leads to increased peristalsis and decreased intestinal transit time for the fecal mass. The resultant stool is semifluid. These laxatives are used when rapid bowel evacuation is needed. With oral magnesium preparations, effects occur within 0.5 to 6 hours; with sodium phosphate-containing rectal enemas, effects occur within 15 minutes.

Saline laxatives are generally useful and safe for short-term treatment of constipation, cleansing the bowel before endoscopic examinations, and treating fecal impaction. However, they are not safe for frequent or prolonged usage or for certain patients because they may produce fluid and electrolyte imbalances. For example, patients with impaired renal function are at risk of developing hypermagnesemia with magnesium-containing laxatives because some of the magnesium is absorbed systemically. Patients with congestive heart failure are at risk of fluid retention and edema with sodium-containing laxatives.

**Polyethylene glycol–electrolyte solution** (e.g., **NuLytely**) is a nonabsorbable oral solution that induces diarrhea within 30 to 60 minutes and rapidly evacuates the bowel, usually within 4 hours. It is a prescription drug used for bowel cleansing before GI examination (e.g., colonoscopy) and is contraindicated in patients with GI obstruction, gastric retention, colitis, or bowel perforation. Combination products such as **HalfLytely** combine polyethylene glycol with a stimulant cathartic, bisacodyl, to evacuate the colon in preparation for a colonoscopy. **Polyethylene glycol solution**

Table 60-1

## Drugs at a Glance: Laxatives and Cathartics

Generic/Trade Name	ROUTES AND DOSAGES RANGES	
	Adults	Children
<b>Bulk-Forming Laxatives</b>		
Methylcellulose (Citrucel)	PO 1 heaping tbsp 1–3 times daily with water (8 oz or more)	12 y and older: PO same dosage as adults 6–11 y: PO 1/2 the adult dosage in 8 oz water once daily
Polycarbophil (FiberCon, Mitrolan)	PO 1 g 1–4 times daily or PRN with 8 oz of fluid; maximum dose 4 g/24 h	6–12 y: PO 500 mg 1–3 times daily or PRN; maximum dose 2 g/24 h 2–6 y: products vary, consult labels
Psyllium preparations (Metamucil, Effersyllium, Serutan, Perdiem Plain)	PO 1 rounded tsp 1–3 times daily, stirred in at least 8 oz water or other liquid	12 y and older: PO same dosage as adults 6–11 y: PO 1/2 the adult dosage in 8 oz water once daily
<b>Surfactant Laxatives (Stool Softeners)</b>		
Docusate sodium (Colace)	PO 50–300 mg daily	12 y and older: PO same dosage as adults 6–11 y: 100 mg daily 2–6 y: products vary, consult labels
Docusate calcium (Surfak)	PO 240 mg daily	12 y and older: PO same dosage as adults
<b>Saline Cathartics</b>		
Magnesium citrate solution	PO 1/2–1 bottle at bedtime	12 y and older: PO same dosage as adults 6–11 y: 1/2–1/4 bottle at bedtime
Magnesium hydroxide (milk of magnesia, magnesia magma)	Regular liquid: PO 30–60 mL at bedtime Concentrated liquid: PO 15–30 mL at bedtime	Regular liquid: 12 y and older: PO same dosage as adults 6–11 y: 15–30 mL at bedtime 2–5 y: 5–15 mL at bedtime Concentrated liquid: 12 y and older: PO same dosage as adults 6–11 y: 7.5–15 mL at bedtime 2–5 y: 2.5–7.5 mL at bedtime
Polyethylene glycol (PEG) solution (Miralax)	PO 17 g in 8 oz water	No pediatric dosage
Polyethylene glycol-electrolyte solution (PEG-ES) (CoLyte, GoLyteLy, NuLyteLy, OCL)	For bowel cleansing before GI examination: PO 240 mL every 10 min until 4 L is consumed	No recommended children's dose
Sodium phosphate and sodium biphosphate (Fleet Phosphosoda, Fleet Enema)	PO 20–40 mL in 8 oz water Rectal enema, 60–120 mL	10 y and older: PO 10–20 mL in 8 oz of water 5–10 y: PO 5–10 mL in 8 oz of water Rectal enema, 60 mL
<b>Stimulant Cathartics</b>		
Bisacodyl (Dulcolax)	PO 10–15 mg Rectal suppository, 10 mg	6 y and older: PO 5 mg Rectal suppository, 5 mg
Cascara sagrada	PO tablets, 325 mg PO aromatic, 2.5–5 mL PO aromatic fluid extract, 2–6 mL	PO tablets and aromatic fluid extract: 12 y and older: same dosage as adults PO aromatic: 2–12 y: PO 1/5–1/2 tsp
Castor oil (Neoloid)	PO 15–60 mL	5–15 y: PO 5–30 mL depending on strength of emulsion under 2 y: PO 1.25–7.5 mL depending on strength of emulsion

(continued on page 974)

Table 60-1

## Drugs at a Glance: Laxatives and Cathartics (continued)

Generic/Trade Name	ROUTES AND DOSAGES RANGES	
	Adults	Children
Glycerin	Rectal suppository, 3 g	under 6 y: rectal suppository 1–1.5 g
Senna preparations (Senokot, Black Draught)	Granules, PO 1 level tsp once or twice daily Syrup, PO 2–3 tsp once or twice daily Tablets, PO 2 tablets once or twice daily For geriatric, obstetric, gynecologic patients, reduce all dosages by half	Weight > 27 kg: granules, syrup, and tablets, 1/2 the adult dosage
<b>Combination Product</b> Halflytely and bisacodyl tablets Bowel Prep Kit	For bowel cleansing before colonoscopy: PO 4 bisacodyl tablets (5 mg each) with water. After bowel movement occurs, drink 8 oz of Halflytely solution every 10 min until 2 L of solution is consumed.	Pediatric dosage not established
<b>Lubricant Laxative</b> Mineral oil (Agoral Plain, Milkinol, Fleet Mineral Oil Enema)	PO 15–30 mL at bedtime Rectal enema, 30–60 mL	older than 6 y: PO 5–15 mL at bedtime Rectal enema, 30–60 mL
<b>Miscellaneous Medications</b> Lactulose (Chronulac, Cephulac)	For constipation: PO 15–30 mL daily; maximum dose 60 mL daily Portal systemic encephalopathy: PO 30–45 mL 3 or 4 times daily, adjusted to produce two or three soft stools daily Rectally as retention enema, 300 mL with 700 mL water or normal saline, retained 30–60 min, every 4–6 h	Infants: PO 2.5–10 mL daily in divided doses older children: PO 40–90 mL daily in divided doses
Lubiprostone (Amitiza)	For chronic idiopathic constipation: PO 24 mcg twice daily with food	Pediatric dosage not established
Sorbitol	For hyperkalemia (with Kayexalate), PO 30–50 g daily	

(MiraLax) is an oral laxative that may be used to treat occasional constipation. Effects may require 2 to 4 days. It is a prescription drug and should not be taken longer than 2 weeks.

### Stimulant Cathartics

The stimulant cathartics are the strongest and most abused laxative products. These drugs act by irritating the GI mucosa and pulling water into the bowel lumen. As a result, feces are moved through the bowel too rapidly to allow colonic absorption of fecal water, so a watery stool is eliminated. These drugs should not be used frequently or for longer than 1 week

because they may produce serum electrolyte and acid–base imbalances (e.g., hypocalcemia, hypokalemia, metabolic acidosis or alkalosis).

Oral stimulant cathartics include **bisacodyl**, **cascara sagrada**, **castor oil**, and **senna products**. These products produce laxative effects in 6 to 12 hours. As a result, a single bedtime dose usually produces a morning bowel movement. Rectal suppository products include bisacodyl, which produces effects within 15 minutes to 2 hours, and **glycerin**. In addition to irritant, stimulant effects, glycerin exerts hyperosmotic effects in the colon. It usually acts within 30 minutes. Glycerin is not given orally for laxative effects.

## Lubricant Laxative

**Mineral oil** is the only lubricant laxative used clinically. It lubricates the fecal mass and slows colonic absorption of water from the fecal mass, but the exact mechanism of action is unknown. Effects usually occur in 6 to 8 hours. Oral mineral oil may cause several adverse effects and is not recommended for long-term use. Mineral oil enemas are sometimes used to soften fecal impactions and aid their removal.

## Miscellaneous Medications for Constipation

**Lactulose** is a disaccharide that is not absorbed from the GI tract. It exerts laxative effects by pulling water into the intestinal lumen. It is used to treat constipation and hepatic encephalopathy. The latter condition usually results from alcoholic liver disease in which ammonia accumulates and causes stupor or coma. Ammonia is produced by metabolism of dietary protein and intestinal bacteria. Lactulose decreases production of ammonia in the intestine. The goal of treatment is usually to maintain two to three soft stools daily; effects usually occur within 24 to 48 hours. The drug should be used cautiously because it may produce electrolyte imbalances and dehydration.

**Lubiprostone (Amitiza)** is indicated for the treatment of chronic idiopathic constipation in adults. Chronic idiopathic constipation, defined as the infrequent or difficult passage of stool, is characterized by abnormal GI motility, abdominal discomfort, bloating, and straining to pass hard, lumpy stools. Lubiprostone is poorly absorbed into the circulation and exerts its effect locally, activating chloride channels in the GI tract to increase the secretion of chloride rich fluids into the intestine. Increased intestinal fluid secretion stimulates intestinal motility, improving the passage of stool. Lubiprostone is metabolized by enzymes in the stomach and excreted in the urine and feces. Adverse effects include nausea and severe diarrhea. Taking lubiprostone with food may aid in decreasing nausea.

**Sorbitol** is a monosaccharide that pulls water into the intestinal lumen and has laxative effects. It is often given with sodium polystyrene sulfonate (Kayexalate), a potassium-removing resin used to treat hyperkalemia, to prevent constipation, and aid expulsion of the potassium-resin complex.

## Herbal and Dietary Supplements

Many of the commonly used laxatives are plant based (e.g., cascara, psyllium, senna, castor oil). These have long been used and are safe and effective when used as directed.

Aloe is used most often as a topical remedy for burns and possibly other minor wounds. When used for this purpose, a gel-like liquid can be squeezed directly from a plant leaf onto the burned area. Oral aloe is sometimes used as a laxative. However, it is not recommended for this use because it is a strong stimulant laxative. With oral ingestion, aloe can cause

severe cramping and other potentially serious adverse effects, including hypokalemia and cardiac dysrhythmias.

### Applying Your Knowledge 60-1

Based on Ms. Campbell's past health history, what is the most likely drug of choice?

.....

### Applying Your Knowledge 60-2

Given Ms. Campbell's complaint of constipation, what would you assess with regard to her bowel pattern and risk for constipation?

.....

## Nursing Process

### Assessment

Assess patients for current or potential constipation.

- Identify risk factors.
- Diet with minimal fiber (e.g., small amounts of fruits, vegetables, and whole-grain products)
- Low fluid intake (e.g., <2000 mL daily)
- Immobility or limited activity
- Drugs that reduce intestinal function and motility (e.g., opioid analgesics, antacids containing aluminum or calcium, anticholinergics, calcium channel blockers, clozapine, diuretics, iron, phenothiazines, cholestyramine, colestipol, sucralfate, tricyclic antidepressants, vincristine). Overuse of antidiarrheal agents also may cause constipation.
- Conditions that may reduce intestinal function and motility (e.g., depression, eating disorders such as anorexia nervosa, hypothyroidism, hypercalcemia, multiple sclerosis, Parkinson's disease, spinal lesions)
- Hemorrhoids, anal fissures, or other conditions characterized by painful bowel elimination
- Elderly or debilitated patients
- Signs and symptoms include the following:
  - Decreased number and frequency of stools
  - Passage of dry, hard stools
  - Abdominal distention and discomfort
  - Flatulence

### Nursing Diagnoses

- Constipation related to decreased activity; inadequate dietary fiber; inadequate fluid intake; drugs; or disease processes

*Nursing Process continues on page 976*

- Pain (abdominal cramping and distention) related to constipation or use of laxatives
- Noncompliance with recommendations for nondrug measures to prevent or treat constipation
- Risk for Deficient Fluid Volume related to diarrhea from frequent or large doses of laxatives
- Deficient Knowledge: Nondrug measures to prevent constipation and appropriate use of laxatives

## Planning/Goals

### The patient will

- Take laxative drugs appropriately
- Use nondrug measures to promote normal bowel function and prevent constipation
- Regain normal patterns of bowel elimination
- Avoid excessive losses of fluids and electrolytes from laxative use
- Be protected from excessive fluid loss, hypotension, and other adverse drug effects, when possible
- Be assisted to avoid constipation when at risk (eg, has illness or injury that prevents activity and food and fluid intake; takes medications that decrease GI function)

## Interventions

- Assist patients with constipation and caregivers to
  - Understand the importance of diet, exercise, and fluid intake in promoting normal bowel function and preventing constipation
  - Increase activity and exercise
  - Increase intake of dietary fiber (e.g., vegetables, fruits, cereal grains)
  - Drink at least 2000 mL of fluid daily
  - Establish and maintain a routine for bowel elimination (e.g., going to the bathroom immediately after breakfast)
  - Understand and comply with drug therapy (see accompanying Patient Teaching Guidelines)
- Monitor client responses.
  - Record number, amount, and type of bowel movements.
  - Record vital signs. Hypotension and weak pulse may indicate deficient fluid volume.

## Evaluation

- Observe and interview for improved patterns of bowel elimination.
- Observe for use of nondrug measures to promote bowel function.
- Observe for appropriate use of laxatives.
- Observe and interview regarding adverse effects of laxatives.

## Principles of Therapy

### Laxative Abuse

Laxatives and cathartics are widely available on a nonprescription basis and are among the most frequently abused drugs. One reason for overuse is the common misconception that a daily bowel movement is necessary for health and well-being, even with little intake of food or fluids. This notion may lead to a vicious cycle of events in which a person fails to have a bowel movement, takes a strong laxative, again fails to have a bowel movement, and takes another laxative before the fecal column has had time to become re-established (2–3 days with normal food intake). Thus, a pattern of laxative dependence and abuse is established.

Laxatives are also abused for weight control, probably most often by people with eating disorders and those who must meet strict weight requirements (e.g., some athletes). This is a very dangerous practice because it may lead to life-threatening fluid and electrolyte imbalances.

### Drug Selection

In 2005, a review of published studies of efficacy and safety of medications for chronic constipation was completed to provide evidence-based recommendations for treatment. This review concluded that there was good evidence for the use of polyethylene glycol, lactulose, and psyllium to treat chronic constipation. There was minimal evidence in the published literature for many commonly used agents, including magnesium hydroxide, senna, bisacodyl, and stool softeners.

Clinically, the choice of a laxative or cathartic often depends on the reason for use and the patient's condition:

- For long-term use of laxatives or cathartics in patients who are older, unable or unwilling to eat an adequate diet, or debilitated, bulk-forming laxatives (e.g., Metamucil) usually are preferred. However, because obstruction may occur, these agents should not be given to patients with difficulty in swallowing or adhesions or strictures in the GI tract or to those who are unable or unwilling to drink adequate fluids.
- For patients in whom straining is potentially harmful or painful, stool softeners (e.g., docusate sodium) are the agents of choice.
- For occasional use to cleanse the bowel for endoscopic or radiologic examinations, saline or stimulant cathartics are acceptable (e.g., magnesium citrate, polyethylene glycol–electrolyte solution, bisacodyl). These drugs should not be used more than once per week. Frequent use is likely to produce laxative abuse.
- Oral use of mineral oil may cause potentially serious adverse effects (decreased absorption of fat-soluble vitamins and some drugs; lipid pneumonia if aspirated into the lungs). Thus, mineral oil is not an oral laxative of choice in any condition, although occasional use in the alert patient is unlikely to be harmful. It should not be used regularly.

## Patient Teaching Guidelines

### Laxatives

#### General Considerations

- Diet, exercise, and fluid intake are important in maintaining normal bowel function and preventing or treating constipation.
- Eat foods high in dietary fiber daily. Fiber is the portion of plant food that is not digested. It is contained in fruits, vegetables, and whole-grain cereals and breads. Bran, the outer coating of cereal grains such as wheat or oats, is an excellent source of dietary fiber and is available in numerous cereal products.
- Drink at least 6 to 10 glasses (8 oz each) of fluid daily if not contraindicated.
- Exercise regularly. Walking and other activities aid movement of feces through the bowel.
- Establish a regular time and place for bowel elimination. The defecation urge is usually strongest after eating and the defecation reflex is weakened or lost if repeatedly ignored.
- Laxative use should be temporary and not regular, as a general rule. Regular use may prevent normal bowel function, cause adverse drug reactions, and delay treatment for conditions that cause constipation.
- Never take laxatives when acute abdominal pain, nausea, or vomiting is present. Doing so may cause a ruptured appendix or other serious complication.
- After taking a strong laxative, it takes 2 to 3 days of normal eating to produce enough feces in the bowel for a bowel movement. Frequent use of a strong laxative promotes loss of normal bowel function, loss of fluids and electrolytes that your body needs, and laxative dependence.
- If you have chronic constipation and are unable or unwilling to eat enough fiber-containing foods in your diet, the next-best action is regular use of a bulk-forming laxative

(e.g., Metamucil) as a dietary supplement. These laxatives act the same way as increasing fiber in the diet and are usually best for long-term use. When taken daily, they can prevent constipation. However, they may take 2 to 3 days to work and are not effective in relieving acute constipation.

- Your urine may be discolored if you take a laxative containing senna (e.g., Senokot) or cascara sagrada. The color change is not harmful.
- Some people use strong laxatives for weight control. This is an inappropriate use and a dangerous practice because it can lead to life-threatening fluid and electrolyte imbalances, including dehydration and cardiovascular problems.

#### Self- or Caregiver Administration

- Take all laxatives as directed and do not exceed recommended doses to avoid adverse effects.
- With bulk-forming laxatives, mix in 8 oz of fluid immediately before taking and follow with additional fluid, if able. Never take the drug dry. Adequate fluid intake is essential with these drugs.
- With bisacodyl tablets, swallow whole (do not crush or chew), and do not take within 1 hour of an antacid or milk. This helps prevent stomach irritation, abdominal cramping, and possible vomiting.
- Take magnesium citrate or milk of magnesia on an empty stomach with 8 oz of fluid to increase effectiveness.
- Refrigerate magnesium citrate before taking to improve taste and retain effectiveness.
- Mix lactulose with fruit juice, water, or milk, if desired, to improve taste.
- Take lubiprostone (Amitiza) with food.
- Notify your health care provider if severe diarrhea develops while taking lubiprostone.

Mineral oil is probably most useful as a retention enema to soften hard, dry feces and aid in their expulsion.

- In fecal impaction, a rectal suppository (e.g., bisacodyl) or an enema (e.g., oil retention or Fleet enema) is preferred. Oral laxatives are contraindicated when fecal impaction is present but may be given after the rectal mass is removed. After the impaction is relieved, measures should be taken to prevent recurrence. If dietary and other nonpharmacologic measures are ineffective or contraindicated, use of a bulk-forming agent daily or another laxative once or twice weekly may be necessary.
- Saline cathartics containing magnesium, phosphate, or potassium salts are contraindicated in patients with renal failure because hypermagnesemia, hyperphosphatemia, or hyperkalemia may occur.
- Saline cathartics containing sodium salts are contraindicated in patients with edema or congestive heart failure because enough sodium may be absorbed to cause further fluid retention and edema. They also should not be used in patients with impaired renal function or those following a sodium-restricted diet for hypertension.

- Polyethylene glycol–electrolyte solution is formulated for rapid and effective bowel cleansing without significant changes in water or electrolyte balance.

### Use in Special Populations

#### Use in Children

Constipation is responsible for 3% of visits to pediatric clinics and up to 30% of visits to pediatric gastroenterologists. As in adults, increasing fluids, high-fiber foods, and exercise is preferred when possible.

Guidelines for treating constipation in infants and children developed by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition include the following recommendations:

- For infants:
  - Glycerin suppositories are often effective in infants and small children.
  - Lactulose or sorbitol can be used as stool softeners in infants.
  - Mineral oil or stimulant laxatives are not recommended for infants.

- For children:
  - Mineral oil, magnesium hydroxide, lactulose and sorbitol are effective for treating constipation in children.
  - Stimulant laxatives, such as senna or bisacodyl, can be used short-term as rescue therapy or in carefully selected patients with constipation that is difficult to treat. Polyethylene glycol–electrolyte solution in low dosages may be an effective long-term treatment for difficult to treat cases.

Parents should be advised not to give children any laxative more than once a week without consulting a health care provider. Polyethylene glycol–electrolyte solution is effective in treating acute iron overdose in children, although it is not approved by the U.S. Food and Drug Administration for this indication.

### Applying Your Knowledge 60-3

#### How Can You Avoid This Medication Error?

Ms. Campbell is concerned about not having a bowel movement. She takes a psyllium preparation at 8 A.M. She does not have a result by noon, so she takes milk of magnesia. She has not had a stool by supper, so she takes a glycerin suppository.

### Use in Older Adults

As many as 15% to 20% of community-dwelling older adults and up to 50% of nursing home residents experience constipation. Laxatives are often used or overused. Nondrug measures to prevent constipation (e.g., increasing fluids and high-fiber foods, exercise) are much preferred to laxatives. If a laxative is required on a regular basis, a bulk-forming psyllium compound (e.g., Metamucil) is best because it is most physiologic in its action. If taken, it should be accompanied by a full glass of fluid. There have been reports of obstruction in the GI tract when a psyllium compound was taken with insufficient fluid. Regular use of stronger laxatives should be avoided; however, when necessary they should be taken infrequently at the lowest effective dose. Mineral oil should be avoided in bedfast elderly individuals due to the risks of lipid-aspiration pneumonia.

### Use in Patients With Cancer

Many patients with cancer require moderate to large amounts of opioid analgesics for pain control. The analgesics slow GI motility and cause constipation. These patients often need a bowel-management program that includes routine laxative administration; however, a recent Cochrane review of research on laxatives for the management of constipation in palliative care found insufficient data to make a recommendation on the best laxative for these patients. Bulk-forming laxatives are not usually recommended for patients with cancer because they may not be able to drink adequate amounts of fluids required with these medications. One treatment option, stimulant laxatives (e.g., a senna preparation, bisacodyl) increase intestinal

motility, which is the action that opiates suppress. These drugs may cause abdominal cramping, which may be lessened by giving small doses three or four times daily.

### Use in Patients With Spinal Cord Injury

Spinal cord injury (SCI) impairs the ability of an individual to sense that a bowel movement is imminent and the ability to control the timing and place of bowel evacuation. Common problems that the individual with SCI must cope with include incontinence and fecal impaction, which if left untreated may result in perforation of the bowel.

SCIs above the twelfth thoracic vertebrae (T12) are referred to as upper motor neuron injuries. Individuals with this type of SCI are unable to sense when the bowel is full. The anal sphincter remains closed until the bowel becomes distended with stool, resulting in uncontrolled reflex emptying. Individuals with upper motor neuron injuries usually follow a bowel program that includes taking a daily stool softener such as docusate sodium and stimulating bowel movements at the desired time using digital stimulation and rectal suppositories such as bisacodyl or glycerin.

SCIs below T12 are referred to as lower motor neuron injuries. With this type of SCI, the muscles of the colon and anus remain relaxed or flaccid, resulting in constipation and incontinence. The bowel-control program for individuals with lower motor neuron injuries involves digital stimulation and manual removal of the stool. Initially, digital disimpaction should be done every other day. It may be necessary to increase the frequency of digital disimpaction to every day to avoid unplanned bowel movements or constipation and impaction.

With both types of SCIs the goal of the bowel program is to have regular bowel movements at a predictable time and place and to minimize “accidents.” It is recommended to implement the bowel program at the same time each day, preferably after a meal. Factors that influence bowel activity must be considered in the bowel program. These factors include eating at regular intervals, including high-fiber foods in the diet, adequate intake of fluids in the diet, avoidance of medications and foods that may cause diarrhea or constipation, and an awareness of cues that a bowel movement may be imminent, such as sweating, restlessness, sensations of fullness in the lower abdomen, and piloerection or “goose bumps.”

### Use in Patients With Renal Impairment

Saline cathartics containing phosphate, sodium, magnesium, or potassium salts are usually contraindicated or must be used cautiously in the presence of impaired renal function. Ten percent or more of the magnesium in magnesium salts may be absorbed and cause hypermagnesemia; sodium phosphate and sodium biphosphate may cause hyperphosphatemia, hypernatremia, acidosis, and hypocalcemia; and potassium salts may cause hyperkalemia.

### Use in Patients With Hepatic Impairment

Because most laxatives are not absorbed or metabolized extensively, they can usually be used without difficulty in patients with hepatic impairment. In fact, they are used therapeutically

in patients with hepatic encephalopathy to decrease absorption of ammonia from dietary protein in the GI tract. Lactulose is usually given in dosages to produce two to three soft stools daily.

### Use in Home Care

Laxatives are commonly self-prescribed and self-administered in the home setting. The home care nurse may become

involved when visiting a patient for other purposes. The role of the home care nurse may include assessing usual patterns of bowel elimination, identifying patients at risk of developing constipation, promoting lifestyle interventions to prevent constipation, obtaining laxatives when indicated, and counseling about rational use of laxatives.

## Nursing Actions Laxatives and Cathartics

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give bulk-forming laxatives with at least 8 oz of water or other fluid. Mix with fluid immediately before administration.
- b. With bisacodyl tablets, instruct the client to swallow the tablets without chewing and not to take them within an hour after ingesting milk or gastric antacids or while receiving cimetidine therapy.
- c. Give saline cathartics on an empty stomach with 240 mL of fluid.
- d. Take lubiprostone with food.
- e. Refrigerate magnesium citrate and polyethylene glycol electrolyte solution before giving.
- f. Castor oil may be chilled and followed by fruit juice or other beverage.
- g. Insert rectal suppositories to the length of the index finger, next to rectal mucosa.

#### 2. Observe for therapeutic effects

- a. Soft to semiliquid stool
- b. Liquid to semiliquid stool
- c. Decreased abdominal pain when used in clients with irritable bowel syndrome or diverticulosis
- d. Decreased rectal pain when used in clients with hemorrhoids or anal fissures

#### 3. Observe for adverse effects

- a. Diarrhea—several liquid stools, abdominal cramping. Severe, prolonged diarrhea may cause hyponatremia, hypokalemia, dehydration, and other problems.
- b. With bulk-forming agents, impaction or obstruction
- c. With saline cathartics, hypermagnesemia, hyperkalemia, fluid retention, and edema
- d. With mineral oil, lipid pneumonia and decreased absorption of vitamins A, D, E, and K

### RATIONALE/EXPLANATION

- To prevent thickening and expansion in the gastrointestinal (GI) tract with possible obstruction. These substances absorb water rapidly and solidify into a gelatinous mass.
- The tablets have an enteric coating to delay dissolution until they reach the alkaline environment of the small intestine. Chewing or giving the tablets close to antacid substances or to cimetidine-treated clients causes premature dissolution and gastric irritation and results in abdominal cramping and vomiting.
- To increase effectiveness
- Presence of food may help decrease nausea.
- To increase palatability and retain potency
- To increase palatability
- These drugs are not effective unless they are in contact with intestinal mucosa.
- Therapeutic effects occur in approximately 1–3 days with bulk-forming laxatives and stool softeners; 6–8 hours with bisacodyl tablets, cascara sagrada, and senna products; 15–60 minutes with bisacodyl and glycerin suppositories.
- Effects occur in approximately 1–3 hours with saline cathartics and castor oil.
- Pain results from straining to expel hard, dry feces.
- Diarrhea is most likely to result from strong, stimulant cathartics (e.g., castor oil, bisacodyl, senna preparations), large doses of saline cathartics (e.g., milk of magnesia), or use of lubiprostone.
- Impaction or obstruction of the GI tract can be prevented by giving ample fluids with these agents and not giving the drugs to clients with known dysphagia or strictures anywhere in the alimentary canal.
- Hypermagnesemia and hyperkalemia are more likely to occur in patients with renal insufficiency because of impaired ability to excrete magnesium and potassium. Fluid retention and edema are more likely to occur in patients with congestive heart failure or other conditions characterized by edema. Polyethylene glycol–electrolyte solution produces the least change in water and electrolyte balance.
- Lipid pneumonia can be prevented by not giving mineral oil to patients with dysphagia or impaired consciousness.
- Decreased absorption of fat-soluble vitamins can be prevented by not giving mineral oil with or shortly after meals or for longer than 2 weeks.

## Nursing Actions Laxatives and Cathartics (continued)

### NURSING ACTIONS

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of laxatives and cathartics:
  - (1) GI stimulants (e.g., metoclopramide)
- b. Drugs that *decrease* effects of laxatives and cathartics:
  - (1) Anticholinergic drugs (e.g., atropine) and other drugs with anticholinergic properties (e.g., phenothiazine antipsychotic drugs, tricyclic antidepressants, some antihistamines, and antiparkinson drugs)
  - (2) Central nervous system depressants (e.g., opioid analgesics)

### RATIONALE/EXPLANATION

Additive stimulation of intestinal motility

These drugs slow intestinal motility. Patients receiving these agents are at risk for development of constipation and requiring laxatives, perhaps on a long-term basis.

Opioid analgesics commonly cause constipation.

## Key Concepts

- Constipation is the infrequent and painful expulsion of hard, dry stools.
- Lifestyle modifications such as fluid and fiber intake and exercise are preferred to medications in the treatment of constipation.
- Laxatives and cathartics are drugs to promote bowel elimination.
- Common reasons for abuse of laxatives and cathartics include eating disorders, desire for strict weight control, or the belief that a daily bowel movement is necessary for health.
- Laxatives and cathartics should not be used in the presence of undiagnosed abdominal pain or other signs of intestinal obstruction due to the risks of perforation and peritonitis.
- Bulk-forming laxatives add mass to the feces, stimulating peristalsis and defecation. They must be taken with water to avoid obstruction. Generally, bulk-forming drugs are the most desirable laxative for long-term use.
- Surfactant laxatives decrease the surface tension of the fecal mass to allow water and fat to penetrate into the stool, making it softer and easier to expel. They have little true laxative effect.
- Saline laxatives increase the osmotic pressure in the intestinal lumen, resulting in the retention of water, which distends the bowel and stimulates peristalsis. They produce a semifluid stool and may lead to fluid and electrolyte imbalances.
- Polyethylene glycol–electrolyte solution is a nonabsorbable oral solution that rapidly evacuates the bowel within 4 hours. It is useful for bowel cleansing before GI procedures.
- Stimulant cathartics are the strongest and most abused laxative products. They irritate the GI mucosa, pull water into the colon, and stimulate peristalsis. They produce a watery stool and may lead to fluid, electrolyte, and acid-base imbalances.
- Lubricant laxatives lubricate the fecal mass and slow colonic absorption of water from the fecal mass. These medications may interfere with the absorption of fat-soluble vitamins and if aspirated may result in a lipid aspiration pneumonia.
- Lactulose exerts an osmotic effect, pulling water into the colon and stimulating peristalsis. It is also useful in treating hepatic encephalopathy by decreasing the production of the waste product ammonia.
- Sorbitol is often given with sodium polystyrene sulfonate (Kayexalate) in the treatment of hyperkalemia to aid in the expulsion of the potassium-resin complex.
- Lubiprostone (Amitiza) aids in treating chronic idiopathic constipation by increasing intestinal fluid secretion, stimulating intestinal motility and defecation.

## Review and Application Exercises

### Short Answer Exercises

1. What are risk factors for development of constipation?
2. Describe nonpharmacologic strategies to prevent constipation.
3. Which type of laxative is, in general, the most desirable for long-term use? Which is the least desirable?
4. What are the most significant adverse effects of strong laxatives?

5. If an adult patient asked you to recommend an over-the-counter laxative, what information about the patient's condition would you need, and what would you recommend? Why?

### NCLEX-Style Questions

6. Important points to include when teaching measures to promote healthy bowel function include all of the following except

- Increase activity.
- Eat a low-residue diet.
- Increase fluid intake.
- Establish regular bowel habits.

7. Which of the following oral medications is safe to use in a 60-year-old constipated patient with dysphagia?

- methylcellulose (Citrucel)
- psyllium (Metamucil)
- mineral oil (Agoral Plain)
- docusate sodium (Colace)

8. For which of the following patients is a laxative contraindicated?

- a patient with cancer taking daily narcotics for pain control
- a patient complaining of abdominal pain and distention
- a patient scheduled for a colonoscopy
- a patient with limited mobility due to Parkinson's disease

# Antidiarrheals

## KEY TERMS

- Diarrhea
- Inflammatory bowel disorders
- Irritable bowel syndrome (IBS)
- Travelers' diarrhea

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify patients at risk for development of diarrhea.
2. Discuss guidelines for assessing diarrhea.
3. Describe types of diarrhea in which antidiarrheal drug therapy may be indicated.
4. Differentiate the major types of antidiarrheal drugs.
5. Discuss characteristics, effects, and nursing process implications of commonly used antidiarrheal agents.

## Applying Your Knowledge

Frederico Mendoza is a 47-year-old salesman who travels extensively as part of his job. He recently returned from a trip to Mexico. He has been having diarrhea for the past 10 days and seeks advice on how to manage his symptoms.

## Introduction

Antidiarrheal drugs are used to treat *diarrhea*, defined as the frequent expulsion of liquid or semi-liquid stools. Diarrhea is a symptom of numerous conditions that increase bowel motility, cause secretion or retention of fluids in the intestinal lumen, and cause inflammation or irritation of the gastrointestinal (GI) tract. As a result, bowel contents are rapidly propelled toward the rectum, and absorption of fluids and electrolytes is limited. Some causes of diarrhea include the following:

- Excessive use or abuse of laxatives. Laxative abuse may accompany eating disorders such as anorexia nervosa or bulimia.
- Intestinal infections with viruses, bacteria, or protozoa. A common source of infection is ingested food or fluid contaminated by a variety of organisms.
  - *Escherichia coli* O157:H7–related hemorrhagic colitis most commonly occurs with the ingestion of undercooked ground beef. A serious complication of *E. coli* O157:H7 colitis is hemolytic uremic syndrome (HUS), characterized by thrombocytopenia, microangiopathic hemolytic anemia, and renal failure. Children are especially susceptible to HUS, which is the leading cause of dialysis in pediatric patients. So-called *travelers' diarrhea* is usually caused by an enterotoxigenic strain of *E. coli* (ETEC). Fecal contamination of food or water is the most common source of ETEC-induced diarrhea.
- Consumption of improperly prepared poultry may result in diarrhea due to infection with *Campylobacter jejuni*. In the United States, this is the most common bacterial organism identified in infectious diarrhea. In addition to diarrhea, vomiting, fever, and abdominal discom-

fort, *Campylobacter* bacteria produce neurotoxins, which may result in paralysis.

- *Salmonella* infections may occur when contaminated poultry and other meats, eggs, and dairy products are ingested. Elderly patients are especially susceptible to *Salmonella*-associated colitis.
- Several strains of *Shigella* may produce diarrhea. Infection most often results from direct person-to-person contact but may also occur via food or water contamination. Handwashing is especially important in preventing the spread of *Shigella* from person to person.
- Other diarrhea-producing organisms associated with contamination of specific foods include *Vibrio vulnificus* and *Vibrio parahaemolyticus* contamination of raw shellfish and oysters (particularly in the Gulf Coast states), *Clostridium perfringens* contamination of inadequately heated or reheated meats, *Staphylococcus aureus* contamination of processed meats and custard-filled pastries, *Bacillus cereus* contamination of rice and bean sprouts, and *Listeria monocytogenes* contamination of hot dogs and luncheon meats. Newborns, pregnant women, and older and immunocompromised individuals are especially susceptible to *L. monocytogenes* infection.
- Two of the most common viral organisms responsible for gastroenteritis and diarrhea are rotavirus or Norwalk-like virus (calicivirus). Vomiting is usually a prominent symptom accompanying virus-induced diarrhea.
- Undigested, coarse, or highly spiced food in the GI tract. The food acts as an irritant and attracts fluids in a defensive attempt to dilute the irritating agent. This may result from inadequate chewing of food or lack of digestive enzymes.
- Lack of digestive enzymes. Deficiency of pancreatic enzymes inhibits digestion and absorption of carbohydrates, proteins, and fats. Deficiency of lactase, which breaks down lactose to simple sugars (i.e., glucose and galactose) that can be absorbed by GI mucosa, inhibits digestion of milk and milk products. Lactase deficiency commonly occurs among people of African and Asian descent.
- *Inflammatory bowel disorders*, such as gastroenteritis, diverticulitis, ulcerative colitis, and Crohn's disease. In these disorders, the inflamed mucous membrane secretes large amounts of fluids into the intestinal lumen, along with mucus, proteins, and blood, and absorption of water and electrolytes is impaired. In addition, when the ileum is diseased or a portion is surgically excised, large amounts of bile salts reach the colon, where they act as cathartics and cause diarrhea. Bile salts are normally reabsorbed from the ileum.
- *Irritable bowel syndrome (IBS)* is a functional disorder of intestinal motility with no evidence of inflammation or tissue changes. It occurs more commonly in women than in men, affecting approximately 12% of adults in the United States. A change in bowel pattern (constipation, diarrhea, or a combination of both) accompanied by abdominal pain, bloating, and distention are the presenting symptoms. The

etiology is unknown; however, activation of 5-HT<sub>3</sub> (serotonin) receptors, which affect the regulation of visceral pain, colonic motility, and GI secretions, are thought to be involved in the pathophysiology of IBS.

- Drug therapy. Many oral drugs irritate the GI tract and may cause diarrhea, including acarbose, antacids that contain magnesium, antibacterials, antineoplastic agents, colchicine, laxatives, metformin, metoclopramide, misoprostol, selective serotonin reuptake inhibitors, tacrine, and tacrolimus. Antibacterial drugs are commonly used offenders that also may cause diarrhea by altering the normal bacterial flora in the intestine.

Antibiotic-associated colitis (also called pseudomembranous colitis) is a serious condition that results from oral or parenteral antibiotic therapy. By suppressing normal flora in the colon, antibiotics allow proliferation of other bacteria, especially gram-positive, anaerobic *Clostridium difficile* organisms. These organisms produce a toxin that causes fever, abdominal pain, inflammatory lesions of the colon, and severe diarrhea with stools containing mucus, pus, and sometimes blood. Symptoms may develop within a few days or several weeks after the causative antibiotic is discontinued. Other enteric pathogens that may overgrow in the presence of antibiotic therapy and result in colitis include *Salmonella*, *Clostridium perfringens* type A, *S. aureus*, and *Candida albicans*. Antibiotic-associated colitis is more often associated with ampicillin, cephalosporins, and clindamycin but may occur with any antibiotic or combination of antibiotics that alters intestinal microbial flora.

- Intestinal neoplasms. Tumors may increase intestinal motility by occupying space and stretching the intestinal wall. Diarrhea sometimes alternates with constipation in colon cancer.
- Functional disorders. Diarrhea may be a symptom of stress or anxiety in some patients. No organic disease process can be found in such circumstances.
- Hyperthyroidism. This condition increases bowel motility.
- Surgical excision of portions of the intestine, especially the small intestine. Such procedures decrease the absorptive area and increase fluidity of stools.
- Human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS). Diarrhea occurs in most patients with HIV infection, often as a chronic condition that contributes to malnutrition and weight loss. It may be caused by drug therapy, infection with a variety of microorganisms, or other factors.

Diarrhea may be acute or chronic and mild or severe. Most episodes of acute diarrhea are defensive mechanisms by which the body tries to rid itself of irritants, toxins, and infectious agents. These episodes are usually self-limiting and subside within 24 to 48 hours without serious consequences. If it is severe or prolonged, acute diarrhea may lead to serious fluid and electrolyte depletion, especially in young children

and older adults. Chronic diarrhea may cause malnutrition and anemia and is often characterized by remissions and exacerbations.

## Characteristics, Classifications, and Individual Antidiarrheal Drugs

Antidiarrheal drugs include a variety of agents, most of which are discussed in other chapters. When used for treatment of diarrhea, the drugs may be given to relieve the symptom (nonspecific therapy) or the underlying cause of the symptom (specific therapy). Individual drugs are listed in Table 61-1.

### Nonspecific Therapy

A major element of nonspecific therapy is adequate fluid and electrolyte replacement. When drug therapy is required, non-prescription antidiarrheal drugs (e.g., loperamide) may be effective.

Overall, **opiates** and **opiate derivatives** (see Chap. 6) are the most effective agents for symptomatic treatment of diarrhea. These drugs decrease diarrhea by slowing propulsive movements in the small and large intestines. Morphine, codeine, and related drugs are effective in relieving diarrhea but are rarely used for this purpose because of their adverse effects. Opiates have largely been replaced by the synthetic drugs **diphenoxylate** and **loperamide**, which are used only for treatment of diarrhea and do not cause morphine-like adverse effects in recommended doses. Diphenoxylate requires a prescription.

**Loperamide** (Imodium) is a synthetic derivative of meperidine that decreases GI motility by its effect on intestinal muscles. Because loperamide does not penetrate the central nervous system (CNS) well, it does not cause the CNS effects associated with opioid use and lacks potential for abuse. Although adverse effects are generally few and mild, loperamide can cause abdominal pain, constipation, drowsiness, fatigue, nausea, and vomiting. For nonprescription use, dosages for adults should not exceed 8 milligrams per day; with supervision by a health care provider, maximum daily dosage is 16 milligrams per day. In general, loperamide should be discontinued after 48 hours if clinical improvement has not occurred.

Bismuth salts have antibacterial and antiviral activity; **bismuth subsalicylate** (Pepto-Bismol, a commonly used over-the-counter [OTC] drug) also has antisecretory and possibly anti-inflammatory effects because of its salicylate component.

**Octreotide acetate** is a synthetic form of somatostatin, a hormone produced in the anterior pituitary gland and in the pancreas. The drug may be effective in diarrhea because it decreases GI secretion and motility. It is used for diarrhea associated with carcinoid syndrome, intestinal tumors, HIV/AIDS, and diarrhea that does not respond to other antidiarrheal drugs.

Other nonspecific agents sometimes used in diarrhea are anticholinergics (see Chap. 20) and polycarbophil and psyllium preparations (see Chap. 60). Anticholinergic drugs,

of which atropine is the prototype, are infrequently used because doses large enough to decrease intestinal motility and secretions cause intolerable adverse effects. The drugs are occasionally used to decrease abdominal cramping and pain (antispasmodic effects) associated with acute nonspecific diarrhea and chronic diarrhea associated with inflammatory bowel disease.

**Polycarbophil** (e.g., FiberCon) and psyllium are most often used as bulk-forming laxatives. They are occasionally used in diarrhea to adsorb toxins and water, decreasing the fluidity of stools. Polycarbophil is the only adsorbent drug evaluated to be effective by the U.S. Food and Drug Administration (FDA) over-the-counter review panel. Polycarbophil absorbs large amounts of water and produces stools of gelatin-like consistency. It may cause abdominal discomfort and bloating and may reduce the absorption of co-administered medications.

### Specific Therapy

Specific drug therapy for diarrhea depends on the cause of the symptom and may include the use of enzymatic replacement therapy, bile salt-binding drugs, antibacterial agents, and 5-HT<sub>3</sub> serotonin receptor antagonists. Enzymatic replacement with **pancreatin** or **pancrelipase** is recommended when a deficiency of pancreatic enzymes results in malabsorption of nutrients and steatorrhea, which is a loose fatty stool. Bile-binding drugs such as **cholestyramine** or **colestipol** are useful in treating diarrhea due to bile salt accumulation in conditions such as Crohn's disease or surgical excision of the ileum. Antibacterial drugs are recommended for bacterial enteritis when diarrhea lasts longer than 48 hours, when the patient passes six or more loose stools in 24 hours, when diarrhea is associated with fever, or when blood or pus is seen in the stools. Although effective in preventing travelers' diarrhea, antibiotics usually are not recommended because their use may promote the emergence of drug-resistant microorganisms. Although effective in reducing diarrhea due to *Salmonella* and *E. coli* intestinal infections, antibiotics may induce a prolonged carrier state during which the infection can be transmitted to other people.

**Rifaximin** (Xifaxan) is a structural analog of the antimycobacterial drug, rifampin. It is a nonsystemic antibiotic that remains in the gut and is not absorbed into the bloodstream. It was specifically developed to treat travelers' diarrhea due to noninvasive strains of *E. coli* in patients older than 12 years of age. It should not be used for diarrhea in the presence of fever or bloody stools or for diarrhea due to pathogens other than *E. coli*. As with the use of other broad-spectrum antibiotics, superinfections may occur with rifaximin therapy, requiring termination of the medication and treatment.

**Nitazoxanide** (Alinia) is an antiprotozoal agent used specifically for treating diarrhea resulting from infection with *Giardia lamblia* or *Cryptosporidium parvum*. Caution should be used when administering Alinia concurrently with highly plasma-protein-bound medications such as warfarin, because the active metabolite of nitazoxanide is highly plasma-protein bound and such concurrent use may result in competitive drug interactions.

Table 61-1

Drugs at a Glance: Antidiarrheal Drugs

ROUTES AND DOSAGE RANGES				
Generic/Trade Name	Characteristics	Clinical indications	Adults	Children
<b>Opiate-Related Drugs</b>				
<b>Paregoric</b>	<p>Morphine is the active ingredient. Paregoric contains 0.4 mg/mL of morphine.</p> <p>A Schedule III drug alone and a Schedule V in the small amounts combined with other drugs.</p> <p>Recommended doses and short-term use do not produce euphoria, analgesia, or dependence.</p>	Symptomatic treatment of acute diarrhea	PO 5–10 mL 1–4 times daily (maximum of 4 doses) until diarrhea is controlled	PO 0.25–0.5 mL/kg 1–4 times daily (maximum of 4 doses) until diarrhea is controlled
<b>Diphenoxylate with atropine sulfate</b> (Lomotil)	<p>A derivative of meperidine (Demerol)</p> <p>Commonly prescribed; decreases intestinal motility</p> <p>In recommended doses, does not produce euphoria, analgesia, or dependence. In high doses, produces morphine-like effects, including euphoria, dependence, and respiratory depression</p> <p>Naloxone (Narcan) is the antidote for overdose.</p> <p>Each tablet or 5 mL of liquid contains 2.5 mg of diphenoxylate and 0.025 mg of atropine. The atropine is added to discourage drug abuse.</p> <p>Contraindicated in patients with severe liver disease or glaucoma</p> <p>A Schedule V drug</p>	Symptomatic treatment of acute or chronic diarrhea	PO 5 mg (2 tablets or 10 mL of liquid) 3 or 4 times daily; maximal daily dose, 20 mg	<p>Liquid preparation (2.5 mg diphenoxylate and 0.025 mg atropine per 5 mL), PO 0.3–0.4 mg/kg/day in 4 divided doses.</p> <p>Contraindicated in children &lt;2 y of age</p>
<b>Loperamide</b> (Imodium)	<p>A derivative of meperidine; decreases intestinal motility</p> <p>As effective as diphenoxylate, with fewer adverse effects in recommended doses. High doses may produce morphine-like effects.</p> <p>Naloxone (Narcan) is the antidote for overdose.</p>	Symptomatic treatment of acute or chronic diarrhea	PO 4 mg initially, then 2 mg after each loose stool to a maximal daily dose of 16 mg. For chronic diarrhea, dosage should be reduced to the lowest effective amount (average 4–8 mg daily).	<p>8–12 y, &gt;30 kg: PO 2 mg 3 times daily</p> <p>6–8 y, 20–30 kg: PO 2 mg twice daily</p> <p>2–5 y, 13–20 kg: PO 1 mg 3 times daily</p> <p>Safety not established for children &lt;2 y of age.</p>

(continued on page 986)

Table 61-1

## Drugs at a Glance: Antidiarrheal Drugs (continued)

Generic/Trade Name	Characteristics	ROUTES AND DOSAGE RANGES		
		Clinical indications	Adults	Children
<b>Antibacterial Agents</b>				
<b>Azithromycin</b>	A macrolide (see Chap. 33)	Traveler's diarrhea acquired in SE Asia. Regardless of destination, may be preferred antibiotic for children and those unable to take quinolones.	PO 500 mg daily for 3 days.	PO 10 mg/kg on day 1, up to 500 mg; and 5 mg/kg on days 2 and 3, up to 250 mg.
<b>Ciprofloxacin</b> (Cipro)	A fluoroquinolone (See Chap. 31)	Diarrhea caused by susceptible strains of <i>Escherichia coli</i> , <i>Campylobacter jejuni</i> , and <i>Shigella</i> species	PO 500 mg q12h for 5–7 d	Not recommended for use
<b>Erythromycin</b> (E-Mycin)	A macrolide (see Chap. 33)	Intestinal amebiasis caused by <i>Entamoeba histolytica</i>	PO 250 mg 4 times daily for 10–14 d	PO 30–50 mg/kg/d, in divided doses, for 10–14 d
<b>Metronidazole</b> (Flagyl)	See Chap. 33	Diarrhea and colitis caused by <i>Clostridium difficile</i> organisms	<i>C. difficile</i> infection, PO 500 mg 3 times daily or 250 mg 4 times daily	Dosage not established for <i>C. difficile</i> infection
		Intestinal amebiasis	Intestinal amebiasis, PO 750 mg 3 times daily for 5–10 d	Intestinal amebiasis, PO 35–50 mg/kg/24 h (maximum 750 mg/dose), in 3 divided doses for 10 d
<b>Nitazoxanide</b> (Alinia)	Antiprotozoal agent	Diarrhea caused by <i>Giardia lamblia</i> or <i>Cryptosporidium parvum</i>	For <i>G. lamblia</i> : PO 500 mg tablet every 12 h with food or 25 mL (500 mg) oral suspension every 12 h with food for 3 d For <i>C. parvum</i> : adult dose not established	For <i>G. lamblia</i> and <i>C. parvum</i> : >12 y, same as adults 4–11 y, 10 mL (200 mg) oral suspension every 12 h with food for 3 d 1–3 y, 5 mL (100 mg) oral suspension every 12 h with food for 3 d
<b>Rifaximin</b> (Xifaxan)	Structural analog of rifampin; a broad-spectrum, nonspecific antibiotic that remains in the gut where it exerts its effects	Traveler's diarrhea caused by <i>E. coli</i>	PO 200 mg 3 times a day for 3 d	Dosage not established for children <12 y of age
<b>Trimethoprim-sulfamethoxazole</b> (TMP-SMX) (Bactrim, Septra)	See Chap. 32	Diarrhea caused by susceptible strains of <i>E. coli</i> or <i>Shigella</i> organisms Traveler's diarrhea	PO 160 mg of TMP and 800 mg of SMX q12h for 5 d or longer	PO 8 mg/kg of TMP and 40 mg/kg of SMX daily, in 2 divided doses, q12h, for 5 d or longer

Generic/Trade Name	ROUTES AND DOSAGE RANGES			
	Characteristics	Clinical indications	Adults	Children
<b>Vancomycin</b>	Cell wall synthesis inhibitor (see Chap. 33)	Diarrhea and colitis caused by <i>C. difficile</i> organism	PO 500 mg to 2 g per day in 3–4 divided doses for 7–10 d or PO 125 mg 3 or 4 times daily	PO 400 mg/kg/d in 4 divided doses for 7–10 d. Do not exceed 2 g/d.
<b>Miscellaneous Drugs</b>				
<b>Alosetron</b> (Lotronex)	A 5-HT <sub>3</sub> receptor antagonist	For women with diarrhea-predominant irritable bowel syndrome (IBS)	PO 0.5mg twice a day. May increase to 1mg after 4 weeks if needed	Not recommended
<b>Bismuth subsalicylate</b> (Pepto-Bismol)	Has antimicrobial, antisecretory, and possibly anti-inflammatory effects	Control of diarrhea, including traveler's diarrhea, and relief of abdominal cramping	PO 2 tablets or 30 mL every 30–60 min, if needed, up to 8 doses in 24 h	9–12 y, PO 1 tablet or 15 mL 6–9 y, PO 2/3 tablet or 10 mL 3–6 y, PO 1/3 tablet or 5 mL Under 3 y, consult pediatrician
<b>Cholestyramine</b> (Questran)	Binds and inactivates bile salts in the intestine (see chap. 55)	Diarrhea due to bile salts reaching the colon and causing a cathartic effect. "Bile salt diarrhea" is associated with Crohn's disease or surgical excision of the ileum.	PO 16–32 g/d in 120–180 mL of water, in 2–4 divided doses before or during meals and at bedtime	
<b>Colestipol</b> (Colestid)	Same as cholestyramine, above (see Chap. 55)	Same as cholestyramine	PO 15–30 g/d in 120–180 mL of water, in 2–4 divided doses before or during meals and at bedtime	
<b>Octreotide</b> (Sandostatin)	In GI tract, decreases secretions and motility (see Chap. 22)	Diarrhea associated with carcinoid tumors, HIV/AIDS, cancer chemotherapy or radiation, or diarrhea unresponsive to other drugs	Sub-Q IV 150–750/day divided over 2–4 doses. Start at 200–300 mcg/day divided over 2–4 doses for 2 weeks, then individualize dose to response.	Dosage not established
<b>Pancreatin or pancrelipase</b> (Viokase, Pancrease, Cotazym)	Pancreatic enzymes used only for replacement	Diarrhea and malabsorption due to deficiency of pancreatic enzymes	PO 1–3 tablets or capsules or 1–2 packets of powder with meals and snacks	PO 1–3 tablets or capsules or 1–2 packets of powder with each meal
<b>Polycarbophil preparations</b> (FiberCon)	Absorbs water and toxins and decreases fluidity of stools	Possibly effective for symptomatic treatment of diarrhea	PO 1g, 1–4 times daily. Do not exceed 4 g in 24 h. For severe diarrhea repeat dose every 30 min but do not exceed maximum dose.	6–12y: PO 500 mg 1–4 times daily. Do not exceed 2 g 124 h. Under 6y: products vary consist labels. For severediarrhea repeat dose every 30 min but do not exceed maximum dose.

AIDS, acquired immunodeficiency syndrome; GI, gastrointestinal; HIV, human immunodeficiency virus.

**Alosetron** (Lotronex) is a selective 5-HT<sub>3</sub> receptor antagonist indicated for treating women with chronic severe diarrhea-predominant IBS that has not responded to conventional therapy. Clinical studies have not demonstrated safety and efficacy of alosetron in men. Alosetron is rapidly absorbed orally with a bioavailability of 50% to 60%. It is moderately plasma protein bound (82%). Alosetron is extensively metabolized by the CYP 450 enzyme system (CYP 2C9, CYP 3A4, and CYP 1A2) with multiple metabolites produced that are excreted primarily in the urine. Caution must be used with concurrent administration with CYP1A2 and CYP3A4 inhibitors, and concurrent administration with fluvoxamine is contraindicated. Alosetron is also contraindicated in women with severe hepatic impairment. Reduced dosages may be needed in some women over 65 years of age to prevent drug accumulation and toxicity. A **BLACK BOX WARNING** alerts nurses to the serious GI adverse effects of alosetron. Severe constipation with possible obstruction, perforation, and hemorrhage is the most common problem. Ischemic colitis (reduced blood flow to the intestinal tract resulting in tissue damage) has also occurred. These serious conditions have resulted in hospitalizations, blood loss necessitating transfusion, surgery, and death in severe cases. Alosetron should not be given to patients with a history of GI disorders including chronic or severe constipation or sequelae of constipation, intestinal obstruction, stricture, toxic megacolon, GI perforation and/or adhesions, ischemic colitis, impaired intestinal circulation, thrombophlebitis or hypercoagulable state, Crohn's disease or ulcerative colitis, or diverticulitis.

To ensure safe and appropriate use of alosetron, the drug manufacturer has established a prescribing program, and only qualified health care providers enrolled in the program can prescribe this medication. Pharmacists must provide patients with a medication guide developed by the manufacturer at the time the medication is dispensed that includes the risks of taking alosetron and the situations under which the drug should be immediately discontinued. Each patient must sign a patient–physician agreement indicating that she (1) understands the risks of taking alosetron and agrees to take the medication, (2) will discontinue taking alosetron if constipation occurs, (3) will immediately notify the physician if constipation or signs of ischemic colitis occur, and (4) will stop taking alosetron and contact the physician after 4 weeks of therapy with alosetron if the symptoms of IBS are not controlled. The medication guide and patient–physician agreement are available at <http://www.lotronex.com>

### Indications for Use

Despite the limitations of drug therapy in the prevention and treatment of diarrhea, antidiarrheal drugs are indicated in the following circumstances:

- Severe or prolonged diarrhea (>2–3 days), to prevent severe fluid and electrolyte loss
- Relatively severe diarrhea in young children and older adults. These groups are less able to adapt to fluid and electrolyte losses.
- In chronic inflammatory diseases of the bowel (ulcerative colitis and Crohn's disease), to allow a more nearly normal lifestyle
- In ileostomies or surgical excision of portions of the ileum, to decrease fluidity and volume of stool
- To reduce symptoms of diarrhea-predominant IBS
- HIV/AIDS–associated diarrhea
- When specific causes of diarrhea have been determined

### Contraindications to Use

Contraindications to the use of antidiarrheal drugs include diarrhea caused by toxic materials, microorganisms that penetrate intestinal mucosa (e.g., pathogenic *E. coli*, *Salmonella*, *Shigella*), or antibiotic-associated colitis. In these circumstances, antidiarrheal agents that slow peristalsis may aggravate and prolong diarrhea. Opiates (morphine, codeine) usually are contraindicated in chronic diarrhea because of possible opiate dependence. Diphenoxylate and loperamide are contraindicated in children younger than 2 years of age.

### Herbal and Dietary Supplements

Several herbal remedies are promoted for treatment of diarrhea. Most include tannins, substances with astringent properties that reduce intestinal inflammation and secretions. The leaves of edible berry plants (i.e., blackberry, blueberry, raspberry) are sometimes used in a “tea” made by pouring boiling water over 1 to 2 teaspoons of leaves, drunk up to six times daily. There is little objective evidence of effectiveness or toxicity.

### Nursing Process

#### Assessment

Assess for acute or chronic diarrhea.

- Try to determine the duration of diarrhea; number of stools per day; amount, consistency, color, odor, and presence of abnormal components (e.g., undigested food, blood, pus, mucus) in each stool; precipitating factors; accompanying signs and symptoms (i.e., nausea, vomiting, fever, abdominal pain or cramping); and measures used to relieve diarrhea. When possible, look at stool specimens for possible clues to causation. Blood may indicate inflammation, infection, or neoplastic disease; pus or mucus may indicate inflammation or infection. Infections caused by *Shigella* organisms produce blood-tinged mucus. Infections caused by *Salmonella* or *E. coli* usually produce green, liquid or semiliquid stools. Inflammatory bowel disorders often produce nonbloody mucus.

- Try to determine the cause of the diarrhea. This includes questioning about such causes as chronic inflammatory diseases of the bowel, food intake, possible exposure to contaminated food, living or traveling in areas of poor sanitation, and use of laxatives or other drugs that may cause diarrhea. When available, check laboratory reports on stool specimens (e.g., culture reports).
- With severe or prolonged diarrhea, especially in young children and older adults, assess for dehydration, hypokalemia, and other fluid and electrolyte disorders.

## Nursing Diagnoses

- Diarrhea related to GI infection or inflammatory disorders, other disease processes, dietary irritants, or overuse of laxatives
- Anxiety related to availability of bathroom facilities
- Deficient Fluid Volume related to excessive losses in liquid stools
- Pain (abdominal cramping) related to intestinal hypermotility and spasm
- Deficient Knowledge: Factors that cause or aggravate diarrhea and appropriate use of antidiarrheal drugs

## Planning/Goals

### The patient will

- Take antidiarrheal drugs appropriately
- Obtain relief from acute diarrhea (reduced number of liquid stools, reduced abdominal discomfort)
- Maintain fluid and electrolyte balance
- Maintain adequate nutritional intake
- Avoid adverse effects of antidiarrheal medications
- Re-establish normal bowel patterns after an episode of acute diarrhea
- Have fewer liquid stools with chronic diarrhea

## Interventions

Use measures to prevent diarrhea.

- Prepare and store food properly and avoid improperly stored foods and those prepared under unsanitary conditions. Dairy products, cream pies, and other foods may cause diarrhea (“food poisoning”) if not refrigerated.
- Wash hands before handling any foods, after handling raw poultry or meat, and always before eating.
- Chew food well.
- Do not overuse laxatives (i.e., amount per dose or frequency of use). Many OTC products contain senna or other strong stimulant laxatives.

Provide education about drug therapy (see accompanying Patient Teaching Guidelines).

Regardless of whether antidiarrheal drugs are used, supportive therapy is required for the treatment of diarrhea. Elements of supportive care include the following:

- Replacement of fluids and electrolytes (2–3 quarts daily). Fluids such as weak tea; water; bouillon; clear soup; noncarbonated, caffeine-free beverages; and gelatin are usually tolerated and helpful. If the patient cannot tolerate adequate amounts of oral liquids or if diarrhea is severe or prolonged, intravenous fluids may be needed (i.e., solutions containing dextrose, sodium chloride, and potassium chloride).
- Avoid foods and fluids that may further irritate GI mucosa (e.g., highly spiced foods; “laxative” foods, such as raw fruits and vegetables).
- Increase frequency and length of rest periods, and decrease activity. Exercise and activity stimulate peristalsis.
- If perianal irritation occurs because of frequent liquid stools, cleanse the area with mild soap and water after each bowel movement, then apply an emollient, such as white petrolatum (Vaseline).

## Evaluation

- Observe and interview for decreased number of liquid or loose stools.
- Observe for signs of adequate food and fluid intake (e.g., good skin turgor and urine output, stable weight).
- Observe for appropriate use of antidiarrheal drugs.
- Observe and interview for return of pre-diarrheal patterns of bowel elimination.
- Interview regarding knowledge and use of measures to prevent or minimize diarrhea.

## Applying Your Knowledge 61-1

What factors would you include in your assessment of Mr. Mendoza?

.....

## Principles of Therapy

In most cases of acute, nonspecific diarrhea in adults, fluid losses are not severe and patients need only simple replacement of fluids and electrolytes lost in the stool. Acceptable replacement fluids during the first 24 hours include 2 to 3 liters of clear liquids (e.g., flat ginger ale, decaffeinated cola drinks or tea, broth, gelatin). Also, the diet should consist of bland foods (e.g., rice, soup, bread, salted crackers, cooked cereals, baked potatoes, eggs, applesauce). A regular diet may be resumed after 2 to 3 days.

## Drug Selection

The choice of antidiarrheal agent depends largely on the cause, severity, and duration of diarrhea.

- For symptomatic treatment of diarrhea, diphenoxylate with atropine (Lomotil) or loperamide (Imodium) is probably the drug of choice for most people.

## Patient Teaching Guidelines Antidiarrheals

### General Considerations

- Taking a medication to stop diarrhea is not always needed or desirable because diarrhea may mean the body is trying to rid itself of irritants or bacteria. Treatment is indicated if diarrhea is severe, prolonged, or occurs in young children or older adults, who are highly susceptible to excessive losses of body fluids and electrolytes.
- Try to drink 2 to 3 quarts of fluid daily. This helps prevent dehydration from fluid loss in stools. Water, clear broths, and noncarbonated, caffeine-free beverages are recommended because they are unlikely to cause further diarrhea.
- Avoid highly spiced or “laxative” foods, such as fresh fruits and vegetables, until diarrhea is controlled.
- Frequent and thorough handwashing and careful food storage and preparation can help prevent diarrhea.
- Consult a health care provider if diarrhea is accompanied by severe abdominal pain or fever, lasts longer than 3 days, or if stools contain blood or mucus. These signs and symptoms may indicate more serious disorders for which other treatment measures are needed.
- Stop antidiarrheal drugs when diarrhea is controlled to avoid adverse effects such as constipation.
- Bismuth subsalicylate (Pepto-Bismol) and loperamide (Imodium A-D) are available over the counter; diphenoxylate (Lomotil) is a prescription drug.
- Diphenoxylate and loperamide may cause dizziness or drowsiness and should be used with caution if driving or performing other tasks requiring alertness, coordination, or physical dexterity. In addition, alcohol and other drugs that cause drowsiness should be avoided.
- Pepto-Bismol may temporarily discolor bowel movements a grayish-black.
- Keep antidiarrheal drugs out of reach of children.

### Self- or Caregiver Administration

- Take or give antidiarrheal drugs only as prescribed or directed on nonprescription drug labels.
- Do not exceed maximal daily doses of diphenoxylate (Lomotil), loperamide, or paregoric.
- With liquid diphenoxylate, use only the calibrated dropper furnished by the manufacturer for accurate measurement of dosages.
- With Pepto-Bismol liquid, shake the bottle well before measuring the dose; with tablets, chew them well or allow them to dissolve in the mouth.
- Add at least 30 mL of water to each dose of paregoric to help the drug dose reach the stomach. The mixture appears milky.
- Take cholestyramine or colestipol with at least 4 oz of water. These drugs should never be taken without fluids because they may block the gastrointestinal tract. Also, do not take within 4 hours of other drugs because they may combine with and inactivate other drugs.
- Take rifaximin with or without food for 3 days. Notify health care provider if your condition worsens or does not improve after 1 to 2 days.
- Use caution driving or operating machinery if experiencing dizziness while using rifaximin.
- Diabetic patients should be aware that Alinia oral suspension contains 1.48 g of sucrose per 5 mL.
- With Lotronex, if you become constipated, notice blood in your bowel movements, or experience a new worse or different pain in your stomach or abdomen, STOP taking Lotronex and notify your health care provider.

- In bacterial gastroenteritis or diarrhea, the choice of antibacterial drug depends on the causative microorganism and susceptibility tests.
- In ulcerative colitis, sulfonamides, adrenal corticosteroids, and other anti-inflammatory agents such as balsalazide (Colazal), mesalamine (Pentasa), and olsalazine (Dipentum) are the drugs of choice. The latter drugs are related to aspirin and nonsteroidal anti-inflammatory drugs (see Chap. 7 and Appendix A) and are contraindicated in patients with hypersensitivity to salicylates or any other product component. They are given orally or rectally and are thought to exert topical anti-inflammatory effects in ulcerative colitis.
- For treatment of women with diarrhea-predominant IBS that has not responded to conventional treatment, alosetron, a 5-HT<sub>3</sub> receptor antagonist may be prescribed.
- In antibiotic-associated colitis, stopping the causative drug is the initial treatment. If symptoms do not improve within 3 or 4 days, oral metronidazole or vancomycin is given for 7 to 10 days. Both are effective against *C. difficile*, but metron-

idazole is the drug of first choice and is much less expensive. Vancomycin may be given for severe disease or when metronidazole is ineffective. For approximately 6 weeks after recovery, relapse often occurs and requires re-treatment. Because relapse is not due to emergence of drug-resistant strains, the same drug used for the initial bout may be used to treat the relapse.

- In diarrhea caused by enzyme deficiency, pancreatic enzymes are given rather than antidiarrheal drugs.
- In bile-salt diarrhea, cholestyramine or colestipol may be effective.
- Although morphine and codeine are contraindicated in chronic diarrhea, they may occasionally be used in the treatment of acute, severe diarrhea. Dosages required for antidiarrheal effects are smaller than those required for analgesia. The following oral drugs and dosages are approximately equivalent in antidiarrheal effectiveness: 4 mg morphine, 30 mg codeine, 10 mL paregoric, 5 mg diphenoxylate, and 2 mg loperamide. A common and potentially fatal drug error is confusing paregoric

(camphorated tincture of opium) with the much more potent drug Opium Tincture. Paregoric contains only 0.4 mg/mL of morphine, whereas Opium Tincture is much more concentrated, containing 10 mg/mL of morphine. Labels should be in place on Opium Tincture packaging identifying it as a poison, identifying the strength of morphine per mL as 10 mg/mL, and containing the statement, “Warning! DO NOT use Opium Tincture in place of paregoric.”

### Applying Your Knowledge 61-2

What is the most likely drug of choice for Mr. Mendoza?

## Use in Special Populations

### Use in Children

Antidiarrheal drugs, including antibiotics, are often used in children to prevent excessive losses of fluids and electrolytes. In small children, serious fluid volume deficit may rapidly develop with diarrhea. Worldwide, from 2000 to 2003, the World Health Organization estimated that diarrhea accounted for 18% of deaths in children less than 5 years of age during the first 28 days of life. Drug therapy should be accompanied by appropriate fluid replacement and efforts to decrease further stimuli. Oral rehydration solutions (e.g., Pedialyte solution and freezer popsicles) are commercially available in ready-to-use formulations in the United States. Packets of powder (containing glucose, sodium, potassium, chloride, and citrate), to be mixed with 1 liter of boiled or treated water, are available in developing countries and are usually provided by the World Health Organization.

Diphenoxylate contains atropine, and signs of atropine overdose may occur with usual doses. Diphenoxylate is contraindicated in children younger than 2 years of age; loperamide should not be used in children younger than 6 years, except with a pediatrician’s supervision and should generally not be used for longer than 2 days in older children. Loperamide is a nonprescription drug.

### Use in Older Adults

Diarrhea is less common than constipation in older adults, but it may occur from laxative abuse and bowel-cleansing procedures before GI surgery or diagnostic tests. Fluid volume deficits may rapidly develop in older adults with diarrhea. General principles of fluid and electrolyte replacement, measures to decrease GI irritants, and drug therapy apply as for

younger adults. Most antidiarrheal drugs may be given to older adults, but cautious use is indicated to avoid inducing constipation.

### Use in Patients With Renal Impairment

Diphenoxylate should be used with extreme caution in patients with severe hepatorenal disease because hepatic coma may be precipitated.

### Use in Patients With Hepatic Impairment

Diphenoxylate should be used with extreme caution in patients with abnormal liver-function test results or severe hepatorenal disease because hepatic coma may be precipitated. With loperamide, monitor patients with hepatic impairment for signs of CNS toxicity. Loperamide normally undergoes extensive first-pass metabolism, which may be lessened by liver disease. As a result, a larger portion of a dose reaches the systemic circulation and may cause adverse effects. Dosage may need to be reduced. Alosetron is contraindicated in women with severe liver impairment.

### Use in Immunocompromised Patients

Diarrhea often occurs in immunocompromised patients (e.g., those with AIDS, organ transplant, or anticancer chemotherapy) and may be difficult to treat with the usual antidiarrheal drugs. Octreotide may be effective, but it should be used only after other medications have failed because it is given by injection and is expensive.

### Use in Home Care

Prescription and OTC antidiarrheal aids are often taken in the home setting. The role of the home care nurse may include advising patients and caregivers about appropriate use of the drugs, trying to identify the cause and severity of the diarrhea (i.e., risk of fluid and electrolyte deficit), and teaching strategies to manage the current episode and prevent future episodes. If octreotide is taken at home, the home care nurse may need to teach the patient or a caregiver how to administer subcutaneous injections.

### Applying Your Knowledge 61-3

#### How Can You Avoid This Medication Error?

Mr. Mendoza is given loperamide for his diarrhea and sent home. He has a stool specimen examined for microorganisms. His report shows the presence of salmonella organisms. He continues to have diarrhea so you increase the dose of loperamide.

## Nursing Actions Antidiarrheals

### NURSING ACTIONS

#### 1. Administer accurately

- With liquid diphenoxylate, use only the calibrated dropper furnished by the manufacturer for measuring dosage.
- Add at least 30 mL of water to each dose of paregoric. The mixture appears milky.
- Do not exceed maximal daily doses of diphenoxylate, loperamide, and paregoric. Also, stop the drugs when diarrhea is controlled.
- Give cholestyramine and colestipol with at least 120 mL of water. Also, do not give within approximately 4 hours of other drugs.

#### 2. Observe for therapeutic effects

- Decreased number, frequency, and fluidity of stools
- Decreased or absent abdominal cramping pains
- Signs of normal fluid and electrolyte balance (adequate hydration, urine output, and skin turgor)
- Resumption of usual activities of daily living

#### 3. Observe for adverse effects

- Constipation
- Drug dependence
- With diphenoxylate, anorexia, nausea, vomiting, dizziness, abdominal discomfort, paralytic ileus, toxic megacolon, hypersensitivity (pruritus, urticaria, angioneurotic edema), headache, and tachycardia  
With overdoses of a diphenoxylate-atropine or difenoxin-atropine combination, respiratory depression and coma may result from diphenoxylate or difenoxin content and anticholinergic effects (eg, dry mouth, blurred vision, urinary retention) from atropine content.
- With loperamide, abdominal cramps, dry mouth, dizziness, nausea, and vomiting
- With cholestyramine and colestipol, constipation, nausea, and abdominal distention
- With octreotide, diarrhea, headache, cardiac dysrhythmias, and injection-site pain
- With rifaximin, flatulence, headache, stomach pain, urgent bowel movements, nausea, constipation, fever, vomiting, dizziness
- With alosetron, constipation abdominal pain, abdominal distention, nausea, blood in bowel movements

#### 4. Observe for drug interactions

- Drugs that increase effects of antidiarrheal agents:
  - Central nervous system (CNS) depressants (alcohol, sedative-hypnotics, opioid analgesics, antianxiety agents, antipsychotic agents)

### RATIONALE/EXPLANATION

For accurate measurement

To add sufficient volume for the drug to reach the stomach

To decrease risks of adverse reactions, including drug dependence

The drugs may cause obstruction of the gastrointestinal (GI) tract if swallowed in a dry state. They may combine with and inactivate other drugs.

Therapeutic effects are usually evident within 24–48 hours.

Constipation is the most common adverse effect. It can be prevented by using antidiarrheal drugs only as prescribed and stopping the drugs when diarrhea is controlled. With Lotronex constipation may indicate a severe adverse effect and the health care provider should be notified.

Dependence is unlikely with recommended doses but may occur with long-term use of large doses of paregoric, diphenoxylate, and difenoxin.

Although numerous adverse reactions have been reported, their incidence and severity are low when diphenoxylate is used appropriately.

Deliberate overdose and abuse are unlikely because of unpleasant anticholinergic effects. Overdose can be prevented by using the drug in recommended doses and only when required. Overdose can be treated with naloxone (Narcan) and supportive therapy.

Abdominal cramps are the most common adverse effect. No serious adverse effects have been reported with recommended doses of loperamide. Overdose may be treated with naloxone, gastric lavage, and administration of activated charcoal.

Adverse effects are usually minor and transient because these drugs are not absorbed from the GI tract.

These are commonly reported adverse effects.

These are commonly reported adverse effects.

These adverse effects indicate severe adverse GI effects including ischemic colitis and severe constipation. The medication should be discontinued and the health care provider notified.

Few clinically significant drug interactions have been reported with commonly used antidiarrheal agents.

Additive CNS depression with opiate and related antidiarrheals. Opioid analgesics have additive constipating effects.

**NURSING ACTIONS**

- (2) Anticholinergic agents (atropine and synthetic anticholinergic antispasmodics; antihistamines and antidepressants with anticholinergic effects)
  - (3) With alosetron: CYP1A2 inhibitors (e.g., cimetidine, fluvoxamine, quinolone antibiotics) will increase the effects of alosetron.
  - (4) With Alosetron: CYP3A4 inhibitors (e.g., clarithromycin, ketoconazole, protease inhibitors) will increase the effects of alosetron.
- b. Nitazoxanide may increase the effect of highly protein-bound, narrow therapeutic-index drugs, such as warfarin, resulting in toxicity.

**RATIONALE/EXPLANATION**

Additive anticholinergic adverse effects (dry mouth, blurred vision, urinary retention) with diphenoxylate-atropine (Lomotil).

CYP1A2 enzyme inhibition will reduce metabolism of alosetron. Co-Administration with fluvoxamine is contraindicated.

CYP3A4 enzyme inhibition will reduce metabolism of alosetron.

The active metabolite of nitazoxanide is 99.9% protein bound and may compete with other protein-bound medications at plasma protein binding sites.

**Key Concepts**

- Diarrhea is the frequent expulsion of liquid or semiliquid stools resulting from increased bowel motility, increased secretion or retention of fluids in the intestinal lumen, or inflammation/irritation of the GI tract.
- Overall, opiates and opiate derivatives are the most effective nonspecific therapy for symptomatic treatment of diarrhea.
- Octreotide, a synthetic form of somatostatin, decreases GI secretion and motility. It is used for diarrhea associated with carcinoid syndrome, intestinal tumors, HIV/AIDS, and diarrhea that does not respond to other antidiarrheal drugs.
- Bismuth subsalicylate has antisecretory, antimicrobial, and possibly anti-inflammatory effects. It is used in the control of travelers' diarrhea and relief of abdominal cramping.
- Polycarbophil is used to treat diarrhea by adsorbing toxins and water, decreasing the fluidity of stools.
- Specific therapy for diarrhea is directed at the cause of the symptom and may include enzymatic replacement therapy, bile-salt binding drugs, antibacterial agents, and 5-HT<sub>3</sub> receptor antagonists.
- In bacterial gastroenteritis or diarrhea, the choice of antibacterial drug depends on the causative organism and susceptibility tests.
- Because of the risk of severe GI adverse effects, use of alosetron is subject to a mandated prescribing program. Only qualified health care providers enrolled in the program can prescribe this medication. Pharmacists are required to distribute educational materials when dispensing alosetron. Patients must sign a patient–physician agreement before taking this medication.

**Review and Application Exercises****Short Answer Exercises**

1. What are some common causes of diarrhea?
2. In which populations is diarrhea most likely to cause serious problems?
3. Which types of diarrhea do not require antidiarrheal drug therapy, and why?
4. How do antidiarrheal drugs decrease frequency or fluidity of stools?
5. What are adverse effects of commonly used antidiarrheal drugs?
6. If a patient asked you to recommend an OTC antidiarrheal agent, which would you recommend, and why?
7. Would your recommendation differ if the proposed recipient were a child? Why or why not?

**NCLEX-Style Questions**

8. The nurse knows that an appropriate nursing measure when treating a 5-year-old child with a 1-day onset of mild diarrhea would be to
  - a. Encourage a regular diet.
  - b. Encourage intake of clear liquids.
  - c. Encourage intake of milk products.
  - d. Encourage no fluids for 24 hours.
9. A hospitalized patient on antibiotic therapy begins to experience fever, abdominal pain, and diarrhea containing

mucus, pus, and blood. The best nursing action in this situation is to

- a. Continue the antibiotic because the patient has signs of a GI infection.
- b. Monitor the patient's vital signs and notify the provider if there is further deterioration.
- c. Withhold the antibiotic and notify the provider of the patient's condition.
- d. Encourage fluid intake because fever is a sign of dehydration.

10. A patient with diarrhea begins to complain of eye pain after administration of diphenoxylate with atropine (Lomotil). The nurse should
  - a. Offer an OTC analgesic such as acetaminophen.
  - b. Discontinue the diphenoxylate with atropine and notify the provider.
  - c. Tell the patient this is a common side effect and will soon pass.
  - d. Apply a cool compress to the eyes for relief of the discomfort.

# Antiemetics

## KEY TERMS

- Anticipatory nausea
- Antiemetic
- Cannabinoid
- Chemoreceptor trigger zone (CTZ)
- Emesis
- Emetogenic
- Motion sickness
- Nausea
- Prokinetic
- Substance P
- Vomiting
- Vomiting center

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify patients at risk of developing nausea and vomiting.
2. Discuss guidelines for preventing, minimizing, or treating nausea and vomiting.
3. Differentiate the major types of antiemetic drugs.
4. Discuss characteristics, effects, and nursing process implications of selected antiemetic drugs.

## Applying Your Knowledge

Nellie Snyder is a 38-year-old woman who has breast cancer. She is receiving radiation and chemotherapy. Ms. Snyder is experiencing significant nausea and vomiting. Her physician orders ondansetron 32 mg IV to be administered 30 minutes prior to her chemotherapy and 8 to 16 mg PO every 8 hours as needed. She also receives metoclopramide 10 mg PO four times a day: 30 minutes before meals and at bedtime.

## Introduction

*Antiemetic* drugs are used to prevent or treat nausea and vomiting. *Nausea* is an unpleasant sensation of abdominal discomfort accompanied by a desire to vomit. *Vomiting* is the expulsion of stomach contents through the mouth. Nausea may occur without vomiting, and vomiting may occur without prior nausea, but the two symptoms often occur together.

Nausea and vomiting are common symptoms experienced by virtually everyone. These symptoms may accompany almost any illness or stress situation. Causes of nausea and vomiting include the following:

- Gastrointestinal (GI) disorders, including infection or inflammation in the GI tract, liver, gallbladder, or pancreas; impaired GI motility and muscle tone (e.g., gastroparesis); and overeating or ingestion of foods or fluids that irritate the GI mucosa
- Cardiovascular, infectious, neurologic, or metabolic disorders
- Drug therapy. Nausea and vomiting are the most common adverse effects of drug therapy. Although the symptoms may occur with most drugs, they are especially associated with alcohol, aspirin, digoxin, anticancer drugs, antimicrobials, estrogen preparations, and opioid analgesics.
- Pain and other noxious stimuli, such as unpleasant sights and odors
- Emotional disturbances; physical or mental stress
- Radiation therapy
- Motion sickness

- Postoperative status, which may include pain, impaired GI motility, and receiving various medications
- Pregnancy

Vomiting occurs when the *vomiting center* (a nucleus of cells in the medulla oblongata) is stimulated (Figure 62-1). Stimuli are relayed to the vomiting center by afferent signals from the *chemoreceptor trigger zone (CTZ)*, the cerebral cortex, the sensory organs and the vestibular apparatus. The CTZ, composed of neurons in the fourth ventricle, can be activated by a variety of stimuli, including the presence of emetic substances (e.g., chemotherapy, opioids, ipecac) in the blood and cerebrospinal fluid and stimuli from the pharynx and gastrointestinal tract. In cancer chemotherapy, *emetogenic* drugs are thought to stimulate the release of serotonin from the enterochromaffin cells of the small intestine; this released serotonin then activates 5-HT<sub>3</sub> receptors located on vagal afferent nerves in the CTZ to initiate the vomiting reflex. Activation of the CTZ is also thought to play a role in the nausea and

vomiting associated with pregnancy. *Anticipatory nausea* triggered by memories and fear of nausea and vomiting is mediated by afferent signals from the higher centers of the cerebral cortex to the vomiting center. Noxious stimuli such as unpleasant odors or sights as well as pain are transmitted by afferent pathways from the sensory organs to the vomiting center. In *motion sickness*, rapid changes in body motion stimulate receptors in the inner ear (vestibular branch of the auditory nerve, which is concerned with equilibrium), and nerve impulses are transmitted to the vomiting center.

The vomiting center, CTZ, and GI tract contain benzodiazepine, cholinergic, dopamine, histamine, opiate, substance P/neurokinin, and serotonin receptors, which are stimulated by emetogenic drugs and toxins. When stimulated, the vomiting center initiates efferent impulses that stimulate the salivary center, cause closure of the glottis, contraction of abdominal muscles and the diaphragm, relaxation of the gastroesophageal sphincter, and reverse peristalsis, which moves stomach contents toward the mouth for ejection.

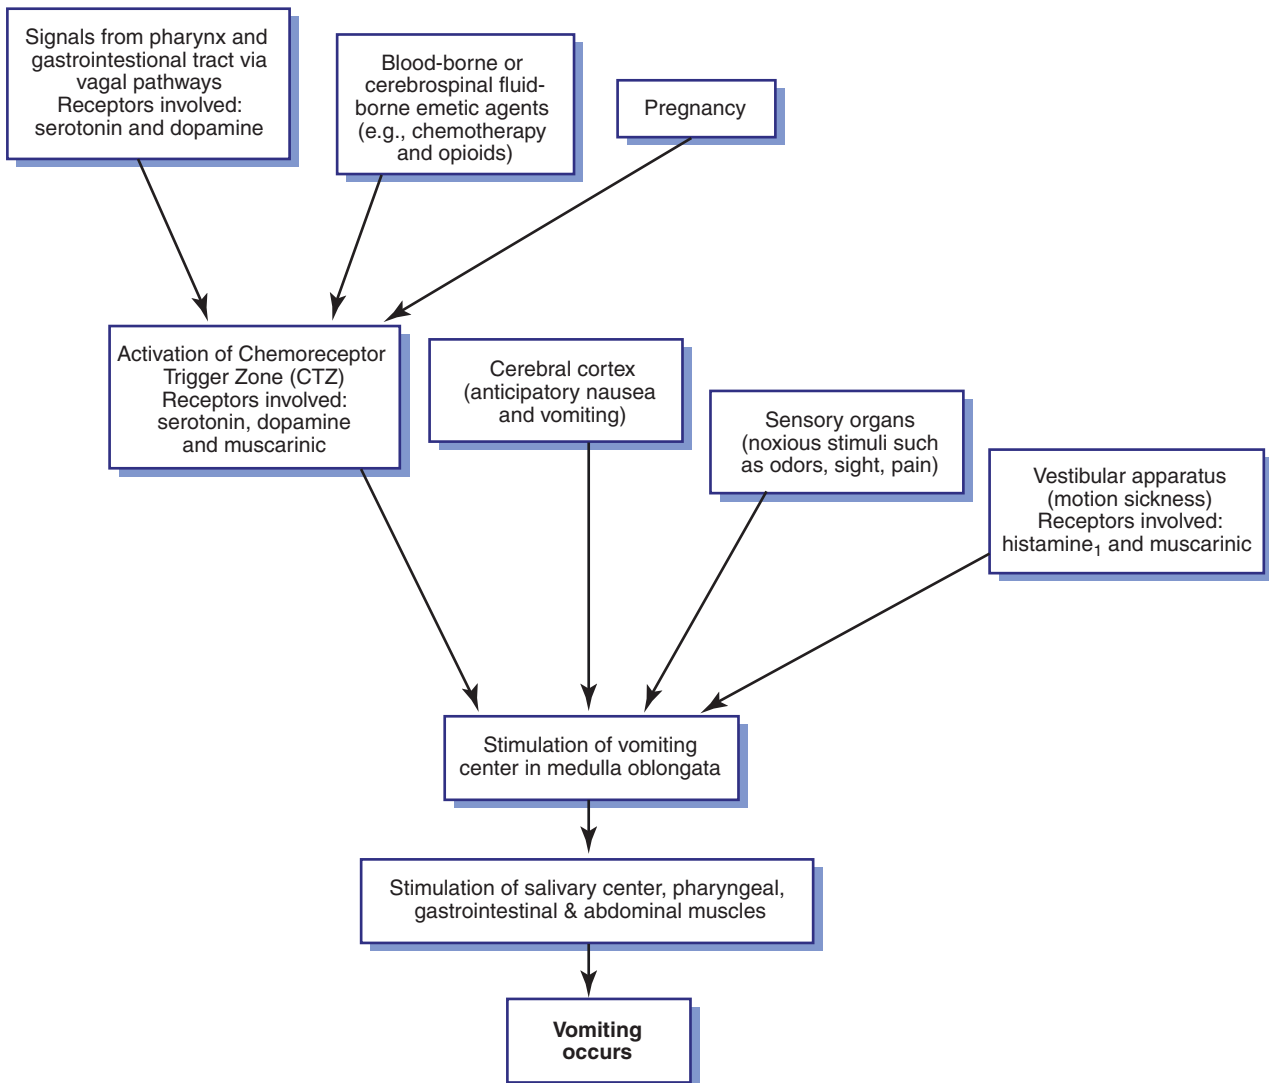

Figure 62-1 ■ Pathophysiology of nausea and vomiting.

## General Characteristics of Antiemetic Drugs

### Indications for Use

Antiemetic drugs are indicated to prevent and treat nausea and vomiting associated with surgery, pain, motion sickness, cancer chemotherapy, radiation therapy, and other causes.

### Contraindications to Use

Antiemetic drugs are usually contraindicated when their use may prevent or delay diagnosis and when signs and symptoms of drug toxicity may be masked.

## Classifications and Individual Drugs

Drugs used to prevent or treat nausea and vomiting belong to several different therapeutic classifications, and most have anticholinergic, antidopaminergic, antihistaminic, or antisero-tonergic effects. In general, the drugs are more effective in prophylaxis than treatment. Most antiemetics prevent or relieve nausea and vomiting by acting on the vomiting center, CTZ, cerebral cortex, vestibular apparatus, or a combination of these. Major drugs are described in the following sections and in Table 62-1.

Table 62-1

Drugs at a Glance: Antiemetic Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Phenothiazines</b>		
<b>Prochlorperazine</b>	PO 5–10 mg 3 or 4 times daily (sustained-release capsule, 10 mg twice daily) IM 5–10 mg q3–4h to a maximum of 40 mg daily Rectal suppository 25 mg twice daily	>10 kg, PO 0.4 mg/kg/d, in 3 or 4 divided doses IM 0.2 mg/kg as a single dose Rectal suppository 0.4 mg/kg/d, in 3 or 4 divided doses
<b>Promethazine</b> (Phenergan)	PO, IM, IV, rectal suppository 12.5–25 mg q4–6h (max dose PO, IM, rectal 50 mg. Max dose IV 25 mg)	over 2 y, PO, IM, IV rectal suppository 0.25–0.5 mg/kg q4–6h (Max dose 25 mg) use lowest dose possible to prevent respiratory depression
<b>Antihistamines</b>		
<b>Dimenhydrinate</b> (Dramamine)	PO 50–100 mg q4–6h as needed (maximal dose, 400 mg in 24 h) IM 50 mg as needed IV 50 mg in 10 mL of sodium chloride injection, over 2 min	6–12 y, PO 25–50 mg q6–8h (maximal dose, 150 mg in 24 h) IM 1.25 mg/kg 4 times daily (maximal dose, 300 mg in 24 h)
<b>Hydroxyzine</b> (Vistaril)	IM 25–100 mg q4–6h as needed	IM 0.5–1 mg/kg q4–6h
<b>Meclizine</b> (Antivert, Bonine)	Motion sickness, PO 25–50 mg 1 h before travel Vertigo, PO 25–100 mg daily in divided doses	Motion sickness, >12 y, PO 25–50 mg/d divided into 2 or 3 doses
<b>Prokinetic Agent</b>		
<b>Metoclopramide</b> (Reglan)	PO 10 mg 30 min before meals and at bedtime for 2–8 wk IV 2 mg/kg 30 min before injection of cisplatin and 2 h after injection of cisplatin, then 1–2 mg/kg q2–3h if needed, up to 4 doses	Dosage not established
<b>5-HT<sub>3</sub> (Serotonin) Receptor Antagonists</b>		
<b>Dolasetron</b> (Anzemet)	Prevention of PONV, PO 100 mg 2 h before surgery  Prevention or treatment of PONV, IV 12.5 mg as a single dose, 15 min before cessation of anesthesia or as soon as nausea or vomiting develops	2–16 y, prevention of PONV, PO 1.2 mg/kg within 2 h before surgery. Maximum dose, 100 mg Prevention or treatment of PONV, IV 0.35 mg/kg as a single dose, 15 min before cessation of anesthesia or as soon as

(continued on page 998)

Table 62-1

**Drugs at a Glance: Antiemetic Drugs** (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
	Prevention of chemotherapy-induced nausea and vomiting, PO 100 mg within 1 h before chemotherapy; IV 1.8 mg/kg as a single dose approximately 30 min before chemotherapy	nausea or vomiting develops. Maximum dose, 12.5 mg Prevention of chemotherapy-induced nausea and vomiting, PO 1.8 mg/kg within 1 h before chemotherapy, maximum dose 100 mg; IV 1.8 mg/kg as a single dose approximately 30 min before chemotherapy, maximum dose 100 mg
<b>Granisetron</b> (Kytril)	Cancer chemotherapy, PO 1 mg twice daily, first dose approximately 1 h before emetogenic drug, second dose 12 h later, only on days receiving chemotherapy; IV 10 mcg/kg infused over 5 min, 30 min before emetogenic drug, only on days receiving chemotherapy	2–16 y, IV 10 mcg/kg
<b>Ondansetron</b> (Zofran)	<i>Nausea and vomiting associated with highly emetogenic cancer chemotherapy:</i> PO 24 mg 30 min before start of single day chemotherapy IV 0.15 mg/kg for 3 doses given 30 minutes before chemotherapy, repeat in 4 and 8 h; IV 32 mg as a single dose. Infuse over 15 min <i>Nausea and vomiting associated with moderately emetogenic cancer chemotherapy:</i> PO 8 mg for 2 doses given 30 min before chemotherapy, repeat in 8 h. <i>Post operative nausea and vomiting:</i> PO 16 mg 1h before anesthesia IV 4 mg given over 2–5 min. IM 4 mg	Pediatric dosage not established  6–18 mos, IV 0.15 mg/kg for 3 doses given 30 minutes before chemotherapy, repeat in 4 and 8 h. Infuse over 15 min.  ≥12 y, PO dosage same as adult 4–11 y, PO 4 mg given for 3 doses given 30 min before chemotherapy, repeat in 8 and 16 h. PO dosage not established  1 mo–12 y, ≤40 kg: IV 0.1 mg/kg; ≥40 kg: IV 4 mg. Given over 2–5 min.
<b>Palonosetron</b> (Aloxi)	Cancer chemotherapy, IV 0.25 mg 30 min before emetogenic drug. Repeat dosing within a 7-day interval is not recommended.	Dosage not established
<b>Substance P/Neurokinin 1 Receptor Antagonist</b>		
<b>Aprepitant</b> (Emend)	Prevention of nausea and vomiting associated with highly emetic and moderately emetic chemotherapy: (administered as part of a 3-drug treatment that also includes a serotonin receptor antagonist and dexamethasone) Day 1: PO 125 mg 1 h before chemotherapy Day 2, 3: PO 80 mg in the morning	Pediatric dosage not established
<b>Miscellaneous Agents</b>		
<b>Dronabinol</b> (Marinol)	PO 5 mg/m <sup>2</sup> (square meter of body surface area) 1–3 h before chemotherapy, then q2–4h for a total of 4–6 doses daily. Dosage can be increased by 2.5 mg/m <sup>2</sup> increments to a maximal dose of 15 mg/m <sup>2</sup> if necessary.	Same as adults for treatment of chemotherapy-induced nausea and vomiting
<b>Phosphorated carbohydrate solution</b> (Emetrol)	PO 15–30 mL repeated at 15-min intervals until vomiting ceases	PO 5–10 mL repeated at 15-min intervals until vomiting ceases

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children
<b>Scopolamine</b> (Transderm Scop)	Motion sickness, PO IM, Sub-Q, 0.3–0.6 mg as a single dose Transdermal disc (1.5 mg scopolamine) placed behind the ear every 3 d if needed	Motion sickness, PO, Sub-Q 0.006 mg as a single dose

PONV, postoperative nausea and vomiting.

## Phenothiazines

Phenothiazines, of which **P** **chlorpromazine** (Thorazine) is the prototype, are central nervous system depressants used in the treatment of psychosis and psychotic symptoms in other disorders (see Chap. 9). These drugs have widespread effects on the body. Their therapeutic effects in nausea and vomiting (as in psychosis) are attributed to their ability to block dopamine from receptor sites in the brain and CTZ. When used as antiemetics, phenothiazines act on the CTZ and the vomiting center. Not all phenothiazines are effective antiemetics.

Phenothiazines are usually effective in preventing or treating nausea and vomiting induced by drugs, radiation therapy, surgery, and most other stimuli but are usually ineffective in motion sickness. These drugs cause sedation; **prochlorperazine** (Compazine) and **promethazine** (Phenergan) are commonly used. Because of their adverse effects (e.g., sedation, cognitive impairment, extrapyramidal reactions), phenothiazines are mainly indicated when other antiemetic drugs are ineffective or only a few doses are needed.

## Antihistamines

Antihistamines are used primarily to prevent histamine from exerting its widespread effects on body tissues (see Chap. 45). Antihistamines used as antiemetic agents are the “classic” antihistamines or H<sub>1</sub> receptor blocking agents (as differentiated from cimetidine and related drugs, which are H<sub>2</sub> receptor blocking agents). The drugs are thought to relieve nausea and vomiting by blocking the action of acetylcholine in the brain. Antihistamines may be effective in preventing and treating motion sickness. Not all antihistamines are effective as antiemetic agents. Adverse anticholinergic effects include dizziness, confusion, dry mouth, thickened respiratory secretions, blurred vision, urinary retention, and tachycardia; therefore, patients with narrow-angle glaucoma, prostatic hyperplasia, and asthma are at greater risk for adverse effects.

## Corticosteroids

Although corticosteroids are used mainly as antiallergic, anti-inflammatory, and antistress agents (see Chap. 23), they have antiemetic effects as well. The mechanism by which the drugs exert antiemetic effects is unknown; they may block prostaglandin activity in the cerebral cortex. **Dexamethasone** and **methylprednisolone** are commonly used in the management of chemotherapy-induced *emesis* and postoperative

nausea and vomiting either alone or in combination with 5-HT<sub>3</sub> receptor antagonists and/or substance P/neurokinin 1 receptor antagonists. With short-term use, adverse effects associated with corticosteroids are mild (e.g., euphoria, insomnia, mild fluid retention).

## Benzodiazepine Antianxiety Drugs

These drugs (see Chap. 8) are not antiemetics, but they are often used in multidrug regimens to prevent nausea and vomiting associated with cancer chemotherapy. The drugs produce relaxation, relieve anxiety, and inhibit cerebral cortex input to the vomiting center. They are often prescribed for patients who experience anticipatory nausea and vomiting before administration of anticancer drugs. *Lorazepam* (Ativan) is commonly used.

## Prokinetic Agents

**Metoclopramide** (Reglan) is a *prokinetic* agent that increases GI motility and the rate of gastric emptying by increasing the release of acetylcholine from nerve endings in the GI tract (peripheral cholinergic effects). As a result, it can decrease nausea and vomiting associated with gastroparesis and other nonobstructive disorders characterized by gastric retention of food and fluids. Metoclopramide also has central antiemetic effects; it antagonizes the action of dopamine, a catecholamine neurotransmitter. Metoclopramide is given orally in diabetic gastroparesis and esophageal reflux. Historically, metoclopramide has been used IV during chemotherapy with cisplatin (Platinol) and other antineoplastic drugs to treat acute nausea and vomiting; however, 5-HT<sub>3</sub> receptor antagonists are now the preferred antiemetic for this indication. Metoclopramide is still used to prevent delayed nausea and vomiting associated with chemotherapy.

With oral administration of metoclopramide, action begins in 30 to 60 minutes and peaks in 60 to 90 minutes. With intramuscular (IM) use, action onset occurs in 10 to 15 minutes and peaks in 60 to 90 minutes. With IV use, action onset occurs in 1 to 3 minutes and peaks in 60 to 90 minutes. Adverse effects include sedation, restlessness, and extrapyramidal reactions (e.g., akathisia, dystonia, symptoms of Parkinson's disease).

Metoclopramide may increase the effects of alcohol and cyclosporine (by increasing their absorption) and decrease the effects of cimetidine and digoxin (by accelerating passage through the GI tract and decreasing time for absorption).

Metoclopramide is relatively contraindicated in Parkinson's disease because it further depletes dopamine and reduces the effectiveness of levodopa, a major antiparkinson drug.

## 5-Hydroxytryptamine<sub>3</sub> (5-HT<sub>3</sub> or Serotonin) Receptor Antagonists

**Ondansetron** (Zofran), **granisetron** (Kytril), **dolasetron** (Anzemet), and **palonosetron** (Aloxi) are used to prevent or treat moderate to severe nausea and vomiting associated with cancer chemotherapy, radiation therapy, and postoperative status. These drugs antagonize serotonin receptors, preventing their activation by the effects of emetogenic drugs and toxins.

Ondansetron, granisetron, and dolasetron may be given intravenously (IV) or orally. Palonosetron is only given IV. All four of these drugs are metabolized in the liver. Adverse effects are usually mild to moderate, and common ones include diarrhea, headache, dizziness, constipation, muscle aches, and transient elevation of liver enzymes.

Ondansetron was the first drug of this group. Its half-life is 3 to 5.5 hours in most patients and 9 to 20 hours in patients with moderate or severe liver impairment. With oral drug, action begins in 30 to 60 minutes and peaks in about 2 hours. With IV drug, onset and peak of drug action are immediate.

Granisetron has a half-life of 6 hours with oral drug and 5 to 9 hours with IV drug; its half-life in patients with liver impairment is unknown. Action begins rapidly with IV injection and peaks in 30 to 45 minutes; action begins more slowly with oral drug and peaks in 60 to 90 minutes.

Dolasetron has a half-life of about 7 hours with both IV and oral drug, which is extended to 11 hours in patients with severe liver impairment. Action onset and peak occur rapidly with IV administration; with oral drug, onset is rapid and peak occurs in 1 to 2 hours.

Palonosetron is 62% plasma-protein bound and has a half-life of 40 hours. This prolonged half-life makes palonosetron effective for prevention of delayed emesis after chemotherapy. It is administered over 30 seconds and is given 30 minutes before chemotherapy via the same IV access. Drug action begins rapidly after IV administration.

### Applying Your Knowledge 62-1

For what adverse effects would you assess Ms. Snyder, in relation to ondansetron?

## Substance P/Neurokinin 1 Receptor Antagonists

*Substance P* is a peptide neurotransmitter in the neurokinin family. Substance P plays a role in mediating acute chemotherapy induced nausea and vomiting (along with serotonin) and is believed to be the primary mediator of delayed nausea and vomiting associated with chemotherapy. **Aprepitant** (Emend) is the first approved substance P/neurokinin 1 antagonist and

exerts its antiemetic effect by blockade of the NK<sub>1</sub> receptor. Aprepitant is often prescribed as part of combination therapy along with a 5-HT<sub>3</sub> receptor antagonist and corticosteroids to treat both acute and delayed nausea and vomiting associated with chemotherapy. Oral dosages of dexamethasone or methylprednisolone must be reduced by 50% and IV dosages of methylprednisolone must be reduced by 25% when co-administered with aprepitant due to CYP3A4 inhibition. Aprepitant is also indicated for prevention of postoperative nausea and vomiting.

Aprepitant is orally absorbed, reaching peak levels 4 hours after administration. It is highly protein bound. Aprepitant undergoes extensive hepatic metabolism by CYP450 enzyme systems. CYP3A4 is the primary enzyme of metabolism; however, CYP1A2 and CYP2C19 are also involved. Because aprepitant moderately inhibits as well as induces CYP3A4 enzymes and induces CYP2C9 enzymes, it has the potential for multiple drug interactions. Co-administration of aprepitant with pimozone (Orap), cisapride (Propulsid), terfenadine (Seldane), or astemizole (Hismanal) can produce life-threatening or fatal reactions and is contraindicated. (Terfenadine and astemizole are no longer available in the United States, and cisapride is only available through a limited access program to patients who have not responded to other treatments.) Aprepitant is eliminated primarily by hepatic metabolism. No dosage adjustments are required for renal impairment, mild to moderate hepatic impairment, or race, gender, or age. Aprepitant is not recommended for children.

Aprepitant reduces the effectiveness of oral contraceptive for up to 28 days after administration; therefore, alternate contraceptive methods are recommended during treatment and for 1 month following administration of aprepitant. Aprepitant induces the metabolism of warfarin. INR levels must be monitored for 2 weeks after treatment is initiated, especially during days 7 to 10 after treatment.

## Miscellaneous Antiemetics

**Dronabinol** is a *cannabinoid* (derivative of marijuana) used in the management of nausea and vomiting associated with anti-cancer drugs and unrelieved by other drugs. Dronabinol causes the same adverse effects as marijuana, including psychiatric symptoms, has a high potential for abuse, and may cause a withdrawal syndrome when abruptly discontinued. As a result, it is a Schedule III drug under federal narcotic laws.

Withdrawal symptoms (e.g., insomnia, irritability, restlessness) may occur if dronabinol is abruptly stopped. Onset occurs within 12 hours, with peak intensity within 24 hours and dissipation within 96 hours. These symptoms are most likely to occur with high doses or prolonged use. Sleep disturbances may persist for several weeks.

*Phosphorated carbohydrate solution* (Emetrol) is a hyperosmolar solution with phosphoric acid. It is thought to reduce smooth muscle contraction in the GI tract and is available over the counter.

**Scopolamine**, an anticholinergic drug (see Chap. 20), is effective in relieving nausea and vomiting associated with

motion sickness and radiation therapy for cancer. A transdermal patch is often used to prevent seasickness.

## Herbal and Dietary Supplements

**Ginger**, commonly used in cooking, is promoted for use in preventing nausea and vomiting associated with motion sickness, pregnancy, postoperative status, and other conditions. A few studies have investigated its antiemetic activity in humans. In one randomized, double-blind study, 60 women undergoing gynecologic surgery were given either 1000 milligrams of powdered ginger root orally, 10 milligrams of metoclopramide (Reglan) IV, or a placebo, 1.5 hours before surgery. Results indicated that ginger was comparable with metoclopramide and that both treatments were more effective than placebo in preventing postoperative nausea and vomiting. Similar results were obtained in another study with 120 patients having gynecologic surgery; in this study, metoclopramide was given orally. Although these studies support the use of ginger, other studies do not. The general consensus seems to be that it is premature to recommend ginger for any therapeutic use until long-term, controlled studies are done.

Marijuana cigarettes, although illegal in most states and under federal law, have been used by some individuals to treat chemotherapy-induced nausea and vomiting. The National Cancer Institute Fact Sheet on Marijuana Use in Supportive Care for Cancer Patients points out concerns surrounding lack of consistent effect due to varying potency of marijuana, the need for additional research concerning the use of marijuana for supportive care, and the opinion that currently available antiemetic drugs are more effective for this purpose.

## Nursing Process

### Assessment

Assess for nausea and vomiting.

- Identify risk factors (e.g., digestive or other disorders in which nausea and vomiting are symptoms; drugs associated with nausea and vomiting).
- Interview regarding frequency, duration, and precipitating causes of nausea and vomiting. Also, question the patient about accompanying signs and symptoms, characteristics of vomitus (amount; color; odor; presence of abnormal components, such as blood), and any measures that relieve nausea and vomiting. When possible, observe and measure the vomitus.

### Nursing Diagnoses

- Deficient Fluid Volume related to uncontrolled vomiting
- Imbalanced Nutrition: Less Than Body Requirements related to impaired ability to ingest and digest food

- Altered Tissue Perfusion: Hypotension related to fluid volume depletion or antiemetic drug effect
- Risk for Injury related to adverse drug effects
- Deficient Knowledge related to nondrug measures to reduce nausea and vomiting and appropriate use of antiemetic drugs

## Planning/Goals

### The patient will

- Receive antiemetic drugs at appropriate times, by indicated routes
- Take antiemetic drugs as prescribed for outpatient use
- Obtain relief of nausea and vomiting
- Eat and retain food and fluids
- Have increased comfort
- Maintain body weight
- Maintain normal bowel elimination patterns
- Have fewer vomiting episodes and less discomfort with cancer chemotherapy or surgical procedures

## Interventions

Use measures to prevent or minimize nausea and vomiting.

- Assist patients to identify situations that cause or aggravate nausea and vomiting.
- Avoid exposure to stimuli when feasible (e.g., unpleasant sights and odors; excessive ingestion of food, alcohol, or nonsteroidal anti-inflammatory drugs).
- Because pain may cause nausea and vomiting, administration of analgesics before painful diagnostic tests and dressing changes or other therapeutic measures may be helpful.
- Administer antiemetic drugs 30 to 60 minutes before a nausea-producing event (e.g., radiation therapy, cancer chemotherapy, travel), when possible.
- Many oral drugs cause less gastric irritation, nausea, and vomiting if taken with or just after food. For any drug likely to cause nausea and vomiting, check reference sources to determine whether it can be given with food without altering beneficial effects.
- When nausea and vomiting occur, assess the patient's condition and report to the physician. In some instances, a drug (e.g., digoxin, an antibiotic) may need to be discontinued or reduced in dosage. In other instances (e.g., paralytic ileus, GI obstruction), preferred treatment is restriction of oral intake and nasogastric intubation.
- Eating dry crackers before rising in the morning and ingestion of small frequent protein meals may help prevent nausea and vomiting associated with pregnancy.
- Avoid oral intake of food, fluids, and drugs during acute episodes of nausea and vomiting. Oral intake may increase vomiting and risks of fluid and electrolyte imbalances.

- Minimize activity during acute episodes of nausea and vomiting. Lying down and resting quietly are often helpful.

Give supportive care during vomiting episodes.

- Give replacement fluids and electrolytes. Offer small amounts of food and fluids orally when tolerated and according to patient preference.
- Record vital signs, intake and output, and body weight at regular intervals if nausea or vomiting occurs frequently.
- Decrease environmental stimuli when possible (e.g., noise, odors). Allow the patient to lie quietly in bed when nauseated. Decreasing motion may decrease stimulation of the vomiting center in the brain.
- Help the patient rinse his or her mouth after vomiting. Rinsing decreases the bad taste and corrosion of tooth enamel caused by gastric acid.
- Provide requested home remedies when possible (e.g., a cool, wet washcloth to the face and neck).

Provide appropriate education for any drug therapy (see accompanying Patient Teaching Guidelines).

### Evaluation

- Observe and interview for decreased nausea and vomiting.
- Observe and interview regarding ability to maintain adequate intake of food and fluids.
- Compare current weight with baseline weight.
- Observe and interview regarding appropriate use of antiemetic drugs.

### Applying Your Knowledge 62-2

What nursing measures, in addition to the administration of medication, should you implement to reduce Ms. Snyder's nausea and vomiting?

.....

## Principles of Therapy

### Drug Selection

Choice of an antiemetic drug depends largely on the cause of nausea and vomiting and the patient's condition.

- To prevent chemotherapy-induced nausea and vomiting before receiving drugs with high emetic risk, the American Society of Clinical Oncology recommends a three-drug combination consisting of a 5-HT<sub>3</sub> receptor antagonist (ondansetron, granisetron, dolasetron, or palonosetron), dexamethasone, and aprepitant. For prevention of nausea and vomiting accompanying chemotherapy with moderate emetic risk, a 5-HT<sub>3</sub> receptor antagonist and dexamethasone are recommended. To prevent delayed emesis in

patients receiving cisplatin and other high emetic risk chemotherapeutic agents, dexamethasone and aprepitant are recommended.

- 5-HT<sub>3</sub> receptor antagonists are usually considered drugs of first choice for postoperative nausea and vomiting.
- Drugs with anticholinergic and antihistaminic properties are preferred for motion sickness. Antihistamines such as meclizine and dimenhydrinate are also useful for vomiting caused by labyrinthitis, uremia, or postoperative status.
- For ambulatory patients, drugs causing minimal sedation are preferred. However, most antiemetic drugs cause some sedation in usual therapeutic doses.
- Promethazine (Phenergan), a phenothiazine, is often used clinically for its antihistaminic, antiemetic, and sedative effects.
- Although phenothiazines are effective antiemetic agents, they may cause serious adverse effects (e.g., hypotension, sedation, anticholinergic effects, extrapyramidal reactions that simulate signs and symptoms of Parkinson's disease). Consequently, phenothiazines other than promethazine usually should not be used, especially for pregnant, young, older, and postoperative patients, unless vomiting is severe and cannot be controlled by other measures.
- Metoclopramide (Reglan) may be preferred when nausea and vomiting are associated with nonobstructive gastric retention.
- When the nausea and vomiting associated with pregnancy are not controlled with lifestyle measures, some pharmacologic interventions may be appropriate (see Evidence-Based Practice Box: 62-1 Nausea and Vomiting During Pregnancy).

### Drug Dosage and Administration

Dosage and route of administration depend primarily on the reason for use.

- Doses of phenothiazines are much smaller for antiemetic effects than for antipsychotic effects.
- Most antiemetic agents are available in oral, parenteral, and rectal dosage forms. As a general rule, oral dosage forms are preferred for prophylactic use and rectal or parenteral forms are preferred for therapeutic use.
- Antiemetic drugs are often ordered PRN (as needed). As for any PRN drug, the patient's condition should be assessed before drug administration.
- The use of antiemetic drugs is usually short term, from a single dose to a few days.
- When nausea and vomiting are likely to occur because of travel, administration of emetogenic anticancer drugs, diagnostic tests, or therapeutic procedures, an antiemetic drug should be given before the emetogenic event. Pretreatment usually increases patient comfort and allows use of lower drug doses. It also may prevent aspiration and other potentially serious complications of vomiting.

## Evidence-Based Practice

### 62-1 Nausea and Vomiting During Pregnancy

Seventy to eighty-five percent of pregnant women experience nausea and vomiting during pregnancy, also known as “morning sickness.” The majority of these women experience mild to moderate symptoms, predominantly during the first 9 weeks of pregnancy. However, 0.5% to 2% of pregnant women will experience severe nausea and vomiting or hyperemesis gravidarum. Hyperemesis gravidarum is the second most common reason for hospitalization of pregnant women (after preterm labor) and is characterized by persistent vomiting, dehydration, ketonuria, electrolyte imbalances, and weight loss.

Practice guidelines from the American College of Obstetricians and Gynecologists (ACOG) include the following pharmacologic recommendations for treating nausea and vomiting during pregnancy:

- Taking a multivitamin at the time of conception may be effective in decreasing the severity of morning sickness.
- Treating nausea and vomiting early may aid in preventing progression to more severe symptoms.
- There is consistent scientific evidence to support pyridoxine (vitamin B<sub>6</sub>) 10 mg alone or with the antihistamine doxylamine 12.5 mg every 8 hours as needed.
- Ginger 250 mg four times daily is a nonpharmacologic treatment supported by limited scientific evidence.
- Antihistamine H<sub>1</sub>-receptor blockers and phenothiazines have been shown to be safe and effective in treating nausea and vomiting that has not responded to other measures.
- Although corticosteroids such as methylprednisolone may be effective in treating severe hyperemesis gravidarum, they should be reserved as a treatment of last resort due to the increased risk for fetal malformations such as cleft lip and cleft palate.

## Use in Special Populations

### Use in Patients Undergoing Chemotherapy

Several anticancer drugs may cause severe nausea and vomiting and much discomfort for patients. Cisplatin is one of the most emetogenic drugs. For this reason, new antiemetics are usually compared with older drugs in the treatment of cisplatin-induced nausea and vomiting. Some general management guidelines include the following:

- Chemotherapy may be given during sleeping hours.
- Some patients may experience less nausea and vomiting if they avoid or decrease food intake for a few hours before scheduled chemotherapy.
- Antiemetic drugs should be given before the emetogenic drug to prevent nausea and vomiting when possible. Most often, they are given IV for rapid effects and continued for 2 to 3 days. Continuous IV infusion may be more effective than intermittent bolus injections.
- The 5-HT<sub>3</sub> receptor antagonists (e.g., ondansetron) are usually considered the most effective antiemetics. They may be given in a single daily dose.
- Metoclopramide, given IV in high doses, may be used alone or in combination with various other drugs. Diphenhydramine (Benadryl) may be given at the same time or PRN because high doses of metoclopramide often cause extrapyramidal effects (see Chap. 9).
- Various combinations of antiemetic and sedative-type drugs are used, and research continues in this area. A commonly used regimen for prophylaxis when highly emetic chemotherapy is used is a corticosteroid (e.g., dexamethasone 12 mg PO on day 1 followed by 8 mg on days 2–4),

## Patient Teaching Guidelines

### Antiemetic Drugs

#### General Considerations

- Try to identify the circumstances that cause or aggravate nausea and vomiting and avoid them when possible.
- Drugs are more effective in preventing nausea and vomiting than in stopping them. Thus, they should be taken before the causative event when possible.
- Do not eat, drink, or take oral medications during acute vomiting episodes, to avoid aggravating the stomach upset.
- Lying down may help nausea and vomiting to subside; activity tends to increase stomach upset.
- After your stomach has settled down, try to take enough fluids to prevent dehydration and potentially serious problems. Tea, broth, and gelatins are usually tolerated.
- Do not drive an automobile or operate dangerous machinery if drowsy from antiemetic drugs, to avoid injury.
- If taking antiemetic drugs regularly, do not drink alcohol or take other drugs without consulting a health care provider. Several drugs interact with antiemetic agents, to increase adverse effects.
- Dronabinol, which is derived from marijuana and recommended only for nausea and vomiting associated with cancer chemotherapy, can cause dizziness, drowsiness, mood changes, and other mind-altering effects. You

should avoid alcohol and other drugs that cause drowsiness. Also, do not drive or perform hazardous tasks requiring alertness, coordination, or physical dexterity, to decrease risks of injury.

#### Self- or Caregiver Administration

- Take the drugs as prescribed: Do not increase dosage, take more often, or take when drowsy, dizzy, or unsteady on your feet. Several of the drugs cause sedation and other adverse effects, which are more severe if too much is taken.
- To prevent motion sickness, take medication 30 minutes before travel and then every 4 to 6 hours, if necessary, to avoid or minimize adverse effects.
- Take or give antiemetic drugs 30 to 60 minutes before a nausea-producing event, when possible. This includes cancer chemotherapy, radiation therapy, painful dressings, or other treatments.
- Take dronabinol only when you can be supervised by a responsible adult because of its sedative and mind-altering effects.
- Aprepitant (Emend) reduces the effectiveness of oral contraceptives; therefore, use an alternative form of birth control during therapy and for 1 month after therapy.

a 5-HT<sub>3</sub> receptor antagonist (e.g., ondansetron 32 mg IV on day 1), and aprepitant (125 mg PO day 1 and 80 mg PO on days 2–3).

### Applying Your Knowledge 62-3

The physician orders Ms. Snyder to also receive diphenhydramine with her metoclopramide. What is the rationale for giving these two medications together?

#### Use in Children

Few studies of antiemetics have been done in children, and their usage is not clearly defined. Thus, antiemetic drug therapy should be cautious and limited to prolonged vomiting of known etiology.

- With the 5-HT<sub>3</sub> receptor antagonists, safety and efficacy of granisetron and dolasetron have not been established for children younger than 2 years of age, and there is little information available about the use of ondansetron in children 3 years of age and younger. Safety and efficacy of palonosetron has not been established in patients below the age of 18 years.
- The American Society of Clinical Oncology recommends the use of a 5-HT<sub>3</sub> receptor antagonist plus a corticosteroid before administering high-dose chemotherapy or chemotherapy with high to moderate emetic risk to pediatric oncology patients.
- Phenothiazines are more likely to cause dystonias and other neuromuscular reactions in children than in adults. Promethazine is the preferred phenothiazine, because its action is more like that of the antihistamines than the phenothiazines. However, promethazine should not be used in children with hepatic disease, Reye's syndrome, a history of sleep apnea, or a family history of sudden infant death syndrome. A **BLACK BOX WARNING** alerts nurses that promethazine is contraindicated in children less than 2 years of age due to the risk of potentially fatal respiratory depression. When using promethazine, the lowest effective dosage should be used and other drugs with respiratory depressant effects should not be given concurrently. Excessive doses may cause hallucinations, convulsions, and sudden death.
- Several antiemetics (e.g., cyclizine, scopolamine) are not recommended for use in children younger than 12 years of age.
- Metoclopramide often causes extrapyramidal reactions (e.g., dystonia) in children, even in small doses.
- Dronabinol may be used to prevent or treat chemotherapy-induced nausea and vomiting in children who do not respond to other antiemetic drugs. However, the drug should be used cautiously in children because of its psychoactive effects.

#### Use in Older Adults

Most antiemetic drugs cause drowsiness, especially in older adults, and therefore should be used cautiously. Efforts should be made to prevent nausea and vomiting when possible. Older adults are at risk of fluid volume depletion and electrolyte imbalances with vomiting.

Dronabinol should be used cautiously because older adults are usually more sensitive to the drug's psychoactive effects than young or middle-aged adults.

#### Use in Patients With Renal Impairment

Several drugs are commonly used for patients with renal impairment who have nausea and vomiting.

- Metoclopramide dosage should be reduced in patients with severe renal impairment to decrease drowsiness and extrapyramidal effects.
- Phenothiazines are metabolized primarily in the liver, and dosage reductions are not usually needed for patients with renal impairment. However, these drugs have anticholinergic effects and can cause urinary retention and orthostatic hypotension. They also can cause extrapyramidal symptoms and sedation in patients with end-stage renal disease (ESRD).

#### Use in Patients With Hepatic Impairment

Most antiemetic drugs are metabolized in the liver and should be used cautiously in patients with impaired hepatic function.

- With oral ondansetron, do not exceed an 8-mg dose; with IV use, a single, maximal daily dose of 8 mg is recommended.
- Phenothiazines are metabolized in the liver and eliminated in urine. In the presence of liver disease (e.g., cirrhosis, hepatitis), metabolism may be slowed and drug elimination half-lives prolonged, with resultant accumulation and increased risk of adverse effects. Thus, the drugs should be used cautiously in patients with hepatic impairment. Cholestatic jaundice has been reported with promethazine.
- Dronabinol normally undergoes extensive first-pass hepatic metabolism to active and inactive metabolites. Resultant plasma levels consist of approximately equal portions of the parent drug and the main active metabolite. In addition, the drug is eliminated mainly by biliary excretion, over several weeks. Thus, long-term use at recommended doses may lead to accumulation of toxic amounts of the drug and its metabolite, even in patients with normal liver function.

In patients with hepatic impairment, more of the parent drug and less of the active metabolite are likely to reach the bloodstream. Thus, therapeutic and adverse effects are less predictable. Also, impaired liver function can decrease metabolism and excretion in bile so that accumulation is likely and adverse effects may be increased and prolonged. The drug should be used very cautiously, if at all, in patients with moderate to severe hepatic impairment.

## Use in Home Care

Antiemetics are usually given orally or by rectal suppository in the home setting. The home care nurse may need to assess patients for possible causes of nausea and vomiting and assist patients and caregivers with appropriate use of the drugs and other interventions to prevent fluid and electrolyte depletion. Teaching safety precautions with sedating drugs may also be needed.

## Applying Your Knowledge 62-4

Ms. Snyder is concerned about the amount of medication she is receiving. She asks you to withhold her antiemetics until she actually vomits. You do as she requests.

.....

## Nursing Actions Antiemetics

### NURSING ACTIONS

#### 1. Administer accurately

- a. For prevention of motion sickness, give antiemetics 30 minutes before travel and q4–6h, if necessary.
- b. For prevention of vomiting with cancer chemotherapy and radiation therapy, give antiemetic drugs 30–60 minutes before treatment.
- c. Inject intramuscular antiemetics deeply into a large muscle mass (e.g., gluteal area).
- d. In general, do not mix parenteral antiemetics in a syringe with other drugs.
- e. Omit antiemetic agents and report to the physician if the patient appears excessively drowsy or is hypotensive.
- f. Mix intravenous (IV) ondansetron in 50 mL of 5% dextrose or 0.9% sodium chloride injection and infuse over 15 minutes.
- g. Mix granisetron in 20–50 mL of 5% dextrose or 0.9% sodium chloride injection and infuse over 5 minutes.
- h. With dolasetron:
  - (1) Give oral drug 1–2 hours before chemotherapy; give IV drug about 30 minutes before chemotherapy.
  - (2) Give IV drug (up to 100-mg dose) by direct injection over 30 seconds or longer or dilute up to 50 mL with 0.9% sodium chloride, 5% dextrose, or 5% dextrose and 0.45% sodium chloride and infuse over 15 minutes.
- i. Infuse palonosetron IV over 30 seconds. Do not mix with other drugs. Flush the IV line with normal saline before and after administration of palonosetron.

#### 2. Observe for therapeutic effects

- a. Verbal reports of decreased nausea
- b. Decreased frequency or absence of vomiting

#### 3. Observe for adverse effects

- a. Excessive sedation and drowsiness
- b. Anticholinergic effects—dry mouth, urinary retention
- c. Hypotension, including orthostatic hypotension
- d. Extrapyramidal reactions—dyskinesia, dystonia, akathisia, parkinsonism
- e. With ondansetron and related drugs, observe for headache, diarrhea or constipation, dizziness, fatigue, and muscle aches. Bradycardia and hypotension may also occur.

### RATIONALE/EXPLANATION

To allow time for drug dissolution and absorption

Drugs are more effective in preventing than in stopping nausea and vomiting.

To decrease tissue irritation

To avoid physical incompatibilities

To avoid potentiating adverse effects and central nervous system (CNS) depression

For oral administration to patients who cannot swallow tablets, dolasetron injection can be mixed in apple or apple–grape juice. Specific instructions should be obtained from a pharmacy. When kept at room temperature, the diluted oral solution should be used within 2 hours.

Manufacturer's instructions

Excessive sedation may occur with usual doses of antiemetics and is more likely to occur with high doses. This may be minimized by avoiding high doses and assessing the patient's level of consciousness before each dose.

These effects are common to many antiemetic agents and are more likely to occur with large doses.

Most likely to occur with phenothiazines; may also occur with 5-HT<sub>3</sub> antagonists

These disorders may occur with phenothiazines and metoclopramide.

These drugs are usually well tolerated, with mild to moderate adverse effects.

## Nursing Actions Antiemetics (continued)

### NURSING ACTIONS

- f. With dronabinol, observe for alterations in mood, cognition, and perception of reality; dysphoria; drowsiness; dizziness; anxiety; tachycardia; and conjunctivitis. Dronabinol may also cause seizures or seizure-like activity. May lower the seizure threshold in those with pre-existing seizure disorders.
- g. With aprepitant, observe for weakness, tiredness, dizziness, diarrhea or constipation, stomach pain, upset stomach, hiccups, and loss of appetite. Rare but serious adverse effects include hives, skin rashes, swelling of face, airways and extremities, hoarseness.

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of antiemetic agents:
- (1) CNS depressants (alcohol, sedative-hypnotics, antianxiety agents, other antihistamines or antipsychotic agents)
  - (2) Anticholinergics (e.g., atropine)
  - (3) Antihypertensive agents
- b. Drugs that *alter* effects of 5-HT<sub>3</sub> receptor antagonists:
- (1) Atenolol and cimetidine *increase* effects of dolasetron.
  - (2) Rifampin (and presumably other enzyme inducers) *decreases* effects of dolasetron and granisetron.
- c. Drugs that *increase* effects of aprepitant:
- (1) CYP3A4 inhibitors (e.g., clarithromycin, diltiazem, ketoconazole, itraconazole, nelfinavir, ritonavir, troleandomycin)
- d. Drugs that *decrease* effects of aprepitant:
- (1) CYP3A4 inducers (e.g., carbamazepine, phenytoin, rifampin)
  - (2) Paroxetine

### RATIONALE/EXPLANATION

Tachycardia may be prevented with a beta-adrenergic blocking drug, such as propranolol (Inderal).

Notify provider if rare serious adverse effects occur.

Additive CNS depression

Additive anticholinergic effects. Some phenothiazines and antiemetic antihistamines have strong anticholinergic properties.

Additive hypotension

The drugs decrease dolasetron metabolism and clearance.

Enzyme inducers accelerate metabolism of affected drugs.

These drugs decrease the metabolism of aprepitant.

These drugs increase the metabolism of aprepitant.

## Key Concepts

- Antiemetic drugs are used to prevent or treat nausea and vomiting associated with surgery, pain, motion sickness, cancer chemotherapy, radiation therapy, and other causes.
- Antiemetic drugs are most effective when given before nausea and vomiting occurs.
- Nausea is an unpleasant sensation of abdominal discomfort accompanied by the desire to vomit.
- Vomiting is the expulsion of stomach contents through the mouth.
- The vomiting center, CTZ, and GI tract contain benzodiazepine, cholinergic (muscarinic), dopamine, histamine, opiate, substance P/neurokinin, and serotonin receptors that are stimulated by emetogenic drugs and toxins. Antiemetic drugs produce their effects by blockade of one or more of these receptors.
- The antiemetic effect of phenothiazines such as prochlorperazine and promethazine is due to blockade of dopamine receptors in the brain and CTZ. They are used to treat nausea induced by drugs, radiation therapy, surgery, and other stimuli but are considered ineffective in motion sickness.
- Classic H<sub>1</sub> blocking antihistamine drugs such as dimenhydrinate are thought to produce an antiemetic effect due to their anticholinergic properties. Antihistamines are used to prevent and treat nausea and vomiting due to motion sickness.

- The antiemetic mechanism of action of corticosteroids such as dexamethasone and methylprednisolone is unknown. These drugs are commonly used alone or in combination with 5-HT<sub>3</sub> serotonin receptor antagonists and/or substance P/neurokinin 1 receptor antagonists in the management of chemotherapy-induced emesis and postoperative nausea and vomiting.
- Benzodiazepines such as lorazepam produce relaxation, relieve anxiety, and inhibit cerebral cortex input to the vomiting center. They are prescribed for anticipatory nausea associated with cancer chemotherapy.
- Prokinetic agents such as metoclopramide increase the release of acetylcholine from nerve endings in the GI track, increasing GI motility and gastric emptying. It also antagonizes dopamine in the brain. Metoclopramide is prescribed to treat nausea and vomiting associated with gastroparesis and other nonobstructive disorders characterized by gastric retention of food and fluids and in the treatment of esophageal reflux. It is also useful in prevention of delayed nausea and vomiting associated with chemotherapy.
- 5-HT<sub>3</sub> serotonin receptor antagonists such as ondansetron, granisetron, dolasetron, and palonosetron antagonize serotonin receptors, preventing their activation by emetogenic drugs and toxins. They are used to prevent and treat moderate to severe nausea associated with cancer chemotherapy, radiation therapy, and postoperative status.
- Substance P, a peptide neurotransmitter in the neurokinin family, plays a role in acute and delayed chemotherapy-induced nausea and vomiting. Aprepitant antagonizes the neurokinin 1 receptor, preventing activation by emetogenic chemotherapeutic drugs.
- Dronabinol is a cannabinoid used in the management of nausea and vomiting associated with chemotherapy unrelieved by other antiemetic drugs. It is a Schedule III drug under federal narcotic laws.
- Scopolamine is an anticholinergic drug effective in relieving nausea and vomiting associated with motion sickness and radiation therapy for cancer.

## Review and Application Exercises

### Short Answer Exercises

1. List common causes of nausea and vomiting or circumstances in which nausea and vomiting often occur.
2. How do antiemetic drugs prevent or relieve nausea and vomiting?
3. What are adverse effects of commonly used antiemetics?
4. Are antiemetics more effective if given before, during, or after nausea and vomiting?
5. Which antiemetics are usually given to control the nausea and vomiting that occur with certain antineoplastic drugs?

### NCLEX-Style Questions

6. The nurse knows that antiemetics are most effective when administered
  - a. before an emetogenic event occurs
  - b. during an episode of nausea but before vomiting has occurred
  - c. after the patient has experienced nausea and vomiting
  - d. timing of administration has no impact on drug effectiveness
7. The nurse would question an order for which of the following antiemetics for treatment of motion sickness-induced nausea?
  - a. prochlorperazine (Compazine)
  - b. dimenhydrinate (Dramamine)
  - c. meclizine (Antivert)
  - d. scopolamine (Transderm Scop)
8. When administering 5-HT<sub>3</sub> receptor antagonists before cancer chemotherapy, the nurse should also be prepared to administer which of the following adjunctive medications?
  - a. promethazine
  - b. dexamethasone
  - c. dronabinol
  - d. hydroxyzine

SECTION

# 10

## Drugs Used in Special Conditions

### Chapter Outline

- 63 ■ Drugs Used in Ophthalmic Conditions
- 64 ■ Drugs Used in Dermatologic Conditions
- 65 ■ Drug Use During Pregnancy and Lactation

# Drugs Used in Ophthalmic Conditions

## KEY TERMS

- Conjunctiva
- Glaucoma
- Intraocular pressure (IOP)
- Keratitis
- Lacrimation
- Miosis
- Mydriasis
- Nasolacrimal occlusion
- Refraction
- Tonometry

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review characteristics of ocular structures that influence drug therapy for eye disorders.
2. Discuss selected drugs in relation to their use in ocular disorders.
3. Use correct techniques to administer ophthalmic medications.
4. Assess for ocular effects of systemic drugs and systemic effects of ophthalmic drugs.
5. Teach patients, family members, or caregivers correct administration of eye medications.
6. For a patient with an eye disorder, teach about the importance of taking medications as prescribed to protect and preserve eyesight.

## Applying Your Knowledge

Irene Molnar is a 75-year-old woman who has glaucoma. You are a home care nurse visiting Mrs. Molnar. Her physician has prescribed the following:

Acetazolamide (Diamox), 250 mg PO, every 6 hours

Timolol (Timoptic), one drop in each eye, twice daily

Pilocarpine (Isopto-Carpine), one drop of 2% solution in each eye, three times daily

## Introduction

### Basic Structure and Function of the Eye

The eye is the major sensory organ through which a person receives information about the external environment. Extensive discussion of vision and ocular anatomy is beyond the scope of this chapter, but some characteristics and functions are described to facilitate understanding of ocular drug therapy:

- The eyelids and lacrimal system function to protect the eye. The eyelid is a barrier to the entry of foreign bodies, strong light, dust, and other potential irritants. The *conjunctiva* is the mucous membrane lining of the eyelids. The canthi (singular, canthus) are the angles where the upper and lower eyelids meet. The lacrimal system produces a fluid that constantly moistens and cleanses the anterior surface of the eyeball. The fluid drains through two small openings in the inner canthus and flows through the nasolacrimal duct into the nasal cavity. When the *conjunctiva* is irritated or certain emotions are experienced (e.g., sadness), the lacrimal gland produces more fluid than the drainage system can accommodate. The excess fluid overflows the eyelids and becomes tears.

- The eyeball is a spherical structure composed of the sclera, cornea, choroid, and retina, plus special refractive tissues. The sclera is a white, opaque, fibrous tissue that covers the posterior five sixths of the eyeball. The cornea is a transparent, special connective tissue that covers the anterior sixth of the eyeball. The cornea contains no blood vessels. The choroid, composed of blood vessels and connective tissue, continues forward to form the iris. The iris is composed of pigmented cells, the opening called the pupil, and muscles that control the size of the pupil by contracting or dilating in response to stimuli. Pupil constriction is called *miosis*; dilation is called *mydriasis*. The retina is the innermost layer of the eyeball.
- For vision to occur, light rays must enter the eye through the cornea; travel through the pupil, lens, and vitreous body (discussed below); and be focused on the retina. Light rays do not travel directly to the retina. Instead, they are deflected in various directions according to the density of the ocular structures through which they pass. This process, called *refraction*, is controlled by the aqueous humor, lens, and vitreous body. The optic disk is the area of the retina where ophthalmic blood vessels and the optic nerve enter the eyeball.
- The structure and function of the eyeball are further influenced by the lens, aqueous humor, and vitreous body. The lens is an elastic, transparent structure; its function is to focus light rays to form images on the retina. It is located behind the iris and is held in place by ligaments attached to the ciliary body. The aqueous humor is a clear fluid produced by capillaries in the ciliary body. Most of the fluid flows through the pupil into the anterior chamber (between the cornea and the lens and anterior to the iris). A small amount flows into a passage called Schlemm's canal, from which it enters the venous circulation. Normally, production and drainage of aqueous humor are approximately equal, and normal *intraocular pressure (IOP)* is maintained. Impaired drainage of aqueous humor causes increased IOP. The vitreous body is a transparent, jelly-like mass located in the posterior portion of the eyeball. It functions to refract light rays and maintain the normal shape of the eyeball.

## Disorders of the Eye

The eye is subject to the development of many disorders that threaten its structure, function, or both. Some disorders in which ophthalmic drugs play a prominent role are discussed in the following sections.

### Refractive Errors

Refractive errors include myopia (nearsightedness), hyperopia (farsightedness), presbyopia, and astigmatism. These conditions impair vision by interfering with the eye's ability to focus light rays on the retina. Ophthalmic drugs are used only in the diagnosis of the conditions; treatment involves prescription of eyeglasses or contact lenses.

### Glaucoma

*Glaucoma* is one of the leading causes of blindness in the United States and the most common cause of blindness in African Americans. It is a group of diseases characterized by optic nerve damage and changes in visual fields. It is often characterized by increased IOP (above 22 mm Hg) but may also occur with normal IOP (below 21 mm Hg; average 15–16 mm Hg). Diagnostic tests for glaucoma include ophthalmoscopic examination of the optic disk, measurement of IOP (*tonometry*), and testing of visual fields.

The most common type of glaucoma is called primary open-angle glaucoma. Its etiology is unknown, but contributing factors include advanced age, a family history of glaucoma and elevated IOP, diabetes mellitus, hypertension, myopia, long-term use of corticosteroid drugs, and previous eye injury, inflammation, or infection. In addition, the incidence of glaucoma in African Americans is about three times higher than in non-African Americans. Closed-angle glaucoma is usually an acute situation requiring emergency surgery. It may occur when pupils are dilated and the outflow of aqueous humor is blocked. Darkness and drugs with anticholinergic effects (e.g., atropine, antihistamines, tricyclic antidepressants) may dilate the pupil, reduce outflow of aqueous humor, and precipitate acute glaucoma.

### Inflammatory or Infectious Conditions

Inflammation may be caused by bacteria, viruses, allergic reactions, or irritating chemicals. Infections may result from foreign bodies, contaminated hands, contaminated eye medications, or infections in contiguous structures (e.g., nose, face, sinuses). Common inflammatory and infectious disorders include the following:

- **Conjunctivitis** is a common eye disorder that may be caused by allergens (e.g., airborne pollens), bacterial or viral infections, or physical or chemical irritants. Symptoms include redness, tearing, itching, edema, and burning or gritty sensations. Bacterial conjunctivitis is often caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Haemophilus influenzae* and produces mucopurulent drainage. Conjunctivitis with a purulent discharge is most often caused by the gonococcus; corneal ulcers and scarring may result.
- **Blepharitis** is a chronic infection of glands and lash follicles on the margins of the eyelids, characterized by burning, redness, and itching. A hordeolum (commonly called a "stye") is often associated with blepharitis. The most common causes are seborrhea and staphylococcal infections.
- **Keratitis** (inflammation of the cornea) may be caused by microorganisms, trauma, allergy, ischemia, and drying of the cornea (e.g., from inadequate *lacrimation*). The major symptom is pain, which ranges from mild to severe. Vision may not be affected initially. However, if not treated effectively, corneal ulceration, scarring, and impaired vision may result.
- **Bacterial corneal ulcers** are most often caused by pneumococci and staphylococci. Pseudomonal ulcers are less com-

mon but may rapidly progress to perforation. Fungal ulcers may follow topical corticosteroid therapy or injury with plant matter, such as a tree branch. Viral ulcers are usually caused by the herpesvirus.

- **Fungal infections** commonly occur and may often be attributed to frequent use of ophthalmic antibiotics and corticosteroids.

## Ophthalmic Drug Therapy

Drug therapy of ophthalmic conditions is unique because of the location, structure, and function of the eye. Many systemic drugs are unable to cross the blood–eye barrier and achieve therapeutic concentrations in ocular structures. In general, penetration is greater if the drug achieves a high concentration in the blood, is fat soluble, is poorly bound to serum proteins, and if inflammation is present.

Because of the difficulties associated with systemic therapy, various methods of administering drugs locally have been developed. The most common and preferred method is topical application of ophthalmic solutions or suspensions (eye drops) to the conjunctiva. Drugs are distributed through the tear film covering the eye and may be used for superficial disorders (e.g., conjunctivitis) or for relatively deep ocular disorders (e.g., glaucoma). Topical ophthalmic ointments may also be used. In addition, ophthalmologists may inject medications (e.g., antibiotics, corticosteroids, local anesthetics) into or around various eye structures.

### Classifications of Ophthalmic Drugs

Drugs used to diagnose or treat ophthalmic disorders represent numerous therapeutic classifications, most of which are discussed in other chapters. Major classes used in ophthalmology are described below.

#### Anesthetics (Local)

Topical ophthalmic anesthetics are used for various diagnostic and therapeutic procedures (e.g., tonometry, removal of foreign bodies or sutures, minor surgery on the cornea and conjunctivae). Proparacaine is a commonly used agent; after administration of one drop, anesthesia begins within 20 seconds and lasts 10 to 15 minutes. Injectable local anesthetics are administered by ophthalmologists, usually for eye surgery. Lidocaine is commonly used; it has a rapid onset and lasts 1 to 2 hours.

#### Antihistamines and Mast Cell Stabilizers

Antihistamines ( $H_1$  receptor antagonists) and mast cell stabilizers (e.g., cromolyn) are used to decrease redness and itching associated with allergic conjunctivitis. Antihistamines inhibit the action of histamine, a substance produced by the body during an allergic reaction and which is the primary cause of itchy eyes. One antihistamine for allergic conjunctivitis, ketotifen (Zaditor), is available for over-the-counter purchase after several years of use as a prescription drug. Cromolyn acts by inhibiting the release of histamine and slow reacting substance of anaphylaxis (SRS-A) from mast cells. It is not useful in

treatment of acute symptoms, and several days to weeks of use may be needed to elicit a therapeutic response.

#### Antimicrobials

Antimicrobials are used to treat bacterial, viral, and fungal infections of the external portion of the eye. Bacterial infections include conjunctivitis, keratitis, blepharitis, and corneal ulcers. The drugs are usually applied topically but may be given orally or intravenously. Sulfonamides (e.g., sulfacetamide) are commonly used to treat bacterial conjunctivitis. They have activity against both gram-positive and gram-negative organisms. Bacitracin, neomycin, polymyxin, erythromycin, tetracycline, gentamicin, tobramycin, and several fluoroquinolones (e.g., ciprofloxacin, ofloxacin) are also commonly used topical antibacterial drugs. Some clinicians recommend that the fluoroquinolones be reserved for bacterial keratitis and other serious infections. Natamycin is used to treat fungal infections; trifluridine is used for viral infections.

#### Autonomic Nervous System Drugs

These drugs are used for diagnostic and therapeutic purposes (see Chaps. 16 through 20). Phenylephrine is often used to dilate the pupil before ophthalmologic examinations or surgical procedures. Dosage is usually one drop initially and a second drop in 5 to 10 minutes. Dilation occurs within 30 minutes and lasts 2 to 3 hours. Numerous drugs are used to decrease IOP in glaucoma; they act by decreasing formation or increasing outflow of aqueous humor. Ophthalmic beta-adrenergic blocking agents (e.g., timolol) are most commonly used. Adrenergic vasoconstricting (decongestant) drugs are commonly used to decrease redness associated with allergic conjunctivitis.

Autonomic drugs indicated in one disorder may be contraindicated in another (e.g., anticholinergic drugs may be contraindicated in glaucoma). In addition, adrenergic mydriatics (e.g., phenylephrine) should be used cautiously in patients with hypertension, cardiac dysrhythmias, arteriosclerotic heart disease, and hyperthyroidism. Ophthalmic beta blockers usually have the same contraindications and precautions as oral or injected drugs (e.g., bradycardia, heart block, bronchospastic disorders).

#### Corticosteroids

Corticosteroids (see Chap. 23) are often used to treat inflammatory conditions of the eye (e.g., conjunctivitis, uveitis, keratitis) to reduce scarring and prevent loss of vision. The duration of treatment varies with the type of lesion and may range from a few days to several months. Corticosteroids are generally more effective in acute than chronic inflammatory conditions. Because these drugs are potentially toxic, they should not be used to treat minor disorders or disorders that can be effectively treated with safer drugs. When used, corticosteroids should be administered in the lowest effective dose and for the shortest effective time. Long-term use should be avoided when possible, because it may result in glaucoma, increased IOP, optic nerve damage, defects in visual acuity and fields of vision, cataracts, or secondary ocular infections.

Ophthalmologic corticosteroids may be administered topically, systemically, or both. They are contraindicated in eye infections caused by the herpesvirus because the drugs increase the severity of the infection. Ophthalmic preparations of corticosteroids combined with antimicrobial drugs are also available and commonly used for conditions in which both types of drugs are needed (e.g., keratoconjunctivitis, postoperatively).

### Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs, in ophthalmic formulations for topical use, may be used in eye disorders (see Table 63-3 and Chap. 7). As in other conditions, the drugs are thought to act by blocking the synthesis of inflammatory prostaglandins. Some clinicians use combinations of topical NSAIDs and corticosteroids to manage inflammatory disorders.

### Prostaglandin Analogs

These are antiglaucoma drugs that reduce IOP by increasing the outflow of aqueous humor. The drugs may be used when a patient's IOP is not lowered adequately with a beta blocker or when a beta blocker is contraindicated for a patient. When compared with twice-daily ophthalmic timolol, the drugs were considered as effective as timolol. The drugs may be used in conjunction with other antiglaucoma medications (e.g., a beta blocker or carbonic anhydrase inhibitor [CAI]) if multiple drugs are required.

In clinical trials, the most common adverse effects were ocular burning, stinging, and itching. In addition, the drugs may cause a permanent darkening of eye color, especially in light-colored eyes, and alter eyelashes.

Nurses who are pregnant should handle prostaglandin analogs very carefully because the drugs may be absorbed through the skin. If accidental contact occurs, the exposed area should be washed immediately with soap and water.

### Carbonic Anhydrase Inhibitors (CAIs) and Osmotic Agents

CAIs and osmotic agents are given to decrease IOP in glaucoma and before certain surgical procedures. CAIs lower IOP by decreasing production of aqueous humor. Oral CAIs are rarely used since the development of topical CAIs, beta blockers, and other newer glaucoma medications. Topical CAIs may be used alone but are most often used in combination with other glaucoma medications. With glycerin, a commonly used osmotic agent, maximum lowering of IOP occurs in 1 hour and lasts 4 to 5 hours.

### Fluorescein

Fluorescein is a dye used in diagnosing lesions or foreign bodies in the cornea, fitting contact lenses, and studying the lacrimal system and flow of aqueous humor.

### Individual Drugs

Individual drugs are described in Tables 63-1, 63-2, and 63-3.

Table 63-1

Drugs at a Glance: Drugs Used in Ocular Disorders\*

CLASSES OF DRUGS/ OCULAR EFFECTS	CLINICAL INDICATIONS	GENERIC/TRADE NAME	DOSAGE RANGES
<b>Autonomic Nervous System Drugs</b>			
<b>Adrenergics</b>			
Decreased production of aqueous humor Mydriasis Decreased IOP Vasoconstriction Photophobia	Glaucoma Ophthalmoscopic examination Reduction of adhesion formation with uveitis Preoperative and postoperative mydriasis Local hemostasis	<b>Phenylephrine (2.5% and 10% solutions)</b> (Neo-Synephrine)	Before ophthalmoscopy or refraction, 1 drop of 2.5% or 10% solution Preoperatively, 1 drop of 2.5% or 10% solution 30–60 min before surgery Postoperatively, 1 drop of 10% solution once or twice daily <i>Children:</i> Refraction, 1 drop of 2.5% solution
<b>Alpha2 Adrenergic Agonists</b>			
Decreased IOP	Glaucoma Prevention of increased IOP after ocular surgery	<b>Brimonidine</b> (Alphagan P)	1 drop in affected eye(s) 3 times daily, q8h
<b>Beta Blockers</b>			
Decreased production of aqueous humor Reduced IOP	Glaucoma	<b>Betaxolol</b> (Betoptic) <b>Carteolol</b>	1 or 2 drops in affected eye(s) twice daily 1 drop in affected eye(s) twice daily

(continued on page 1014)

Table 63-1

## Drugs at a Glance: Drugs Used in Ocular Disorders\* (continued)

CLASSES OF DRUGS/ OCULAR EFFECTS	CLINICAL INDICATIONS	GENERIC/TRADE NAME	DOSAGE RANGES
		<b>Levobunolol</b> (Betagan)	1 or 2 drops in affected eye(s) once or twice daily
		<b>Metipranolol</b> (OptiPranolol)	1 drop in affected eye(s) twice daily
		<b>Timolol maleate</b> (Timoptic, Timoptic-XE)	1 drop in affected eye(s) twice daily; gel, 1 drop once daily
<b>Cholinergics</b>			
Increased outflow of aqueous humor Miosis	Glaucoma	<b>Pilocarpine (0.25%–10% solutions)</b> (Isopto Carpine, Pilocar) <b>Pilocarpine ocular system</b> (Ocuser Pilo-20 or -40)	Glaucoma, 1 drop of 1% or 2% solution in each eye 3 or 4 times daily One system in conjunctival sac per wk
<b>Anticholinergics</b>			
Mydriasis Cycloplegia Photophobia	Mydriasis for refraction and other diagnostic purposes Before and after intraocular surgery Treatment of uveitis	<b>Atropine sulfate</b> (0.5%–3% solutions)  <b>Cyclopentolate hydrochloride</b> (Cyclogyl)  <b>Homatropine hydrobromide</b> (2% and 5% solutions)  <b>Tropicamide (0.5% and 1% solutions)</b> (Mydracyl)	Before intraocular surgery, 1 drop After intraocular surgery, 1 drop once daily For refraction, 1 drop of 0.5% or 2% solution Before ophthalmoscopy, 1 drop of 0.5% solution <i>Children:</i> For refraction, 1 drop of 0.5%, 1%, or 2% solution, repeated in 10 min Refraction, 1 drop of 5% solution every 5 min for 2 or 3 doses or 1 or 2 drops of 2% solution every 10–15 min for 5 doses Uveitis, 1 drop of 2% or 5% solution 2 or 3 times daily Before refraction or ophthalmoscopy, 1 drop, repeated in 5 min, then every 20–30 min as needed to maintain mydriasis
<b>Diuretics</b>			
<b>Carbonic Anhydrase Inhibitors</b>			
Decreased production of aqueous humor Decreased IOP	Glaucoma Preoperatively in intraocular surgery	<b>Acetazolamide</b> (Diamox)  <b>Brinzolamide</b> (Azopt) <b>Dorzolamide</b> (Trusopt)	PO 250 mg q6h; sustained-release capsules, PO 500 mg q12h IV, IM 5–10 mg/kg/d in divided doses, q6h <i>Children:</i> PO 10–15 mg/kg/d in divided doses, q6–8h IV, IM 5–10 mg/kg q6h 1 drop 3 times daily 1 drop 3 times daily
<b>Osmotic Agents</b>			
Reduced volume of vitreous humor Decreased IOP	Before intraocular surgery Treatment of acute glaucoma	<b>Glycerin</b> (Osmoglyn)	PO 1–1.5 g/kg, usually as a 50% or 75% solution 1–1½ h before surgery <i>Children:</i> Same as adults

CLASSES OF DRUGS/ OCULAR EFFECTS	CLINICAL INDICATIONS	GENERIC/TRADE NAME	DOSAGE RANGES
		<b>Isosorbide</b> (Ismotic)	Emergency reduction of IOP, PO 1.5 g/kg up to 4 times daily IV 1.5–2 g/kg as a 20% solution over 30–60 min Children: Same as adults
		<b>Mannitol</b> (Osmitrol)	
<b>Prostaglandin Analogs</b> Decreased IOP	Glaucoma	<b>Bimatoprost</b> (Lumigan)	1 drop once daily in the evening
		<b>Latanoprost</b> (Xalatan)	1 drop once daily in the evening
		<b>Travoprost</b> (Travatan)	1 drop once daily in the evening
<b>Miscellaneous Agents</b> <b>Anesthetics, Local</b> Surface anesthesia of conjunctiva and cornea	Tonometry Removal of foreign bodies Removal of sutures	<b>Proparacaine</b> (Alcaine)	Minor procedures, 1 or 2 drops of 0.5% solution
		<b>Tetracaine</b> (Pontocaine)	Minor procedures, 1 or 2 drops of 0.5% solution
<b>Lubricants</b> Serve as “artificial tears”	Protect the cornea during keratitis or diagnostic procedures Moisten contact lenses	<b>Methylcellulose</b> (Methulose) <b>Polyvinyl alcohol</b> (Liquifilm)	1 or 2 drops as needed 1 or 2 drops as needed

\*Antimicrobial agents are listed in Table 63-2; anti-allergic and anti-inflammatory agents are listed in Table 63-3.  
IOP, intraocular pressure.

Table 63-2

Drugs at a Glance: Ophthalmic Antimicrobial Agents

Generic/Trade Name	DOSAGE RANGES	
	Adults	Children
<b>Antibacterial Agents</b>		
<b>Ciprofloxacin 3.5 mg/mL solution</b> (Ciloxan)	Corneal ulcer: Day 1, 2 drops q15min for 6 h, then q30min for rest of day; day 2, 2 drops q1h; days 3–14, 2 drops q4h Conjunctivitis: 1 or 2 drops q2h while awake for 2 d, then 1 or 2 drops q4h while awake for 5 d	Safety and efficacy not established in infants <1 y
<b>Erythromycin 5% ointment</b> (Ilotycin)		Prevention of neonatal gonococcal or chlamydial conjunctivitis, 0.5–1 cm in each eye
<b>Gatifloxacin</b> (Zymar)	1 drop in affected eye(s) every 2 h while awake, up to 8 times daily, for 2 d, then 1 drop up to 4 times daily while awake, for 5 d	Dosage not established
<b>Gentamicin 3 mg/mL solution or 3 mg/g ointment</b> (Garamycin)	1 drop q1–4h; ointment, apply 2 or 3 times daily	Same as adults
<b>Levofloxacin 5 mg/mL solution</b> (Quixin)	1 or 2 drops q2h up to 8 doses/d for 1 or 2 d, then q4h up to 4 doses/d for 5 d	Dosage not established

(continued on page 1016)

Table 63-2

Drugs at a Glance: Ophthalmic Antimicrobial Agents (continued)

Generic/Trade Name	DOSAGE RANGES	
	Adults	Children
<b>Moxifloxacin</b> (Vigamox)	1 drop in affected eye(s) 3 times daily for 7 d	Same as adults for children 1 y and older
<b>Ofloxacin 3 mg/mL solution</b> (Ocuflox)	Conjunctivitis: 1 or 2 drops q2–4h while awake for 2 d, then 4 times daily for 3–5 d Corneal ulcer: 1 or 2 drops q30min while awake, q4–6h during sleep, for 1–2 d, then q1h while awake for 4–6 d, then q4h while awake until healed	Same as adults for children 1 y and older Dosage not established
<b>Sulfacetamide 10% solution or ointment</b> (Bleph-10), <b>15% solution</b> (Isopto Cetamide), <b>10% and 30% solution, 10% ointment</b> (Sodium Sulamyd)	Conjunctivitis, corneal ulcers, or other superficial infections caused by susceptible organisms: 1 or 2 drops q4h or 0.5 inch ointment 3 or 4 times daily, for 7–10 days	Safety and efficacy not established. Contraindicated in infants <2 mo of age
<b>Sulfisoxazole 4% solution</b> (Gantrisin)	1 or 2 drops 3 or more times daily	Safety and efficacy not established. Contraindicated in infants <2 mo of age
<b>Tobramycin (0.3% solution and 3 mg/g ointment)</b> (Tobrex)	1 or 2 drops 2–6 times daily or ointment 2 or 3 times daily	See manufacturer's instructions
<b>Antiviral Agent</b> <b>Trifluridine 1% solution</b> (Viroptic)	Keratoconjunctivitis or corneal ulcers caused by herpes simplex virus: 1 drop q2h while awake (maximum, 9 drops/d) until corneal ulcer heals, then 1 drop q4h (minimum, 5 drops/d), for 7 d	older than 6 y: Same as adults
<b>Antifungal Agent</b> <b>Natamycin 5% suspension</b> (Natacyn)	1 drop q1–2h for 3–4 d, then q3–4h for 14–21 d	Safety and efficacy not established

Table 63-3

Drugs at a Glance: Topical Ophthalmic Antiallergic and Anti-Inflammatory Agents

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Antiallergic Agents</b>		
<b>Azelastine</b> (Optivar)	Allergic conjunctivitis	1 drop in affected eye(s) twice daily
<b>Cromolyn</b> (Crolom, Opticrom)	Treatment of seasonal allergic conjunctivitis, keratitis, and keratoconjunctivitis	1 or 2 drops in each eye 4–6 times daily at regular intervals
<b>Emedastine</b> (Emadine)	Allergic conjunctivitis	1 or 2 drops twice daily
<b>Epinastine</b> (Elestat)	Allergic conjunctivitis	1 drop in each eye twice daily
<b>Ketotifen</b> (Zaditor)	Allergic conjunctivitis	1 drop in affected eye(s) q8–12h
<b>Lodoxamide</b> (Alomide)	Conjunctivitis Keratitis	1 or 2 drops in affected eye(s) 4 times daily, for up to 3 mo
<b>Olopatadine</b> (Patanol)	Allergic conjunctivitis	1 or 2 drops twice daily

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Corticosteroids</b>		
<b>Dexamethasone</b> (Decadron, Maxidex)	Inflammatory disorders of the conjunctiva, cornea, eyelid, and anterior eyeball (e.g., conjunctivitis, keratitis) Corneal injury from chemical, radiation, or thermal burns, or penetration of foreign bodies Prevention of graft rejection after corneal transplant	Solution or suspension 1 or 2 drops q1h daytime, q2h nighttime until response; then 1 drop q4h Postoperative inflammation, 1 or 2 drops 4 times daily, starting 24 h after surgery, for 2 wk Ointment thin strip 3 or 4 times daily until response, then once or twice daily
<b>Fluorometholone</b> (FML)	Inflammatory disorders	Solution 1 drop q1–2h until response, then less often Ointment thin strip 3 or 4 times daily until response, then once or twice daily
<b>Loteprednol</b> (Lotemax, Alrex)	Allergic conjunctivitis Keratitis Treatment of inflammation after ocular surgery	Allergic conjunctivitis, 0.2%, 1 drop in affected eye(s) 4 times daily Keratitis, 0.5%, 1 or 2 drops in affected eye(s) 4 times daily Postoperative inflammation, 0.5%, 1 or 2 drops in affected eye(s) 4 times daily starting 24 h after surgery and continuing for 2 wk
<b>Prednisolone</b> (Econopred, others)	Inflammatory disorders	Solution or suspension 1 or 2 drops q1–2h until response, then 1 drop q4h, then less frequently Ointment thin strip 3 or 4 times daily until response, then once or twice daily
<b>Rimexolone</b> (Vexol)	Treatment of anterior uveitis Treatment of inflammation after ocular surgery	Uveitis, 1 or 2 drops in affected eye q1h during waking hours for 1 wk, then 1 drop q2h for 1 wk, then taper until uveitis resolved Postoperative inflammation, 1 or 2 drops in affected eye(s) 4 times daily starting 24 h after surgery and continuing for 2 wk
<b>Nonsteroidal Anti-Inflammatory Drugs</b>		
<b>Diclofenac</b> (Voltaren)	Treatment of inflammation after cataract surgery	1 drop to affected eye 4 times daily, starting 24 h after surgery, for 2 wk
<b>Flurbiprofen</b> (Ocufen)	Inhibition of pupil constriction during eye surgery	1 drop q30min for 4 doses, starting 2 h before surgery
<b>Ketorolac</b> (Acular)	Treatment of ocular itching due to seasonal allergic conjunctivitis	1 drop 4 times daily for approximately 1 wk

## Nursing Process

### Assessment

Assess the patient's condition in relation to ophthalmic disorders.

- Determine whether the patient has impaired vision and, if so, the extent of the impairment. Minimal assessment

includes the vision-impaired patient's ability to participate in activities of daily living, including safe ambulation. Maximal assessment depends on the nurse's ability and working situation. Some nurses do vision testing and ophthalmoscopic examinations.

- Identify risk factors for eye disorders. These include trauma, allergies, infection in one eye (a risk factor for

infection in the other eye), use of contact lenses, infections of facial structures or skin, and occupational exposure to chemical irritants or foreign bodies.

- Signs and symptoms vary with particular disorders:
  - Pain is usually associated with corneal abrasions or inflammation. Sudden, severe pain may indicate acute glaucoma, which requires immediate treatment to lower IOP and minimize damage to the optic nerve.
  - Signs of inflammation (redness, edema, heat, tenderness) are especially evident with infection or inflammation of external ocular structures, such as the eyelids and conjunctiva. A watery or mucoid discharge also often occurs.
  - Pruritus is most often associated with allergic conjunctivitis.
  - Photosensitivity commonly occurs with keratitis.

## Nursing Diagnoses

- Disturbed Sensory Perception: Visual, related to eye disorders
- Risk for Injury: Blindness related to inadequately treated glaucoma or ophthalmic infections
- Deficient Knowledge related to prevention and treatment of ocular disorders

## Planning/Goals

### The patient will

- Take ophthalmic medications as prescribed
- Follow safety precautions to protect eyes from trauma and disease
- Experience improvement in signs and symptoms (e.g., decreased drainage with infections, decreased eye pain with glaucoma)
- Avoid injury from impaired vision (e.g., falls)
- Avoid systemic effects of ophthalmic drugs
- Have regular eye examinations to monitor effects of antiglaucoma drugs

## Interventions

Use measures to minimize ocular disorders.

- Promote regular eye examinations. This is especially important among middle-aged and older adults, who are more likely to have several types of ocular disorders. These patients are also more likely to experience ocular disorders as adverse effects of drugs taken for nonocular disorders.
- Assist patients at risk of eye damage from IOP (e.g., those with glaucoma; those who have had intraocular surgery, such as cataract removal) to avoid straining at stool (use laxatives or stool softeners if needed), heavy lifting, bending over, coughing, and vomiting when possible.

- Promote hand washing and keeping hands away from eyes to prevent eye infections.
- Cleanse contact lenses or assist patients in lens care, when needed.
- Treat eye injuries appropriately:
  - For chemical burns, irrigate the eyes with copious amounts of water as soon as possible (i.e., near the area where the injury occurred). Do not wait for transport to a first-aid station, hospital, or other health care facility. Damage continues as long as the chemical is in contact with the eye.
  - For thermal burns, apply cold compresses to the area.
  - Superficial foreign bodies may be removed by irrigation with water. Foreign bodies embedded in ocular structures must be removed by a health care provider.
- Warm, wet compresses are often useful in ophthalmic inflammation or infections. They relieve pain and promote healing by increasing the blood supply to the affected area.

## Evaluation

- Observe and interview for compliance with instructions regarding drug therapy and follow-up care.
- Observe and interview for relief of symptoms.
- Observe for systemic adverse effects of ophthalmic drugs (e.g., tachycardia and dysrhythmias with adrenergics; bradycardia or bronchoconstriction with beta blockers).

## Applying Your Knowledge 63-1

When you arrive at Mrs. Molnar's house, she is in the middle of brushing her hair. She drops her hair brush and bends over to pick it up. This provides an opportunity to provide what patient teaching?

.....

## Principles of Therapy

### General Guidelines for Ophthalmic Drug Therapy

- Topical application is the most common route of administration for ophthalmic drugs, and correct administration is essential for optimal therapeutic effects.
- Systemic absorption of eye drops can be decreased by closing the eye and applying pressure over the tear duct (*naso-lacrimal occlusion*) for 3 to 5 minutes after instillation.
- When multiple eye drops are required, there should be an interval of 5 to 10 minutes between drops because of limited eye capacity and rapid drainage into tear ducts.

- Absorption of eye medications is increased in eye disorders associated with hyperemia and inflammation.
- Many ophthalmic drugs are available as eye drops (solutions or suspensions) and ointments. Ointments are administered less frequently than drops and often produce higher concentrations of drug in target tissues. However, they also cause blurred vision, which limits their daytime use, at least for ambulatory patients. For some patients, drops may be used during waking hours and ointments at bedtime.
- Topical ophthalmic medications should not be used after the expiration date; cloudy, discolored solutions should be discarded.
- Topical eye medications contain a number of inactive ingredients, such as preservatives, buffers, tonicity agents, antioxidants, and so forth. Some contain sulfites, to which some people may have an allergic reaction.
- Some eye drops contain benzalkonium hydrochloride, a preservative, which is absorbed by soft contact lenses. The medications should not be applied while wearing soft contacts and should be instilled 15 minutes or longer before inserting soft contacts.
- To increase safety and accuracy of ophthalmic drug therapy, the labels and caps of eye medications are color coded.

## Patient Teaching Guidelines

## Topical Eye Medications

### General Considerations

- Prevent eye disorders, when possible. For example, try to avoid long periods of reading and computer work; minimize exposure to dust, smog, cigarette smoke, and other eye irritants; wash hands often and avoid touching the eyes to decrease risks of infection. Use protective eyewear when indicated.
- Do not use nonprescription eye drops (e.g., Murine, Visine) on a regular basis for longer than 48 to 72 hours. Persistent eye irritation and redness should be reported to a health care provider.
- Have regular eye examinations and testing for glaucoma after 40 years of age.
- Eye-drop preparations often contain sulfites, which can cause allergic reactions in some people.
- If you have glaucoma, do not take any drugs without the ophthalmologist's knowledge and consent. Many drugs given for purposes other than eye disorders may cause or aggravate glaucoma. Also, wear a medical alert bracelet or carry identification that states you have glaucoma. This helps to avoid administration of drugs that aggravate glaucoma or to maintain treatment of glaucoma, in emergencies.
- If you have an eye infection, wash hands before and after contact with the infected eye to avoid spreading the infection to the unaffected eye or to other people. Also, avoid touching the unaffected eye.
- If you wear contact lenses, wash your hands before inserting them and follow instructions for care (e.g., cleaning, inserting or removing, and duration of wear). Improper or infrequent cleaning may lead to infection. Overwearing is a common cause of corneal abrasion and may cause corneal ulceration. The lens wearer should consult an ophthalmologist when eye pain occurs. Antibiotics are often prescribed for corneal abrasions to prevent development of ulcers.
- If you wear soft contact lenses, do not use any eye medication without consulting a specialist in eye care. Some eye drops contain benzalkonium hydrochloride, a preservative, which is absorbed by soft contacts. The medication should not be applied while wearing soft contacts and should be instilled 15 minutes or longer before inserting soft contacts.
- Never use eye medications used by someone else and never allow your eye medications to be used by anyone

else. These preparations should be used by one person only and they are dispensed in small amounts for this purpose. Single-person use minimizes cross-contamination and risks of infection.

- Many eye drops and ointments cause temporary blurring of vision. Do not use such medications just before driving or operating potentially hazardous machinery.
- Avoid straining at stool (use laxatives or stool softeners if necessary), heavy lifting, bending over, coughing, and vomiting when possible. These activities increase intraocular pressure, which may cause eye damage in glaucoma and after eye surgery.

### Self-Administration

- If using more than one eye medication, be sure to administer the correct one at the correct time. Benefits depend on accurate administration.
- Check expiration dates; do not use any eye medication after the expiration date and do not use any liquid medications that have changed color or contain particles.
- Shake the container if instructed to do so on the label. Solutions do not need to be shaken; suspensions should be shaken well to ensure the drug is evenly dispersed in the liquid and not settled in the bottom of the container.
- Wash hands thoroughly.
- Tilt head back or lie down and look up.
- Pull the lower eyelid down to expose the conjunctiva (mucous membrane).
- Place the dropper directly over the eye. Avoid contact of the dropper with the eye, finger, or any other surface. Such contact contaminates the solution and may cause eye infections and serious damage to the eye, with possible loss of vision.
- Look up just before applying a drop; look down for several seconds after applying a drop.
- Release the eyelid, close the eyes, and press on the inside corner of the eye with a finger for 3 to 5 minutes. Closing the eyes and blocking the tear duct helps the medication be more effective by slowing its drainage out of the eye.
- Do not rub the eye; do not rinse the dropper.
- If more than one eye drop is ordered, wait 5–10 minutes before instilling the second medication.
- Use the same basic procedure to insert eye ointments.

### Applying Your Knowledge 63-2

You are teaching Mrs. Molnar how to administer her medication. What do you teach her about administering eye drops?

### Ocular Infections

Guidelines for drug therapy of ocular infections include the following:

- Drug therapy is usually initiated as soon as culture material (eye secretions) has been obtained, often with a broad-spectrum antibacterial agent or a combination of two or more antibiotics.
- Topical administration is used most often, and recommended drugs include bacitracin, polymyxin B, and sulfacetamide. These agents are rarely given systemically. They do not cause sensitization to commonly used systemic antibiotics and do not promote growth of drug-resistant microorganisms. Other antibacterial drugs available in ophthalmic formulations include erythromycin, gentamicin, tobramycin, several fluoroquinolones (ciprofloxacin, gatifloxacin, moxifloxacin, ofloxacin), and combination products.
- In severe infections, antibacterial drugs may be given both topically and systemically. Because systemic antibiotics penetrate the eye poorly, large doses are required to attain therapeutic drug concentrations in ocular structures. Drugs that reach therapeutic levels in the eye when given in proper dosage include ampicillin and dicloxacillin. Gentamicin and other antibiotics penetrate the eye when inflammation is present.
- Combination products containing two or more antibacterials are available for topical treatment of external ocular infections. These products are most useful when therapy must be initiated before the infecting microorganism is identified. Mixtures (e.g., polymyxin B and bacitracin) provide a broader spectrum of antibacterial activity than a single drug.
- Fixed-dose combinations of an antibacterial agent and a corticosteroid (e.g., Blephamide, Maxitrol, NeoDecadron, Poly-Pred) are available for topical use in selected conditions (e.g., staphylococcal keratitis, blepharoconjunctivitis, bacterial conjunctivitis, some postoperative inflammatory reactions).
- Trifluridine (Viroptic) is the drug of choice in eye infections caused by the herpes simplex virus. Ganciclovir is available for treatment of cytomegalovirus (CMV) retinitis in patients with acquired immunodeficiency syndrome (AIDS).
- Natamycin (Natacyn) is the drug of choice in fungal eye infections. It has a broad spectrum of antifungal activity and is nonirritating and nontoxic.

### Corneal Abrasions

Injuries to the cornea cause pain, tearing, photophobia, and a foreign-body or gritty feeling in the eye. These symptoms can be worsened by exposure to light, blinking, and rubbing the

injured surface against the inside of the eyelid. Initial management involves removal of foreign bodies and analgesia with topical NSAIDs or oral analgesics. Topical antibiotics also may be used. Most corneal abrasions heal in 24 to 72 hours.

Patients who wear contact lenses are at higher risk of developing abrasions that become infected and ulcerate. For these patients, an antipseudomonal antibiotic (e.g., gentamicin or a fluoroquinolone) should be used. In addition, the patient should avoid wearing contact lenses until the abrasion is healed and antibiotic therapy completed.

### Glaucoma

For chronic glaucoma, the goal of drug therapy is to slow disease progression by reducing IOP. Topical beta blockers are first-line drugs and commonly used. They may be used alone or in combination with other antiglaucoma drugs. Several are available for ophthalmic use. Most adverse effects of systemic beta blockers may also occur with ophthalmic preparations and their use may be restricted in patients with respiratory or cardiac disease.

Other first-line drugs, which may be used with or instead of beta blockers, include brimonidine, prostaglandin analogs, and topical CAIs.

### Use in Special Populations

#### Use in Children

Topical ophthalmic drug therapy in children differs little from that in adults. Few studies of ophthalmic drug therapy in children have been reported, and many conditions for which adults need therapy (e.g., cataract, glaucoma) rarely occur in children. A major use of topical ophthalmic drugs in children is to dilate the pupil and paralyze accommodation for ophthalmoscopic examination. As a general rule, the short-acting mydriatics and cycloplegics (e.g., cyclopentolate, tropicamide) are preferred because they cause fewer systemic adverse effects than atropine and scopolamine. In addition, lower drug concentrations are usually given empirically because of the smaller size of children and the potential risk of systemic adverse effects.

#### Use in Older Adults

Older adults are at risk for development of ocular disorders, especially glaucoma and cataracts. General principles of ophthalmic drug therapy are the same as for younger adults. In addition, older adults are likely to have cardiovascular disorders that may be aggravated by systemic absorption of topical eye medication. Thus, accurate dosage and occlusion of the nasolacrimal duct in the inner canthus of the eye are needed to prevent adverse drug effects (e.g., hypertension, tachycardia, or dysrhythmias with adrenergic drugs; bradycardia, heart block, or bronchoconstriction with beta blockers).

### Applying Your Knowledge 63-3

For what are possible systemic effects of Mrs. Molnar's eye drops the nurse should monitor?

## Use in Home Care

The home care nurse may be involved in the care of patients with acute or chronic eye disorders. As with other drug therapy, the nurse may need to teach patients and caregivers reasons for

use, accurate administration, and assessment of therapeutic and adverse responses to eye medications. The nurse may also need to encourage periodic eye examinations and measurements of IOP to promote optimal vision and prevent blindness.

## Nursing Actions Ophthalmic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- Read labels of ophthalmic medications carefully.
- Read medication orders carefully and accurately.
- For hospitalized patients, keep eye medications at the bedside.
- Wash hands before approaching the patient for instillation of eye medications.
- To administer eye drops, have the client lie down or tilt the head backward and look upward. Then, pull down the lower lid to expose the conjunctival sac, and drop the medication into the sac.  
After instillation, have the patient close the eyes gently, and apply pressure to the inner canthus.
- When instilling ophthalmic ointments, position the patient as above, and apply a ¼-inch to ½-inch strip of ointment to the conjunctiva.
- Do not touch the dropper tip or ointment top to the eye or anything else.
- When crusts or secretions are present, cleanse the eye before administering medication.
- When two or more eye drops are scheduled for the same time, they should be instilled at least 5 minutes apart.

#### 2. Observe for therapeutic effects

- With beta-blocking agents, observe for decreased intraocular pressure (IOP).
- With mydriatics, observe for dilation of the pupil.
- With miotics, observe for constriction of the pupil.
- With antimicrobial drugs, observe for decreased redness, edema, and drainage.
- With osmotic agents, observe for decreased IOP.

#### 3. Observe for adverse effects

- Local effects:
  - Irritation, burning, stinging, blurred vision, discomfort, redness, itching, tearing, conjunctivitis, keratitis, allergic reactions
  - With prostaglandin analogs—permanent darkening of eye color may occur, especially in light-colored eyes. Changes in the length and thickness of eyelashes may also occur.
  - With antibacterial agents—superinfection or sensitization

### RATIONALE/EXPLANATION

To avoid error, because many drugs are available in several concentrations  
To avoid error. Avoid abbreviations (e.g., OS, OD, OU).  
Eye medications should be used by one person only. They are dispensed in small amounts for this purpose. This minimizes cross-contamination and risk of infection.  
To reduce risks of infection

Drug absorption and concentration in ocular tissues depend partly on the length of time the medication is in contact with ocular tissues. Contact time is increased by closing the eyes (delays outflow into the nasolacrimal duct) and by placing pressure on the inner canthus (delays outflow and decreases side effects resulting from systemic absorption).

To avoid contamination of the medication and infection

If the eye is not cleansed, the drug may not be absorbed.

To avoid drug loss by dilution and outflow into the nasolacrimal duct

Therapeutic effects depend on the reason for use.  
Lowering of IOP usually occurs within a month; periodic measurements should be done.  
Mydriasis begins within 5–15 minutes after instillation.

With oral glycerin, maximal decrease in IOP occurs approximately 1 hour after administration, and effects persist for about 5 hours. With intravenous mannitol, maximal decreased IOP occurs within 30–60 minutes and lasts 6–8 hours.

These effects may occur with any topical ophthalmic agent. Burning and stinging occur with instillation and are usually transient. Allergic reactions may occur with the active ingredient, preservatives, or other components.  
Changes in eye color and eyelashes may not be noticeable for months to years after starting drug use. These effects are most problematic in clients receiving treatment in one eye.

Superinfection caused by drug-resistant organisms may occur. Sensitization means that topical application induces antibody formation. Therefore, if the same or a related drug is subsequently administered systemically, an allergic reaction may occur. Sensitization can be prevented or minimized by avoiding topical administration of antibacterial agents that are commonly given systemically.

## Nursing Actions Ophthalmic Drugs (continued)

### NURSING ACTIONS

(4) With anticholinergics, adrenergics, corticosteroids—glaucoma or increased IOP

(5) With miotic drugs—decreased vision in dim light

b. Systemic effects:

(1) With beta-blocking agents—bradycardia, bronchospasm, and others (see Chap. 18)

(2) With miotics—sweating, nausea, vomiting, diarrhea, abdominal pain, bradycardia, hypotension, bronchoconstriction. Toxic doses produce ataxia, confusion, convulsions, coma, respiratory failure, and death.

(3) With anticholinergic mydriatics—dryness of the mouth and skin, fever, rash, tachycardia, confusion, hallucinations, delirium

(4) With adrenergic mydriatics—tachycardia, hypertension, premature ventricular contractions, tremors, headache

(5) With carbonic anhydrase inhibitors—anorexia, nausea, vomiting, diarrhea, paresthesias, weakness, lethargy

(6) With osmotic diuretics—dehydration, nausea, vomiting, headache, hyperglycemia and glycosuria with glycerin (Osmoglyn)

(7) With corticosteroids, see Chapter 23.

(8) With antibacterial agents, see Chapter 29 and the chapter on the individual drug group.

(9) With ophthalmic nonsteroidal anti-inflammatory drugs—potential for increased bleeding

(10) With prostaglandin analogs—headache, cold/flu/upper respiratory infection, bronchitis, sinusitis, muscle and joint pain, chest pain

#### 4. Observe for drug interactions

a. Drugs that increase effects of antiglaucoma drugs:

(1) Other antiglaucoma drugs

b. Drugs that increase effects of adrenergic (sympathomimetic) ophthalmic drugs:

(1) Anticholinergic ophthalmic drugs

(2) Systemic adrenergic drugs

### RATIONALE/EXPLANATION

Mydriatic drugs (anticholinergics and adrenergics) may cause an acute attack of angle closure in patients with closed-angle glaucoma by blocking outflow of aqueous humor. Topical corticosteroids raise IOP in some patients. The “glaucomatous” response occurs most often in patients with chronic, primary open-angle glaucoma and their relatives. It also may occur in clients with myopia or diabetes mellitus. The magnitude of increased IOP depends on the concentration, frequency of administration, duration of therapy, and anti-inflammatory potency of the corticosteroid. This effect can be minimized by checking IOP every 2 months in patients receiving long-term therapy with topical corticosteroids.

These agents prevent pupil dilation, which normally occurs in dim light or darkness.

Systemic absorption and adverse effects of eye drops can be prevented or minimized by closing the eyes or applying pressure to the inner canthus (nasolacrimal occlusion) after instillation of the medications. Pressure may be applied by the nurse or the patient.

These agents may be absorbed systemically and cause all the adverse effects associated with oral or injected drugs. These cholinergic or parasympathomimetic effects occur rarely with pilocarpine. Acute toxicity may be reversed by an anticholinergic agent, atropine, given IV.

These effects are most likely to occur with atropine and in children and older adults. Tropicamide (Mydracyl) rarely causes systemic reactions.

Systemic effects are uncommon. They are more likely to occur with repeated instillations of high drug concentrations (e.g., phenylephrine [Neo-Synephrine] 10%).

Nausea, malaise, and paresthesias (numbness and tingling of extremities) commonly occur with oral drugs, which are given only when topical drugs are not effective.

These agents may produce profound diuresis and dehydration. Oral agents (e.g., glycerin) are less likely to cause severe systemic effects than IV agents (e.g., mannitol). These agents are usually given in a single dose, which decreases the risks of serious adverse reactions unless large doses are given. Serious adverse effects may occur with long-term use of corticosteroids.

Adverse effects may occur with all antibacterial agents.

Systemic absorption may interfere with platelet function and increase risks of bleeding with surgery or anticoagulant therapy.

These were the most commonly reported systemic adverse effects in clinical trials, similar in incidence to placebo.

Antiglaucoma drugs may be used in various combinations for additive effects when a single drug does not decrease IOP sufficiently.

The combination (e.g., atropine and phenylephrine) produces additive mydriasis.

Additive risks of adverse effects (e.g., tachycardia, cardiac dysrhythmias, hypertension)

NURSING ACTIONS	RATIONALE/EXPLANATION
c. Drugs that <i>decrease</i> effects of adrenergic ophthalmic preparations:	Antagonize mydriatic effects of adrenergic drugs
(1) Cholinergic ophthalmic drugs	
d. Drugs that <i>increase</i> effects of antiadrenergic ophthalmic preparations:	When the patient is receiving a topical beta blocker in ocular disorders, administration of systemic beta-blocking agents in cardiovascular disorders may cause additive systemic toxicity.
(1) Systemic antiadrenergics (e.g., propranolol, atenolol, metoprolol, nadolol, timolol)	
e. Drugs that <i>increase</i> effects of anticholinergic ophthalmic drugs:	Additive mydriasis Additive anticholinergic effects (mydriasis, blurred vision, tachycardia). These drugs are hazardous in narrow-angle glaucoma.
(1) Adrenergic ophthalmic agents	
(2) Systemic anticholinergic drugs (e.g., atropine) and other drugs with anticholinergic effects (e.g., some antihistamines, antipsychotic agents, and tricyclic antidepressants)	
f. Drugs that <i>decrease</i> effects of cholinergic ophthalmic drugs:	Antagonize antiglaucoma (miotic) effects of cholinergic drugs
(1) Anticholinergics and drugs with anticholinergic effects (e.g., atropine, antipsychotic agents, tricyclic antidepressants, some antihistamines)	
(2) Corticosteroids	Long-term use of corticosteroids, topically or systemically, raises IOP and may cause glaucoma. Therefore, corticosteroids decrease effects of all drugs used for glaucoma. Antagonize miotic (antiglaucoma) effect
(3) Sympathomimetic drugs	

## Key Concepts

- Drug therapy of eye disorders is unique because of the location, structure, and function of the eye.
- Eye medications represent several different drug classes.
- Most eye medications are given as eye drops.
- Therapeutic effects of eye drops depend on accurate administration.
- Eye medications should be kept sterile to avoid infection.
- Local eye medications may cause systemic effects; systemic drugs may affect eye function.

## Review and Application Exercises

### Short Answer Exercises

1. List common disorders of the eye for which drug therapy is indicated.
2. Do ophthalmic medications need to be sterile? Why or why not?
3. What are important principles and techniques related to the nurse's administration of ophthalmic drugs?
4. For a patient with newly prescribed eye drops, how would you teach self-administration principles and techniques?

### NCLEX-Style Questions

5. What is a major purpose of occluding tear ducts for 3 to 5 minutes after administering eye drops?
  - a. to prevent eye infections
  - b. to prevent systemic absorption of the drug
  - c. to make self-administration easier
  - d. to use a smaller drug dosage
6. When a patient has two different eye drops ordered at the same time, how should the nurse administer them?
  - a. The drops should be given one immediately after the other.
  - b. Wait 5 to 10 minutes between drops.
  - c. Wait 30 seconds between drops.
  - d. Reschedule the medications to be given 1 hour apart.
7. For a patient receiving an ophthalmic beta blocker and a systemic beta blocker, the nurse is alerted that which of the following effects is likely to occur?
  - a. increased bradycardia
  - b. increased nausea
  - c. increased antiglaucoma effect
  - d. increased blood pressure

8. People who wear contact lenses should be educated by the nurse that they are at high risk of developing which of the following eye disorders?
- cataract
  - glaucoma
  - corneal abrasion
  - allergic conjunctivitis
9. A patient with an inflammatory eye disorder has been prescribed corticosteroid eye drops and asks the nurse why this has been prescribed. The nurse is correct in telling the patient that these drops are used to
- dilate pupils prior to surgery
  - constrict pupils in glaucoma
  - prevent cataract development
  - prevent scarring and loss of vision

# Drugs Used in Dermatologic Conditions

## KEY TERMS

- Acne
- Candidiasis
- Dermatitis
- Emollient
- Erythema
- Keratin
- Melanocytes
- Pruritus
- Psoriasis
- Rosacea
- Tinea pedis
- Urticaria

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review characteristics of skin structures that influence drug therapy of dermatologic disorders.
2. Discuss antimicrobial, anti-inflammatory, and selected miscellaneous drugs in relation to their use in dermatologic disorders.
3. Use correct techniques to administer dermatologic medications.
4. Teach patients, family members, or caregivers correct administration of dermatologic medications.
5. For patients with “open lesion” skin disorders, teach about the importance and techniques of preventing infection.
6. Practice and teach measures to protect the skin from the damaging effects of sun exposure.

## Applying Your Knowledge

Ginger Hertzfeld is a 15-year-old female student at the high school where you are the school nurse. She tells you that she has a red and itchy rash. Ginger is very modest and shy and will not show you the rash but wants advice on an over-the-counter preparation she can use to treat it.

## Introduction

### Basic Structure and Function of the Skin

The skin is the largest body organ and the interface between the internal and external environments. It is composed of the epidermis and dermis. Epidermal or epithelial cells begin in the basal layer of the epidermis and migrate outward, undergoing degenerative changes in each layer. The outer layer, called the stratum corneum, is composed of dead cells and keratin. The dead cells are constantly being shed (desquamated) and replaced by newer cells. Normally, approximately 1 month is required for cell formation, migration, and desquamation. When dead cells are discarded, keratin remains on the skin. *Keratin* is a tough protein substance that is insoluble in water, weak acids, and weak bases. Hair and nails, which are composed of keratin, are referred to as appendages of the skin.

*Melanocytes* are pigment-producing cells located at the junction of the epidermis and the dermis. These cells produce yellow, brown, or black skin coloring in response to genetic influences, melanocyte-stimulating hormone released from the anterior pituitary gland, and exposure to ultraviolet (UV) light (e.g., sunlight).

The dermis is composed of elastic and fibrous connective tissue. Dermal structures include blood vessels, lymphatic channels, nerves and nerve endings, sweat glands, sebaceous glands, and

hair follicles. The dermis is supported underneath by subcutaneous tissue, which is composed primarily of fat cells.

The skin has numerous functions, most of which are protective, including the following:

- Serves as a physical barrier against loss of fluids and electrolytes and against entry of microorganisms, foreign bodies, and other potentially harmful substances
- Detects sensations of pain, pressure, touch, and temperature through sensory nerve endings
- Assists in regulating body temperature through production and elimination of sweat
- Serves as a source of vitamin D when exposed to sunlight or other sources of UV light. Skin contains a precursor for vitamin D.
- Excretes water, sodium, chloride, lactate, and urea in sweat
- Inhibits growth of many microorganisms by its acidic pH (4.5–6.5)

Mucous membranes are composed of a surface layer of epithelial cells, a basement membrane, and a layer of connective tissue. They line body cavities that communicate with the external environment (e.g., mouth, vagina, anus). Mucous membranes receive an abundant blood supply because capillaries lie just beneath the epithelial cells.

## Disorders of the Skin

Dermatologic disorders may be primary (i.e., originate in the skin or mucous membranes) or secondary (i.e., result from a systemic condition, such as measles or adverse drug reactions). This chapter emphasizes selected primary skin disorders and the medications used to prevent or treat them.

### Inflammatory Disorders

#### Dermatitis

*Dermatitis*, also called *eczema*, is a general term denoting an inflammatory response of the skin to injuries from irritants, allergens, or trauma. Whatever the cause, dermatitis is usually characterized by *erythema* (redness), *pruritus* (itching), and skin lesions. It may be acute or chronic.

- **Atopic dermatitis** is a common disorder characterized by dry skin, pruritus, and lesions that vary according to the extent of inflammation, stages of healing, and scratching. Scratching damages the skin and increases the risks of secondary infection. Acute lesions are reddened skin areas containing papules and vesicles; chronic lesions are often thick, fibrotic, and nodular.

The cause is uncertain but may involve allergic, hereditary, or psychological elements. Approximately 50% to 80% of patients have asthma or allergic rhinitis; some have a family history of these disorders. Thus, exposure to possible causes or exacerbating factors such as allergens, irritating chemicals, foods, and emotional stress should be considered. The condition may occur in all age groups but is more common in children.

- **Contact dermatitis** results from direct contact with irritants (e.g., soaps, detergents) or allergens (e.g., clothing materials or dyes, jewelry, cosmetics) that stimulate inflammation. Irritants cause tissue damage and dermatitis in anyone with sufficient contact or exposure. Allergens cause dermatitis only in sensitized or hypersensitive people. The location of the dermatitis may indicate the cause (e.g., facial dermatitis may indicate an allergy to cosmetics).

- **Seborrheic dermatitis** is a disease of the sebaceous glands characterized by excessive production of sebum. It may occur on the scalp, face, or trunk. A simple form involving the scalp is dandruff, which is characterized by flaking and itching of the skin. More severe forms are characterized by greasy, yellow scales or crusts with variable amounts of erythema and itching.

- **Urticaria** (“hives”) is an inflammatory response characterized by a skin lesion called a wheal, a raised edematous area with a pale center and red border, which itches intensely. Histamine is the most common mediator of urticaria and it causes vasodilation, increased vascular permeability, and pruritus.

Histamine is released from mast cells and basophils by both allergic (e.g., insect bites, foods, drugs) and nonallergic (e.g., radiocontrast media, opiates, heat, cold, pressure, UV light) stimuli. An important difference between allergic and nonallergic reactions is that many allergic reactions require prior exposure to the stimulus, whereas nonallergic reactions can occur with the first exposure.

- **Drug-induced skin reactions** can occur with virtually any drug and can resemble the signs and symptoms of virtually any skin disorder. Topical drugs usually cause a localized, contact-dermatitis type of reaction and systemic drugs cause generalized skin lesions. Skin manifestations of serious drug reactions include erythema, facial edema, pain, blisters, necrosis, and urticaria. Systemic manifestations may include fever, enlarged lymph nodes, joint pain or inflammation, shortness of breath, hypotension, and leukocytosis. Drug-related reactions usually occur within the first or second week of drug administration and subside when the drug is discontinued.

#### Psoriasis

*Psoriasis* is a chronic, inflammatory disorder attributed to activated T lymphocytes, which produce cytokines that stimulate abnormal growth of affected skin cells and blood vessels. The abnormal growth results in excessively rapid turnover of epidermal cells. Instead of 30 days from formation to elimination of normal epidermal cells, epidermal cells involved in psoriasis are abnormal in structure and have a lifespan of about 4 days. Skin lesions of psoriasis are erythematous, dry, and scaling. The lesions may occur anywhere on the body but commonly involve the skin covering bony prominences, such as the elbows and knees. Skin lesions may be tender, but they do not usually cause severe pain or itching. However, the lesions are unsightly and usually cause embarrassment and mental distress.

The disease is characterized by remissions and exacerbations. Exacerbating factors include infections, winter weather, some drugs (e.g., beta blockers, lithium), and possibly stress, obesity, and alcoholism.

### Rosacea

*Rosacea* is a chronic disease characterized by erythema, telangiectases (fine, red, superficial blood vessels), and acne-like lesions of facial skin. Hyperplasia of the nose (rhinophyma) eventually develops. The etiology is thought to be excessive production of certain inflammatory proteins. Rosacea usually occurs in middle-aged and older people, more often in men than women. Spicy foods, heat, alcohol, and embarrassment can worsen the condition.

## Dermatologic Infections

### Bacterial Infections

Bacterial infections of the skin are common; they are most often caused by streptococci or staphylococci.

- **Cellulitis** is characterized by erythema, tenderness, and edema, which may spread to subcutaneous tissue. Generalized malaise, chills, and fever may occur.
- **Folliculitis** is an infection of the hair follicles that most often occurs on the scalp or bearded areas of the face.
- **Furuncles** and **carbuncles** are infections usually caused by staphylococci. Furuncles (boils) may result from folliculitis. They usually occur in the neck, face, axillae, buttocks, thighs, and perineum. Furuncles tend to recur. Carbuncles involve many hair follicles and include multiple pustules. Carbuncles may cause fever, malaise, leukocytosis, and bacteremia. Healing of carbuncles often produces scar tissue.
- **Impetigo** is a superficial skin infection caused by streptococci or staphylococci. An especially contagious form is caused by group A beta-hemolytic streptococci. This form occurs most often in children.

### Fungal Infections

Fungal infections of the skin and mucous membranes are most often caused by *Candida albicans*.

- **Oral candidiasis** (thrush) involves mucous membranes of the mouth. It often occurs as a superinfection after the use of broad-spectrum systemic antibiotics.
- **Candidiasis of the vagina and vulva** occurs with systemic antibiotic therapy and in women with diabetes mellitus.
- **Intertrigo** involves skin folds or areas where two skin surfaces are in contact (e.g., groin, pendulous breasts).
- **Tinea infections** (ringworm) are caused by fungi (dermatophytes). These infections may involve the scalp (*tinea capitis*), the body (*tinea corporis*), the foot (*tinea pedis*), and other areas of the body. *Tinea pedis*, commonly called athlete's foot, is a common type of ringworm infection.

### Viral Infections

Viral infections of the skin include verrucal (warts) and herpes infections. There are two types of herpes simplex infections:

type 1 usually involves the face or neck (e.g., fever blisters or cold sores on the lips), and type 2 involves the genitalia. Other herpes infections include varicella (chickenpox) and herpes zoster (shingles).

### Trauma

Trauma refers to a physical injury that disrupts the skin. When the skin is broken, it may not be able to function properly. The major problem associated with skin wounds is infection. Common wounds include lacerations (cuts or tears), abrasions (shearing or scraping of the skin), puncture wounds, surgical incisions, and burn wounds.

### Ulcerations

Cutaneous ulcerations are usually caused by trauma and impaired circulation. They may become inflamed or infected.

- **Pressure ulcers** (also called decubitus ulcers) may occur anywhere on the body when external pressure decreases blood flow. They are most likely to develop in patients who are immobilized, incontinent, malnourished, and debilitated. Common sites include the sacrum, trochanters, ankles, and heels. In addition, abraded skin is susceptible to infection and ulcer formation.
- **Venous stasis ulcers**, which usually occur on the legs, result from impaired venous circulation. Other signs of venous insufficiency include edema, varicose veins, stasis dermatitis, and brown skin pigmentation. Bacterial infection may occur in the ulcer.

### Acne

*Acne* is a common disorder characterized by excessive production of sebum and obstruction of hair follicles, which normally carry sebum to the skin surface. As a result, hair follicles expand and form comedones (blackheads and whiteheads). *Acne* lesions vary from small comedones to *acne vulgaris*, the most severe form, in which follicles become infected and irritating secretions leak into surrounding tissues to form inflammatory pustules, cysts, and abscesses. Most patients have a variety of lesion types at one time. At least four pathologic events take place within acne-infected hair follicles: (1) androgen-mediated stimulation of sebaceous gland activity, (2) abnormal keratinization leading to follicular plugging (comedone formation), (3) proliferation of the bacterium *Propionibacterium acnes* within the follicle, and (4) inflammation.

*Acne* occurs most often on the face, upper back, and chest because large numbers of sebaceous glands are located in these areas. One etiologic factor is increased secretion of male hormones (androgens), which occurs at puberty in both sexes. This leads to increased production of sebum and proliferation of *P. acnes* bacteria, which depend on sebum for survival. The *P. acnes* organisms contain lipase enzymes that break down free fatty acids and produce inflammation in acne lesions. Other causative factors may include medications (e.g., phenytoin, corticosteroids) and stress (i.e., the stress mechanism may involve stimulation of androgen secretion). There is no evidence that certain foods (e.g., chocolate) or lack of cleanliness cause acne.

## External Otitis

External otitis is an infection of the external ear characterized by pain, itching, and drainage. The external ear is lined with epidermal tissue, which is susceptible to the same skin disorders that affect other parts of the body. External otitis is most often caused by *Pseudomonas aeruginosa* and *Staphylococcus aureus* organisms and may be treated with antimicrobial ear drops for 7 to 10 days.

## Anorectal Disorders

Hemorrhoids and anal fissures are common anorectal disorders characterized by pruritus, bleeding, and pain. Inflammation and infection may occur.

## Dermatologic Drug Therapy

Many dermatologic medications are applied topically to skin and mucous membranes. The drugs may improve barrier function, soften and remove scaly lesions, alter inflammation in the skin, alter blood flow, exert antimicrobial effects, or affect proliferating cells. Components of topical medications include an active drug and additives that facilitate application to skin and mucous membranes. Numerous dosage forms have been developed for topical application to various parts of the body and for various therapeutic purposes (see Box 64-1). Many topical drugs are available in several dosage forms.

Topical medications are used primarily for local effects and systemic absorption is undesirable. Major factors that increase systemic absorption of topical agents include damaged or inflamed skin, high concentrations of drug, and application of drug to the face or mucous membranes, to large areas of the body, or for prolonged periods.

## Types of Dermatologic Drugs

Many different drugs are used to prevent or treat dermatologic disorders; most fit into one or more of the following categories:

- **Antimicrobials** are used to treat infections caused by bacteria, fungi, and viruses (see Chaps. 29–36). When used in dermatologic infections, antimicrobials may be administered locally (topically) or systemically (orally or parenterally). Topical antibacterials (Table 64-1) are used to treat superficial skin disorders such as acne and skin infections. Systemic antibacterials (e.g., cephalosporins) are used for soft-tissue infections such as cellulitis and postoperative wound infections. Tetracyclines are used for acne and rosacea; fluoroquinolones (e.g., ciprofloxacin) may be used to treat soft-tissue infections caused by gram-negative organisms.
- **Antiseptics** kill or inhibit the growth of bacteria, viruses, or fungi. They are used primarily to prevent infection. Skin surfaces should be clean before application of antiseptics.
- **Corticosteroids** (see Chap. 23) are used to treat the inflammation present in many dermatologic conditions. They are most often applied topically (Table 64-2) but also may be given orally or parenterally.

### Box 64-1

### Dosage Forms of Topical Medications

Medications for application to skin and mucous membranes mix an active drug with preservatives, emulsifying agents, and an appropriate base or vehicle. Numerous dosage forms are available for various conditions and therapeutic uses, as follows.

- **Creams** are emulsions of oil in water that may be greasy or nongreasy. They leave a thin coating of oil on the skin as the water evaporates. Creams retain moisture in the skin and are cosmetically acceptable for use on the face and other visible areas of the body. They also may be used in hairy, moist, intertriginous areas. Creams are especially useful in subacute dermatologic disorders.
  - **Gels** are transparent colloids, which are solid at room temperature but melt on contact with the skin. They dry and leave a film over the area that helps retain moisture in the skin. They are especially useful in subacute dermatologic disorders.
  - **Lotions** are suspensions of insoluble substances in water. They cool, dry, and protect the skin. They are most useful in subacute dermatologic disorders.
  - **Ointments** are oil-based substances that usually contain a medication in an emollient vehicle, such as petrolatum or lanolin. Ointments occlude the skin and promote retention of moisture. Thus, they are especially useful in chronic skin disorders characterized by dry lesions. Ointments should usually be avoided in hairy, moist, and intertriginous areas of the body because of potential maceration, irritation, and secondary infection.
  - **Pastes** are a mixture of powder and ointment.
  - **Powders** have absorbent, cooling, and protective effects. Powders usually should not be applied in acute exudative disorders or on denuded areas because they tend to cake, occlude the lesions, and retard healing. Also, some powders (e.g., cornstarch) may lead to secondary infections by promoting growth of bacteria and fungi.
  - **Solutions** include water, alcohol, and propylene glycol, but not oil.
  - **Sprays and aerosols** are similar to lotions.
  - **Topical otic medications** are usually liquids. However, creams or ointments may be used for dry, crusted lesions, and powders may be used for drying effects.
  - **Topical vaginal medications** may be applied as douche solutions, vaginal tablets, or vaginal creams used with an applicator.
  - **Anorectal medications** may be applied as ointments, creams, foams, and rectal suppositories.
- **Emollients and moisturizers** (e.g., lanolin) are used to relieve dry skin and pruritus.
  - **Enzymes** may be used to débride burn wounds, decubitus ulcers, and venous stasis ulcers. They promote healing by removing necrotic tissue.
  - **Immunosuppressants** (see Chap. 41) may be used to treat inflammatory skin disorders. Two topical agents, tacrolimus

(Protopic) ointment and pimecrolimus (Elidel) cream, are used for moderate to severe atopic dermatitis. However, the drugs have **BLACK BOX WARNINGS** about a possible increased risk of skin cancer and lymphoma. Precautions include using the drugs only when other drugs are ineffective and avoiding long-term use. Several systemic biologic agents, including alefacept (Amevive), efalizumab (Raptiva), etanercept (Enbrel), and infliximab (Remicade), are used for the treatment of severe psoriasis. These agents have **BLACK BOX WARNINGS** about increased risks for developing infections and their long-term effects are unknown.

- **Keratolytics** are used to treat keratin-containing skin conditions. Alpha hydroxy acids (e.g., glycolic acid) are used to treat wrinkles and sun-damaged skin. These acids are a component of many “antiaging” cosmetics and other products. Salicylic acid is used to remove warts, corns, and calluses.
- **Retinoids** are vitamin A derivatives that are active in proliferation and differentiation of skin cells. These agents are commonly used to treat acne, psoriasis, aging and wrinkling of skin from sunlight exposure, and skin cancers. Retinoids are contraindicated in women of childbearing potential unless the women have negative pregnancy tests; agree to use effective contraception before, during, and after drug therapy; and agree to take the drugs as prescribed. These drugs have been associated with severe fetal abnor-

malities and have **BLACK BOX WARNINGS** about the risks and precautions for safe use. With isotretinoin (Accutane), for example, manufacturers are required to maintain records of doctors who prescribe the drug, pharmacies that distribute it, and patients who take it. Prescribers and pharmacies must inform patients about the risks of taking the drug, have them sign informed-consent documents, and obtain proof of negative pregnancy tests (two tests before starting isotretinoin and a monthly test during therapy).

- **Sunscreens** are used to protect the skin from the damaging effects of UV radiation, thereby decreasing skin cancer and signs of aging, including wrinkles. Dermatologists recommend sunscreen preparations that block both UVA and UVB and have a “sun protection factor” (SPF) value of 30 or higher. The SPF is determined by the ratio of sunlight exposure needed to cause erythema in users of a sunscreen versus the exposure needed to cause erythema in nonusers. These highly protective sunscreens are especially needed by people who are fair skinned, allergic to sunlight, or using medications that increase skin sensitivity to sunlight (e.g., estrogens, tetracyclines).

## Individual Drugs

Individual Drugs are described in Tables 64-1, 64-2, and 64-3.

Table 64-1

### Drugs at a Glance: Topical Antimicrobial Agents

GENERIC/TRADE NAME	INDICATIONS FOR USE	APPLICATION
<b>Antibacterial Agents</b>		
<b>Azelaic acid</b> (Azelex, Finacea)	Acne Rosacea	To lesions, twice daily
<b>Bacitracin</b>	Bacterial skin infections	To affected area, 1–3 times daily
<b>Benzoyl peroxide</b>	Acne	To affected areas, once or twice daily
<b>Clindamycin</b> (Cleocin T)	Acne	To affected areas, twice daily
<b>Erythromycin</b> (Akne-Mycin)	Acne	To affected areas, twice daily
<b>Gentamicin</b> (Garamycin)	Skin infections caused by susceptible organisms	To infected areas, 3–4 times daily
<b>Metronidazole</b> (MetroGel, Noritate)	Rosacea	To affected area, once or twice daily
<b>Mupirocin</b> (Bactroban)	Impetigo caused by <i>Staphylococcus aureus</i> , beta-hemolytic streptococci, or <i>Streptococcus pyogenes</i> Eradication of nasal colonization with methicillin-resistant <i>S. aureus</i>	Impetigo: Ointment, to affected areas, 3 times daily. Other skin lesions: Cream, 3 times daily for 10 d Eradication of nasal colonization: Ointment from single-use tube, one half in each nostril, morning and evening for 5 d
<b>Retaptamulin</b> (Altabax)	Impetigo	To affected area, twice daily for 5 d
<b>Silver sulfadiazine</b> (Silvadene)	Prevent or treat infection in burn wounds caused by <i>Pseudomonas</i> and many other organisms	To affected area, once or twice daily, using sterile technique

(continued on page 1030)

Table 64-1

## Drugs at a Glance: Topical Antimicrobial Agents (continued)

GENERIC/TRADE NAME	INDICATIONS FOR USE	APPLICATION
<b>Combination Products</b>		
<b>Bacitracin and polymyxin B</b> (Polysporin)	Bacterial skin infections	To lesions, 1–3 times daily
<b>Erythromycin/benzoyl peroxide</b> (Benzamycin)	Acne	To affected areas, twice daily
<b>Neomycin, polymyxin B, and bacitracin</b> (Neosporin)	Bacterial skin infections	To lesions, 2 or 3 times daily
<b>Antifungal Agents</b>		
<b>Butenafine</b> (Mentax)	Tinea pedis	To affected area, once daily for 2–4 wk
<b>Ciclopirox</b> (Loprox)	Tinea infections Cutaneous candidiasis	To affected area, twice daily for 2–4 wk
<b>Clotrimazole</b> (Lotrimin)	Tinea infections Cutaneous candidiasis	To affected areas, twice daily for 2–4 wk
<b>Econazole</b> (Spectazole)	Tinea infections Cutaneous candidiasis	To affected areas, once daily for tinea infections, twice daily for candidiasis
<b>Ketoconazole</b> (Nizoral)	Tinea infections Cutaneous candidiasis Seborrheic dermatitis	Tinea infections and candidiasis, to affected areas once daily for 2–4 wk Seborrheic dermatitis, twice daily for 4 wk
<b>Miconazole</b> (Micatin)	Tinea infections Cutaneous candidiasis	To affected area, once daily for 2–4 wk
<b>Naftifine</b> (Naftin)	Tinea infections	To affected areas, once daily with cream, twice daily with gel
<b>Nystatin</b> (Mycostatin)	Candidiasis of skin and mucous membranes	To affected areas, 2 or 3 times daily until healed
<b>Oxiconazole</b> (Oxistat)	Tinea infections	To affected areas, once or twice daily for 2–4 wk
<b>Terbinafine</b> (Lamisil)	Tinea infections	To affected areas, twice daily for 1–4 wk
<b>Tolnaftate</b> (Tinactin)	Tinea infections	To affected areas, twice daily for 2–4 wk
<b>Antiviral Agents</b>		
<b>Acyclovir</b> (Zovirax)	Herpes genitalis Herpes labialis in immunosuppressed patients	To lesions, q3h 6 times daily for 7 d
<b>Penciclovir</b> (Denavir)	Herpes labialis	To lesions, q2h while awake for 4 d

Table 64-2

## Drugs at a Glance: Topical Corticosteroids

GENERIC/TRADE NAME	DOSAGE FORMS	POTENCY
<b>Alclometasone</b> (Aclovate)	Cream, ointment	Low
<b>Augmented betamethasone dipropionate</b> (Diprolene)	Cream, gel, lotion, ointment	Ointment, very high; cream, high
<b>Betamethasone dipropionate</b> (Alphatrex, others)	Aerosol, cream, lotion, ointment	Cream and ointment, high; lotion, medium
<b>Betamethasone valerate</b> (Valisone, others)	Cream, foam, lotion, ointment	Ointment, high; cream, medium

GENERIC/TRADE NAME	DOSAGE FORMS	POTENCY
<b>Clobetasol</b> (Temovate)	Cream, gel, ointment, scalp application	Very high
<b>Desonide</b> (Tridesilon)	Cream, lotion, ointment	Low
<b>Desoximetasone</b> (Topicort)	Cream, gel, ointment	Medium
<b>Dexamethasone</b> (Decadron)	Aerosol, cream	Low
<b>Fluocinolone</b> (Synalar, others)	Cream, oil, ointment, shampoo, solution	High
<b>Fluocinonide</b> (Lidex)	Cream, gel, ointment, solution	High
<b>Flurandrenolide</b> (Cordran)	Cream, lotion, ointment, tape	Medium
<b>Fluticasone</b> (Cutivate)	Cream, ointment	Medium
<b>Halobetasol</b> (Ultravate)	Cream, ointment	Very high
<b>Hydrocortisone</b> (Cortaid, others)	Cream, lotion, ointment, solution, spray, roll-on stick	Medium or low
<b>Mometasone</b> (Elocon)	Cream, lotion, ointment	Medium
<b>Triamcinolone acetonide</b> (Aristocort, Kenalog, others)	Aerosol, cream, lotion, ointment	0.5% cream and ointment, high; lower concentrations, medium

Table 64-3

**Drugs at a Glance: Miscellaneous Dermatologic Agents**

GENERIC/TRADE NAME	DERMATOLOGIC EFFECTS	CLINICAL INDICATIONS	METHOD OF ADMINISTRATION
<b>Enzyme</b>			
<b>Trypsin</b> (Granulex)	Débriding effects	Débridement of infected wounds (e.g., decubitus and varicose ulcers)	Topically by spray twice daily
<b>Immunomodulators</b>			
<b>Pimecrolimus</b> (Elidel)	Anti-inflammatory	Atopic dermatitis	Topically to affected skin, twice daily
<b>Tacrolimus</b> (Protopic)	Anti-inflammatory	Atopic dermatitis	Topically to affected skin, twice daily
<b>Retinoids</b>			
<b>Acitretin</b> (Soriatane)	Related to vitamin A	Severe psoriasis	PO 25–50 mg/d
<b>Adapalene</b> (Differin)	Reportedly causes less burning, itching, redness, and dryness than tretinoin	Acne vulgaris	Topically to skin lesions once daily
<b>Isotretinoin</b> (Accutane)	Inhibits sebum production and keratinization	Severe cystic acne Disorders characterized by excessive keratinization (e.g., pityriasis, ichthyosis) <i>Mycosis fungoides</i>	PO 1–2 mg/kg/d, in 2 divided doses, for 15–20 wk
<b>Tazarotene</b> (Tazorac)	A prodrug; mechanism of action is unknown	Acne Psoriasis	Topically to skin, after cleansing, once daily in the evening
<b>Tretinoin</b> (Retin-A)	Irritant	Acne vulgaris	Topically to skin lesions once daily
<b>Other Agents</b>			
<b>Becaplermin</b> (Regranex)	A recombinant human platelet-derived growth factor	Diabetic skin ulcers	Topically to ulcer; amount calculated according to size of the ulcer
<b>Calcipotriene</b> (Dovonex)	Synthetic analog of vitamin D that helps to regulate skin-cell production and development	Psoriasis	Topically to skin lesions twice daily

(continued on page 1032)

Table 64-3

**Drugs at a Glance: Miscellaneous Dermatologic Agents** (continued)

GENERIC/ TRADE NAME	DERMATOLOGIC EFFECTS	CLINICAL INDICATIONS	METHOD OF ADMINISTRATION
<b>Capsaicin</b> (Zostrix)	Depletes substance P (which transmits pain impulses) in sensory nerves of the skin	Relief of pain associated with rheumatoid arthritis, osteoarthritis, and neuralgias	Topically to affected area, up to 3 or 4 times daily
<b>Coal tar</b> (Balnetar, Zetar, others)	Irritant	Psoriasis Dermatitis	Topically to skin, in various concentrations and preparations (e.g., creams, lotions, shampoos, bath emulsion). Also available in combination with hydrocortisone and other substances
<b>Colloidal oatmeal</b> (Aveeno)	Antipruritic	Pruritus	Topically as a bath solution (1 cup in bathtub of water)
<b>Dextranomer</b> (Debrisan)	Absorbs exudates from wound surfaces	Cleansing of ulcers (e.g., venous stasis, decubitus) and wounds (e.g., burn, surgical, traumatic)	Apply to a clean, moist wound surface q12h initially, then less often as exudate decreases
<b>Fluorouracil</b> (Efudex)	Antineoplastic	Actinic keratoses Superficial basal cell carcinomas	Topically to skin lesions twice daily for 2–6 wk
<b>Masoprocol</b> (Actinex)	Inhibits proliferation of keratin-containing cells	Actinic keratoses	Topically to skin lesions morning and evening for 28 d
<b>Salicylic acid</b>	Keratolytic, antifungal	Removal of warts, corns, calluses Superficial fungal infections Seborrheic dermatitis Acne Psoriasis	Topically to skin lesions
<b>Selenium sulfide</b> (Selsun)	Antifungal, antidandruff	Dandruff Tinea versicolor	Topically to scalp as shampoo once or twice weekly

### Applying Your Knowledge 64-1

You ask Ginger to describe her rash. She says that it is red and very itchy. Upon further questioning, she tells you that she has had it before but cannot remember what it is called. She also has a history of seasonal allergies. Ginger agrees to let you look at the rash. Her history and the appearance of the rash suggest dermatitis. What can Ginger use to help relieve the itching and inflammation?

### Herbal Preparations

Many supplements are promoted for use in skin conditions. Most have not been tested adequately to ensure effectiveness. At the same time, however, topical use rarely causes serious

adverse effects or drug interactions. Two topical agents for which there is some support of safety and effectiveness are aloe and oat preparations.

**Aloe** is often used as a topical remedy for minor burns and wounds (e.g., sunburn, cuts, abrasions) to decrease pain, itching, and inflammation and to promote healing. Its active ingredients are unknown. Wound healing is attributed to moisturizing effects and increased blood flow to the area. Reduced inflammation and pain may result from inhibition of arachidonic acid metabolism and formation of inflammatory prostaglandins. Reduced itching may result from inhibition of histamine production.

Commercial products are available for topical use, but fresh gel from the plant may be preferred. When used for this purpose, a clear, thin, gel-like liquid can be squeezed directly from a plant leaf onto the burned or injured area several times daily if needed.

Aside from oral use as a cereal, a good source of dietary fiber, and a well-documented cholesterol-lowering product, oat preparations are used topically to treat minor skin irritation and pruritus associated with common skin disorders. Oats contain gluten, which forms a sticky mass that has emollient effects and holds moisture in the skin when it is mixed with a liquid. For topical use, oats are contained in bath products, cleansing bars, and lotions (e.g., Aveeno products) that can be used once or twice daily. They should not be used near the eyes or on inflamed skin. After use, bath products should be washed off with water.

## Nursing Process

### Assessment

Assess the patient's skin for characteristics or lesions that may indicate current or potential dermatologic disorders.

- When a skin rash is present, interview the patient and inspect the area to determine the following:
  - **Appearance of individual lesions.** Lesions should be described as specifically as possible so that changes can be identified. Terms commonly used in dermatology include *macule* (flat spot), *papule* (raised spot), *nodule* (small, solid swelling), *vesicle* (blister), *pustule* (pus-containing lesion), *petechia* (flat, round, purplish-red spot the size of a pinpoint, caused by intradermal or submucosal bleeding), and *erythema* (redness). Lesions also may be described as weeping, dry and scaly, or crusty.
  - **Location or distribution.** Some skin rashes occur exclusively or primarily on certain parts of the body (e.g., face, extremities, trunk), and this distribution may indicate the cause.
  - **Accompanying symptoms.** Pruritus occurs with most dermatologic conditions. Fever, malaise, and other symptoms may occur as well.
  - **Historic development.** Appropriate questions include
    - When and where did the skin rash appear?
    - How long has it been present?
    - Has it changed in appearance or location?
    - Has it occurred previously?
  - **Etiologic factors.** In many instances, appropriate treatment is determined by the cause. Some etiologic factors include the following:
    - **Drug therapy.** Many commonly used drugs may cause skin lesions, including antibiotics (e.g., penicillins, sulfonamides, tetracyclines), narcotic analgesics, and thiazide diuretics. Skin rashes due to drug therapy are usually generalized and appear abruptly.
    - **Irritants or allergens** may cause contact dermatitis. For example, dermatitis involving the hands may be caused by soaps, detergents, or various other cleansing agents. Dermatitis involving the trunk may result from allergic reactions to clothing.
- **Communicable diseases** (e.g., measles, chickenpox) cause characteristic skin rashes and systemic signs and symptoms.
- When skin lesions other than rashes are present, assess appearance, size or extent, amount and character of any drainage, and whether the lesion appears infected or contains necrotic material. Bleeding into the skin is usually described as *petechiae* (pinpoint hemorrhages) or *ecchymoses* (bruises). Burn wounds are usually described in terms of depth (partial or full thickness of skin) and percentage of body surface area. Burn wounds with extensive skin damage are rapidly colonized with potentially pathogenic microorganisms. Venous stasis, pressure, and other cutaneous ulcers are usually described in terms of diameter and depth.
- When assessing the skin, consider the age of the patient. Infants are likely to have “diaper” dermatitis, miliaria (heat rash), and tinea capitis (ringworm infection of the scalp). School-aged children have a relatively high incidence of measles, chickenpox, and tinea infections. Adolescents often have acne. Older adults are more likely to have dry skin, actinic keratoses (lesions on sun-exposed skin formerly thought to be premalignant but now considered early-stage squamous cell cancer), and skin cancer.
- Assess for skin neoplasms. Basal cell carcinoma, the most common type, may initially appear as a pale nodule, most often on the head and neck. Squamous cell carcinomas may appear as actinic keratoses or ulcerated areas. These lesions may occur anywhere on the body but are more common on sun-exposed parts, such as the face and hands. Malignant melanoma is the most serious skin cancer. It involves melanocytes, the pigment-producing cells of the skin. Malignant melanoma may occur in pigmented nevi (moles) or previously normal skin. In nevi, malignant melanoma may be manifested by enlargement and ulceration. In previously normal skin, lesions appear as irregularly shaped pigmented areas. Although it can occur in almost any area, malignant melanoma is most likely to be located on the back in Caucasians and in toe webs and on soles of the feet in African Americans or Asians.
- Color changes and skin rashes are more difficult to detect when assessing dark-skinned patients. Some guidelines include the following:
  - Adequate lighting is required; nonglare daylight is best. The illumination provided by overhead lights is inadequate for most purposes.
  - Some skin rashes may be visible on oral mucous membranes.
  - Petechiae are not visible on dark-brown or black skin, but they may be visible on oral mucous membranes or the conjunctiva.

Nursing Process continues on page 1034)

- When skin disorders are present, assess the patient's psychological response to the condition. Many patients, especially those with chronic disorders, feel self-conscious and depressed.

## Nursing Diagnoses

- Disturbed Body Image related to visible skin lesions
- Anxiety related to potential for permanent scarring or disfigurement
- Pain related to skin lesions and pruritus
- Risk for Injury: Infection related to entry of microbes through damaged skin

## Planning/Goals

### The patient will

- Apply topical drugs correctly
- Experience relief of symptoms
- Use techniques to prevent or minimize skin damage and disorders
- Avoid scarring and disfigurement when possible
- Be encouraged to express concerns about acute and chronic body-image changes

## Interventions

Use measures to prevent or minimize skin disorders.

- Use general measures to promote health and increase resistance to disease (i.e., maintain nutrition, rest, and exercise).
- Practice good personal hygiene, with at least once-daily cleansing of skin areas with high bacterial counts, such as underarms and perineum.
- Practice safety measures to avoid injury to the skin. Any injury, especially one that disrupts the integrity of the skin (e.g., lacerations, puncture wounds, scratching of skin lesions) increases the likelihood of skin infections.
- Avoid known irritants or allergens. Have the patient substitute nonirritating soaps or cleaning supplies for irritating ones; use hypoallergenic jewelry and cosmetics if indicated; wear cotton clothing if indicated.
- Use measures to relieve dry skin and pruritus. Dry skin causes itching, and itching promotes scratching. Scratching relieves itching only if it is strong enough to damage the skin and serve as a counterirritant. Skin damaged or disrupted by scratching is susceptible to invasion by pathogenic microorganisms. Thus, dry skin may lead to serious skin disorders. Older adults are especially likely to have dry, flaky skin. Measures to decrease skin dryness include the following:
  - Alternating complete and partial baths. For example, the patient may alternate a shower or tub bath with a

sponge bath (of face, hands, underarms, and perineal areas). Warm water, mild soaps, and patting dry are recommended because hot water, harsh soaps, and rubbing with a towel have drying effects on the skin.

- Liberal use of lubricating creams, lotions, and oils. Bath oils, which usually contain mineral oil or lanolin oil and a perfume, are widely available. If bath oils are used, precautions against falls are necessary because the oils make bathtubs and shower floors slippery. Creams and lotions may be applied several times daily.
- Prevent pressure ulcers by avoiding trauma to the skin and prolonged pressure on any part of the body. In patients at high risk for development of pressure ulcers, major preventive measures include frequent changes of position and correct lifting techniques. Various pressure-relieving devices (e.g., special beds and mattresses) also are useful. Daily inspection of the skin is needed for early detection and treatment of beginning pressure ulcers.
- Avoid excessive exposure to sunlight and other sources of UV light. Although controlled amounts of UV light are beneficial in some dermatologic disorders (e.g., acne, psoriasis), excessive amounts cause wrinkling, dryness, and malignancies. If prolonged exposure is necessary, protective clothing and sunscreen lotions decrease skin damage.
- When skin rashes are present, cool, wet compresses or baths are often effective in relieving pruritus. Water or normal saline may be used alone or with additives, such as colloidal oatmeal (e.g., Aveeno) or baking soda. A cool environment also tends to decrease pruritus. The patient's fingernails should be cut short and kept clean to avoid skin damage and infection from scratching.
- For severe itching, a systemic antihistamine may be needed.

## Evaluation

- Observe and interview regarding use of dermatologic drugs.
- Observe for improvement in skin lesions and symptoms.
- Interview regarding use of measures to promote healthy skin and prevent skin disorders.

## Applying Your Knowledge 64-2

What nonpharmacologic measures would you recommend for Ginger?

.....

## Principles of Therapy

### Goals of Therapy

General treatment goals for many skin disorders are to relieve symptoms (e.g., dryness, pruritus, inflammation, infection), eradicate or improve lesions, promote healing and repair, restore skin integrity, and prevent recurrence. Specific goals often depend on the condition being treated. With acne, for example, goals are to reduce the number of lesions.

### General Guidelines for Dermatologic Drug Therapy

- Pharmacologic therapy may include a single drug or multiple agents used concurrently or sequentially.
- For severe skin conditions, a dermatologist is best qualified to prescribe medications and other treatments. Because

many skin conditions are so visible, early and aggressive treatment may be needed to prevent additional tissue damage, repeated infections, scarring, and mental anguish.

- Topical medications are preferred, when effective, and many preparations are available. Astringents and lotions are usually used as drying agents for “wet,” oozing lesions, and ointments and creams are used as “wetting” agents for dry, scaling lesions.
- To relieve pruritus, skin lubricants, systemic antihistamines, and topical corticosteroids are important elements.
- Topical corticosteroids are used for both acute and chronic inflammatory and pruritic lesions. However, when acute lesions involve extensive areas or chronic lesions are resistant to topical drugs, systemic corticosteroid therapy may be needed. Prednisone 0.5 to 1 mg/kg/day is often used for 1 to 3 weeks.

## Patient Teaching Guidelines

## Topical Medications for Skin Disorders

### General Considerations

- Severe dermatologic disorders should be treated by a dermatologist.
- Promote healthy skin by a balanced diet, personal hygiene measures, avoiding excessive exposure to sunlight, avoiding skin injuries, and lubricating dry skin. Healthy skin is less susceptible to inflammation, infections, and other disorders. It also heals more rapidly when disorders or injuries occur.
- Prevent actinic keratosis and skin cancer by minimizing sun exposure, wearing sun-protective clothing, and using sunscreen. Such measures should begin in early childhood.
- Common symptoms of skin disorders are inflammation, infection, and itching and the goal of most drug therapy is to relieve these symptoms and promote healing. Systemic medications (e.g., oral antihistamines, antibiotics and corticosteroids) may be used for severe disorders, at least initially, but most medications are applied directly to the skin. There is a wide array of topical products, both prescription and over-the-counter.
- It is important to use the correct topical medication and the correct amount for the condition being treated. Topical corticosteroids, for example, come in many vehicles (e.g., creams, lotions, ointments) that cannot be used interchangeably. In addition, they should not be covered with occlusive dressings unless instructed to do so
- Adverse effects of topical medications may involve the skin (e.g., irritation, infection) where the drug is applied or the entire body, when the drug is absorbed into the bloodstream. Systemic absorption is increased when the drug is highly potent; applied to inflamed skin, over a large surface area, or frequently; or covered with an occlusive dressing (e.g., plastic wrap). Systemic absorption is of most concern with corticosteroid preparations.
- Some ways to prevent or decrease skin disorders include
  - Identifying and avoiding, when possible, substances that cause skin irritation and inflammation (e.g.,

harsh cleaning products, latex gloves, cosmetics, pet dander)

- Bathing in warm water with a mild cleanser (e.g., Cetaphil), patting skin dry, and applying lotions or oils (e.g., Eucerin, mineral oil) to lubricate skin and decrease dryness
- Avoiding scratching, squeezing, or rubbing skin lesions. These behaviors cause additional skin damage and increase risks of infection. Fingernails should be cut short; cotton gloves can be worn at night.
- Maintaining a cool environment; preventing sweating
- Applying cold compresses to inflamed, itchy skin
- Using baking soda or colloidal oatmeal (Aveeno) in bath water to relieve itching
- If you are taking an oral antihistamine to relieve itching, it should be taken on a regular schedule, around the clock, for greater effectiveness.
- Misinformation about acne is common. Acne is not caused by dirt, washing does not improve acne, and vigorous scrubbing may worsen acne lesions. There is also no evidence that acne is caused by eating chocolate or other foods. Recommendations for managing acne include using non-acne-producing cosmetics, moisturizers, and sunscreens; washing and bathing with lukewarm water and a gentle cleanser (e.g., Dove); and avoiding sun exposure if taking a tetracycline or retinoid anti-acne medication. (The drugs increase risks of sunburn.) After treatment is started, improvement may take several weeks.
- People with psoriasis can obtain information and support from
 

National Psoriasis Foundation (NPF)  
6600 SW 92nd Avenue, Suite 30  
Portland, OR 97223  
Telephone: 1-800-723-9166  
E-mail: [getinfo@npfusa.org](mailto:getinfo@npfusa.org)  
Web site: <http://www.psoriasis.org>
- Unavoidable skin lesions or scars can often be hidden or rendered less noticeable with make-up or clothing.

(continued on page 1036)

## Patient Teaching Guidelines

## Topical Medications for Skin Disorders (continued)

- Women can wear cosmetics over most topical medications. If unclear, ask a health care provider whether makeup is permissible. With acne, use noncomedogenic make-up, moisturizers, and sunscreens.
- If taking an oral retinoid (e.g., Accutane), avoid vitamin supplements containing vitamin A and excessive exposure to sunlight to decrease risks of excessive vitamin A intake and photosensitivity.
- Because adult household contacts of children with ringworm of the scalp may be asymptomatic carriers, they should use a shampoo containing ketoconazole daily until the infected child is clear of signs and symptoms.

### Self-Administration

- Use topical medications only as prescribed or according to the manufacturer's instructions (for over-the-counter products). Use the correct preparation for the intended area of application (i.e., skin, ear, vagina).
- For topical application to skin lesions, cleanse the skin and remove previously applied medication to promote drug contact with the affected area of the skin.
  - Wash the skin and pat it dry.
  - Apply a small amount of the drug preparation and rub it in well. A thin layer of medication is effective and decreases the incidence and severity of adverse effects. With acne and rosacea, preventing skin lesions is easier than eliminating lesions that are already present. As a result, topical medications should be applied to the general area of involvement rather than individual lesions.
  - For burn wounds, broken skin, or open lesions, apply the drug with sterile gloves or sterile cotton-tipped applicators to prevent infection.
- Wash hands before and after application. Wash before to avoid infection; wash afterward to avoid transferring the drug to the face or eyes and causing adverse reactions.
- For minor wounds and abrasions, cleansing with soap and water is usually adequate. If an antiseptic is used, an iodine preparation (e.g., aqueous iodine solution 1%) is preferred. Alcohol should not be applied to open wounds. Hydrogen peroxide may help with cleansing but it is a weak antiseptic.
- With azelaic acid (Azelex) for acne, use for the full prescribed period, do not use occlusive dressings or wrappings, and keep away from mouth, eyes, and other mucous membranes (if it gets into eyes, wash eyes with a large amount of water).
- With benzoyl peroxide for acne:
  - With cleansing solutions, wash affected areas once or twice daily. Wet skin areas to be treated before applying the cleanser. Rinse thoroughly and pat dry. Reduce use if excessive drying or peeling occurs.
  - With other dosage forms, apply once daily initially and gradually increase to two or three times daily if needed. Cleanse skin, let dry completely, and apply a small amount over the affected area. Reduce dosage if excessive drying, redness, or discomfort occurs. If excessive stinging or burning occurs after any single application, remove with mild soap and water and resume use the next day. Keep away from eyes, mouth, and inside of nose. Rinse with water if contact occurs with these areas. Avoid other sources of skin irritation (e.g., sunlight, sunlamps, other topical acne medications).

## Applying Your Knowledge 64-3

Ginger requires teaching about applying the hydrocortisone. What points should you cover?

## Use of Topical Corticosteroids

Because of the extensive use of topical corticosteroids and the risks of potentially serious adverse effects, numerous precautions, guidelines, and recommendations have evolved to increase safety and effectiveness of these drugs.

### Drug Selection

Choice of drug depends mainly on the acuity, severity, location, and extent of the condition being treated. For acute lesions, a more potent corticosteroid may be needed, at least initially; for chronic lesions, the least-potent preparation that is effective is indicated (see Table 64-2).

- Low-potency drugs (e.g., hydrocortisone) are preferred when likely to be effective. They are especially recommended for use in children, on large areas, and on body sites

especially prone to corticosteroid damage (e.g., face, scrotum, axillae, flexures, skin folds).

- Mid-potency drugs (e.g., flurandrenolide) are usually effective in nonintertriginous areas in children and adults.
- High-potency drugs (e.g., fluocinolone) are used for acute or severe disorders and areas resistant to lower-potency agents. Short-term or intermittent use (e.g., every other day, 3 or 4 consecutive days per week, once per week) may be more effective and cause fewer adverse effects than continuous use of lower-potency products. These drugs may also be alternated with lower-potency agents.
- Very-high-potency drugs (e.g., clobetasol, halobetasol) usually are used for less absorptive areas such as soles of feet, palms of hands, and thick skin plaques. Usage should not exceed 2 consecutive weeks and total dosage should not exceed 50 g/week because of the potential for these drugs to suppress the hypothalamic–pituitary–adrenal (HPA) axis. Clobetasol suppresses the HPA axis at doses as low as 2 g/day. These drugs should not be used with occlusive dressings or for children younger than 12 years of age.

- Drug potency and clinical use vary with the dosage form, and many topical corticosteroids are available in creams, ointments, and other preparations. Creams are usually the most acceptable to patients; ointments penetrate the epidermis better and are often used for chronic dry or scaly lesions; lotions are recommended for intertriginous areas and the scalp. Some preparations are available in aerosol sprays, gels, and other dosage forms.

### Drug Dosage

Dosage depends on the drug concentration, the area of application, and the method of application.

- The skin covering the face, scalp, scrotum, and axillae is more permeable to corticosteroids than other skin surfaces, and these areas can usually be treated with less potent formulations, smaller amounts, or less frequent applications.
- Drug absorption and risks of systemic toxicity are significantly increased when the drug is applied to inflamed skin or covered by an occlusive dressing. Application should be less frequent and limited to isolated, resistant areas when occlusive dressings are used.
- The drug should be applied sparingly. Some clinicians recommend twice-daily applications until a clinical response is obtained, then decreasing to the least-frequent schedule needed to control the condition.
- With continuous use, one or two applications daily may be as effective as three or four applications, because the drugs have a repository effect.
- If an occlusive dressing is applied, leave it on overnight or for at least 6 hours. However, do not leave it in place for more than 12 hours in a 24-hour period.
- After long-term use or after using a potent drug, taper dosage by switching to a less potent agent or applying the drug less frequently. Discontinuing the drug abruptly can cause a rebound effect, in which the skin condition worsens.

### Drug Therapy in Selected Skin Conditions

The choice of topical dermatologic agents depends primarily on the reason for use and patient response.

#### Acne

Numerous prescription and nonprescription anti-acne products are available.

Antimicrobial drugs include both topical and systemic agents. Topical drugs are indicated for mild to moderate acne, often in combination with a topical retinoid to maximize reduction in severity and number of lesions. Azelaic acid (Azelex) has antibacterial activity against *P. acnes* and is reportedly as effective as benzoyl peroxide or topical erythromycin. Benzoyl peroxide is an effective topical agent that is available in numerous preparations (e.g., gel, lotion, cream, wash) and concentrations (e.g., 2.5%–10%). Lotion and cream preparations are the least irritating. Clindamycin and erythromycin are also available in topical dosage forms. These drugs

reduce *P. acnes* bacteria and are equally effective. Combination products of topical clindamycin or erythromycin and benzoyl peroxide are more effective than antibiotics alone. Best results require 8 to 12 weeks of therapy, and maintenance therapy is usually required. Adverse effects of topical antibiotics include erythema, peeling, dryness, and burning as well as development of resistant strains of *P. acnes*. Recommendations for reducing drug resistance include using topical retinoids or benzoyl peroxide or both when using topical antibiotics and avoiding long-term use of topical or oral antibiotics when feasible. Benzoyl peroxide can also cause an irritant dermatitis and bleach hair, clothes, and bed linens.

Oral antimicrobials are first-line treatment for patients with moderate to severe inflammatory acne. These drugs have both antimicrobial and anti-inflammatory effects. They reduce *P. acnes*-induced inflammatory cytokines. Commonly used oral antibiotics include tetracycline, doxycycline, minocycline, and erythromycin. Tetracycline and erythromycin suppress leukocyte chemotaxis and bacterial lipase activity; minocycline and doxycycline inhibit cytokines and proteinase enzymes that contribute to inflammation and tissue breakdown. Resistance to the tetracyclines is less common than to erythromycin and is least with minocycline. All oral antibiotics require at least 6 to 8 weeks of use. Although there are no established guidelines for duration of use, some clinicians encourage using the drugs for shorter periods and avoiding long-term use as maintenance therapy, to decrease the development of resistant *P. acnes* organisms.

Retinoids, in both systemic and topical forms, may be used for moderate to severe acne. All topical retinoids (tretinoin, adapalene, tazarotene) reduce acne lesions, usually within 12 weeks. Tretinoin is often used with other products because it may require several months to decrease acne lesions if used alone. Adapalene gel causes less skin irritation and is better tolerated than tretinoin and tazarotene, but tazarotene may be more effective. Topical retinoids should be applied to the entire area of involvement, starting with about 30 seconds' duration and building up to an hour or more. Maintenance therapy is usually required.

Oral isotretinoin (Accutane) may be used for patients with severe acne who do not respond to safer drugs. Its anti-acne effects include suppression of sebum production, inhibition of comedone formation, and inhibition of inflammation. Approximately 70% to 80% of patients have a long-term remission. Major drawbacks are teratogenic and other adverse effects. This drug must never be given to a woman of child-bearing potential unless she agrees to baseline and monthly pregnancy tests and to practice adequate contraceptive measures during and for 6 months after the drug is discontinued. In addition, baseline and 1-month measurements of cholesterol, fasting triglycerides, and liver function are recommended because the drug may increase these values.

Oral antiandrogens may be given to female patients with high blood levels of androgens (e.g., testosterone). Combination oral contraceptive pills decrease the amount of free

testosterone circulating in the bloodstream and therefore may improve acne. Norgestimate/ethinyl estradiol (Ortho Tri-Cyclen) and norethindrone acetate/ethinyl estradiol (Estrostep) are FDA-approved for treatment of acne.

### Anorectal Disorders

In anorectal disorders, most preparations contain a local anesthetic, emollients, and perhaps a corticosteroid. These preparations relieve pruritus and pain but do not cure the underlying condition. Some preparations contain ingredients of questionable value, such as vasoconstrictors, astringents, and weak antiseptics. No particular mixture is clearly superior.

### Dermatitis

Both systemic and topical agents are usually needed. Sedating, systemic antihistamines such as diphenhydramine or hydroxyzine are often used to relieve itching and promote rest and sleep. An oral antibiotic such as clindamycin, dicloxacillin, a cephalosporin, or a macrolide may be given for a week to treat secondary infections. An oral corticosteroid such as prednisone may be needed initially for severe inflammation, but topical corticosteroids are most often used.

Coal-tar preparations have anti-inflammatory and antipruritic actions and can be used alone or with topical corticosteroids. However, these agents have an unpleasant odor and they stain clothing. They are usually applied at bedtime.

Additional preparations include moisturizers and lubricants (e.g., Aquaphor) for dry skin and itching, mild skin cleansers (e.g., Basis, Cetaphil) to avoid further skin irritation, and baking soda or colloidal oatmeal (e.g., Aveeno) in baths or soaks for pruritus.

### External Otitis

Otic preparations of various dermatologic medications are used. Hydrocortisone is the corticosteroid most often included in topical otic preparations. It relieves pruritus and inflammation in chronic external otitis. Systemic analgesics are usually required.

### Pressure Ulcers

In pressure ulcers, the only clear-cut guideline for treatment is avoiding further pressure on the affected area. Many topical agents are used, most often with specific procedures for dressing changes, skin cleansing, and so on. No one agent or procedure is clearly superior. Consistent implementation of a protocol (e.g., position changes; inspection of current or potential pressure areas; dressing changes; use of alternating, pressure-relieving mattresses) may be more effective than drug therapy.

### Psoriasis

Localized lesions are usually treated by a combination of topical agents, such as a corticosteroid during daytime hours and a coal-tar ointment at night. Coal-tar preparations work slowly but produce longer remissions. Newer antipsoriasis drugs such as calcipotriene (Dovonex) or tazarotene (Tazorac) may also be used. Calcipotriene is reportedly as effective as topical fluocinonide. However, its onset of action is slower than that of a topical corticosteroid. A combination of calcipotriene and

a topical corticosteroid may be used initially for rapid improvement, after which the calcipotriene can be continued as monotherapy. Tazarotene is a topical retinoid that may cause cutaneous irritation.

Generalized psoriasis, which requires systemic treatment or body phototherapy, should be managed by dermatologists. Systemic therapy may involve oral retinoids, methotrexate, or biologic immunosuppressants. Acitretin is the oral retinoid of choice for treatment of severe psoriasis. Like other oral retinoids, acitretin is teratogenic. Thus, women of childbearing potential who take acitretin should be instructed to avoid ingesting alcohol and to use adequate contraception while taking the drug and for at least 3 years thereafter. Methotrexate is an antineoplastic drug that has long been used to treat psoriasis because it suppresses inflammation and proliferation of T lymphocytes. It may cause significant adverse effects. Biologic immunosuppressants (e.g., alefacept, efalizumab, etanercept, infliximab) reduce the activity of T lymphocytes and the inflammation of skin lesions. They are used to treat moderate to severe psoriasis and all have potentially serious adverse effects.

Phototherapy can involve natural sunlight, which is highly effective. Most patients with psoriasis notice some remission during summer months. Office phototherapy treatments are usually performed three to five times weekly.

### Rosacea

Mild skin cleansers (e.g., Cetaphil), oral tetracycline, and topical metronidazole are commonly used; oral isotretinoin and topical metronidazole are also effective. These medications prevent or treat acneiform lesions; they have little to no effect on other aspects (e.g., erythema, telangiectasia, hyperplasia of connective tissue and sebaceous glands).

### Urticaria

Systemic drug therapy with antihistamines ( $H_1$  receptor antagonists) is the major element of drug therapy. In addition, an epinephrine injection may be used initially, and topical medications may be applied to relieve itching. With chronic *urticaria*, the goal of treatment is symptom relief. Antihistamines are most effective when given before histamine-induced urticaria occurs and should be given around the clock, not just when lesions appear.

## Use in Special Populations

### Use in Children

Children and adolescents may develop a wide range of dermatologic disorders, including acne, atopic dermatitis, skin rashes, and skin and skin structure infections. Few guidelines have been developed for drug therapy of most skin disorders in this group; some precautions with topical and systemic drugs are described below.

With topical agents, cautious use is recommended. Infants, and perhaps older children, have more permeable skin and are more likely to absorb topical drugs than adults. In addition, absorption is increased in the presence of broken or dam-

aged skin. With topical corticosteroids, which are often used to treat atopic dermatitis, suppression of the HPA axis (see Chap. 23), Cushing's disease, and intracranial hypertension have been reported in children. Signs of impaired adrenal function may include delayed growth and low plasma cortisol levels. Signs of intracranial hypertension may include headaches and swelling of the optic nerve (papilledema) on ophthalmoscopic examination. The latter may lead to blindness if pressure on the optic nerve is not relieved. Because children are at high risk for development of systemic adverse effects with topical corticosteroids, these drugs should be used only if clearly indicated, in the smallest effective dose, for the shortest effective time, and usually without occlusive dressings. In addition, a low-potency agent should be used initially in infants and in intertriginous areas of older children. If a more potent drug is required for severe dermatitis, the child should be examined often and the strength of the drug reduced as skin lesions improve.

With systemic drugs, an oral antibiotic is often needed to treat skin and skin structure infections. Most of these infections are caused by *Staphylococcus aureus* and *Streptococcus pyogenes*. However, the prevalence of infections caused by methicillin-resistant *S. aureus* continues to increase, and the choice of drug should be based on culture and sensitivity tests. In areas with high resistance rates, the commonly prescribed

cephalosporin antibiotics may not be effective. Further, if an oral retinoid (e.g., isotretinoin) is prescribed for adolescent females with severe acne, all precautions regarding negative pregnancy tests and thorough counseling must be followed.

### Use in Older Adults

Older adults often have thin, dry skin and are at risk of pressure ulcers if mobility, nutrition, or elimination is impaired. Principles of topical drug therapy are generally the same as for younger adults. In addition, topical corticosteroids should be used with caution on thinned or atrophic skin.

### Use in Home Care

Skin disorders are commonly treated at home by patients or caregivers. When a home care nurse is involved, responsibilities may include assessing patients, other members of the household, and the home environment for risks of skin disorders; teaching preventive or treatment measures; assisting with treatment; and assessing response to treatment.

### Applying Your Knowledge 64-4

Ginger's rash has spread to her face. As a teenager, she thinks it looks horrible. What would be an appropriate nursing diagnosis?

## Nursing Actions Dermatologic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Use the correct preparation for the intended use (i.e., dermatologic, otic, vaginal, anorectal)
- b. For topical application to skin lesions:
  - (1) Wash the skin, and pat it dry.
  - (2) Apply a small amount of the drug preparation, and rub it in well.
  - (3) For burn wounds, broken skin, or open lesions, apply the drug with sterile gloves or sterile cotton-tipped applicators.
  - (4) Use the drug only for the individual patient.
  - (5) Wash hands before and after application.

#### 2. Observe for therapeutic effects

- a. With dermatologic conditions, observe for healing of skin lesions.
- b. With external otitis, observe for decreased pain and pruritus.
- c. With vaginal disorders, observe for decreased vaginal discharge and pruritus.
- d. With anorectal disorders, observe for decreased pain and pruritus.

### RATIONALE/EXPLANATION

Preparations may differ in drug contents and concentrations.

To cleanse the skin and remove previously applied medication. This facilitates drug contact with the affected area of the skin.

A thin layer of medication is effective and decreases the incidence and severity of adverse effects.

To prevent infection

To avoid bacterial cross-contamination between patients Wash hands before to avoid exposing the patient to infection; wash hands afterward to avoid transferring the drug to your own face or eyes and causing adverse reactions.

Therapeutic effects depend on the medication being used and the disorder being treated.

With acne and rosacea, improvement may require 6-12 weeks of therapy.

## Nursing Actions Dermatologic Drugs (continued)

### NURSING ACTIONS

#### 3. Observe for adverse effects

- a. Local irritation or inflammation—burning on application, erythema, skin rash, pruritus
- b. With topical corticosteroids, observe for local and systemic effects.
  - (1) Local effects include skin atrophy, striae, telangiectasia, hypopigmentation, rosacea, dermatitis, acne, and allergic and irritant reactions.
  - (2) Systemic effects include suppression of adrenal function, hypertension, hyperglycemia, muscle weakness, osteoporosis, cataracts, glaucoma, and growth retardation in children.
- c. With topical antibiotics, superinfection and sensitization may occur.
- d. With oral retinoids, observe for hypervitaminosis A (nausea, vomiting, headache, blurred vision, eye irritation, conjunctivitis, skin disorders, abnormal liver function, musculoskeletal pain, increased plasma triglycerides, depression, and suicidal ideation).

#### 4. Observe for drug interactions

### RATIONALE/EXPLANATION

Incidence of adverse effects is low with topical agents. Local effects may occur with most topical agents but may be more likely with antiseptics, local anesthetics, and antimicrobials.

These effects commonly occur with prolonged use, frequent application, and higher-potency drugs. Atrophy or thinning of skin is more likely in the face, groin, and axillae.

Allergic and irritant reactions to preservatives, fragrances, and other ingredients may prevent healing or worsen dermatitis. Systemic effects are more likely with more potent agents (e.g., clobetasol can cause suppression of the hypothalamic-pituitary-adrenal axis with as little as 2 g daily); application over large areas of skin; prolonged use; and the use of occlusive dressings. In addition, children are at higher risk because they may absorb proportionally larger amounts and be more sensitive to systemic toxicity.

Little adrenal suppression is likely to occur with doses less than 50 grams weekly for an adult and 15 grams weekly for a small child, unless occlusive dressings are used.

Superinfection with drug-resistant organisms may occur with any antibacterial agent; diarrhea and pseudomembranous colitis may occur with topical clindamycin. Sensitization may cause serious allergic reactions if the same drug is given systemically at a later time.

Adverse effects commonly occur with usual doses but are more severe with higher doses.

Clinically significant drug interactions rarely occur with topical agents.

## Key Concepts

- Staphylococci and streptococci are the most common bacterial causes of skin infection, and methicillin-resistant *S. aureus* (MRSA) infections are increasing.
- Careful assessment of types and locations of lesions can aid diagnosis and treatment of many skin disorders.
- Topical drugs are used to treat most skin disorders; accurate application is essential to maximize therapeutic effects.
- Special precautions are needed for safe use of topical corticosteroids, especially in children.
- Special precautions are needed for safe use of oral retinoids in female patients of childbearing potential.
- Systemic adverse effects may occur with topical drug therapy; skin disorders may occur with systemic drugs.

## Review and Application Exercises

### Short Answer Exercises

1. What are the main functions of the skin?
2. Describe interventions to promote skin health and integrity.
3. During initial assessment of a patient, what signs and symptoms may indicate common skin disorders?
4. Which patient groups are at risk for development of common skin disorders (e.g., skin infections, pressure ulcers)?

5. Compare topical and systemic corticosteroids in terms of adverse effects.
  6. If an adolescent patient with acne asks your advice about over-the-counter topical drugs, which would you recommend, and why?
  7. List general principles of using topical agents for common skin disorders.
- NCLEX-Style Questions**
8. Neosporin topical ointment has been ordered for a teenaged outpatient being seen for follow-up care for several healing lesions following a bicycle accident. The nurse knows that topical medications are usually applied for what kinds of effects?
    - a. rapid
    - b. slow
    - c. local
    - d. systemic
  9. Systemic absorption of topical medications is greatest in
    - a. damaged skin
    - b. intact skin
    - c. soles of the feet
    - d. skin of the elbows and knees
  10. Your teenaged client is using tretinoin (Retin-A). Which of the following statements indicates that he understands the teaching you have done?
    - a. "I will apply the medication three times daily for 6 weeks."
    - b. "My skin may become red and irritated from the medication."
    - c. "I am excited that my acne should be mostly gone by next week."
    - d. "This medication will increase my tolerance to sunlight."
  11. Over-the-counter benzoyl peroxide is an effective treatment for many cases of
    - a. acne
    - b. psoriasis
    - c. tinea infections
    - d. dermatitis
  12. In general, a licensed health care provider with prescriptive authority should prescribe the use of all topical
    - a. antifungal drugs
    - b. anti-acne drugs
    - c. antibacterial drugs
    - d. high-potency corticosteroids

# Drug Use During Pregnancy and Lactation

## KEY TERMS

- Abortifacients
- Eclampsia
- Fetotoxic
- Organogenesis
- Oxytocic
- Preeclampsia
- Preterm labor
- Prostaglandins
- Teratogenic
- Tocolytics

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss reasons for minimizing drug use during pregnancy and lactation.
2. Describe selected fetotoxic and teratogenic drugs.
3. Discuss guidelines for drug therapy of pregnancy-associated signs and symptoms.
4. Discuss guidelines for drug therapy of selected chronic disorders during pregnancy and lactation.
5. Discuss which immunizations are considered safe for use during pregnancy and which are contraindicated.
6. Teach females of childbearing potential to avoid prescribed and over-the-counter drugs when possible and to inform all health care providers if there is a possibility of pregnancy.
7. Discuss the role of the home care nurse working with the pregnant woman.
8. Discuss drugs used during pregnancy complications and normal labor and delivery in terms of their effects on the mother and newborn infant.
9. Describe abortifacients in terms of characteristics and nursing process implications.

## Applying Your Knowledge

Annie Blevins is a 30-year-old woman who comes to the primary care facility where you work to receive her annual checkup. She was recently married and both she and her husband want to start trying to get pregnant. Before her marriage, Mrs. Blevins took Ortho Tri-Cyclen to prevent pregnancy. She has since discontinued taking the oral contraceptive.

.....

## Introduction

Drug use before and during pregnancy and during lactation requires special consideration and, in general, should be avoided or minimized when possible. In sexually active women of reproductive age and ability who may become pregnant (i.e., are not consistently using effective contraception), the concern is that the woman may ingest drugs that are potentially harmful to the fetus (*fetotoxic*) before she knows she is pregnant. *Organogenesis* (formation of fetal organs) occurs during the first 2 to 8 weeks after conception. During pregnancy, any drugs ingested by the mother may affect the fetus. Drug effects on the fetus are often unknown, especially with newer drugs, and few drugs are considered completely safe. During lactation, many drugs are excreted in breast milk and reach the nursing infant in varying amounts. Some drugs should be avoided during

lactation; some can be continued with precautions to decrease infant exposure.

Despite these concerns, however, many pre-pregnant, pregnant, and lactating women take drugs for various reasons, including acute disorders that may or may not be associated with pregnancy, chronic disorders that require continued treatment during pregnancy or lactation, and habitual use of non-therapeutic drugs (e.g., alcohol, tobacco, others). Many of the drugs in this chapter are described elsewhere; they are discussed here in relation to pregnancy and lactation. Other drugs that are used mainly during pregnancy are discussed in greater detail, including those used to terminate pregnancy (*abortifacients*), drugs used to stop preterm labor (*tocolytics*), and drugs used during labor and delivery.

## Pregnancy

During pregnancy, mother and fetus undergo physiologic changes that influence drug effects. In pregnant women, physiologic changes alter drug pharmacokinetics (Table 65-1). In general, drug effects are less predictable because plasma volume expansion decreases plasma drug concentrations, and increased metabolism by the liver and increased elimination by the kidneys shorten the duration of drug actions and effects.

### Maternal–Placental–Fetal Circulation

Drugs ingested by the pregnant woman reach the fetus through the maternal–placental–fetal circulation, which is completed

about the third week after conception. On the maternal side, arterial blood pressure carries blood and drugs to the placenta. In the placenta, maternal and fetal blood are separated by a few thin layers of tissue, which drugs can readily cross. Placental transfer begins the fifth week after conception. After drugs enter the fetal circulation, relatively large amounts are pharmacologically active because the fetus has low levels of serum albumin and thus low levels of drug binding. Most drug molecules are transported to the liver, where they are metabolized. Metabolism occurs slowly because the fetal liver is immature in quantity and quality of drug-metabolizing enzymes. Drugs metabolized by the fetal liver are excreted by fetal kidneys into amniotic fluid. Excretion also is slow and inefficient due to immature development of fetal kidneys. Other drug molecules are transported directly to the heart, which then distributes them to the brain and coronary arteries. Drugs enter the brain easily because the blood–brain barrier is poorly developed in the fetus. Approximately half of the drug-containing blood is then transported through the umbilical arteries to the placenta, where it re-enters the maternal circulation. Thus, the mother can metabolize and excrete some drug molecules for the fetus.

### Drug Effects on the Fetus

Drug effects are determined mainly by the type and amount of drugs, the duration of exposure, and the level of fetal growth and development when exposed to the drugs. The fetus is sensitive to drug effects because it is small, has few plasma

**Table 65-1**

**Pregnancy: Physiologic and Pharmacokinetic Changes**

PHYSIOLOGIC CHANGE	PHARMACOKINETIC CHANGE
Increased plasma volume and body water, approximately 50% in a normal pregnancy Increased cardiac output (30%–50%) and increased blood flow to the uterus, kidneys, skin, and breasts	After it is absorbed into the bloodstream, a drug (especially if water soluble) is distributed and “diluted” more than in the nonpregnant state. Drug dosage requirements may increase. However, this effect may be offset by other pharmacokinetic changes of pregnancy.
Increased weight (average 25 lb) and body fat	Drugs (especially fat-soluble ones) are distributed more widely. Drugs that are distributed to fatty tissues stay in the body longer because they are slowly released from storage sites into the bloodstream.
Decreased serum albumin. The rate of albumin production is increased. However, serum levels fall because of plasma volume expansion. Also, many plasma-protein binding sites are occupied by hormones and other endogenous substances that increase during pregnancy.	The decreased capacity for drug binding leaves more free drug available for therapeutic or adverse effects on the mother and for placental transfer to the fetus. Thus, a given dose of a drug may produce greater effects than it would in the nonpregnant state.
During most of a pregnancy, increased renal blood flow and glomerular filtration rate secondary to increased cardiac output In late pregnancy, renal blood flow may decrease when the woman assumes a supine position, secondary to the increased size and weight of the uterus.	Increased excretion of drugs by the kidneys, especially those excreted primarily unchanged in the urine (e.g., lithium, penicillins) Decreased renal blood flow may result in delayed excretion and prolonged effects of renally excreted drugs.
Increased hormones (e.g., estrogen, progesterone) induce drug-metabolizing enzymes in the liver.	Increased metabolism and clearance of many drugs

proteins that can bind drug molecules, and has a weak capacity for metabolizing and excreting drugs. In addition, the fetus is exposed to any drugs circulating in maternal blood. When drugs are taken on a regular schedule, fetal blood usually contains 50% to 100% of the amount in maternal blood. This means that *any drug that stimulates or depresses the central nervous, cardiovascular, respiratory, or other body system in the mother has the potential to stimulate or depress those systems in the fetus.* In some cases, fetotoxicity occurs.

A major concern about drug effects on the fetus is teratogenicity (anatomic malformations or birth defects). Drug-induced teratogenicity is most likely to occur when drugs are taken during the first trimester of pregnancy (Fig. 65-1). For drugs taken during the second and third trimesters, adverse effects are usually manifested in the neonate (birth to 1 month) or infant (1 month to 1 year) as growth retardation, respiratory problems, infection, or bleeding. It should be emphasized, however, that *drugs taken at any time during pregnancy can affect the baby's brain because brain development continues throughout pregnancy and after birth.*

The incidence of drug-induced teratogenicity is unknown. The U.S. Food and Drug Administration (FDA) requires manufacturers to assign a pregnancy risk category to new drugs to indicate their potential for causing birth defects (Box 65-1). Relatively few therapeutic drugs are considered fetotoxic or *teratogenic* (Box 65-2), and these can usually be avoided during pregnancy. In contrast, nontherapeutic drugs (e.g., alcohol, cocaine, heroin, marijuana, methamphetamine,

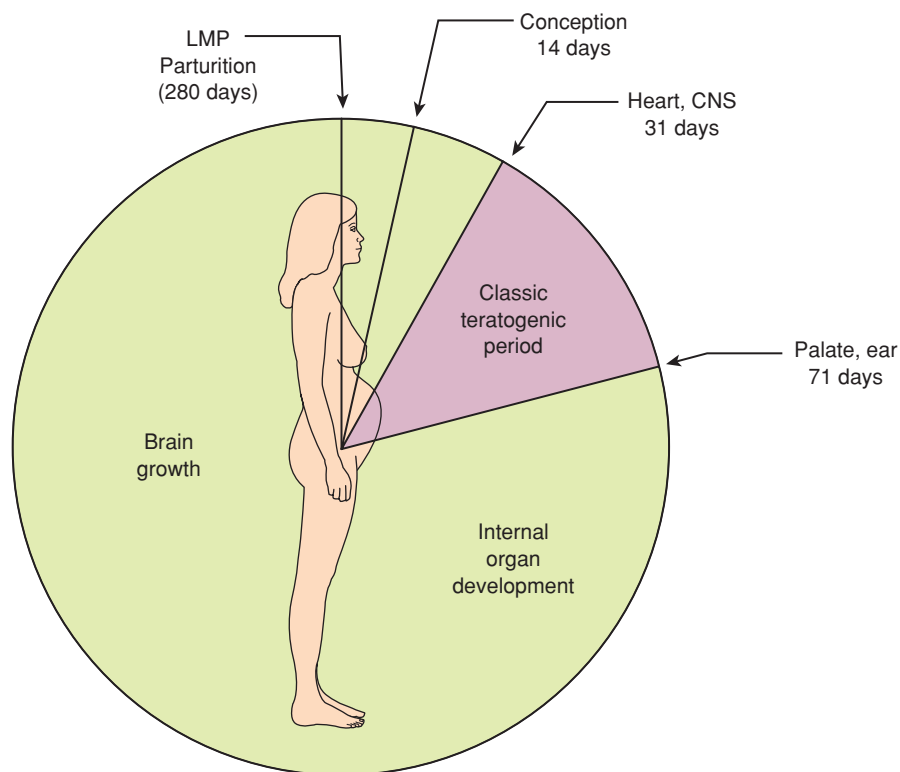

nicotine) are fetotoxic or teratogenic and should be avoided during pregnancy. Caffeine has not been associated with birth defects, but high amounts (more than 400 mg/day) have been associated with preterm births and other complications of pregnancy and should also be avoided.

## Fetal Therapeutics

Although the major concern about drugs ingested during pregnancy is adverse effects on the fetus, a few drugs are given to the mother for therapeutic effects on the fetus. These include digoxin for fetal tachycardia or heart failure, levothyroxine for hypothyroidism, penicillin for exposure to maternal syphilis, and prenatal corticosteroids to promote surfactant production to improve lung function and decrease respiratory distress syndrome in preterm infants.

## Maternal Therapeutics

Thus far, the main emphasis on drug use during pregnancy has related to actual or potential adverse effects on the fetus. Despite the general principle that drug use should be avoided when possible, pregnant women may require drug therapy for various illnesses, increased nutritional needs, pregnancy-associated problems, chronic disease processes, treatment of preterm labor, induction of labor, and pain management during labor.

**Figure 65-1** ■ The gestational clock showing the classic teratogenic risk assessment. (Adapted from Niebyl, J. [1999]. *Drugs and related areas in pregnancy*. In J. Sciarra [Ed.], *Obstetrics and gynecology*. Philadelphia: Lippincott Williams & Wilkins.)

## Box 65-1

## FDA Pregnancy Categories

- A. Adequate studies in pregnant women demonstrate no risk to the fetus.
- B. Animal studies indicate no risk to the fetus, but there are no adequate studies in pregnant women, or animal studies show adverse effects, but adequate studies in pregnant women have not demonstrated a risk.
- C. Risk is unknown and cannot be ruled out. Animal studies demonstrate fetotoxicity, but the drugs have not been adequately studied in humans. However, potential benefits may justify the potential risks.
- D. Positive evidence of harm to human fetuses. If needed in a life-threatening situation or a serious disease, the drug may be acceptable if safer drugs cannot be used or are ineffective.
- X. Contraindicated in pregnancy. Studies in animals or humans, or postmarketing adverse reaction reports, or both, have demonstrated fetal abnormalities. The risk of use in a pregnant woman clearly outweighs potential benefit.

## Herbal and Dietary Supplements

Pregnancy increases nutritional needs, and vitamin and mineral supplements are commonly used. **Folic acid** supplementation is especially important to prevent neural-tube birth defects (e.g., spina bifida). Such defects occur early in pregnancy, often before the woman realizes she is pregnant. For this reason, it is recommended that all women of childbearing potential ingest 400 or 600 micrograms of folic acid daily from food and/or a supplement. In addition, pregnancy increases folic acid requirements and deficiencies are common. A supplement is usually needed to supply adequate amounts.

**Herbal** supplements are not recommended during pregnancy. **Ginger** has been used to relieve nausea and vomiting during pregnancy, with a few studies supporting its use. Overall, it has not been proven effective but is probably safe for use.

## Pregnancy-Associated Symptoms and Their Management

### Anemias

Three types of anemia are common during pregnancy. One is physiologic anemia (often defined as a hemoglobin below 10 g/dL or hematocrit below 30%), which results from

## Box 65-2

## Selected Drugs That Are Fetotoxic or Teratogenic

### Risk Category D

- \*Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril and others)
- \*Angiotensin II receptor blockers (ARBs; e.g., losartan and others)
- Antibacterials (aminoglycosides, tetracyclines, tigecycline, trimethoprim in third trimester)
- Antidepressants (imipramine, nortriptyline, paroxetine)
- Antiepileptics (carbamazepine, phenytoin, valproic acid)
- Antifungals (voriconazole)
- Antimanic agent (lithium)
- Antineoplastics (ibritumab, idarubicin, ifosfamide, imatinib, irinotecan)
- Antithyroid agents (e.g., propylthiouracil)
- Antivirals (efavirenz)
- Benzodiazepine anti-anxiety agents (e.g., alprazolam, diazepam, lorazepam)
- Beta blockers (atenolol; acebutolol, betaxolol, esmolol, metoprolol, propranolol, timolol, second and third trimesters, by experts, category B or C by manufacturer)
- Bisphosphonates (pamidronate, zoledronic acid)
- Diuretic (hydrochlorothiazide, by expert, category B by manufacturer)
- Nicotine replacement products (oral inhaler, nasal spray, transdermal patch)
- Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen; during third trimester)
- Opioid analgesics (with prolonged use or high doses at term)

### Risk Category X

- Anticoagulant (warfarin)
- Antineoplastics (e.g., cyclophosphamide, methotrexate)
- Antirheumatoid arthritis drug (leflunomide)
- Antiviral (ribavirin)
- Benzodiazepine sedative/hypnotics (e.g., flurazepam)
- Female sex hormones (estrogens, progestins, oral contraceptives)
- Male sex hormones (androgens, anabolic steroids)
- Nicotine replacement product, chewing gum
- Retinoids (e.g., acitretin, isotretinoin, and several topical preparations)
- Statin cholesterol-lowering drugs (e.g., atorvastatin, others)

*\*ACE inhibitors and ARBs were formerly considered category C during the first trimester and category D during the second and third trimesters. Recent evidence indicates that the drugs are fetotoxic if taken at any time during pregnancy.*

*Sources: Drug Facts and Comparisons; Drug Information Handbook.*

expanded blood volume. A second is iron-deficiency anemia, which is often related to long-term nutritional deficiencies. A third type is folic acid-deficiency anemia. The recommended daily intake of folic acid doubles during pregnancy, from 400 to 800 micrograms, and a folic acid supplement is often prescribed.

For many years, it was considered “best practice” to routinely prescribe daily iron supplements for pregnant women to prevent or treat iron-deficiency anemia. More recently, studies indicate that use of the supplements in women who are not anemic may lead to excessive levels of hemoglobin, iron overload, and hypertension in the mother and premature birth or low birth weight (for gestational age) in the infant.

### Constipation

Constipation often occurs during pregnancy, probably from decreased peristalsis. Preferred treatment, if effective, is to increase exercise and intake of fluids and high-fiber foods. If a laxative is required, a bulk-producing agent (e.g., Metamucil) is the most physiologic for the mother and safest for the fetus because it is not absorbed systemically. A stool softener (e.g., docusate) or an occasional saline laxative (e.g., milk of magnesia) may also be used. Mineral oil should be avoided because it interferes with absorption of fat-soluble vitamins. Reduced absorption of vitamin K can lead to bleeding in newborns. Castor oil, all strong laxatives, and excessive amounts of any laxative should be avoided because they can cause uterine contractions and initiate labor.

### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD), of which heartburn (pyrosis) is the main symptom, occurs in one third or more of pregnant women. Hormonal changes relax the lower esophageal sphincter, and the growing fetus increases abdominal pressure. These developments allow gastric acid to splash into the esophagus and cause discomfort and esophagitis. In addition, GERD may trigger asthma attacks in pregnant women with asthma.

Nonpharmacologic interventions include eating small meals; not eating for 2 to 3 hours before bedtime; avoiding caffeine, gas-producing foods, and constipation; and sitting in an upright position. For patients who do not obtain adequate relief with these measures, drug therapy may be needed. Antacids may be used if necessary. Because little systemic absorption occurs, the drugs are unlikely to harm the fetus if used in recommended doses. A histamine<sub>2</sub> (H<sub>2</sub>) receptor antagonist such as ranitidine (Zantac) may also be used. Proton pump inhibitors such as esomeprazole (Nexium) are thought to be safe, but some clinicians reserve them for patients for whom H<sub>2</sub> blockers are ineffective.

### Gestational Diabetes

Gestational diabetes is glucose intolerance first found during pregnancy. Women with risk factors (e.g., obesity; age older than 35 years; family history of diabetes; being Hispanic, Native American, Asian, or African American; previous pregnancy with stillbirth, spontaneous abortion, fetal anomalies, or large baby) should be screened at the first prenatal visit. Most women without risk factors, or whose initial test was normal, should be tested between 24 and 28 weeks of gestation. The criterion for a diagnosis of diabetes is a fasting plasma glucose level of more than 126 milligrams per deciliter or a nonfasting glucose level of more than 200 milligrams per

deciliter. Women with gestational diabetes are at higher risk for complications of pregnancy.

The goal of treatment is to keep blood glucose levels as nearly normal as possible because even mild hyperglycemia is detrimental to the fetus. Initial management includes diet, moderate exercise, and frequent self-monitoring of blood glucose levels. For women who are obese, mild calorie restriction may be indicated (severe calorie restriction is harmful to the developing fetus and should be avoided). If these interventions are inadequate, drug therapy may be needed. Insulin is usually the drug of choice for treatment of diabetes during pregnancy because it does not cross the placenta and has a long history of safe usage. Oral antidiabetic drugs have generally been contraindicated. However, several studies indicate that glyburide is safe to use and acarbose, metformin, and miglitol seem to cause minimal fetal risk.

When the pregnancy ends, blood glucose levels usually return to a normal range within a few weeks. However, two thirds of these women will have gestational diabetes in subsequent pregnancies and up to half will develop overt diabetes within 15 years.

### Nausea and Vomiting

Nausea and vomiting often occur, especially during early pregnancy. Dietary management (e.g., eating small, frequent meals, limiting or avoiding high fat and high fiber foods) is recommended. Antiemetic drugs should be given only if nausea and vomiting are severe enough to threaten the mother's nutritional or metabolic status. No antiemetic medications are FDA-approved for use during pregnancy, although some have been used without apparent teratogenic effects.

### Pregnancy-Induced Hypertension

Pregnancy-induced hypertension includes preeclampsia and eclampsia, conditions that endanger the lives of mother and fetus. *Preeclampsia* is manifested by hypertension and proteinuria (blood pressure with systolic above 140 mm Hg or diastolic above 90 mm Hg and proteinuria above 300 mg in 24 hours). It may occur after 20 weeks of gestation and up to 6 weeks postpartum.

Preeclampsia most often occurs during a first pregnancy, but it may occur in women with chronic hypertension, diabetes mellitus, or multiple fetuses. Some women can be observed on an outpatient basis, with frequent monitoring of mother and fetus. Women who are noncompliant with follow-up care or who have severe preeclampsia should be hospitalized. Drug therapy for severe preeclampsia includes intravenous hydralazine or labetalol (see Chap. 52) for blood pressure control, and magnesium sulfate (see Chap. 57 and “Tocolytics,” below) for prevention or treatment of seizures. Drug therapy reduces perinatal deaths and severe maternal hypertension. If not effectively treated, preeclampsia may progress to *eclampsia*, which is characterized by potentially fatal seizures. The only cure is delivery of the baby; cesarean section is needed in some cases.

## Selected Infections

Group B streptococcal infections may affect the pregnant woman and the neonate. Women colonized with group B streptococci (estimated at 10%–30% of pregnant women) have increased risks of adverse fetal outcomes (e.g., transmitting the bacteria to the infant during delivery, resulting in potential bacteremia, meningitis, or pneumonia) and maternal outcomes (urinary tract infection, preterm delivery, postpartum endometritis). Because of the potentially serious consequences of infection with group B streptococci, pregnant women should have a vaginal culture performed at 35 to 37 weeks of gestation. A positive culture indicates infection that should be treated. In addition, an IV antibiotic that is effective against group B streptococci should be started at the onset of labor or with rupture of membranes and continued until delivery.

Human immunodeficiency virus (HIV) infection in pregnant women requires antiretroviral drug therapy for the mother and to prevent transmission to the infant. In general, highly active antiretroviral therapy (HAART) is recommended as for nonpregnant women. The goal of treatment is to achieve an HIV plasma RNA load of less than 400 copies per milliliter.

For young children, almost all HIV infections are transmitted perinatally, either in utero, during labor and delivery, or in breast milk. Antiretroviral drug therapy for the pregnant woman reduces perinatal transmission by about two thirds. During labor, IV zidovudine is given until delivery. After delivery, the infant should be given zidovudine for 6 weeks, with or without other antiretroviral drugs.

Children with HIV infection have failure to thrive, central nervous system abnormalities, and developmental delays as major manifestations. *Pneumocystis jiroveci* pneumonia (PCP) is an opportunistic infection that may occur in infants, most often between 3 and 6 months of age, and is a major cause of early mortality in HIV-infected children. Trimethoprim-sulfamethoxazole (TMP-SMZ; Bactrim) is recommended for prophylaxis and should be started by 4 to 6 weeks of age for all infants born to HIV-infected mothers. Because of the potentially serious consequences for infants born to HIV-infected mothers, it is recommended that all pregnant women be tested for HIV infection.

Urinary tract infections (UTIs) commonly occur during pregnancy and may include asymptomatic bacteriuria, cystitis, and pyelonephritis. Asymptomatic bacteriuria should be treated in pregnant women because of its association with cystitis and pyelonephritis. If untreated, symptomatic cystitis occurs in approximately 30% of pregnant women. Asymptomatic bacteriuria and UTIs are also associated with increased preterm deliveries and low birth weights. Hospitalization and IV antibiotics may be needed for management of pyelonephritis.

.....

## Management of Chronic Diseases During Pregnancy

### Asthma

Asthma is one of the most common, potentially serious medical conditions to complicate pregnancy. It is associated with increased risk of infant death, preeclampsia, preterm birth, low birth weight, and congenital malformations. These risks are higher with severe asthma and lower with well-controlled asthma. Asthma attacks, which are usually accompanied by hypoxia, hypocapnia, and alkalemia, should be treated promptly, with hospitalization if indicated. Respiratory infections are common triggers for acute asthma exacerbations.

Because asthma is unpredictable during pregnancy (i.e., symptoms may improve, worsen, or stay about the same), all women with asthma should be monitored closely when pregnant and treated when indicated. Some women with asthma do not require drug therapy during pregnancy. For those who need drug therapy, treatment is considered safer for the fetus than poor asthma control. In general, drug therapy during pregnancy is similar to that in nonpregnant women. Commonly used drugs include orally inhaled beta<sub>2</sub> agonists (e.g., albuterol), inhaled cromolyn, and inhaled and systemic corticosteroids (e.g., budesonide, beclomethasone, prednisone). The regular use of inhaled corticosteroids decreases the number of asthma exacerbations during pregnancy, and systemic corticosteroids are used for severe exacerbations. Women taking an oral corticosteroid near term require “stress doses” at the time of delivery. Oral theophylline may also be used. Serum theophylline levels should be monitored, and values of 5 to 12 micrograms per milliliter are recommended during pregnancy.

The National Asthma Education and Prevention Program (NAEPP) publishes recommendations for drug therapy and other aspects of managing asthma during pregnancy. These recommendations, which were updated in 2007 and continued previous drug therapy guidelines, are summarized in Box 65-3.

Antiasthma drug therapy is continued during lactation for mothers breast-feeding their baby. The amount of medication reaching the infant through breast milk is less than the amount received in utero through the placenta.

### Diabetes Mellitus

Diabetes increases the risks of pregnancy for both mother and fetus, and the hormonal changes of pregnancy have diabetogenic effects that may cause or aggravate diabetes. Maternal risks include retinopathy, preeclampsia, and pyelonephritis; fetal risks include congenital malformations and perinatal death. Because diabetic retinopathy progresses in many pregnant women, patients should be examined by an ophthalmologist each trimester.

The goal of treatment is to maintain a near-normal blood glucose level, because even mild hyperglycemia may be harmful to the fetus. In general, pregnancy makes diabetes more

## Box 65-3

## National Asthma Education and Prevention Program (NAEPP) Expert Panel Report: Managing Asthma During Pregnancy: Recommendations for Pharmacologic Treatment—2007 Update

## General Recommendations

- Controlling asthma during pregnancy is important because poorly controlled asthma can lead to serious medical problems for pregnant women and their fetus(es).
- Because asthma severity changes during pregnancy for most women, pregnant patients with persistent asthma should have their asthma checked at least monthly by a health care provider (e.g., clinicians providing obstetric care should monitor asthma severity during each prenatal visit).
- Assist patients to identify and avoid or limit exposure to triggers that precipitate or worsen acute asthma symptoms (e.g., tobacco smoke, allergens such as dust mites).
- Women with other conditions that can worsen asthma (e.g., allergic rhinitis, sinusitis, gastroesophageal reflux) should have those conditions treated as well.

## Drug Therapy Recommendations

- Evidence indicates that it is safer to take medications than to have asthma exacerbations.
- A stepwise approach to asthma care similar to that used in the NAEPP general asthma treatment guidelines for children and nonpregnant adults is recommended (see Chap. 44). Under this approach, medication is stepped up in intensity if needed and stepped down when possible, depending on asthma severity.
- For quick relief of acute asthma symptoms, albuterol, a short-acting, inhaled beta<sub>2</sub> agonist, should be used, and

pregnant women with asthma should have this medication available at all times.

- For treatment of persistent asthma (e.g., women who have symptoms at least 2 days a week or 2 nights a month), asthma medication is needed daily to prevent exacerbations. Inhaled corticosteroids are preferred to control the underlying inflammation. Budesonide (Pulmicort) is often used because there are more data on its safety during pregnancy than for other inhaled corticosteroids. However, there are no data indicating that other inhaled corticosteroids are unsafe during pregnancy, and other inhaled corticosteroids may be continued if they effectively control a patient's asthma. Alternative daily medications are leukotriene receptor antagonists such as montelukast (Singulair) or zafirlukast (Accolate), cromolyn (Intal), or theophylline.
- For patients whose persistent asthma is not well controlled on low doses of inhaled corticosteroids alone, the guidelines recommend either increasing the dose of inhaled corticosteroid or adding another medication (e.g., a long-acting beta agonist such as salmeterol [Serevent]).
- Oral corticosteroids may be required for the treatment of severe asthma. The guidelines note that there are conflicting data regarding the safety of oral corticosteroids during pregnancy. However, severe, uncontrolled asthma poses a definite risk to the mother and fetus and use of oral corticosteroids may be warranted.

difficult to manage effectively. Some women who were previously able to control diabetes with diet may require insulin during pregnancy. Women who already take insulin usually need larger doses as pregnancy advances. Recommendations for management include the following:

- For a planned pregnancy, women with diabetes can have a better outcome if they can maintain normal or near-normal blood glucose levels and normal glycosylated hemoglobin (A<sub>1c</sub>) levels for at least 2 months prior to conception. Previously, it was recommended that women taking oral antidiabetic drugs should be switched to insulin prior to pregnancy. Although insulin is still the drug of choice during pregnancy, several studies indicate that oral glyburide is safe and effective. In addition, acarbose, miglitol, and metformin are thought to have little risk for the fetus.
- Tight blood glucose control is needed throughout pregnancy. It is especially important early in the first trimester, when fetal organs are being formed, because poor glycemic control increases the risks of birth defects. The usual goals for tight glucose control are fasting and preprandial capillary blood glucose levels of approximately 65 mg/dL (equivalent to a plasma concentration of 75 mg/dL) and 1-hour

postprandial levels of less than 120 mg/dL (plasma value less than 140 mg/dL). During this time, it is recommended that women monitor their blood glucose levels at least daily and sometimes more often.

- Insulin is the antidiabetic drug of choice during pregnancy. Human insulin should be used because it is least likely to cause an allergic response. Because insulin requirements vary according to the stage of pregnancy, the diabetic patient's blood glucose levels must be monitored closely and insulin therapy individualized. It is especially important that sufficient insulin is given to prevent maternal acidosis. Uncontrolled acidosis is likely to interfere with neurologic development of the fetus. Careful dietary control and other treatment measures are also necessary throughout pregnancy.
- Insulin requirements usually decrease during the first trimester and increase during the second and third trimesters. During the ninth month, insulin needs are approximately 50% greater than at preconception and the increase is greater among women with type 2 diabetes. Obese women with type 2 diabetes may need much higher insulin doses because of the additional insulin resistance of pregnancy.

- During labor and delivery, short-acting insulin and frequent blood glucose tests are used to control diabetes, as during other acute situations.
- During the postpartum period, insulin requirements fluctuate because stress, trauma, infection, surgery, or other factors associated with delivery tend to increase blood glucose levels and insulin requirements. At the same time, termination of the pregnancy reverses the diabetogenic hormonal changes and decreases insulin requirements. Short-acting insulin is given, and dosage is based on frequent measurements of blood glucose. After the insulin requirement is stabilized, the patient may be able to return to the pre-pregnancy treatment program.

### Epilepsy

Although antiepileptic drugs (AEDs) are generally considered fetotoxic or teratogenic, they must often be taken during pregnancy because seizures may also be harmful to mother and fetus. Fortunately, most pregnancies (more than 90%) result in normal infants. Despite the usually good outcomes, women with epilepsy have higher risks of preeclampsia, preterm labor, and stillborn births. In addition, the incidence of birth defects is two to three times higher in fetuses exposed to AEDs than in those not exposed. If an AED is required, one drug (monotherapy) should be used because the rate of major birth defects (e.g., cardiac defects, neural tube defects) in infants exposed to one AED is higher than those not exposed and even higher in infants exposed to two or more AEDs. The lowest dose that controls seizures is also recommended. Infants whose mothers took AEDs for bipolar disorder rather than for epilepsy also have higher rates of birth defects. The effects of newer AEDs during pregnancy are largely unknown.

Plasma drug levels should be checked monthly during pregnancy. Approximately one third of women with epilepsy have an increased number of seizures during pregnancy. This is attributed to physiologic changes of pregnancy (e.g., increased blood volume) that lower plasma levels of AEDs.

Women with epilepsy should take a folic acid supplement (at least 400 mcg daily) all the time and 800 micrograms or more during pregnancy to prevent or reduce neural tube defects (e.g., spina bifida). Supplemental vitamin K (e.g., 10 mg/day) is also recommended during the last month of pregnancy to prevent bleeding in neonates. AEDs are associated with a neonatal bleeding disorder characterized by decreased levels of vitamin K–dependent clotting factors. The prenatal vitamin K supplement is in addition to the injection of vitamin K usually given to all neonates immediately after birth.

### Hypertension

Chronic hypertension is defined as blood pressure above 140/90 mm Hg that begins before conception or in the first 20 weeks of pregnancy and persists after delivery. Hypertension that is initially diagnosed during pregnancy and does not resolve after pregnancy also is classified as chronic. Whenever it occurs, chronic hypertension is associated with increased maternal and fetal risks (e.g., preeclampsia, abruptio placentae,

intrauterine growth restriction, preterm delivery, perinatal death). In women with chronic hypertension, blood pressure often decreases during the first and second trimesters and increases during the third trimester.

Management of chronic hypertension during pregnancy consists of nonpharmacologic and pharmacologic therapies. Nonpharmacologic interventions (e.g., avoiding excessive weight gain, sodium restriction, increased rest) should be emphasized. If drug therapy is required, methyldopa has not been associated with adverse effects on the fetus or neonate. Beta blockers and calcium channel blockers may also be used. With beta blockers, fetal and neonatal bradycardia, hypotension, hypoglycemia, and respiratory depression have been reported. As a result, some authorities recommend avoiding the drugs during the first trimester and stopping them 2 to 3 days before delivery. *Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs), which are commonly used in other populations, are contraindicated during pregnancy.*

## Drugs That Alter Uterine Motility

### Abortifacients

Abortion is the termination of pregnancy before 20 weeks. It may occur spontaneously or be intentionally induced. Medical abortion may be induced by prostaglandins and an antiprogesterin (Table 65-2). *Prostaglandins* may be used to terminate pregnancy during the second trimester. In the female reproductive system, prostaglandins E and F are found in the ovaries, myometrium, and menstrual fluid. They stimulate uterine contraction and probably help initiate and maintain the normal birth process. Drug preparations of prostaglandins are capable of inducing labor at any time during pregnancy. **Misoprostol** (Cytotec), a prostaglandin developed to prevent gastric ulcers associated with nonsteroidal anti-inflammatory drugs (NSAIDs) (see Chap. 59), is being given orally or intravaginally for first- or second-trimester termination. It is not FDA approved for this use.

### Tocolytics

Drugs given to inhibit labor and maintain the pregnancy are called tocolytics. Uterine contractions with cervical changes before 37 weeks of gestation are considered *preterm labor*. Preterm labor may occur spontaneously or be precipitated by premature rupture of membranes or other factors. Drug therapy is most effective when the cervix is minimally dilated and membranes are intact. Tocolytic drugs do not reduce the number of preterm births, but they may prolong pregnancy from 2 to 7 days. The goal of tocolytic treatment is to postpone birth long enough to reduce problems associated with prematurity (e.g., respiratory distress, bleeding in the brain, infant death). For example, the delay may allow antenatal administration of a corticosteroid (e.g., betamethasone) to the mother to

Table 65-2

## Drugs at a Glance: Abortifacients, Prostaglandins, Tocolytics, and Oxytocics

GENERIC/TRADE NAME	ROUTES AND DOSAGE RANGES
<b>Prostaglandins</b>	
<b>Carboprost</b> tromethamine (Hemabate)	IM 250 mcg q1.5–3.5h, depending on uterine response, up to 48 hours. Maximum total dose, 12 mg.
<b>Dinoprostone</b> (Prostin E <sub>2</sub> vaginal suppository)	Intravaginally 20 mg, repeated q3–5h until abortion occurs. Maximum dose, 240 mg.
<b>Misoprostol</b> (Cytotec)	PO 200–400 mcg q12h; termination usually complete within 48 h Intravaginally 25 mcg (1/4 of a 100-mcg tablet) q3–6h
<b>Tocolytics</b>	
<b>Magnesium sulfate</b>	IV infusion, loading dose 3–4 g mixed in 5% dextrose injection and administered over 15–20 min Maintenance dose 1–2 g/h, according to serum magnesium levels and deep-tendon reflexes PO 250–450 mg q3h, to maintain a serum level of 2.0–2.5 mEq/L
<b>Nifedipine</b> (Procardia)	PO 10 mg every 20 min for 3 or 4 doses; maximum dose 40 mg in 1 h; then 10–20 mg q4–6h
<b>Terbutaline</b> (Brethine)	IV infusion 10 mcg/min, titrated up to a maximum dose of 80 mcg/min until contractions cease PO 2.5 mg q4–6h as maintenance therapy
<b>Oxytocic</b>	
Oxytocin (Pitocin)	During labor and delivery, IV by infusion pump, 2 milli units/min, gradually increased to 10 milli units/min, if necessary, to produce 3 or 4 contractions within 10-min periods. Prepare a solution of 10 mU/mL by adding 10 units (1 mL) of oxytocin to 1000 mL of 0.9% sodium chloride. To control postpartum hemorrhage, IV 10–40 units added to 1000 mL of 0.9% sodium chloride, infused at a rate to control bleeding To prevent postpartum bleeding, IM 3–10 units (0.3–1 mL) as a single dose

improve pulmonary maturity and function in the infant when it is born. In addition, the mother may need to be transported to a facility equipped to deal with high-risk deliveries. Magnesium sulfate, nifedipine, some NSAIDs, and terbutaline are used as tocolytics. They are described below and in Table 65-2.

**Magnesium sulfate** has long been given IV as a first-line agent. However, studies indicate that the drug is ineffective as a tocolytic, and some clinicians recommend stopping usage for this purpose. In addition, if used, the drug requires special precautions for administration and monitoring because of potentially severe adverse effects. Safety measures include a unit protocol that standardizes drug concentration, flow rate, type of infusion pump, and frequency and type of assessment data to be documented (e.g., serum magnesium levels, respiratory status, reflexes, uterine activity, urine output). The antidote, calcium gluconate, should be readily available for use if hypermagnesemia occurs.

These safety measures are needed because hypotension, muscle paralysis, respiratory depression, and cardiac arrest can occur with overdoses of magnesium sulfate. Close monitoring of serum levels and signs of hypermagnesemia is required. In addition, infants born to mothers who recently received magnesium sulfate should be assessed for hypermagnesemia and respiratory depression.

**Nifedipine** is a calcium channel blocking drug that decreases uterine contractions. Its use is associated with fewer adverse effects than magnesium sulfate or terbutaline. However, a common adverse effect is maternal hypotension, which may reduce blood flow between the placenta and the uterus.

NSAIDs, such as **indomethacin**, inhibit uterine prostaglandins that help to initiate the uterine contractions of normal labor. Maternal adverse effects include nausea, heartburn, dizziness, and GI bleeding. In addition, a few instances of serious neonatal complications, including patent ductus arteriosus, have been reported.

**Terbutaline** is a beta-adrenergic agent that inhibits uterine contractions by reducing intracellular calcium levels. Adverse effects may include hyperkalemia, hyperglycemia, cardiac dysrhythmias, hypotension, and pulmonary edema.

## Drugs Used During Labor and Delivery at Term

At the end of gestation, labor usually begins spontaneously and proceeds through delivery of the neonate. If labor does not occur spontaneously, it may be induced by a drug that stimulates uterine contraction. Drugs often used during labor, deliv-

ery, and the immediate postpartum period include an oxytocic, analgesics, and anesthetics.

## Labor Induction

Prostaglandin preparations (e.g., Prepidil or Cervidil formulations of **dinoprostone**) may be administered to promote cervical ripening (i.e., the cervix becomes softer and thinner, to facilitate labor) or induce labor at or near full-term gestation. Prostaglandins  $F_{2\alpha}$  and  $E_2$  stimulate uterine contractions by increasing intracellular calcium concentrations and activating the actin–myosin contractile units of uterine muscle. About 13% of pregnancies end in labor induction. Reasons for induction include gestation longer than 42 weeks, suspected fetal growth retardation, maternal hypertension, and premature rupture of membranes.

## Oxytocics

The most commonly used *oxytocic* drug is **Pitocin**, a synthetic form of oxytocin (a hormone produced in the hypothalamus and released by the posterior pituitary gland; see Chap. 22). Pitocin may be used to induce labor or to strengthen weak uterine contractions during labor. Physiologic doses produce a rhythmic uterine contraction–relaxation pattern that approximates the normal labor process. An IV solution of 10 milliunits per milliliter is used for infusion, and dosage (flow rate) is titrated according to frequency and strength of contractions. Pitocin is contraindicated for antepartum use in the presence of fetal distress, preterm labor, previous uterine surgery, and severe preeclampsia. Maternal condition and fetal heart rate must be closely monitored during Pitocin administration. Maternal adverse effects include hypotension, excessive uterine stimulation, and uterine rupture.

After delivery, Pitocin is the drug of choice for prevention or control of postpartum uterine bleeding. The drug reduces uterine bleeding by contracting uterine muscle. It also plays a role in letdown of breast milk to the nipples during lactation.

## Analgesics

During early labor, pain occurs with uterine contractions; during later stages, pain occurs with perineal stretching. Parenteral opioid analgesics (e.g., IV or IM **meperidine**, **morphine**, or **fentanyl**) are commonly used to control pain during labor and delivery. They may prolong labor and cause sedation and respiratory depression in the mother and neonate. Meperidine may cause less neonatal depression than other opioid analgesics. **Butorphanol** is also widely used. If neonatal respiratory depression occurs, it can be reversed by **naloxone** (Narcan).

Regional analgesia may also be used and may be more effective than IV analgesics. Epidural analgesia involves administration of an opioid (e.g., fentanyl, morphine) through a catheter placed in the epidural space for that purpose. Following a cesarean section, a long-acting form of morphine (e.g., Duramorph) can be injected into the epidural catheter to provide analgesia up to 24 hours. Possible adverse effects include maternal urinary retention, but no significant effects on the fetus have been noted.

## Anesthetics

Local anesthetics also are used to control discomfort and pain. They are injected by physicians for regional anesthesia in the pelvic area. Epidural blocks involve injection into the epidural space of the spinal cord. **Bupivacaine** is commonly used. With regional anesthesia, the mother is usually conscious and comfortable, and the neonate is rarely depressed. **Fentanyl** may be combined with a small amount of a local anesthetic for both analgesia and anesthesia.

## Neonatal Therapeutics

In the neonate, any drug must be used cautiously. Drugs are usually given less often because they are metabolized and excreted slowly. Immature liver and kidney function prolongs drug action and increases risks of toxicity. Also, drug therapy should be initiated with low doses, especially with drugs that are highly bound to plasma proteins. Neonates have few binding proteins, which leads to increased amounts of free, active drug and increased risk of toxicity. When a health care provider is assessing the neonate, drugs received by the mother during pregnancy, labor and delivery, and lactation must be considered.

At birth, some drugs are routinely administered to prevent hemorrhagic disease of the newborn and ophthalmia neonatorum. Hemorrhagic disease of the newborn occurs because the intestinal tract lacks the bacteria that normally synthesize vitamin K and there is little if any dietary intake of vitamin K. Vitamin K is required for liver production of several clotting factors, including prothrombin. Thus, the neonate is at increased risk of bleeding during the first week of life. One dose of phytonadione 0.5 to 1 milligram is injected at delivery or on admission to the nursery.

Ophthalmia neonatorum is a form of bacterial conjunctivitis that may cause ulceration and blindness. It may be caused by several bacteria, most commonly *Chlamydia trachomatis*, a sexually transmitted organism. Erythromycin ointment 0.5% is applied to each eye at delivery. It is effective against both chlamydial and gonococcal infections.

## Nursing Process

### Assessment

Assess each female patient of reproductive age for possible pregnancy. If the patient is known to be pregnant, assess status in relation to pregnancy, as follows:

- Length of gestation
- Use of prescription, over-the-counter, herbal, nontherapeutic, and illegal drugs. If used, assess specifically for those drugs known to be fetotoxic or teratogenic.
- Acute and chronic health problems that may influence the pregnancy or require drug therapy

*Nursing Process continues on page 1052*

- With preterm labor, assess length of gestation, the frequency and quality of uterine contractions, the amount of vaginal bleeding or discharge, and the length of labor. Also determine whether any tissue has been expelled from the vagina. When abortion is inevitable, an oxytocic drug may be given. When stopping labor is possible or desired, a tocolytic drug may be given.
- When spontaneous labor occurs in normal, full-term pregnancy, assess frequency and quality of uterine contractions, amount of cervical dilatation, fetal heart rate and quality, and maternal blood pressure.
- Assess antepartum women for intention to breast-feed.

### Nursing Diagnoses

- Risk for Injury: Damage to mother, fetus, or neonate from maternal ingestion of drugs
- Noncompliance related to ingestion of nonessential drugs during pregnancy
- Risk for Injury related to possible damage to mother or infant during the birth process
- Deficient Knowledge: Drug effects during pregnancy and lactation

### Planning/Goals

#### The patient will

- Avoid unnecessary drug ingestion when pregnant or likely to become pregnant
- Use nonpharmacologic measures to relieve symptoms associated with pregnancy or other health problems when possible
- Obtain optimal care during pregnancy, labor and delivery, and the postpartum period
- Avoid behaviors that may lead to complications of pregnancy and labor and delivery
- Breast-feed safely and successfully if desired

### Interventions

- Use nondrug measures to prevent or minimize the need for drug therapy during pregnancy.
- Promote or provide optimal prenatal care to promote a healthy pregnancy (e.g., regular monitoring of blood pressure, weight, blood sugar, urine protein; counseling about nutrition and other healthful activities).
- Assist women with chronic health problems (e.g., asthma, diabetes, hypertension) to manage the disorders effectively and decrease risks of harm to themselves and their babies.
- Help patients and families cope with complications of pregnancy.
- Counsel candidates for therapeutic abortion about methods and expected outcomes; counsel abortion patients about contraceptive techniques.

### Evaluation

- Observe and interview regarding actions taken to promote reproductive and general health.
- Observe and interview regarding compliance with instructions for promoting and maintaining a healthy pregnancy.
- Interview regarding ingestion of therapeutic and nontherapeutic drugs during pre-pregnant, pregnant, and lactating states.
- Observe and interview regarding the health status of the mother and neonate.

### Principles of Therapy

#### General Guidelines: Pregnancy

- Regardless of the designated pregnancy risk category or presumed safety, no drug should be used during pregnancy unless it is clearly needed and potential benefit to the mother outweighs the risk of potential harm to the fetus.
- Although the teratogenicity of many drugs is unknown, most medications required by pregnant women can be used safely and most children are born healthy.
- When drug therapy is required, the choice of drug should be based on the stage of pregnancy and available drug information. During the first trimester, for example, an older drug that has not been associated with fetotoxic or teratogenic effects is usually preferred over a newer drug of unknown fetotoxicity or teratogenicity.
- Any drugs used during pregnancy should be given in the lowest effective doses and for the shortest effective time.
- Counsel pregnant women about the use of immunizations during pregnancy. Live-virus vaccines (e.g., measles, mumps, rubella) should be avoided because of possible harmful effects to the fetus. Vaccines against pneumococcal pneumonia, meningococcal meningitis, and hepatitis A can be used if indicated. Influenza vaccine is indicated in all women who are pregnant during influenza season. (However, FluMist, a live virus vaccine given by nasal spray, should *not* be given to pregnant women.) In addition, hepatitis B vaccine (if the mother is high risk and negative for hepatitis B antigen) and toxoids (e.g., diphtheria, tetanus) are considered safe for use. Hyperimmune globulins can be given to pregnant women who are exposed to hepatitis B, tetanus, or varicella (chickenpox).

#### Applying Your Knowledge 65-3

Mrs. Blevins asks you about over-the-counter and prescription drug use during her pregnancy. What do you tell her?

## General Guidelines: Lactation

- The American Academy of Pediatrics (AAP) supports breast-feeding as optimal nutrition for infants during the first year of life and does not recommend stopping maternal drug therapy unless necessary. In some instances, mothers may pump and discard breast milk while receiving therapeutic drugs to maintain lactation.
- Most systemic drugs taken by the mother reach the infant in breast milk. For some, the amount of drug is too small to cause significant effects; for others, effects on the nursing infant are unknown or potentially adverse. Drugs that are generally contraindicated are listed in Box 65-4.
- Give medications only when clearly indicated, weighing potential benefit to the mother against possible harm to the nursing infant. For contraindicated drugs, it is usually recommended that the mother stop the drug or stop breast-feeding.
- Any drugs used during lactation should be given in the lowest effective dose for the shortest effective time.
- Most over-the-counter and prescription drugs, taken in moderation and only when needed, are thought to be safe.
- Women with HIV infection should not breast-feed. The virus can be transmitted to the nursing infant.

## Patient Teaching Guidelines

## Drug Use During Pregnancy and Lactation

- Any systemic drug ingested by a pregnant woman reaches the fetus and may interfere with fetal growth and development. For most drugs, safety during pregnancy has not been established, and all drugs are relatively contraindicated. Therefore, any drug use must be cautious and minimal to avoid potential damage to the fetus.
- Avoid drugs when possible and use them very cautiously when necessary. If women who are sexually active and not using effective contraception take any drugs, there is a high risk that potentially harmful agents may be ingested before pregnancy is suspected or confirmed. It is estimated that 50% or more of pregnancies are unplanned.
- Lifestyle or nontherapeutic drugs associated with problems during pregnancy include alcohol, caffeine, and cigarette smoking. Women should completely avoid alcohol when trying to conceive and throughout pregnancy; no amount is considered safe. Caffeine intake should be limited to about three caffeinated beverages per day; excessive intake should be avoided. Women who smoke should quit if possible during pregnancy to avoid the effects of nicotine, carbon monoxide, and other chemicals on the fetus. However, the use of nicotine replacement products during pregnancy is not recommended.
- Herbal supplements are not recommended; their effects during pregnancy are largely unknown.
- Measures to prevent the need for drug therapy include a healthful lifestyle (adequate nutrition, exercise, rest, and sleep; avoiding alcohol and cigarette smoking) and avoiding infection (personal hygiene, avoiding contact with people known to have infections, maintaining indicated immunizations).
- Nondrug measures to relieve common health problems include positioning, adequate food and fluid intake, and deep breathing.
- See a health care provider as soon as pregnancy is suspected.
- Inform any health care provider from whom treatment is sought if there is a possibility of pregnancy.
- Many drugs are excreted in breast milk to some extent and reach the nursing infant. The infant's health care provider should be informed about medications taken by the nursing mother and consulted about potential drug effects on the infant. Before taking over-the-counter medications, consult a health care provider. In regard to nontherapeutic drugs, recommendations include the following:
  - Alcohol should be used in moderation and nursing should be withheld temporarily after alcohol consumption (1–2 hours per drink). Alcohol reaches the baby through breast milk, with the highest concentration about 30 to 60 minutes after drinking (60–90 minutes if taken with food). The effects of alcohol on the baby are directly related to the amount of alcohol the mother consumes. Moderate to heavy drinking (two or more drinks per day) can interfere with the ability to breast-feed, harm the baby's motor development, and slow the baby's weight gain. If you plan to drink (e.g., wine with dinner), you can avoid breast-feeding for a few hours (until the alcohol has time to leave your system) or you can pump your milk before drinking alcohol and give it to the baby after you have had the alcohol. You can also pump and discard the milk that is most affected by the ingested alcohol.
  - Caffeine is considered compatible with breast-feeding. However, large amounts should be avoided because infants may be jittery and have difficulty sleeping.
  - Cigarette smoking is contraindicated. Nicotine and an active metabolite are concentrated in milk and the amounts reaching the infant are proportional to the number of cigarettes smoked by the mother. Ideally, the mother who smokes would stop. If unable or unwilling to stop, she should decrease the number of cigarettes as much as possible, avoid smoking before nursing, and avoid smoking (or allowing other people to smoke) in the same room with the infant. The risk for sudden infant death syndrome (SIDS) is greater when a mother smokes or when the baby is around secondhand (passive) smoke. Maternal smoking and passive smoke may also increase respiratory and ear infections in infants.
  - All drugs of abuse (e.g., cocaine, heroin, marijuana, methamphetamine, phencyclidine) are contraindicated.

## Applying Your Knowledge 65-4

### How Can You Avoid This Medication Error?

Mrs. Blevins delivers a healthy baby and is breast-feeding. At her 6-week checkup, she is told she can resume normal sexual relations. Mrs. Blevins does not want to have another child for a while, so she resumes taking the birth control pills that she took prior to becoming pregnant.

## Home Care

Many obstetric patients with conditions such as preterm labor, hyperemesis, and elevated blood pressure are managed in the home. The home care nurse who assists in managing these

patients should be an obstetric specialist who is knowledgeable about normal pregnancy and potential complications. The nurse should be aware of the drugs being used to treat the complicated obstetric patient as well as maternal use of any non-prescription and nontherapeutic drugs. A systematic assessment of maternal and fetal responses should be made on each visit.

Home care visits also allow for assessment of compliance with the proposed management plan. Understanding of previous teaching should be evaluated on each visit. It is especially important for the patient to know the danger signs and symptoms that may necessitate notifying a health care provider.

The overall goal of home care is to maintain the pregnancy to the most advanced gestational age possible. Home care follow-up by a nurse has been demonstrated to positively affect the outcome of a high-risk pregnancy.

### Box 65-4

## Selected Drugs That Are Contraindicated or Not Recommended During Lactation

Angiotensin converting enzyme (ACE) inhibitors (e.g., captopril, others)  
 Angiotensin receptor blockers (ARBs; e.g., losartan, others)  
 Antibacterials (aminoglycosides, fluoroquinolones, tetracyclines, sulfamethoxazole/trimethoprim)  
 Antidepressants (e.g., amitriptyline, bupropion, citalopram, fluoxetine, venlafaxine, others)  
 Antidiabetic drugs (oral) (e.g., glimepiride, glipizide, metformin, pioglitazone, rosiglitazone)  
 Antiepileptics (carbamazepine, lamotrigine, levetiracetam, phenytoin, tiagabine, topiramate, zonisamide)  
 Antifungals (e.g., itraconazole, terbinafine)  
 Antihistamines (cetirizine, clemastine, desloratadine, diphenhydramine, loratadine)  
 Antimanic agent (lithium)  
 Antipsychotics (e.g., clozapine, olanzapine, risperidone, others)  
 Antirheumatic immunosuppressant drugs (e.g., etanercept, infliximab)

Antivirals (e.g., famciclovir)  
 Benzodiazepine anti-anxiety and sedative/hypnotic drugs (e.g., alprazolam, diazepam, triazolam, others)  
 Beta blockers (e.g., metoprolol, others)  
 Calcium channel blockers (e.g., amlodipine, diltiazem, others)  
 Diuretics (e.g., hydrochlorothiazide)  
 Histamine<sub>2</sub> receptor antagonists (e.g., cimetidine, ranitidine)  
 Nonbenzodiazepine sedative/hypnotics (e.g., ramelteon, zolpidem)  
 Nonsteroidal anti-inflammatory drugs (e.g., naproxen, tolmetin)  
 Opioid analgesics (codeine, hydromorphone, methadone)  
 Proton pump inhibitors (e.g., esomeprazole, omeprazole, others)  
 Retinoids (e.g., isotretinoin)  
 Statin cholesterol-lowering drugs (e.g., atorvastatin, simvastatin, others)

## Nursing Actions

## Abortifacients, Prostaglandins, Tocolytics, and Oxytocics

### NURSING ACTIONS

#### 1. Administer accurately

- With prostaglandin abortifacients (e.g., Hemabate, Prostin E<sub>2</sub>) and prostaglandin cervical ripening agents (e.g., Cervidil), consult manufacturers' instructions.
- Give intravenous magnesium sulfate via an infusion pump; read the drug label carefully to be sure of using the correct preparation for the intended use; when available, use premixed IV bags of 20 g magnesium sulfate in 500 mL of IV fluid; clearly label IV bags; use a

### RATIONALE/EXPLANATION

These drugs are given according to specific protocols and should be administered only by nurses experienced in their use and aftercare of patients. Magnesium sulfate is a high-risk drug and should be given only by experienced labor and delivery nurses who are knowledgeable about safe administration and monitoring patients. The nurse should assess and document maternal status and fetal status before starting the drug infusion, remain at the

**NURSING ACTIONS**

separate 100-mL (4 g) or 150-mL (6 g) IV piggyback solution for the initial bolus dose; give the initial bolus over 20–30 minutes; titrate the maintenance dose (1–2 g/hour) according to serum magnesium levels; have a second nurse check all IV bags containing magnesium sulfate and all infusion pump settings; have IV calcium gluconate readily available.

- c. Give terbutaline IV initially, via an infusion pump, then by mouth (PO).
- d. For IV oxytocin, dilute the drug in an IV sodium chloride solution, and piggyback the solution into a primary IV line. Use an infusion pump to administer.
- e. Give intramuscular oxytocin immediately after delivery of the placenta.

**2. Observe for therapeutic effects**

- a. When an abortifacient is given, observe for the onset of uterine bleeding and the expulsion of the fetus and placenta.
- b. When a tocolytic drug is given in threatened abortion or preterm labor, observe for absent or decreased uterine contractions.
- c. When magnesium sulfate is given in preeclampsia, observe for an absence or decrease of seizures.
- d. When oxytocin is given to induce or augment labor, observe for firm uterine contractions at a rate of three to four per 10 minutes. Each contraction should be followed by a palpable relaxation period. Examine periodically for cervical dilatation and effacement.
- e. When oxytocin is given to prevent or control postpartum bleeding, observe for a small, firm uterus and minimal vaginal bleeding.

**3. Observe for adverse effects**

- a. With prostaglandins, observe for:
  - (1) Nausea, vomiting, diarrhea
  - (2) Fever, cardiac dysrhythmias, bronchospasm, convulsions, chest pain, muscle aches
- b. With magnesium sulfate, observe for:
  - (1) Hypermagnesemia—respiratory depression and failure, depressed deep-tendon reflexes, muscle weakness, hypotension, cardiac dysrhythmias, cardiac arrest
  - (2) Headache, vomiting, nausea, chest pain, lethargy, visual disturbances, weakness
  - (3) Change in fetal heart rate
- c. With oxytocin, observe for:
  - (1) Excessive stimulation of uterine contractility (hypertonicity; rupture; cervical and perineal lacerations; fetal hypoxia; dysrhythmias; death or damage from rapid, forceful propulsion through the birth canal)
  - (2) Hypotension or hypertension
  - (3) Water intoxication (convulsions, coma)

**4. Observe for drug interactions**

- a. Drugs that alter effects of prostaglandins:
  - (1) Aspirin and other nonsteroidal anti-inflammatory agents, such as ibuprofen

**RATIONALE/EXPLANATION**

bedside during bolus infusions, and monitor the patient frequently throughout drug administration.

Magnesium sulfate is available in different concentrations and sizes as well as a multidose vial.

Calcium gluconate is an antidote for an overdose of magnesium sulfate. One ampule of 1 g (10 mL of a 10% solution) can be given IV over 3 minutes to relieve signs and symptoms of hypermagnesemia.

Although not FDA-approved for tocolysis, there is extensive clinical experience with the drug.

Oxytocin may cause water intoxication, which is less likely to occur if the drug is given in a saline solution. Piggybacking allows regulation of the oxytocin drip without interrupting the main IV line.

To prevent excessive postpartum bleeding

Abortion usually occurs within 24 hours after a prostaglandin is administered.

The goal of drug therapy is to stop the labor process. Uterine activity may be assessed by maternal self-report, palpation, or electronic fetal monitoring. Tocolytic blood levels of magnesium sulfate range from 4.8–9.6 mg/dL.

Blood levels of 3–6 mg/dL are considered optimal for anti-seizure effects.

Uterine contractions should become regular and increase in duration and intensity.

These agents control bleeding by causing strong uterine contractions. The uterus can be palpated in the lower abdomen.

These are the most common adverse effects; they result from stimulation of gastrointestinal smooth muscle.

These effects occur less often. Bronchospasm is more likely to occur in patients with asthma; seizures are more likely in patients with known epilepsy.

Hypermagnesemia is most likely to occur with rapid IV administration, high dosages or concentrations, and decreased urine output.

Most likely to occur when excessive doses are given to initiate or augment labor.

Usual doses cause little change in blood pressure; large doses may cause an initial drop, followed by sustained elevation.

These drugs inhibit effects of prostaglandins. When given concurrently with abortifacient prostaglandins, the abortive process is prolonged.

## Nursing Actions Abortifacients, Prostaglandins, Tocolytics, and Oxytocics (continued)

### NURSING ACTIONS

- b. Drug that *alters* effects of magnesium sulfate:  
 (1) Calcium gluconate
- c. Drugs that *alter* effects of oxytocin:  
 (1) Vasoconstrictors, such as epinephrine and other adrenergic drugs

### RATIONALE/EXPLANATION

- Calcium gluconate is an antidote for magnesium sulfate overdose.
- Additive vasoconstriction with risks of severe, persistent hypertension and intracranial hemorrhage

## Key Concepts

- Major concerns with drug use during pregnancy are fetotoxicity and teratogenicity. A developing fetus is exposed to any drugs circulating in the mother's bloodstream.
- Fetal organs are formed during the first trimester of pregnancy, possibly before a woman knows she is pregnant. The fetus' brain continues to develop throughout pregnancy and after birth.
- A folic acid supplement is recommended for women who may become pregnant and during pregnancy to prevent neural tube defects.
- Drugs should be avoided during pregnancy when possible and used cautiously when required.
- Some drugs should be avoided during lactation; all drugs should be used cautiously.

## Review and Application Exercises

### Short Answer Exercises

1. Why should drugs be avoided during pregnancy and lactation when possible?
2. How does insulin therapy for diabetes mellitus differ during pregnancy?
3. What is the rationale for using methyldopa to treat hypertension during pregnancy?
4. How are asthma and seizure disorders managed during pregnancy?
5. In a patient receiving a tocolytic drug to inhibit uterine contractions, how would you assess the patient for adverse drug effects?
6. In a patient receiving an oxytocin infusion to induce or augment labor, what interventions are needed to increase safety and decrease adverse drug effects?
7. Which immunizations are safe to be administered during pregnancy? Which are contraindicated?
8. A pregnant patient asks you about using herbal supplements. What would you tell her? Why?

### NCLEX-Style Questions

9. A daily vitamin K supplement is recommended during the last month of pregnancy for women receiving long-term drug therapy for which of the following conditions?
  - a. asthma
  - b. diabetes mellitus
  - c. hypertension
  - d. seizure disorders
10. For a patient receiving a continuous IV magnesium sulfate infusion for tocolysis, which of the following medications should the nurse have readily available?
  - a. diazepam (Valium)
  - b. methyldopa
  - c. calcium gluconate
  - d. phenytoin (Dilantin)
11. Betamethasone (Celestone) is ordered for a patient experiencing preterm labor at 34 weeks gestation. The nurse explains to the patient that the drug is being given to
  - a. enhance fetal lung maturity
  - b. counteract the effects of tocolytic therapy
  - c. treat intrauterine infection
  - d. decrease need for a cesarean section

12. A drug of choice for treating group B streptococcal infection in a pregnant woman is
- penicillin
  - fluoroquinolone
  - aminoglycoside
  - tetracycline
13. Which of the following drugs is used after delivery to prevent or control postpartum uterine bleeding?
- vitamin K
  - oxytocin
  - magnesium sulfate
  - betamethasone

## A

# The International System of Units

The International System of Units (Système International d'Unités or SI units), which is based on the metric system, has been adopted by many countries in an attempt to standardize reports of clinical laboratory data among nations and disciplines. A major reason for using SI units is that biologic substances react in the human body on a molar basis.

The International System, like the conventional or traditional system, uses the kilogram for measurement of mass or weight and the meter for measurement of length. The major difference is that the International System uses the mole for measurement of amounts per volume of a substance. A mole is the amount of a chemical compound of which its weight in grams equals its molecular weight. Thus, the concentrations of solutions are expressed in moles, millimoles, or micromoles per liter (mol/L, mmol/L, micromol/L) rather than the conventional measurement of mass per volume, such as grams or milligrams per 100 mL or dL. A few laboratory values are the same in conventional and SI units, but many differ dramatically. Moreover, "normal values" in both systems often vary, depending on laboratory methodologies and reference sources. Thus, *laboratory data should be interpreted in light of the patient's clinical status and with knowledge of the "normal values" of the laboratory performing the test.*

# Serum Drug Concentrations

Measuring the amount of a drug in blood plasma or serum is often useful in the clinical management of various disorders. For example, serum drug levels may be used to guide drug dosage (e.g., with aminoglycoside antibiotics such as gentamicin); to evaluate an inadequate therapeutic response; and to diagnose or manage drug toxicity. Listed below are generally accepted therapeutic serum drug concentrations, in conventional and SI units, for some commonly used drugs. In addition, toxic concentrations are listed for acetaminophen and salicylate. Note that SI units have not been established for some drugs.

DRUG	CONVENTIONAL UNITS	SI UNITS
Acetaminophen	0.2–0.6 mg/dL Toxic >5 mg/dL	13–40 $\mu\text{mol/L}$ >300 $\mu\text{mol/L}$
Amikacin	(Peak) 16–32 mcg/mL (Trough) $\leq$ 8 mcg/mL	20–30 mg/L
Amitriptyline	110–250 ng/mL	375–900 nmol/L
Carbamazepine	4–12 mcg/mL	17–50 $\mu\text{mol/L}$
Desipramine	125–300 ng/mL	470–825 nmol/L
Digoxin	0.5–2.2 ng/mL	1–2.6 nmol/L
Disopyramide	2–8 mcg/mL	6–18 $\mu\text{mol/L}$
Ethosuximide	40–110 mcg/mL	280–780 $\mu\text{mol/L}$
Gentamicin	(Peak) 4–8 mcg/mL (Trough) $\leq$ 2 mcg/mL	5–10 mg/L
Imipramine	200–350 ng/mL	530–950 nmol/L
Lidocaine	1.5–6 mcg/mL	6–21 $\mu\text{mol/L}$
Lithium	0.5–1.5 mEq/L	0.5–1.5 mmol/L
Maprotiline	50–200 ng/mL	180–270 nmol/L
Nortriptyline	50–150 ng/mL	190–570 nmol/L
Phenobarbital	15–50 mcg/mL	65–170 $\mu\text{mol/L}$
Phenytoin	10–20 mcg/mL	40–80 $\mu\text{mol/L}$
Primidone	5–12 mcg/mL	25–45 $\mu\text{mol/L}$
Procainamide	4–8 mcg/mL	17–40 $\mu\text{mol/L}$
Propranolol	50–200 ng/mL	190–770 nmol/L
Protriptyline	100–300 ng/mL	380–1140 nmol/L
Quinidine	2–6 mcg/mL	4.6–9.2 $\mu\text{mol/L}$
Salicylate	100–200 mg/L Toxic >200 mg/L	724–1448 $\mu\text{mol/L}$ >1450 $\mu\text{mol/L}$
Theophylline	10–20 mcg/mL	55–110 $\mu\text{mol/L}$

# Anesthetics, Adjunctive Drugs, and Nursing Considerations

*Anesthetics* interrupt the conduction of painful nerve impulses from a site of injury to the brain. They are given to prevent pain and promote relaxation during surgery, childbirth, and some diagnostic tests and treatments.

## General Anesthetics

General anesthetics produce profound central nervous system (CNS) depression, during which there is complete loss of sensation, consciousness, pain perception, and memory. The drugs include inhalation and intravenous (IV) agents and can be used for almost any surgical, diagnostic, or therapeutic procedure. General anesthesia is often started with a fast-acting IV drug (e.g., propofol, thiopental) then maintained with a mixture of an anesthetic gas and oxygen given by inhalation. The IV agent produces rapid loss of consciousness and provides a pleasant induction and recovery. An anesthetic barbiturate or propofol may be used alone for anesthesia during brief diagnostic tests or surgical procedures. Selected agents and their characteristics and uses are listed in Table C-1.

## General Anesthetic Adjunctive Drugs

Several drugs are used along with general anesthetics. *Antianxiety agents* and *sedative-hypnotics* are given to decrease anxiety, promote rest, allow easier induction of anesthesia, and allow smaller doses of anesthetics. These drugs may be given the night before to aid sleep and 1 or 2 hours before the scheduled procedure. In addition, midazolam (Versed) is often used in ambulatory surgical or invasive diagnostic procedures and for regional anesthesia. It has a rapid onset and short duration of action, causes amnesia, produces minimal cardiovascular adverse effects, and reduces the dose of opioid analgesics required during surgery. *Anticholinergic drugs* are given to prevent vagal effects (e.g., bradycardia, hypotension) associated with general anesthesia and surgery. Vagal stimulation occurs with some inhalation anesthetics and with surgical procedures in which there is manipulation of the pharynx, trachea, peritoneum, stomach, intestine, or other viscera, and procedures in which pressure is exerted on the eyeball.

*Neuromuscular blocking agents* (see Table C-1) cause muscle relaxation, an important component of general anesthesia, and allow the use of smaller amounts of anesthetic agents. They are also used to facilitate mechanical ventilation, control increased intracranial pressure, and treat status epilepticus. Artificial ventilation is necessary because these drugs paralyze muscles of respiration as well as other skeletal muscles. The drugs do not cause sedation; therefore, unless recipients are unconscious, they can see and hear environmental activities and conversations. These commonly used drugs prevent acetylcholine from acting at neuromuscular junctions. As a result, the nerve cell membrane is not depolarized, the muscle fibers are not stimulated, and skeletal muscle contraction does not occur. The drugs should be used very cautiously in patients with renal or hepatic impairment because the drug or its metabolites may accumulate and cause prolonged paralysis.

## Nursing Considerations With General Anesthetics and Neuromuscular Blocking Agents

- General anesthetics should be administered *only* by anesthesiologists or nurse anesthetists and *only* in locations where staff, equipment, and drugs are available for emergency use or cardiopulmonary resuscitation. Most nurses care for patients before and after administration of general anesthetics.

Table C-1

## General Anesthetics and Neuromuscular Blocking Agents

GENERIC/TRADE NAME	CHARACTERISTICS
<b>General Inhalation Anesthetics</b>	
Desflurane (Suprane), enflurane (Ethrane), isoflurane (Forane), sevoflurane (Ultane)	These drugs are similar volatile liquids used for induction and maintenance of general anesthesia. They are given by anesthesiologists or nurse anesthetists.
Nitrous oxide	One of the oldest and safest anesthetics; given with oxygen to prevent hypoxia; has rapid induction and recovery; used for anesthesia with IV barbiturates, neuromuscular blocking agents, opioid analgesics, and stronger inhalation anesthetics; used alone for analgesia in dentistry, obstetrics, and brief surgical procedures
<b>General Intravenous Anesthetics</b>	
Alfentanil (Alfenta), remifentanil (Ultiva), sufentanil (Sufenta)	These drugs are rapid-acting opioid-analgesic anesthetics used as a primary anesthetic or as an analgesic adjunct with other general anesthetics.
Etomidate (Amidate)	A nonanalgesic hypnotic used for induction and maintenance of general anesthesia; may be used with nitrous oxide for short operative procedures
Methohexital (Brevital), thiopental (Pentothal)	Ultra-short-acting barbiturates used to induce general anesthesia. For major surgery, the drugs are used with inhalation anesthetics and muscle relaxants.
Midazolam (Versed)	A short-acting benzodiazepine. Given IV or IM for preoperative sedation. Given IV for conscious sedation during short endoscopic or other diagnostic procedures; induction of general anesthesia; and maintenance of general anesthesia with nitrous oxide and oxygen for short surgical procedures. Adverse effects of IV drug include respiratory depression, apnea, and death.
Propofol (Diprivan)	A rapid-acting hypnotic used for induction or maintenance of general anesthesia, with other agents. Also used alone for sedation in critical care units. Recovery occurs a few minutes after the drug is stopped. Adverse effects include hypotension, apnea, and other signs of central nervous system depression.
<b>Neuromuscular Blocking Agents</b>	
Atracurium (Tracium), Cisatracurium (Nimbex), Rocuronium (Zemuron), Vecuronium (Norcuron)	These are intermediate-acting, nondepolarizing skeletal muscle relaxants used with general anesthesia for surgical procedures and to facilitate endotracheal intubation and mechanical ventilation. They may cause hypotension and their effects can be reversed by neostigmine (Prostigmin).
Pancuronium	An older, long-acting drug used during surgery after general anesthesia has been induced or to aid endotracheal intubation or mechanical ventilation. It may cause hypotension, and effects can be reversed by neostigmine (Prostigmin).
Succinylcholine	A depolarizing, short-acting drug that may be used during surgery and brief procedures, such as endoscopy and endotracheal intubation. It is used less often than the nondepolarizing agents described above. Adverse effects include malignant hyperthermia, a life-threatening condition.

- If a medical disorder of a vital organ system (cardiovascular, respiratory, renal) is present, it should be corrected before anesthesia is given, when possible. Such disorders increase the risks of complications with anesthesia and surgery. Additional risk factors include cigarette smoking, obesity, and limited exercise or activity.
- Compared with adults, children are at greater risk of complications (e.g., laryngospasm, bronchospasm, aspiration, postoperative nausea and vomiting) and death from general anesthetics and adjunctive drugs.
- Compared with younger adults, older adults often have physiologic changes and pathologic conditions that make them more susceptible to adverse effects of anesthetics, neuromuscular blocking agents, and adjunctive medications. Thus, lower doses of these agents are usually needed.
- During preanesthetic nursing assessments, patients should be asked about drug allergies and the use of prescription drugs, nonprescription drugs, and herbal or dietary supplements. With herbal products, the American Society of Anesthesiologists recommends that all herbals be stopped 2 or 3 weeks before any surgical procedure because some (e.g., feverfew, garlic, ginkgo biloba, ginseng) can increase risks of bleeding and some (e.g., kava, valerian) can increase effects of sedatives.

- Effects of anesthetics wear off gradually and the nurse must observe and safeguard patients during this recovery period. With general anesthetics and neuromuscular blocking agents, frequent (e.g., every 5–15 minutes) assessment of cardiovascular and respiratory function is needed until the client wakes up and is breathing well. This is usually done in a postanesthesia recovery (PAR) area. Observe for adverse effects, including excessive sedation (e.g., delayed awakening, failure to respond to verbal or tactile stimuli); respiratory problems (e.g., laryngospasm, hypoxia, hypercarbia); cardiovascular problems (e.g., hypotension, tachycardia and other cardiac dysrhythmias, fluid and electrolyte imbalances); and other problems (e.g., restlessness, nausea, vomiting).
- Propofol and neuromuscular blocking agents are commonly used in critical care units, usually for patients who are intubated and mechanically ventilated. These drugs should be administered and monitored only by health care personnel who are skilled in the management of critically ill patients, including cardiopulmonary resuscitation and airway management. Critical care nurses must often care for patients receiving IV infusions of the drugs and titrate dosage and flow rate to achieve desired effects and minimize adverse effects. Consult drug literature regarding accurate administration and monitoring of these drugs.

## Local Anesthetics

*Local anesthetics*, given to produce loss of sensation and motor activity, are applied to or injected into localized areas of the body. The drugs decrease the permeability of nerve cell membranes to ions, especially sodium. This action reduces excitability of cell membranes; when excitability falls low enough, nerve impulses cannot be initiated or conducted by the anesthetized nerves. As a result, the drugs prevent the cells from responding to pain impulses and other sensory stimuli.

Anesthetic effects dwindle as drug molecules diffuse out of neurons into the bloodstream. The drugs are then transported to the liver for metabolism, mainly to inactive metabolites. The metabolites are excreted in the urine, along with a small amount of unchanged drug. Commonly used local anesthetics are listed in Table C-2.

### Selected Types of Local Anesthesia

- *Spinal anesthesia* involves injecting the anesthetic agent into the cerebrospinal fluid, usually in the lumbar spine. The anesthetic blocks sensory impulses at the root of peripheral nerves as they enter the spinal cord. Spinal anesthesia is especially useful for surgery involving the lower abdomen and legs.
- *Epidural anesthesia*, which involves injecting the anesthetic into the epidural space, is used most often in obstetrics during labor and delivery. This route is also used to provide analgesia (often with a combination of a local anesthetic and an opioid) for patients with postoperative or other pain.

When the combination is used, the dosage of both drugs must be reduced to avoid respiratory depression and other adverse effects.

- *Topical anesthesia* involves application of a local anesthetic to skin and mucous membranes. The anesthetic is usually an ingredient in ointments, solutions, or lotions designed for use at particular sites. For example, preparations are available for use on eyes, ears, nose, oral mucosa, perineum, hemorrhoids, and skin. These preparations are used to relieve pain and itching of dermatoses, sunburn, minor skin wounds, hemorrhoids, sore throat, and other conditions. The main adverse effect is allergic reactions.

## Nursing Considerations With Local Anesthetics

- Some local anesthetic is absorbed into the bloodstream and circulated through the body, especially when injected or applied to mucous membrane. *Systemic absorption accounts for most of the potentially serious adverse effects of local anesthetics.* These adverse effects include CNS stimulation (e.g., hyperactivity, excitement, seizure activity) followed by CNS depression; cardiovascular depression (e.g., hypotension, dysrhythmias); and allergic reactions (e.g., hives and other skin lesions; itching; edema; possible anaphylactoid symptoms, including severe hypotension). Serious adverse effects are more likely to occur with large doses, high concentrations, injections into highly vascular areas, or accidental injection into a blood vessel.
- Except with IV lidocaine for cardiac dysrhythmias, local anesthetic solutions must not be injected into blood vessels because of the high risk of serious adverse reactions involving the cardiovascular system and CNS.
- Local anesthetics given during labor cross the placenta and may depress muscle strength, muscle tone, and rooting behavior in newborns. In addition, if a local anesthetic (e.g., bupivacaine) is infused epidurally with an opioid analgesic (e.g., fentanyl), dosage of both agents must be reduced to decrease risks of respiratory arrest.
- Epinephrine, a vasoconstrictor, is often added to a local anesthetic to slow systemic absorption, prolong anesthetic effects, and control bleeding. This combination should *not* be given IV or in excessive dosage because the drugs can cause serious systemic toxicity, including cardiac dysrhythmias. In addition, the combination should *not* be used for nerve blocks in areas supplied by end arteries (fingers, ears, nose, toes, penis) because it may produce ischemia and gangrene.
- For topical anesthesia, use the local anesthetic only on the body part and condition for which it was prescribed. Most preparations are specifically made to apply on certain areas, and they cannot be used effectively and safely on other body parts. Also, teach patients to cleanse the site before application, if needed, so that the drug has direct contact

Table C-2

## Local Anesthetics

GENERIC/TRADE NAME	CHARACTERISTICS
<b>Injectable Drugs</b>	
Articaine (Septodont)	Used for local infiltration (injection) and nerve block for dental and periodontal procedures or oral surgery. Effects occur in 1–6 min and last 1 h.
Bupivacaine (Marcaine)	Used for infiltration, nerve block, and epidural anesthesia during childbirth. With injection, effects occur in 5 min and last 2–4 h. With epidural administration, effects occur in 10–20 min and last 3–5 h. May cause systemic toxicity (e.g., decreased cardiac output, dysrhythmias, CNS stimulation possibly proceeding to seizures).
Chloroprocaine (Nesacaine)	Used for infiltration, nerve block, and epidural anesthesia. Effects occur in 6–12 min and last 30 min. Rapidly metabolized and less likely to cause systemic toxicity than other local anesthetics
Lidocaine (Xylocaine)	Used for local infiltration, nerve block, and spinal and epidural anesthesia. With injection, effects occur in less than 2 min and last 30–60 min. With epidural use, effects occur in 5–15 min and last 1–3 h. Lidocaine is also given IV to prevent or treat cardiac dysrhythmias. ( <b>Warning:</b> Do not use preparations containing epinephrine for dysrhythmias.)
Mepivacaine (Carbocaine)	Used for infiltration, nerve block, and epidural anesthesia. With injection, effects occur in 3–5 min and last 0.75–1.5 h. With epidural use, effects occur in 5–15 min and last 1–3 h.
Prilocaine (Citanest)	Used for infiltration, nerve block, and epidural anesthesia. With injection, effects occur in less than 2 min and last 60 min. With epidural use, effects occur in 5–15 min and last 1–3 h.
Ropivacaine (Naropin)	Used for local or regional surgical anesthesia and obstetric or postoperative analgesia. Given by injection or epidural infusion. With epidural use, effects occur in 10–30 min and last up to 6 h.
<b>Topical Drugs</b>	
Benzocaine (Americaine, Lanacaine, Solarcaine, others)	Used on skin and mucous membranes to relieve pain and itching of sunburn, other minor burns and wounds, skin abrasions, earache, hemorrhoids, sore throat, and other conditions. Available over-the-counter in aerosol sprays, throat lozenges, rectal suppositories, lotions, and ointments. May cause allergic reactions.
Dibucaine (Nupercainal)	Used on skin and mucous membranes. Anesthetic effects occur in less than 15 min and last 3–4 h. May cause local allergic reactions
Dyclonine (Dyclone)	Used to relieve pain of mouth or anogenital lesions and to anesthetize mucous membranes of throat and gastrointestinal tract for endoscopic procedures. Effects occur in less than 10 min and last less than 60 min.
Lidocaine (Xylocaine, Dentipatch, others)	One of the most commonly used local anesthetics. Available in several preparations, including lidocaine viscous, which is used orally for numbing of the mouth and throat, and topical patches for relief of painful conditions such as postherpetic neuralgia and to provide oral anesthesia for superficial dental procedures. With topical use, effects occur in 2–5 min and last 15–45 min.
Pramoxine (Tronothane)	Used for skin wounds, dermatoses, hemorrhoids, endotracheal intubation, and sigmoidoscopy
Proparacaine (Alcaine)	Used to anesthetize the eye for tonometry and for removal of sutures, foreign bodies, and cataracts
Tetracaine (Pontocaine)	Used for topical anesthesia

with the affected area; and to avoid using the product longer or applying more often than directed because skin irritation, rash, and hives can develop.

- When used to anesthetize nasal, oral, pharyngeal, laryngeal, tracheal, bronchial, or urethral mucosa, local anesthetics should be given in low concentrations and at the lowest effective dosages. The drugs are well absorbed through mucous membranes and may cause systemic adverse reactions.
- A mixture of lidocaine and prilocaine (Eutectic Mixture of Local Anesthetics [EMLA]) was formulated to penetrate intact skin, provide local anesthesia, and decrease pain of vaccinations and venipuncture, especially in children. The cream is applied at the injection site with an occlusive dressing at least 60 minutes before vaccination or venipuncture. It should not be used on abraded skin or mucous membranes.

## D

# Drugs For Erectile Dysfunction

## DRUG CATEGORY

Phosphodiesterase  
Type 5 Inhibitors

## CHARACTERISTICS

### Mechanism of Action:

Improves erectile function by inhibiting the enzyme responsible for the breakdown of cyclic guanosine monophosphate (cGMP), a vasodilatory neurotransmitter in corporal tissues of the penis.

### Indications:

Treatment of erectile dysfunction in men who are healthy enough for sexual activity. Sildenafil is also approved for the treatment of pulmonary arterial hypertension.

### Contraindications/Cautions:

Contraindicated in patients taking organic nitrates due to risk of severe hypotension resulting in dizziness, syncope, heart attack or stroke.

Use with caution in patients taking alpha blockers due to risk of hypotension.

Vardenafil prolongs the QT interval and should not be used with other drugs with similar effect particularly Class I and II antiarrhythmics (see Ch. 50).

Concurrent use of substantial amounts of alcohol can increase the risk of orthostatic hypotension, tachycardia, dizziness and headache.

**Adverse Effects:** Common adverse reactions include: headache, facial flushing, dyspepsia, nasal congestion and dizziness. Sildenafil and vardenafil reduce blood pressure. Sildenafil (and to a lesser degree vardenafil) increases the risk of light sensitivity, blurred vision and loss of blue-green color discrimination. Tadalafil is associated with back and muscle pain. Rarely, adverse effects associated with phosphodiesterase inhibitors include development of nonarteritic ischemic optic neuropathy due to obstruction of blood flow to the optic nerve, resulting in irreversible loss of vision; and sudden permanent hearing loss accompanied by dizziness and tinnitus. Priapism is rare and usually associated with excessive dosing or concurrent use with another erectogenic drug. Persistent priapism requires prompt medical treatment to avoid permanent penile damage. Persistent erections are treated by aspiration of blood from the corpus cavernosum, followed by irrigation with a vasoconstrictor such as epinephrine.

## GENERIC (TRADE NAME)

## INDIVIDUAL CHARACTERISTICS

## ROUTES AND DOSAGE RANGES

Sildenafil (Viagra)

Time to peak effect: 1 h  
Duration: 4 h  
High fat meals will delay absorption and reduce peak levels.

PO 25-100 mg 1 h before sexual activity.  
Reduced dose with age over 65 years, concurrent use of CYP 3A4 inhibitors\*, and renal or hepatic impairment.

Tadalafil (Cialis)

Time to peak effect: 2 h  
Duration: 24-36 h  
Meals do not impact absorption rate or peak levels.

PO 5-20 mg 2 h or more before anticipated sexual activity. Reduced dose with age over 65 years, renal or hepatic impairment and concurrent use of CYP3A4 inhibitors\*.

Vardenafil (Levitra)

Time to peak effect: 1 h  
Duration: 4 h  
High fat meals will delay absorption and reduce peak levels.

PO 5-20 mg 1 h before sexual activity.  
Reduced dose with age over 65, hepatic impairment and concurrent use of CYP 3A4 inhibitors.\*

\*CYP3A4 inhibitors include azole antifungals, erythromycin, and saquinavir.

DRUG CATEGORY	CHARACTERISTICS	
Prostaglandin E <sub>1</sub>	<p><b>Mechanism of Action:</b> Relaxes trabecular smooth muscle and dilates cavernosal arteries, resulting in penile engorgement and reduced venous outflow.</p> <p><b>Indications:</b> Treatment of erectile dysfunction in men who are healthy enough for sexual activity.</p> <p><b>Contraindications/Cautions:</b> Not for use in patients at risk for priapism (e.g., sickle cell anemia or trait, multiple myeloma, leukemia). Use intracavernosal injections with caution in patients concurrently receiving anticoagulants due to risk of bleeding. Not recommended for concurrent use with other vasoactive agents. Alprostadil is pregnancy category C. Do not use intraurethral alprostadil if the partner is pregnant unless a condom barrier is used.</p> <p><b>Adverse Effects:</b> Intracavernosal injection is associated with burning sensations, prolonged erection and priapism. Long term use is associated with penile fibrosis. Intraurethral administration is associated with penile pain.</p>	
GENERIC (TRADE NAME)	INDIVIDUAL CHARACTERISTICS	ROUTES AND DOSAGE RANGES
<b>Intracavernosal Injection:</b> Alprostadil (Caverject aqueous, Caverject powder, Edex powder)	<p>Onset: following injection</p> <p>Duration: With proper dose, erection should not last longer than 1 hour</p> <p>Comes in an aqueous preparation and a power preparation that must be reconstituted prior to single use.</p> <p>Aqueous injection may be stored frozen up to 3 months and may be moved to the refrigerator for up to 7 days prior to use. Do not refreeze. Remove foil covering and allow to reach room temperature immediately prior to use.</p> <p>Store Caverject powder at or below 77 ° F for up to 3 months. Reconstituted solution must be used within 24 hours.</p> <p>Edex powder can be stored at controlled room temperature.</p>	<p>Intracavernosal injection: Inject along the dorsolateral aspect of the proximal third of the penis, avoiding visible veins. Rotate injection sites from one side of the penis to the other and change injection site with each dose.</p> <p>Injection may be used no more than 3 times per week and only once in 24 hours.</p> <p>Initial injection done in physician's office to determine dose adequate to achieve satisfactory erection without causing priapism.</p>
<b>Intraurethral Administration:</b> Alprostadil (Muse)	<p>Onset: 5-10 minutes</p> <p>Duration: 30-60 minutes</p> <p>Store unopened foil pouches in refrigerator. May be kept at controlled room temperature up to 14 days prior to use.</p>	<p>Intraurethral: Prior to introducing pellet into urethra, the patient should void. Residual urine in urethra aids in dispersing the medication.</p> <p>Intraurethral administration may be used no more than two times in 24 hours.</p> <p>Adequate dosage to produce satisfactory erection is determined in physician's office.</p>

\*CYP3A4 inhibitors include azole antifungals, erythromycin, and saquinavir.

# Glossary

**Abortifacient:** drug used to terminate pregnancy.

**Absorption:** the process that occurs from the time a drug enters the body to the time it enters the bloodstream to be circulated.

**Acetylcholine:** a neurotransmitter in the cholinergic system located in many areas of the brain, with high concentrations in the motor cortex and basal ganglia; also a neurotransmitter in the autonomic nervous system and at peripheral neuromuscular junctions; exerts excitatory effects at synapses and nerve–muscle junctions and inhibitory effects at some peripheral sites, such as organs supplied by the vagus nerve.

**Acetylcholinesterase:** enzyme responsible for the immediate breakdown of acetylcholine when released from the nerve ending.

**Acne:** a common disorder characterized by excessive production of sebum and obstruction of hair follicles, which normally carry sebum to the skin surface.

**Acromegaly:** a chronic disease, resulting from excessive secretion of growth hormone (GH), characterized by an abnormal pattern of bone and connective-tissue growth associated with an increased incidence of diabetes mellitus and hypertension.

**Addison's disease:** primary adrenocortical insufficiency; inadequate production of both cortisol and aldosterone.

**Addisonian crisis:** also known as adrenocortical insufficiency; mimics hypovolemic and septic shock.

**Adrenocortical insufficiency:** See addisonian crisis.

**Adrenocorticotrophic hormone (ACTH):** also referred to as corticotropin-releasing hormone or factor (CRH or CRF); causes release of corticotropin in response to stress and threatening stimuli; most often secreted during sleep.

**Adrenergic drugs:** produce effects similar to those produced by stimulation of the sympathetic nervous system and therefore have widespread effects on body tissues.

**Aldosterone:** the main mineralocorticoid and is responsible for approximately 90% of mineralocorticoid activity; sodium resorption by the kidneys, potassium is lost in the urine.

**Alopecia:** temporary hair loss; commonly occurs during chemotherapy.

**Agranulocytosis:** an acute condition caused by loss or absence of granulocyte white blood cells.

**Akathisia:** manifested by motor restlessness and inability to be still, usually occurs in the first few months of treatment with antipsychotics.

**Akinesia:** inability to move.

**Agonists:** drugs that produce effects similar to those produced by naturally occurring hormones, neurotransmitters, and other substances.

**Alcohol abuse:** acute or chronic consumption of alcohol in excess of the limits accepted by the person's culture; may not necessarily be dependent on alcohol.

**Alpha-adrenergic blocking drugs:** act primarily in the skin, mucosa, intestines, lungs, and kidneys to block or prevent alpha-mediated vasoconstriction.

**Alpha<sub>1</sub> receptors:** receptors on surface membranes of target tissues and organs; mainly postsynaptic.

**Alpha<sub>2</sub> receptors:** receptors on surface membranes of target tissues and organs; mainly presynaptic.

**Alzheimer's disease:** the most common type of dementia in adults; is characterized by abnormalities in the cholinergic, serotonergic, noradrenergic, and glutamatergic neurotransmission systems.

**Anabolic steroids:** synthetic drugs with increased anabolic activity and decreased androgenic activity compared with testosterone.

**Analgesia:** loss of pain sensation.

**Anaphylactic shock:** characterized by hypotension due to massive vasodilation and acute airway obstruction due to bronchoconstriction caused by release of histamine and other chemical mediators in response to a severe allergic reaction.

**Anaphylaxis:** a type I immunoglobulin E-mediated allergic reaction to a foreign substance (antigen) that has entered the body; occurs on second or subsequent exposure to an antigen. Symptoms develop rapidly; typical symptom onset ranges from 30 minutes to 2 hours after exposure to the antigen.

**Androgens:** male sex hormones, primarily testosterone, secreted by the testes in men, the ovaries in women, and the adrenal cortex of both sexes.

**Angina pectoris:** chest pain that results from a deficit in myocardial oxygen supply (myocardial ischemia) in relation to myocardial oxygen demand, most often caused by atherosclerotic plaque in the coronary arteries.

**Angiogenesis:** the process of forming new blood vessels.

**Angiotensin converting enzyme (ACE) inhibitor:** drug that decreases activation of the renin-angiotensin-aldosterone system; specifically, the drug prevents inactive angiotensin I from being converted to angiotensin II.

**Angiotensin II receptor blocker (ARB):** similar to ACE inhibitor, although the mechanism of action is blockade of the angiotensin II receptor site.

**Anhedonia:** lack of pleasure.

**Anorexiant:** drug that suppresses the appetite.

**Anticipatory nausea:** triggered by fears of nausea and vomiting; conditioned response to either chemotherapy or nausea in pregnancy.

**Antagonist:** drug that inhibits cell function by occupying receptor sites.

**Antiadrenergic drug:** decreases or blocks the effects of sympathetic nerve stimulation.

**Antibacterial:** drug used to treat bacterial infections; used interchangeably with antibiotic.

**Antibiotic:** drug used to treat bacterial infections.

**Antibiotic resistance:** bacteria resistant to the effects of antibiotic drugs; occurs in most human pathogens.

**Anticholinesterase:** indirect-acting cholinergic drug that decreases the inactivation of acetylcholine in the synapse by the enzyme acetylcholinesterase.

**Anticoagulants:** drugs that prevent formation of new clots and extension of clots already present; they do not dissolve formed clots.

**Anticonvulsant:** an antiseizure drug; also referred to as antiepileptic drug (AED).

**Antidepressant discontinuation syndrome:** occurs with sudden termination of most antidepressant drugs; symptoms occur more rapidly and may be more intense with drugs that have a short half-life and/or with long-term antidepressant therapy.

**Antidiuretic hormone (ADH):** functions to regulate water balance; is secreted when body fluids become concentrated and when blood volume is low.

**Antiemetic:** drug that is used to prevent or treat nausea and vomiting.

**Antigen:** foreign substance.

**Anti-inflammatory:** drug that is indicated when the inflammatory response is inappropriate, abnormal, or persistent, or destroys tissue.

**Anti-microbial:** drug used to prevent or treat infections caused by pathogenic microorganisms.

**Antimuscarinic drug:** drug that interacts with muscarinic cholinergic receptors in the brain, secretory glands, heart, and smooth muscle to produce an anticholinergic response.

**Anterograde amnesia:** short-term memory loss.

**Anticholinergic drug:** blocks the action of acetylcholine on the parasympathetic nervous system.

**Antigen:** a foreign substance that initiates immune responses; antigens have specific sites that interact with immune cells to induce the immune response; when discussing hypersensitivity conditions they are referred to as allergens.

**Anti-infective:** drug used to treat infection.

**Anti-oncogene:** a tumor suppressor gene that normally functions to inhibit inappropriate cellular growth and proliferation.

**Antiplatelet drug:** drug that prevents one or more steps in the prothrombotic activity of platelets.

**Antipyretics:** drugs that have the ability to relieve pain, fever, and/or inflammation, symptoms associated with many injuries and illnesses.

**Antiprostaglandin drugs:** drugs such as aspirin, NSAIDs, and acetaminophen that inhibit the synthesis of prostaglandins.

**Antiretroviral drugs:** Antiviral medications used in the treatment of retroviral infections such as HIV.

**Antiretroviral therapy (ART):** used in treatment of HIV infection; newer drugs and drug combinations that are more effective in viral suppression, cause fewer serious adverse effects, and are more convenient for patients to take.

**Antitussives:** drugs that suppress cough by depressing the cough center in the medulla oblongata or the cough receptors in the throat, trachea, or lungs.

**Anxiety:** a common disorder that may be referred to as nervousness, tension, worry, or other terms that denote an unpleasant feeling.

**Anxiety disorder:** severe anxiety that is prolonged and impairs the ability to function in usual activities of daily living.

**Anxiolytics:** anti-anxiety drugs.

**Arachidonic acid:** a fatty acid present in cell membranes that is metabolized by cyclooxygenase (COX) enzymes to produce prostaglandins.

**Atherosclerosis:** disease process that often leads to pathologic thrombosis; begins with accumulation of lipid-filled macrophages (i.e., foam cells) on the inner lining of arteries. Foam cells develop in response to elevated blood lipid levels and eventually become fibrous plaques, often in arteries supplying the heart, brain, and legs.

**Attention-deficit hyperactivity disorder (ADHD):** most common psychiatric or neurobehavioral disorder in children; it is characterized by persistent hyperactivity, a short attention span, difficulty completing assigned tasks or schoolwork, restlessness, and impulsiveness.

**Autonomic nervous system (ANS):** controls involuntary activities in smooth muscle, secretory glands, and in the visceral organs of the body such as the heart.

**Autoregulation:** the ability of body tissues to regulate their own blood flow.

**Bacteria:** unicellular microorganisms sub-classified according to whether they are aerobic (require oxygen) or anaerobic (cannot live in the presence of oxygen), their reaction to Gram's stain (gram positive or gram negative), and their shape (e.g., cocci, bacilli).

**Bactericidal:** the action of an antibacterial drug that kills the microorganism.

**Bacteriostatic:** the action of an antibacterial drug that inhibits growth of the microorganism.

**Basal ganglia:** the area in the midbrain that controls smooth voluntary movement.

**Bioavailability:** the portion of a drug dose that reaches the systemic circulation and is available to act on body cells.

**Biotechnology:** the process of manipulating deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) and recombining genes into hybrid molecules that can be inserted into living organisms (*Escherichia coli* bacteria are often used) and repeatedly reproduced.

**Biotransformation:** also referred to as metabolism; when drugs are altered from their original form into a new form by the body.

**Bipolar disorder:** mood disorder characterized by episodes of depression alternating with episodes of mania.

**Bisphosphonates:** drugs that bind to bone and inhibit calcium resorption from bone; used mainly in the treatment of hypercalcemia and osteoporosis.

**Blood glucose level:** blood sugar level in the body.

**Blood glucose meter:** device that measures how much glucose is in the blood.

**Bradykinesia:** slow movement.

**Body mass index (BMI):** reflects weight in relation to height and is a better indicator than weight alone when determining the fitness level of a person.

**Bradykinin:** a peptide that causes vasodilation and lowers blood pressure.

**Brand or trade name:** name given to a drug designated and patented by the manufacturer.

**Breakthrough pain:** acute pain in people who have been receiving opioids for chronic pain.

**Broad spectrum antibacterials:** drugs that are effective against several groups of microorganisms, including gram positive and gram negative microorganisms.

**Calcitonin:** used in the treatment of hypercalcemia and osteoporosis.

**Cannabinoid:** derivative of marijuana.

**Cancer:** used to describe many disease processes with the common characteristics of uncontrolled cell growth, invasiveness, and metastasis.

**Candidiasis:** infection either containing or caused by *Candida* fungi.

**Carcinomas:** the most common type of malignant cancer; derived from epithelial tissues (skin, mucous membrane, linings and coverings of viscera).

**Cardiogenic shock:** occurs when the myocardium has lost its ability to contract efficiently and maintain an adequate cardiac output.

**Cardioselective beta blockers:** drugs that have more effect on beta<sub>1</sub> receptors than on beta<sub>2</sub> receptors; may cause less bronchospasm, less impairment of glucose metabolism, and less peripheral vascular insufficiency, than non-selective beta blockers.

**Catechol-O-methyltransferase (COMT):** an enzyme that degrades and inactivates catecholamines such as dopamine, epinephrine, norepinephrine.

**Cathartics:** drugs with strong laxative effects and elimination of liquid or semiliquid stool.

**Ceiling drug:** an opioid whose dosage cannot be increased above a certain amount without causing severe adverse effects.

**Cell cycle:** the interval between the “birth” of a cell and its division into two daughter cells.

**Central adiposity:** elevated waist circumference.

**Chemoreceptor trigger zone (CTZ):** one of the central sites that relays stimuli to the vomiting center.

**Chemotherapy:** treatment of disease with drugs that kill cells, usually indicates treatment for cancer or infection.

**Cholesterol:** component of cell membrane that is produced and processed in the liver; a fat that is essential for the formation of steroid hormones; it is produced in cells and taken in by dietary sources.

**Cholinergic drugs:** stimulate the parasympathetic nervous system in the same manner as acetylcholine.

**Choreoathetoid:** twisting, worm-like movements of the face and tongue

**Chronotropy:** affects the rate of occurrence; such as heart rates.

**Clinical pathways:** guidelines for the care of patients with particular conditions.

**Clonic:** spasms that alternate between contraction and relaxation.

**Colonization:** the presence of normal microbial flora or transient environmental organisms that do not harm the host.

**Community-acquired infections:** are usually acquired outside of the hospital.

**Conjunctiva:** the mucous membrane lining of the eyelids.

**Constipation:** the infrequent and painful expulsion of hard, dry stools.

**Controlled substances:** drugs that are categorized by federal law according to therapeutic usefulness and potential for abuse.

**Convulated tubules:** along with glomerul; comprise the nephrons; referred to as convoluted because the tubules contain many twists and turns.

**Convulsion:** a tonic-clonic type of seizure characterized by spasmodic contractions of involuntary muscles.

**Coronary artery disease (CAD):** the development and progression of atherosclerotic plaque; results in impaired blood flow to the myocardium.

**Corticosteroids:** steroid hormones produced by the adrenal cortex; include androgens, glucocorticoids, and mineralocorticoids.

**Corticotropin:** an anterior pituitary hormone obtained from animal pituitary glands; may be used as a diagnostic test to differentiate primary adrenal insufficiency from secondary adrenal insufficiency caused by inadequate pituitary secretion of corticotropin.

**Cortisol:** the main glucocorticoid secreted as part of the body's response to stress.

**Cretinism:** congenital hypothyroidism; occurs when a child is born with a poorly functioning or absent thyroid gland.

**Crystalluria:** presence of crystals in the urine.

**Cyclooxygenase (COX):** enzyme required for prostaglandin formation; there are two forms: Cox-1 and Cox-2.

**Cyclothymia:** a mild type of bipolar disorder that involves periods of hypomania and depression that do not meet the criteria for mania and major depression.

**Cushing's disease:** adrenocortical hyperfunction; may result from excessive corticotropin or a primary adrenal tumor

**Cycloplegia:** paralysis in the ciliary muscle of the eye.

**Decongestants:** drugs that decrease the blood flow to the upper respiratory tract and decrease the overproduction of secretions.

**Defecation:** bowel elimination that is normally stimulated by movements and reflexes in the gastrointestinal (GI) tract.

**Delusions:** false beliefs that persist in the absence of reason or evidence.

**Depression:** the most common mental illness, is characterized by depressed mood, feelings of sadness or emotional upset, and it occurs in all age groups.

**Dermatitis:** a general term denoting an inflammatory response of the skin to injuries from irritants, allergens, or trauma; also referred to as eczema.

**Detection of antigens:** technique to identify pathogens that uses features of culture and serology but reduces the time required for diagnosis.

**Diabetes mellitus:** a chronic disease characterized by disordered metabolism of carbohydrates, fats, and protein, and hyperglycemia, due to a deficiency in the amount or action of insulin. There are 3 main forms of diabetes: Type 1, Type 2, and gestational diabetes.

**Diarrhea:** a symptom of numerous conditions that increase bowel motility; cause secretion or retention of fluids in the intestinal lumen; and cause inflammation or irritation of the gastrointestinal (GI) tract.

**Diuretics:** drugs that increase renal excretion of water, sodium, and other electrolytes – increasing urine formation and output; useful in preventing renal failure by their ability to sustain urine flow.

**Directly observed therapy (DOT):** a health care provider (or other responsible adult) observes the patient taking each dose of anti-TB drugs; recommended for all drug regimens and considered mandatory in intermittent schedules and regimens for MDR-TB.

**Disease modifying antirheumatic drugs (DMARDs):** include a variety of medications used to relieve symptoms and slow joint destruction (so-called disease-modifying effects); the drugs of choice to treat active rheumatoid arthritis (Level B-C).

**Distributive shock:** characterized by massive vasodilation, which results in a relative hypovolemia; further divided into anaphylactic, neurogenic, and septic shock.

**Distribution:** transport of drug molecules within the body; after a drug is injected or absorbed into the bloodstream, it is carried by the blood and tissue fluids to its sites of action, metabolism, and excretion.

**Dopamine:** a neurotransmitter in the dopaminergic system; is inhibitory in the basal ganglia but may be excitatory in other areas. Repeated stimulation of dopamine receptors decreases their numbers (down-regulation) and their sensitivity to dopamine (desensitization).

**Dopaminergic drugs:** increase the amount of dopamine in the brain by various mechanisms.

**Dosage forms:** forms in which drugs are manufactured; vary according to the drugs' chemical characteristics, reason for use and route of administration; some available in one dosage form and others in multiple forms; forms include: liquids, tablets, capsules, suppositories, and transdermal and pump delivery systems.

**Down regulation:** decrease in receptor number or responsiveness.

**Dromotropy:** influencing conduction of electrical impulses in cardiac muscles and nerves.

**Drug classifications:** Drugs are classified according to their effects on particular body systems, their therapeutic uses, and their chemical characteristics.

**Drug withdrawal reactions:** signs and symptoms that occur when some drugs are abruptly discontinued or their dosage is decreased; occur with ethanol dependence, opioids, benzodiazepines, and antidepressants.

**Dwarfism:** a condition marked by severely decreased linear growth and, frequently, severely delayed mental, emotional, dental, and sexual growth as well; caused by a lack of growth hormone (GH).

**Dyskinesia:** difficulty in performing voluntary movements.

**Dyslipidemia:** abnormal lipid levels in the blood, associated with atherosclerosis and its many pathophysiologic effects (e.g., myocardial ischemia and infarction, stroke, peripheral arterial occlusive disease).

**Dysmenorrhea:** pain associated with menstruation

**Dysthymia:** involves a chronically depressed mood and at least two other symptoms of depression for 2 years.

**Dystonia:** uncoordinated, twisting and repetitive movements of the neck, face, eyes, tongue, trunk, or extremities.

**Edema:** the excessive accumulation of fluid in body tissues.

**Effector organ:** target organ containing receptors for a neurotransmitter, hormone or other chemical; stimulation of receptors on an effector organ produces a response.

**Embolus:** an object that migrates through the circulation until it lodges in a blood vessel, causing occlusion; may be a thrombus, fat, air, amniotic fluid, a bit of tissue, or bacterial debris.

**Emesis:** the act of vomiting.

**Emetogenic:** drugs that cause vomiting.

**Emollient:** lubricants used to relieve pruritus and dryness of the skin.

**Endogenous analgesia system:** body system for relieving pain by suppressing the transmission of pain signals from peripheral nerves; may also inhibit pain signals at other points in the pain pathway.

**Endorphins:** peptides found in the brain that interact with opioid receptors to inhibit perception and transmission of pain signals.

**Epinephrine:** the drug of choice for the treatment of anaphylaxis. It relieves bronchospasm, laryngeal edema, and hypotension; a catecholamine.

**Ergogenic:** an increase in muscular work capacity caused by drugs that enhance athletic performance.

**Erythema:** redness of the skin.

**Excretion:** elimination of a drug from the body; effective excretion requires adequate functioning of the circulatory system and of the organs of excretion (kidneys, bowel, lungs, and skin).

**Expectorants:** drugs given orally to liquefy respiratory secretions and allow for ease of removal.

**Extrapyramidal reaction:** movement disorders such as tardive dyskinesia, akathisia, dystonia, and drug-induced parkinsonism that may occur with usage of antipsychotic drugs.

**Extravasation:** leaking of medication into soft tissues around the venipuncture site.

**Enteric-coated:** tablets and capsules that are coated with a substance that is insoluble in stomach acid.

**Enterohepatic recirculation:** drugs or metabolites that are excreted in bile, reabsorbed from the small intestine, returned to the liver, metabolized, and eventually excreted in urine.

**Enzyme inducing drugs:** stimulate liver cells to produce larger amounts of drug-metabolizing enzymes; accelerate drug metabolism because larger amounts of the enzymes (and more binding sites) allow larger amounts of a drug to be metabolized during a given time.

**Enzyme inhibiting drugs:** inhibit production of drug-metabolizing enzymes and often occurs with concurrent administration of two or more drugs that compete for the same metabolizing enzymes; occurs within hours or days of starting an inhibiting agent.

**Epilepsy:** seizures that occur in a chronic, recurrent pattern.

**Estrogen:** produced primarily by the ovaries and secondarily by the adrenal cortex; promotes growth of specific body cells and development of most female secondary sexual characteristics.

**Extensively drug-resistant tuberculosis (XDR-TB):** indicates resistance to the second-line drugs used to treat multidrug-resistant tuberculosis (MDR-TB).

**Euthyroid:** normal thyroid gland functioning.

**Evidence-based practice:** a conscientious and continuing effort to provide high-quality care to patients by obtaining and analyzing the best available scientific evidence from research; the scientific evidence is integrated with the nurse's clinical expertise and the patient's preferences and values to yield "best practices" for a patient with a particular disease process or health problem.

**Extrapyramidal effects:** neuromuscular symptoms (i.e., abnormal movements) brought on by usage of antipsychotic drugs.

**Fetotoxic:** drugs harmful to the fetus

**Fibrinolysin:** see plasmin.

**First messenger:** the ligand that binds the receptor on target tissues.

**First-pass effect:** initial metabolism of some oral drugs as they are carried from the intestine to the liver by the portal circulatory system prior to reaching the systemic circulation for distribution to site of action.

**"Five rights":** the basic requirements for accurate drug administration; require knowledge of the drugs to be given and the patients who are to receive them as well as specific nursing skills and interventions.

**Floppy iris syndrome:** possible surgical complication of cataract surgery for patients taking  $\alpha_1$ -blockers. The drugs may cause the pupil to constrict and the iris to relax.

**Fungi:** plant-like organisms that live as parasites on living tissue or as saprophytes on decaying organic matter.

**Gamma amino butyric acid (GABA):** abundant in the brain and spinal cord; the major inhibitory neurotransmitter in the CNS, with a role in many neuronal circuits.

**Generic name:** is related to the chemical or official name of the drug; independent of the manufacturer and often indicates the drug group.

**Genital herpes:** an infection caused by the herpes simplex virus (HSV) and produces recurrent, painful, blister-like lesions on skin and mucous membranes.

**Gingival hyperplasia:** an overgrowth of gum tissue, common in children.

**Glaucoma:** group of diseases characterized by optic nerve damage and changes in visual fields; characterized by increased IOP (above 22 mm Hg) but may also occur with normal IOP (below 21 mm Hg); average 15–16 mm Hg; one of the leading causes of blindness in the United States.

**Glucagon:** a pancreatic hormone that raises blood glucose levels by stimulating the liver to convert glycogen into glucose. Opposes insulin.

**Gluconeogenesis:** the formation of glucose from non-carbohydrate sources such as fats and amino acids.

**Glucose:** sugar in the blood; major stimulus of insulin secretion.

**Glucocorticoid:** includes cortisol, corticosterone, and cortisone; secreted cyclically, with the largest amount being produced in the early morning and the smallest amount produced during evening hours.

**Glutamate:** the most important excitatory neurotransmitter, occurs in high concentrations in most areas of the CNS.

**Glycylcycline:** a new class of antibiotics that are structurally related to tetracyclines, and share many of their properties; used for the treatment of complicated skin and skin structure infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-sensitive *Enterococcus faecalis*, as well as treatment of complicated intra-abdominal infections.

**Goiter:** visible enlargement of the thyroid gland.

**Gonadotropin-releasing hormone (GnRH):** causes release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

**Graves' disease:** antibody-mediated autoimmune disease resulting in hyperthyroidism. Most common cause of hyperthyroidism.

**Gray syndrome:** a dangerous condition that occurs in newborns who are given chloramphenicol; may lead to fatalities.

**Growth hormone:** stimulates growth of body tissues; regulates cell division and protein synthesis required for normal growth and promotes an increase in cell size and number, including growth of muscle cells and lengthening of bone.

**Hallucinations:** sensory perceptions of people or objects that are not present in the external environment.

**Hallucinogen:** a substance that produces hallucinations.

**Hemostasis:** the prevention or stoppage of blood loss from an injured blood vessel and is the process that maintains the integrity of the vascular compartment.

**Hepatitis:** inflammation of the liver usually caused by a viral infection.

**Herpesvirus:** any virus belonging to the family Herpesviridae.

**Highly active antiretroviral therapy (HAART):** several combinations of antiretroviral drugs used at one time to treat HIV/AIDS.

**Histamine:** found mainly in mast cells surrounding blood vessels and is released when these tissues are injured.

**Hormones:** chemical messengers to transmit information between body cells and organs.

**Human immunodeficiency virus (HIV):** an infection caused by a retrovirus that infects the immune system; there are two types of HIV virus identified, HIV-1 and HIV-2; most infections in U.S. are caused by HIV-1; HIV-2 infection occur mainly in Africa; virus is most commonly spread by sexual intercourse; injection of intravenous drugs with contaminated needles; and mucous membrane contact with infected blood or body fluids.

**Hypnotic:** a drug that produces sleep.

**Hypersensitivity:** or allergy; may occur with almost any drug; it is unpredictable and unrelated to dose; occurs in patients who have been previously exposed to the drug or a similar substance and who have developed antibodies; drugs react with antibodies to cause cell damage and the release of histamine and other intracellular substances; subsequently producing reactions ranging from mild skin rashes to anaphylactic shock.

**Hypercalcemia:** abnormally high blood calcium level.

**Hyperkalemia:** greater than normal concentration of potassium in the blood.

**Hyperlipoproteinemias:** types of dyslipidemias; increased blood levels of lipoproteins.

**Hyperparathyroidism:** excessive production of parathyroid hormone (PTH); caused by a tumor or hyperplasia of a parathyroid gland.

**Hypertensive crisis:** extreme elevations in blood pressure which may result in acute organ damage such as a stroke or MI.

**Hyperuricemia:** elevated levels of uric acid in the blood resulting from accelerated generation of uric acid through purine metabolism or impaired renal excretion of uric acid.

**Hypocalcemia:** abnormally low blood calcium level; may be caused by inadequate intake of calcium and Vitamin D.

**Hypokalemia:** abnormally small amount of potassium in the blood.

**Hypomania:** persistent irritable mood but absence of psychotic symptoms characteristic of true mania.

**Hypoparathyroidism:** insufficient production of parathyroid hormone.

**Hypothalamus:** the link between the nervous and endocrine systems; controls secretions of almost all hormones from the pituitary gland; secretes hormones called releasing and inhibitory factors, which regulate functions of the anterior pituitary.

**Hypothalamic-pituitary-adrenocortical (HPA) axis:** a negative feed back mechanism by which the body controls cortisol secretion.

**Hyperthyroidism:** excessive secretion of thyroid hormone; usually involves an enlarged thyroid gland that has an increased number of cells and an increased rate of secretion.

**Hypothyroidism:** occurs when disease or destruction of thyroid gland tissue causes inadequate production of thyroid hormones.

**Hypovolemic shock:** a loss of intravascular fluid volume that may be due to actual blood loss or relative loss from fluid shifts within the body.

**Immunocompetent:** a normal immune response

**Immunocompromise:** an impaired or weakened immune system.

**Immunosuppression:** suppression of immune system

**Impaction:** a mass of hard, dry stool in the rectum; caused by chronic constipation.

**Impaired fasting glucose (IFG):** an individual with a fasting blood glucose level between 100 mg/dL to 125 mg/dL; also referred to as prediabetes.

**Inflammatory bowel disorder:** disease characterized by inflammation of the intestines (e.g., ulcerative colitis, Crohn's disease).

**Inhibiting hormone:** produced by the hypothalamus; decreases hormone secretion that corresponds to each of the major hormones of the anterior pituitary gland.

**Inotropy:** changes in the force of myocardial contraction.

**Insulin:** a protein hormone secreted by beta cells in the pancreas; facilitates glucose utilization by cells; absence of insulin results in diabetes mellitus.

**Insulin pump:** a wearable delivery system for continuous Sub-Q insulin infusion; the insulin dosage is programmed into the pump and the appropriate amount of insulin is injected into the adipose tissue through a needle inserted into the Sub-Q area.

**Intraocular pressure (IOP):** the pressure inside the eye.

**Intrinsic sympathetic activity (ISA):** partial agonist activity at adrenergic receptors exerted by beta blockers with ISA properties, due to structural similarity with catecholamines.

**Irritable bowel syndrome:** a functional disorder of intestinal motility characterized by absence of inflammation or tissue changes; a change in bowel pattern (constipation, diarrhea, or a combination of both); and abdominal pain, bloating, and distention.

**Jaundice:** yellow discoloration of the skin due to excessive levels of bilirubin in the blood.

**Keratin:** a tough protein substance that is insoluble in water, weak acids, and weak bases.

**Keratitis:** inflammation of the cornea.

**Ketoacidosis:** a metabolic acidosis due to accumulation of ketone bodies formed by the breakdown of fatty acids and amino acids for energy in the absence of insulin.

**Ketolides:** newer class of antibiotics that belong to the macrolide group; have a more broad spectrum effect compared to macrolides, especially in *Streptococcus pneumoniae* infections.

**Lancet:** sharp instrument used to prick the finger for blood test.

**Lacrimation:** production of tears

**Laxatives:** drugs with mild effects and elimination of soft, formed stool.

**Leukemias:** cancers of the bone marrow characterized by overproduction of abnormal white blood cells; there are four main types: acute lymphocytic; acute myelogenous; chronic lymphocytic; and chronic myelogenous.

**Leukopenia:** abnormally low white blood cell count.

**Ligands:** neurotransmitters as well as medications and hormones that can bind to receptors in the ANS.

**Lincosamide:** similar to macrolides in its mechanism of action and antimicrobial spectrum.

**Lipopeptide:** a new class of antibiotics that kills gram positive bacteria by inhibiting synthesis of bacterial proteins, DNA and RNA.

**Lipoproteins:** specific proteins in plasma that transport blood lipids; each contains cholesterol, phospholipid, and triglyceride bound to protein; vary in density and amounts of lipid and protein.

**Loop diuretics:** inhibit sodium and chloride reabsorption in the ascending limb of the loop of Henle, where reabsorption of most filtered sodium occurs; diuretics of choice when rapid effects are required and when renal function is impaired.

**Macrolides:** may be bacteriostatic or bactericidal, depending on drug concentration in infected tissues; widely used for treatment of respiratory tract and skin/soft tissue infections caused by streptococci and staphylococci.

**Malignant:** cells that grow in an uncontrolled fashion and avoid the restraints (e.g., contact with other cells) that stop the growth of normal cells.

**Malignant hyperthermia:** a rare but life-threatening complication of anesthesia characterized by hypercarbia, metabolic acidosis, skeletal muscle rigidity, fever, and cyanosis.

**Mania:** an emotional disorder characterized by euphoria or irritability; usually occurs in bipolar disorder.

**Medication history:** information about a patient's use of prescription and non-prescription drugs.

**Melanocytes:** pigment-producing cells located at the junction of the epidermis and the dermis; produce yellow, brown, or black skin coloring in response to genetic influences, melanocyte-stimulating hormone released from the anterior pituitary gland, and exposure to ultraviolet light.

**Membrane-stabilizing effect:** beta blockers that produce myocardial depression.

**Menopause:** permanent end of the menstrual cycle; usually occurs in women aged 48-55.

**Metabolism:** the rate at which cells burn energy.

**Metabolic syndrome:** a cluster of several cardiovascular risk factors linked with obesity, elevated waist circumference, elevated triglycerides, reduced high-density lipoprotein cholesterol, elevated blood pressure, and elevated fasting glucose.

**Metastasis:** the spread of malignant cells from one part of the body to another.

**Methicillin-resistant *Staphylococcus aureus* (MRSA):** microorganisms resistant to broad-spectrum antibiotics such as penicillin, erythromycin; frequently colonizes nasal passages of health care workers and is increasing as a cause of infection in critical care units.

**Methicillin-resistant staphylococcal species non-aureus (SSNA):** other strains of antibiotic-resistant staphylococci.

**Mineralocorticoid:** steroid hormones released by the adrenal cortex; they cause sodium and water retention and potassium excretion.

**Miosis:** pupil constriction

**Monoamine oxidase inhibitors (MAOIs):** class of antidepressants used to treat depressive disorders; considered third line medications in the treatment of depression because of a high

incidence of food and drug interactions which potentially lead to hypertensive crisis.

**Monotherapy:** the use of a single drug in drug therapy; has the advantages of fewer adverse drug effects, fewer drug-drug interactions, lower cost, and usually greater patient compliance.

**Motion sickness:** rapid changes in body motion stimulate receptors in the inner ear (vestibular branch of the auditory nerve, which is concerned with equilibrium), and nerve impulses are transmitted to the vomiting center.

**Mottling:** permanent discoloration of skin or teeth.

**Mucolytics:** administered by inhalation to liquefy mucus in the respiratory tract; solutions of mucolytic drugs may be nebulized into a face mask or mouthpiece or instilled directly into the respiratory tract through a tracheostomy.

**Mucositis:** inflammation and erosion of oral mucous membrane.

**Multidrug-resistant tuberculosis (MDR-TB):** indicates organisms that are resistant to isoniazid (INH) and rifampin, the most effective drugs available, with or without resistance to other antitubercular drugs; 24 months of drug therapy is often recommended; cure rate is 50%.

**Muscarinic receptors:** located in most internal organs, including the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. When activated by acetylcholine, the affected cells may be excited or inhibited in their functions.

**Muscle spasm:** a sudden, involuntary, painful muscle contraction that occurs with musculoskeletal trauma or inflammation.

**Mutation:** abnormal structural change in the genetic material of a cell.

**Myasthenia gravis:** an autoimmune disorder in which autoantibodies are thought to destroy nicotinic receptors for acetylcholine on skeletal muscle. As a result, acetylcholine is less able to stimulate muscle contraction, and muscle weakness occurs.

**Mycobacterium avium complex (MAC) disease:** caused by atypical mycobacteria; occurs mainly in people with advanced human immunodeficiency virus (HIV) infection.

**Myelosuppression:** bone marrow depression.

**Myocardial infarction:** interruption in blood supply to a portion of the heart; most commonly due to thrombus formation at the site of a ruptured atherosclerotic plaque in the coronary artery. If untreated, infarction or death of myocardium occurs.

**Mydriasis:** pupil dilation.

**Myxedema:** adult hypothyroidism; occurs more often in women than in men.

**Narcolepsy:** sleep disorder that is characterized by daytime "sleep attacks" in which the person goes to sleep at any place or at any time.

**Nasolacrimal occlusion:** applying pressure on the tear duct.

**Nausea:** an unpleasant sensation of abdominal discomfort accompanied by a desire to vomit.

**Negative feedback:** the influence of the output of a system affects the stimulus for the system (e.g., hormone secretion produces an effect that shuts off the stimulus for further hormone secretion).

**Neonatal withdrawal syndrome:** Occurs in newborns who were exposed to CNS depressants during the third trimester.

Common symptoms include irritability, prolonged crying, respiratory distress, rigidity and possibly seizures.

**Nephron:** the functional unit of the kidney; each kidney contains approximately 1 million nephrons.

**Nephropathy:** any disease of the kidney.

**Nephrotoxicity:** toxic or damaging effect of a substance on the kidney; potentially serious because renal damage interferes with drug excretion, causing drug accumulation and increased adverse effects.

**Neuron:** structural unit of the nervous system.

**Neurogenic shock:** due to massive vasodilation caused by suppression of the sympathetic nervous system.

**Neuroleptic:** antipsychotic drug used to treat disorders that involve thought processes.

**Neuroleptic malignant syndrome:** a rare but potentially fatal adverse effect; characterized by rigidity, severe hyperthermia, agitation, confusion, delirium, dyspnea, tachycardia, respiratory failure and acute renal failure.

**Neuropathic:** pain that is caused by lesions or physiologic changes that injure peripheral pain receptors, nerves, or the CNS.

**Neurotransmission:** neurotransmitters, synapses, and receptors work together to produce communication networks; the interactions between and among these systems promote order or disorder in the body's physical and mental processes.

**Neutropenia:** low neutrophil count.

**Neurotransmitters:** chemical substances that carry messages from one neuron to another, or from a neuron to other body tissues, such as cardiac or skeletal muscle.

**Nicotinic receptors:** located in motor nerves and skeletal muscle; when activated by acetylcholine, the cell membrane depolarizes and produces muscle contraction.

**Nitrous oxide:** a nonflammable, nonexplosive gas that supports combustion; widely used as a rapidly acting, reversible, nondepressant to supplement other anesthetics.

**Nociceptors:** pain receptors that are abundant in arterial walls, joint surfaces, muscle fascia, periosteum, skin and soft tissues; they are scarce in most internal organs.

**Non-ceiling opioid:** opioid with no upper limit to the dosage that can be given to patients who have developed tolerance to previous dosages.

**Nonsteroidal anti-inflammatory drugs (NSAIDs):** inhibit the synthesis of prostaglandins; used to prevent and treat mild to moderate pain and inflammation.

**Norepinephrine:** mainly an excitatory neurotransmitter that stimulates the brain to generalized increased activity.

**Nosocomial infections:** hospital-acquired; may be more severe and difficult to manage because they often result from drug-resistant microorganisms and occur in people whose immunity is impaired.

**Nursing process:** systematic way of gathering and using information to plan and provide individualized patient care and to evaluate the outcomes of care through use of assessment, nursing diagnosis, planning/goals, interventions, and evaluation.

**Obesity:** defined as a body mass index (BMI) of 30 or more kg/m<sup>2</sup>

**Oncogenes:** abnormal genes that are mutations of normal growth-regulating genes referred to as proto-oncogenes.

**Opioid receptors:** delta, kappa, and mu receptors located in the brain and spinal cord; endogenous opioids as well as opioid medications serve as ligands.

**Opportunistic:** microorganisms that are usually normal endogenous or environmental flora and nonpathogenic; they produce disease in hosts whose defense mechanisms are impaired.

**Oral glucose tolerance test (OGTT):** test used to determine how the body handles sugar; indicates if a patient has prediabetes or diabetes; test consists of drinking a liquid containing glucose, followed by a blood test 1 hour after consumption.

**Organogenesis:** formation of fetal organs

**Osmotic diuretics:** produce rapid diuresis by increasing the osmolarity of plasma and pulling water out of tissues into the bloodstream.

**Osteoporosis:** decreased bone density and weak, fragile bones that often lead to fractures, pain, and disability.

**Ototoxic:** adverse effects on the structures of the ear, especially the cochlea and auditory nerve.

**Over-the-counter (OTC) drugs:** drugs that are available without a prescription.

**Overweight:** defined as a body mass index (BMI) of 25 to 29.9 kilograms per square meter (kg/m<sup>2</sup>)

**Oxazolidinones:** a newer class of antibiotics; active against aerobic gram-positive bacteria, in which it acts by inhibiting protein synthesis.

**Oxytocin:** posterior pituitary hormone; it initiates uterine contractions at the end of gestation to induce childbirth, and it causes milk to move from breast glands to nipples.

**Paget's disease:** an inflammatory skeletal disease that affects older people; characterized by a high rate of bone turnover, bone deformity and pain.

**Pain:** unpleasant, uncomfortable sensation that usually indicates tissue damage and impels a person to remove the cause of the damage or seek relief from the pain.

**Paranoia:** the belief that other people control their thoughts, feelings, and behaviors or seek to harm them.

**Parasympathetic nervous system:** a division of the autonomic nervous system that regulates the routine activities of digestion and elimination; functions stimulated by the parasympathetic nervous system are often described as resting, reparative, or vegetative functions. They include digestion, excretion, cardiac deceleration, anabolism, and near vision.

**Parathyroid hormone (PTH):** helps regulate calcium and bone metabolism; stimulated by low serum calcium levels

**Parkinson's disease:** a chronic, progressive, degenerative disorder of the central nervous system (CNS) characterized by resting tremor, bradykinesia, rigidity, and postural instability; also called parkinsonism.

**Patient-controlled analgesia:** allows the patient to self-administer pain medication through the push of a button on an infusion pump; the amount of drug in each dose delivered is preset and limited.

**Penicillin-binding proteins:** the binding site within the bacterial cell wall for penicillins; binding disrupts the bacterial cell wall, resulting in bacterial cell lysis.

**Parenteral:** route of drug administration; injected.

**Pharmacoeconomics:** involves the costs of drug therapy, including costs of purchasing; dispensing; storage; administration; laboratory and other tests used to monitor patient responses; and losses due to expiration.

**Pharmacodynamics:** reactions between living systems and drugs; drug actions on target cells and the resulting alterations in cellular biochemical reactions and functions

**Pharmacogenetics:** study of genetic variations that result in interindividual differences in drug response.

**Pharmacotherapy:** the use of drugs to prevent, diagnose, or treat signs, symptoms and disease processes.

**Pharmacokinetics:** drug movement through the body to reach sites of action, metabolism, and excretion.

**Phospholipids:** major components of the cell membrane portion of all body cells.

**Plasmin:** an enzyme that breaks down the fibrin meshwork that stabilizes blood clots; also referred to as fibrinolysin.

**Plasminogen:** an inactive protein found in many body tissues and fluids

**Post antibiotic effect:** a persistent effect of an antimicrobial on bacterial growth after brief exposure of the organisms to a drug.

**Post-ganglionic:** nerve fibers from the ganglia to target or effector tissues of the heart, blood vessels, glands, other visceral organs, and smooth muscle.

**Pre-ganglionic:** nerve fibers from the CNS along the presynaptic nerves to ganglia.

**Postsynaptic:** occurring after a synapse

**Physical dependence:** involves physiologic adaptation to chronic use of a drug so that unpleasant symptoms occur when the drug is stopped, when its action is antagonized by another drug, or when its dosage is decreased.

**Psychological dependence:** involves feelings of satisfaction and pleasure from taking the drug.

**Placebo:** an inactive substance similar in appearance to the actual drug

**Postnatal depression:** a major depressive episode occurring after the birth of a child

**Potassium-sparing diuretics:** act at the distal tubule to decrease sodium reabsorption and potassium excretion; often given in combination with potassium losing diuretics.

**Prediabetes:** see Impaired fasting glucose.

**Preeclampsia/eclampsia:** pregnancy induced hypertension that endangers the lives of mother and fetus; preeclampsia is manifested by hypertension and proteinuria; if not effectively treated it may lead to eclampsia, which is characterized by potentially fatal seizures.

**Prescription drugs:** one of two routes of access to therapeutic drugs; order for medication is written by a licensed health care provider.

**Pressor drug:** raises blood pressure; maintains tissue perfusion and a mean arterial pressure of at least 80 to 100 mm Hg by producing vasoconstriction and increased blood pressure.

**Presynaptic:** occurring before a synapse.

**Preterm labor:** uterine contractions with cervical changes before 37 weeks of gestation; may occur spontaneously or be precipitated by premature rupture of membranes or other factors.

**Prodrugs:** drugs initially inactive and exert no pharmacologic effects until they are metabolized.

**Progesterin:** female sex hormone produced along with estrogen by the ovaries and adrenal cortex; most often used in combination with an estrogen in contraceptive products.

**Prokinetics:** increase the release of acetylcholine from nerve endings in the GI tract, increasing GI motility and gastric emptying; also antagonize dopamine in the brain; useful in prevention of delayed nausea and vomiting associated with chemotherapy.

**Prostaglandins:** chemical mediators found in most body tissues; they help regulate many cell functions and participate in the inflammatory response; help initiate uterine contractions in labor.

**Protein binding:** many drugs form a compound with plasma proteins, mainly albumin, which act as carriers; allows part of a drug dose to be stored and released as needed.

**Proto-oncogenes:** normal growth-regulating genes; present in all body cells; when exposed to carcinogens and genetically altered to oncogenes, they may operate continuously and cause abnormal, disordered, and unregulated cell growth.

**Prototype:** an example of a group of drugs, often the first one of the group to be developed.

**Pruritus:** itching.

**Psoriasis:** a chronic, inflammatory disorder attributed to activated T lymphocytes which produce cytokines that stimulate abnormal growth of affected skin cells and blood vessels; results in excessively rapid turnover of epidermal cells; skin lesions may occur anywhere but typically occur on the elbows and knees.

**Psychosis:** a severe mental disorder characterized by disorganized thought processes, hallucinations, and delusions.

**Pyrogen:** fever producing agent.

**Quaternary amines:** anticholinergic drugs that carry a positive charge and are lipid insoluble; they do not readily cross cell membranes; are poorly absorbed from the GI tract and do not cross the blood-brain barrier.

**Receptors:** proteins that are embedded in cell membranes of body tissues.

**Red man syndrome:** an adverse reaction when vancomycin is administered too quickly; hypotension, flushing, and skin rash may occur.

**Refraction:** light rays deflected in various directions according to the density of the ocular structures through which they pass.

**Releasing hormones:** produced by the hypothalamus; accelerate the secretion of anterior pituitary hormones.

**Remission:** the symptom free period in disease; particularly cancer.

**Retrovirus:** virus with an RNA genome that relies on reverse transcriptase to transform its genome from RNA to DNA. HIV is a retrovirus.

**Reye's syndrome:** a potentially fatal disease characterized by encephalopathy and fatty liver accumulations. It is associated with the use of aspirin and NSAIDs after viral infections such as chickenpox or influenza in children and adolescents.

**Rhinitis:** inflammation and congestion of nasal mucosa; most common cause of sinusitis.

**Rhinorrhea:** secretions discharged from the nose.

**Rosacea:** a chronic disease characterized by erythema, telangiectases (fine, red, superficial blood vessels) and acne-like lesions of facial skin; usually occurs in middle-aged and older people and more commonly in men than women.

**Salicylism:** may occur with an acute overdose of a salicylate drug or with chronic use of therapeutic doses, especially the higher doses taken for anti-inflammatory effects.

**Sarcomas:** malignant tumors that develop from connective tissue (muscle, bone, cartilage, fibrous tissue, fat, blood vessels).

**Schizophrenia:** a variety of related psychotic disorders; symptoms include: agitation, behavioral disturbances, delusions, disorganized speech, hallucinations, insomnia, and paranoia.

**Sedative:** drug that produces CNS depression.

**Second messenger:** a signaling molecule that activates proteins inside cells to exert a cellular response.

**Seizure:** involves a brief episode of abnormal electrical activity in nerve cells of the brain that may or may not be accompanied by visible changes in appearance or behavior.

**Seizure threshold:** the amount of stimulation required to produce a seizure.

**Selective serotonin reuptake inhibitors (SSRIs):** first line medications in the treatment of depression.

**Septic shock:** due to massive vasodilation in response to overwhelming infection.

**Serology:** identifies infectious agents indirectly by measuring the antibody level (titer) in the serum of a diseased host.

**Serotonin:** a major neurotransmitter in the CNS; thought to produce sleep by inhibiting CNS activity and arousal; serotonin receptors are associated with mood, anxiety, and temperature regulation.

**Serotonin syndrome:** a serious and sometimes fatal reaction characterized by hypertensive crisis, hyperpyrexia, extreme agitation progressing to delirium and coma, muscle rigidity, and seizures; may occur due to combined therapy with an SSRI and an MAO inhibitor or other drugs that potentiate serotonin neurotransmission.

**Serum drug level:** a laboratory measurement of the amount of a drug in the blood at a particular time.

**Serum half-life:** also called elimination half-life, is the time required for the serum concentration of a drug to decrease by 50%.

**Signal transduction:** movement of signals from outside the cell to inside the cell.

**Sinusitis:** inflammation of the paranasal sinuses, air cells that connect with the nasal cavity and are lined with similar mucosa.

**Somatotropin:** see growth hormone.

**Spasticity:** caused by nerve damage in the brain and spinal cord, it is a permanent condition that may be painful and disabling; involves increased muscle tone or contraction and stiff, awkward movements.

**Status epilepticus:** repeated seizures or a seizure that lasts for at least 30 minutes; may be convulsive, nonconvulsive, or partial.

**Steroids:** lipid soluble hormones produced by the gonadal organs or the adrenal cortex.

**Stomatitis:** see mucositis.

**Streptogramins:** class of antibacterial drugs; produced by a bacterium of the genus *Streptomyces* (*S. graminofaciens*).

**Substance abuse:** self-administration of a drug for prolonged periods or in excessive amounts to the point of producing physical or psychological dependence; impairing functions of body organs; reducing the ability to function in usual activities of daily living; and decreasing the ability and motivation to function as a productive member of society; excessive use of drugs or alcohol.

**Substance P:** a peptide neurotransmitter in the neurokinin family; plays a role in neurotransmission of pain impulses.

**Substantia nigra:** dopamine producing nerve cells; site of origination for Parkinson's disease.

**Sulfonamides:** bacteriostatic against a wide range of gram-positive and gram-negative bacteria, although increasing resistance is making them less useful.

**Susceptibility:** tests that determine which drugs are likely to be effective against the organism causing an infection.

**Sustained-release:** controlled release oral tablets or capsules; slowly absorbed medication; effects prolonged, usually 12-24 hours; contain relatively large amounts of active drug.

**Sympathetic nervous system:** a branch of the autonomic nervous system responsible for a basal level of activity (sympathetic tone). Becomes more active during stress and its action during the stress response is termed the fight-or-flight reaction.

**Synapse:** a microscopic gap that separates neurons in a chain.

**Systemic effects:** drugs that are absorbed by the body, circulated through the bloodstream to their sites of action in various body tissues, and eventually eliminated from the body.

**Tardive dyskinesia:** an irreversible late extrapyramidal effect of some antipsychotic drugs.

**Teratogenic:** having adverse effects on the fetus.

**Tertiary amines:** anticholinergic drugs that are uncharged lipid-soluble molecules; able to cross cell membranes readily; are well absorbed from the gastrointestinal (GI) tract and conjunctiva, and they cross the blood-brain barrier.

**Testosterone:** male sex hormone; secreted by the Leydig's cells in the testes.

**Tetany:** prolonged and painful spasms of the voluntary muscles, associated with hypocalcemia.

**Tetracyclines:** antibacterials effective against a wide range of gram-positive and gram-negative organisms, although they are usually not drugs of choice.

**Thiazides:** diuretic drugs that are chemically related to the sulfonamides; often prescribed for the management of hypertension and heart failure; they act to decrease reabsorption of sodium, water, chloride, and bicarbonate in the distal convoluted tubule of the kidney.

**Thrombocytopenia:** low platelet count.

**Thrombogenesis:** formation of a blood clot.

**Thrombolysis:** the break down or dissolution of blood clots.

**Thrombolytic:** a drug that dissolves blood clots.

**Thrombus:** presence of a blood clot.

**Thyroiditis:** a common cause of primary hypothyroidism; it is an autoimmune disorder characterized by inflammation of the thyroid gland.

**Thyroid-stimulating hormone (TSH):** regulates secretion of thyroid hormones.

**Thyroid storm:** a rare but severe complication characterized by extreme symptoms of hyperthyroidism; most likely to occur in patients with hyperthyroidism that has been inadequately treated, especially when stressful situations occur; also known as thyrotoxic crisis.

**Thyroxine:** one of three hormones produced by the thyroid gland.

**Tinea pedis:** a common type of ringworm infection; also called athlete's foot.

**Tocolytics:** drugs used to stop preterm labor

**Tolerance:** patients who have developed drug tolerance through long-term use of lesser doses.

**Tonic:** muscle spasms with sustained contraction.

**Tonic-clonic:** most common type of seizure; often referred to as a major motor seizure. The tonic phase involves sustained contraction of skeletal muscles; abnormal postures, such as opisthotonos; and absence of respiration, during which the person becomes cyanotic. The clonic phase is characterized by rapid rhythmic and symmetric jerking movements of the body.

**Tonometry:** diagnostic test to measure the pressure inside the eye (IOP) to determine if glaucoma is present.

**Tophi:** deposits of uric acid crystals in the joints, kidneys, and soft tissues.

**Topical:** application of drug to skin or mucus membrane.

**Transdermal:** absorption of drug through the skin.

**Travelers' diarrhea:** occurs during or shortly after travel; usually caused by fecal contamination of food and/or water.

**Up-regulation:** the increase in receptor responsiveness when they are chronically exposed to substances that block their function.

**Uricosuric:** drug that increases urinary excretion of uric acid.

**Urinary antiseptics:** used only to treat urinary tract infections; may be bactericidal for sensitive organisms in the urinary tract.

**Urticaria:** an inflammatory response characterized by a skin lesion called a wheal, a raised edematous area with a pale center and red border, which itches intensely; also known as hives.

**Vancomycin-resistant enterococci (VRE):** pathogenic bacteria that are resistant to vancomycin.

**Vasodilators:** a drug that causes dilation of the blood vessels.

**Vasogenic shock:** see distributive shock.

**Vasopressor:** a substance that constricts blood vessels and raises blood pressure.

**Viral hepatitis:** liver inflammation due to a virus; there are five different viruses that cause viral hepatitis: Hepatitis A, B, C, D, and G.

**Viral load:** a measure of the number of HIV RNA particles within the blood; it does not measure viral levels in tissues, where viral reproduction may be continuing.

**Virus(es):** intracellular parasites that survive only in living tissues; they are officially classified according to their structure, but are more commonly described according to origin and the disorders or symptoms they produce.

**Vitamin D (calciferol):** a fat-soluble vitamin that includes both ergocalciferol (obtained from foods) and cholecalciferol (formed by exposure of skin to sunlight); functions as a hormone and plays an important role in calcium and bone metabolism; main action of vitamin D is to raise serum calcium levels by increasing intestinal absorption of calcium and mobilizing calcium from bone.

**Vomiting:** the expulsion of stomach contents through the mouth.

**Vomiting center:** a nucleus of cells in the medulla oblongata.

## Applying Your Knowledge Answers

### Chapter 2

- 2-1** Mrs. Green is elderly and has a failing memory. Instead of a calendar, a pill tray or box with divided sections for each day and each time of day might work more effectively. The pill box should be filled by the nurse on her weekly visits and Mrs. Green should be instructed on the proper use of the pill container. The family or some other close support person should also be instructed regarding Mrs. Green's medication schedule and if a family member is available between visits, oversight of her medication should help prevent overdose.

### Chapter 3

- 3-1** This medication error occurred because the medication was given to the wrong patient. You did not check the patient's name band and relied on the patient to respond to your calling his name. In this situation, the patient had been asleep and may have been responding simply to being awakened. Also, Mr. Sanchez's memory deficits and altered mental status may have contributed. Accurate identification of the patient is imperative, especially when the patient may be confused or unable to respond appropriately.

### Chapter 4

- 4-1** Ibuprofen is used to manage Mr. Walker's arthritis. Hypertension is an indication for both furosemide and captopril. Most likely, Mr. Walker takes famotidine to treat heartburn. The dosages are all within the normal range and are on the lower end of the dosage range, which is appropriate for the elderly.
- 4-2** Potential nursing diagnoses for Mr. Walker might include Noncompliance to appropriate drug therapy, Risk for Injury related to Adverse Drug Effects, Risk for Injury related to Overdose, Risk for Loneliness, and Deficient Knowledge related to Drug Administration.
- 4-3** Mr. Walker takes several medications in various amounts at several times during the day. Older adults often have trouble administering more than three or four drugs. Mr. Walker is currently taking four different medications. Implement strategies to make sure Mr. Walker is taking the right drug, in the right dose, at the right time. Make sure that Mr. Walker's drugs are clearly labeled. Create a chart clearly depicting his medication regimen, or use/prepare a special drug container with prepared doses labeled with the correct time. Enlist his daughter's help.

### Chapter 6

- 6-1** 4 mg of morphine. Because this is the initial 24 hours after surgery and the pain is severe, morphine

is the drug of choice. Start with the lowest effective dose and increase as needed. Larger doses have an increased risk of causing adverse effects. Also recognize that Mr. Harris has used pain medication for a long time and may require a higher dose of medication to control his pain.

- 6-2** Prepare to administer naloxone (Narcan) and assist with ventilation as needed. Naloxone is the drug of choice for opioid overdose.
- 6-3** Lortab is 5 mg of hydrocodone and 500 mg of acetaminophen. What is ordered is oxycodone. Roxicet 5/500 is 5 mg of oxycodone and 500 mg of acetaminophen. The nurse must recognize the difference between oral pain medications and these two different opioids.

### Chapter 7

- 7-1** GI bleeding. Taking ASA, caffeine, and naproxen sodium may lead to GI irritation and bleeding.
- 7-2** It is necessary to recognize that cold and flu medication frequently has acetaminophen added for analgesic effect. The cumulative effects of multiple medications with acetaminophen may lead to hepatic failure.
- 7-3** The patient needs to increase fluid intake to 2 to 3 liters of fluid a day and take drugs with food. This will decrease gastric irritation and help maintain kidney function.
- 7-4** The total amount of acetaminophen may approach or exceed 9000 milligrams (9 g) in a 24-hour period, and this may lead to hepatic damage. The maximum recommended daily dose of acetaminophen should not exceed 4 grams in 24 hours.

### Chapter 8

- 8-1** Help Mrs. Portman's daughter understand how the drugs help to manage her mother's anxiety and symptoms of agitation. The concern for the patient's safety needs to be emphasized. Perhaps a team meeting of the health care professionals involved in her mother's care would help her to accept the plan to care for her mother.
- 8-2** Prepare to administer alprazolam 0.25 mg, the smallest ordered dose. Daytime drowsiness or impaired mobility are signs of too much medication. Also, Mrs. Portman is elderly, so one half of the adult dose is recommended.
- 8-3** These symptoms are typical for withdrawal of benzodiazepines. Tapering the drug may reduce the likelihood of withdrawal symptoms or Mrs. Portman may need to continue on the medication for a longer period of time.

## Chapter 9

- 9-1** Parkinsonism is a common side effect of antipsychotic medication. Notify the physician; antiparkinson drugs may be given along with the antipsychotic drugs.
- 9-2** The dizziness is most likely due to orthostatic hypotension as a side effect of the risperidone. Have Ms. Jones change position gradually, lie down for an hour after taking her medication, elevate her legs when in a sitting position, and avoid hot baths.
- 9-3** These symptoms are typical of neuroleptic malignant syndrome. This is a rare but potentially fatal reaction that requires rapid treatment.

## Chapter 10

- 10-1** The nurse should never leave an antidepressant at the bedside. Charting the medication as given when it has not yet been taken by the patient is not truthful, and the patient may forget to take the medication or may hold the medication for a later time and save up multiple doses. This is especially problematic with a patient suffering from depression because he or she may have suicidal ideations.
- 10-2** Some antidepressant medications, such as sertraline, are in the class of selective serotonin reuptake inhibitors (SSRIs), which may not reach a therapeutic effect for up to 2 to 4 weeks. Provide appropriate teaching for both the patient and his wife regarding therapeutic effect. Check to make sure that Mr. Mehring is taking the right dosage. Encourage him to continue taking the medication.
- 10-3** Check with the physician to see if Mr. Mehring's dose can be taken once a day in the morning. If this is not possible, then check to see if a different SSRI can be given that has once-a-day dosing. Taking the dose in the morning may solve Mr. Mehring's sleeping difficulty if the problem is due to the drug and not due to the depression.

## Chapter 11

- 11-1** Monitor the phenytoin level. The normal free phenytoin level is 0.8 to 2 mcg/mL. Adequate serum levels are needed for seizure control.
- 11-2** Ask if Frank is taking a monoamine oxidase (MAO) inhibitor, which may be used to treat depression. Carbamazepine should not be taken within 14 days of an MAO inhibitor.
- 11-3** The patient must always taper the dosage of an AED gradually, or the seizures may exacerbate.

## Chapter 12

- 12-1** Provide patient teaching and inform Mrs. Sung that the drug she is taking acts quickly and must be taken several times a day in order to provide relief of

her symptoms. The half-life of levodopa/carbidopa is only 1 to 3 hours. Her friend is most likely taking a different medication.

- 12-2** A referral for physical therapy is most appropriate. Gait training and a widened stance will provide Mrs. Sung with increased balance and a better base of support.
- 12-3** The pharmacy provided the correct drug and the correct strength; however, it provided the extended-release form of the drug when the immediate-release form was ordered. In addition to checking the drug name and strength, you must check the dosage form.

## Chapter 13

- 13-1** Patients with MS should be encouraged to avoid emotional stress; exposure to extremes in environmental temperature; infection; and excessive fatigue.
- 13-2** Baclofen should not be given if it causes excessive muscle weakness and impairs rather than facilitates mobility and function. Contact Mrs. Milweski's physician.
- 13-3** Provide patient/caregiver teaching. Baclofen should be given with milk or food to reduce gastrointestinal irritation.

## Chapter 14

- 14-1** The first step is for Mr. Wilson to realize he is abusing alcohol and other drugs. His cooperation in the treatment program is critical to his success. The program should consist of psychological counseling, referral to a self-help group, and drug therapy.
- 14-2** A benzodiazepine antianxiety agent is the drug of choice. This drug will help Mr. Wilson participate in his rehabilitation program and can be gradually reduced in dosage. Taking a benzodiazepine will provide Mr. Wilson with adequate sedation and will also have a significant anticonvulsant effect.
- 14-3** Antabuse is a drug that interferes with the metabolism of alcohol. If Mr. Wilson drinks alcohol while on Antabuse, he will experience hypotension, tachycardia, syncope, blurred vision, headache, and confusion. Mr. Wilson must know what he is taking and cooperate with the treatment plan.
- 14-4** Mr. Wilson needs further instruction regarding his medication. He can stop taking Zyban when he no longer craves nicotine; however, he must continue to take the Antabuse.

## Chapter 15

- 15-1** Inform the teacher that there is no legitimate use of this drug by athletes. Kevin, his parents, and the principal of the school should be informed of the behavior. There is no need to disclose any of Kevin's personal health information.

- 15-2** Kevin is most likely having a toxicity reaction. Place him in a cool room that has minimal external stimulation. Monitor Kevin's heart rate, blood pressure, and temperature.
- 15-3** Losing weight is a common adverse effect of methylphenidate. Evaluate how well Kevin is eating. Provide tips on taking drugs safely and accurately. Instruct Kevin to take his medication 30 to 45 minutes before meals and to take his last dose of the day before 6 pm. Taking the drugs before meals will minimize the drug's appetite-suppressing effects, and taking this medication before 6 pm will avoid interference with sleep.

### Chapter 17

- 17-1** Epinephrine is not given orally because the enzymes in the GI tract and liver destroy it.
- 17-2** Epinephrine 1:1000 has a 1 mg/1 mL concentration. To yield a 1:10,000 solution, 10 mL of normal saline should have been used. Read drug-mixing instructions carefully.
- 17-3** Mr. Sobechenko has had an anaphylactic reaction to an antibiotic. Make sure to advise Mr. Sobechenko of his allergy and note it on his chart. Observe the patient for increased blood pressure, tachycardia, and hyperglycemia (adverse effects of epinephrine).

### Chapter 18

- 18-1** Lopressor will act as an antianginal and antihypertensive drug for Mr. Jones. It also may protect the heart from reinfarction.
- 18-2** Clonidine is effective in reducing blood pressure. Clonidine exerts its effect by reducing central nervous system outflow, a physiologic effect that raises blood pressure.
- 18-3** Beta-blocking medication should be discontinued slowly, over 1 to 3 weeks. Notify the physician and pharmacy if the patient cannot/will not take the substituted drug; do not stop the beta-blocker drugs abruptly.
- 18-4** Diabetic patients are prone to hypoglycemia as an adverse effect of their antidiabetic medication. Mr. Jones is at risk for more severe and prolonged hypoglycemia because he is taking Lopressor (metoprolol). The nurse should assess the blood sugar in a diabetic patient more carefully.

### Chapter 19

- 19-1** The nurse should follow the patient request. Most patients with myasthenia gravis require a higher dose of medication with increased physical activity. Ms. Humbarger is probably not as active in the hospital and will require less medication.
- 19-2** Betty Humbarger is experiencing a myasthenic crisis. Signs and symptoms having an onset within

approximately 1 hour after a dose of an anticholinesterase drug are more likely to be caused by a cholinergic crisis or too much drug. Signs and symptoms beginning 3 hours or more after an anticholinesterase drug are more likely to be caused by a myasthenic crisis or too little drug. The nurse should respond to a myasthenic crisis by the administration of more anticholinesterase drug.

### Chapter 20

- 20-1** The nurse should expect to see an increase in the heart rate. Atropine is an anticholinergic drug that blocks the parasympathetic vagus nerve, thereby preventing slowing.
- 20-2** Encourage the patient to increase the fiber in his diet and to drink 2-3 quarts of fluid a day, unless otherwise contraindicated, to help with the constipation. Notify the physician of Mr. Smoot's urinary retention and constipation.
- 20-3** Mr. Bing has a history of glaucoma. Scopolamine is an anticholinergic medication and is contraindicated for a patient with glaucoma.

### Chapter 22

- 22-1** The ordered dose is to be given in two divided doses. The nurse should have administered 0.1 mL in the first dose and the other 0.1 mL in the second dose.
- 22-2** Monitor Mr. Rojas's daily weight, intake and output, and when available, the urine specific gravity. A patient with diabetes insipidus will lose 8 to 10 L of urine a day or more. The nurse must monitor the fluid status of the patient.
- 22-3** Mr. Rojas is most likely having a serious adverse reaction to the desmopressin. Hyponatremia and water retention should be reported to the physician and you should continue to monitor the patient.
- 22-4** The nurse has a professional responsibility to discuss the situation with the boys' mother. Excessive hormone increases the risk of health problems for Miguel and Juan needs an adequate dose to be therapeutic.

### Chapter 23

- 23-1** Notify Ms. Hubble's physician. This is a sign of thrush or oral candidiasis, a fungal infection. The patient requires immediate treatment and may not be able to continue on the prednisone if the infection becomes systemic. Systemic fungal infections are a contraindication to the administration of corticosteroids.
- 23-2** Prednisone is a drug that will treat the symptoms of COPD, but it is not designed to cure the underlying disease process. Because the drug reduces

respiratory inflammation, Ms. Hubble will have less difficulty with breathing.

**23-3** Prednisone causes hyperglycemia in many patients and especially in patients with diabetes mellitus. The physician should be notified for a change in Ms. Hubble's diabetic medication. Also, the nurse should review Ms. Hubble's diet.

**23-4** The teaching plan should include taking the drug as ordered, carrying medical alert identification that includes the drugs taken, taking measures to avoid infection, and observing for any signs of infection or delayed wound healing. The nurse should encourage activity as tolerated to prevent osteoporosis, and teach the patient when to seek medical attention.

## Chapter 24

**24-1** Change the medication time to 7:30 a.m. to assure that Synthroid is given on an empty stomach. Taking the drug on an empty stomach will increase its absorption.

**24-2** Teach Ms. Zalewski to maintain a diet that is low in fat and calories and high in fiber, and to monitor for variations in weight.

**24-3** Evaluate Ms. Zalewski's TSH level. The normal range is 0.5–4.2 microunits/L. Her symptoms are typical of a patient with hyperthyroidism. Notify the prescriber of these symptoms.

**24-4** Synthroid should not be given with an antacid, iron preparation, or sucralfate. These drugs decrease the absorption of Synthroid. If the patient requires an antacid, the antacid should be given 2 hours before or 4 to 6 hours after the dose of Synthroid.

## Chapter 25

**25-1** Alendronate must be taken 30 minutes prior to any intake of food, fluid, or other medication. Alendronate is very poorly absorbed from the gastrointestinal tract and any other substance will diminish the absorption of this medication.

**25-2** For most individuals, a daily intake of between 1000 to 1500 mg of calcium is recommended. Milk and dairy products contain high levels of calcium. Two 8-oz glasses of milk provide one half of the daily calcium requirement (600 mg). Postmenopausal women should increase their calcium intake to 1500 mg per day. Weight-bearing exercise and adequate vitamin D intake are also important teaching points.

**25-3** Any patient taking alendronate needs to be instructed to remain in an upright position for at least 30 minutes after taking this medication. Avoiding the supine position reduces the risk of esophageal irritation.

## Chapter 26

**26-1** This insulin is a mixed type composed of both regular and NPH insulins. The peak times for both of

these insulins would be when Mr. Coulter is most likely to experience hypoglycemia. The nurse should be especially watchful for the signs and symptoms of hypoglycemia at 2 to 3 hours after insulin administration and again at 8 to 12 hours after administration.

**26-2** Measure Mr. Coulter's blood glucose level if possible. Also, give the patient 15 grams of carbohydrate. This would include sugar, candy, fruit juice, or 4 ounces of regular soda.

**26-3** Deficient Knowledge: Antidiabetic drugs and administration, diet and management of hypoglycemia and other complications. Based on assessment data, this is a priority diagnosis and nursing interventions are necessary.

**26-4** You should hold the metformin for 48 hours prior to any diagnostic test involving radiographic contrast media. Mr. Coulter will be NPO the morning of the test and should not take his medication until the test is over and he is able to eat. The metformin will continue on hold for 48 hours after the test. The combination of metformin and contrast media containing iodine may lead to renal failure and/or lactic acidosis.

## Chapter 27

**27-1** Explain to Vickie that her color-coded tablets have different amounts of medication in them, making them more closely resemble the normal variations in hormones in the body. Emphasize the need to take the tablets in the correct sequence.

**27-2** Vickie should stop taking the oral contraceptives and her pregnancy state should be evaluated. Pregnancy is a contraindication for continuation of the hormones. Damage may occur to the fetus if oral contraceptives are taken during pregnancy.

**27-3** Instruct Vickie to take her pills with food or at bedtime to reduce nausea. If the nausea continues and she cannot take the pills in continued sequence, perhaps considering another form of contraception would be appropriate.

**27-4** Vickie should have been instructed to use an alternate method of birth control while she is on antibiotics. Antibiotics decrease the effectiveness of oral contraceptives.

## Chapter 28

**28-1** Teach Ms. Watson to weigh herself and to have her blood pressure assessed regularly. She should call her physician immediately if she becomes pregnant.

**28-2** Assess for hirsutism, deepening of the voice, and menstrual irregularities.

**28-3** You have an obligation to explain the health risks of untreated hypertension. Patient teaching guidelines would include discussing health habits that may be contributing to the problem.

## Chapter 29

- 29-1** Teach all patients to take all of the prescribed doses and not to stop when their symptoms are relieved. Failure to take all of the medication may lead to an increased risk for a drug-resistant infection. Additionally, teach all patients not to take antibiotics left over from a previous illness. The likelihood of having the right drug in the right amount to adequately treat the infection is extremely small. This practice of taking leftover medication may also lead to an increased risk of developing a drug-resistant infection.
- 29-2** Collect specimens for culture before the first dose of an antibiotic is given, unless a life-threatening infection is present. Practice impeccable infection-control principles, including frequent and thorough hand hygiene, proper use of gloves, and proper handling and disposal of body fluids. Schedule antibiotics at evenly spaced intervals around the clock, to maintain therapeutic blood levels. Check specific recommendations with regard to the administration of the antibiotic with food and other medication to decrease binding to food and drugs and prevent inactivation. Follow all instructions for mixing and storing medication and check expiration dates. Give parenteral antibiotics alone; do not mix with any other drug, to avoid chemical and physical incompatibilities that may cause drug precipitation or inactivation. Flush the IV tubing after each dose to ensure the entire dose is administered.

## Chapter 30

- 30-1** First-generation cephalosporins are the drug of choice for surgical prophylaxis. They are active against a large number of bacteria and have a low incidence of adverse effects.
- 30-2** The physician, pharmacist, and nurse should ask Ms. Jang if she has ever taken penicillin and if she has ever had an allergic reaction. Penicillin is the most common cause of drug-induced anaphylaxis.
- 30-3** Tell Ms. Jang to call 911. She should be transported to the nearest emergency facility immediately. This is most likely a severe reaction to the penicillin.
- 30-4** The nurse should recognize that piperacillin-tazobactam (Zosyn) is a combination of a penicillin and a beta-lactamase inhibitor. An allergy to any penicillin means that Ms. Jang cannot receive any other penicillin-containing drug.

## Chapter 31

- 31-1** Mr. Dallas should wait for 2 hours before or after he has taken the Cipro before taking an antacid for his indigestion. Antacids interfere with the absorption of fluoroquinolones from the GI tract.
- 31-2** Assess Mr. Dallas's hearing and his renal function because gentamicin is ototoxic and nephrotoxic.

- 31-3** The patient should be encouraged to take 2 to 3 liters of fluid a day unless contraindicated. The intake of fluid will help prevent nephrotoxicity.

## Chapter 32

- 32-1** Sharon needs fluid intake of at least 2 to 3 liters daily. The fluid will keep her urine diluted and reduce the multiplication of bacteria.
- 32-2** The Bactrim will increase the skin's sensitivity to sunlight and sunburn. Sharon is already at risk due to the tetracycline. Advise her to wear sunscreen and protective clothing.
- 32-3** Tetracyclines should not be taken within 2 hours of food that contains dairy products; antacids; or iron supplements. The combination of a tetracycline with calcium, iron, aluminum, or magnesium results in an insoluble compound that prevents the absorption of tetracycline.

## Chapter 33

- 33-1** Azithromycin should be taken on an empty stomach with 6 to 8 ounces of water. Do not take any antacid products for 2 hours before or 2 hours after a dose of azithromycin. Take the medication at the same time each day until all of the pills are gone. Adequate water intake aids absorption. Taking the drug at regular intervals helps to maintain a therapeutic blood level. Finishing the drug will help decrease the risks of inadequate treatment and drug resistance.
- 33-2** Assess for the occurrence of adverse GI effects such as nausea, vomiting, or continued diarrhea. Mr. Nikki should be aware that he may have a metallic taste in his mouth due to the metronidazole. Also observe for CNS adverse effects, such as seizures or peripheral neuropathy.
- 33-3** Teach Mr. Nikki to monitor himself for abdominal pain, nausea, vomiting, diarrhea, and/or yellow discoloration of the eyes or skin.

## Chapter 34

- 34-1** The primary reason for MDR-TB is a failure to take the medication as prescribed.
- 34-2** Assess for the occurrence of hepatotoxicity. The signs and symptoms might include anorexia, nausea, fatigue, malaise, and/or jaundice. You would also want to monitor the liver enzymes ALT and AST for an increase.
- 34-3** Rifampin may cause a red-orange coloration to the urine and other body fluids. Although it will permanently stain clothing and other objects, it is not harmful to the patient.

## Chapter 35

- 35-1** The nurse should look at the results of the CBC, HIV-RNA and the CD4+ cell count to measure Tony's response to his drug therapy.

## 1084 ■ Applying Your Knowledge Answers

- 35-2** He may take his Combivir with food to decrease the GI upset; however, he should take the Efavirenz on an empty stomach.
- 35-3** Filgrastim is given because zidovudine in the Combivir depresses the bone marrow and causes neutropenia. Filgrastim should increase the white cell count.

### Chapter 36

- 36-1** Charlotte should be assessed for pregnancy before taking fluconazole. Azole drugs are contraindicated in pregnancy.
- 36-2** Assess for nausea, vomiting, diarrhea, abdominal pain, headache, or skin rash, although these symptoms only occur in about 3% of patients. You should also be aware of the risk of liver dysfunction
- 36-3** Patients who receive IV amphotericin B should be assessed for fever, chills, and tachypnea. Infusion reactions from IV amphotericin B should be reported. Charlotte should be premedicated with acetaminophen, diphenhydramine, and a corticosteroid.

### Chapter 37

- 37-1** Metronidazole is contraindicated in the first trimester of pregnancy. Also, the patient should avoid all forms of alcohol while taking this medication.
- 37-2** Teach Ms. Michelson to use proper hand and other personal hygiene techniques. She should avoid raw fish and undercooked meat. Encourage Ms. Michelson to take all of her medication and to have follow-up care.
- 37-3** Chloroquine should be taken with meals to decrease GI irritation.

### Chapter 39

- 39-1.** Assess for the presence of fever, immunosuppressive drug therapy, immunodeficiency states, leukemia, lymphoma or generalized malignancy and pregnancy. The administration of vaccines and toxoids is usually contraindicated with these conditions.
- 39-2.** The best source for current immunization information is the CDC Web site ([www.cdc.gov](http://www.cdc.gov)). Health care providers should update their knowledge at least annually.
- 39-3.** Do not use any vaccine that has been stored at room temperature. To maintain effectiveness of the vaccine, MMR requires refrigeration and protection from light.

### Chapter 40

- 40-1** Teach Mrs. Paul to get adequate rest and sleep, to eat a nutritious diet and to practice meticulous personal hygiene.

- 40-2** Pegfilgrastim should not be administered for 14 days before the next dose of chemotherapy or within 24 hours following a treatment.

- 40-3** An adequate intake of iron is needed for epoetin alfa to be effective. A nutritional supplement of iron is usually necessary in addition to dietary sources.

### Chapter 41

- 41-1** Monitor Mr. Kinney's WBC and platelet counts. The adverse reactions to mycophenolate are neutropenia and thrombocytopenia.
- 41-2** Cyclosporine and sirolimus should not be given at the same time. The drugs should be taken 4 hours apart. The concomitant administration of cyclosporine and sirolimus can increase the blood level of sirolimus to possible toxic levels.
- 41-3** The following teaching points are appropriate: Do not substitute brands of cyclosporine, and report to the primary care provider if a decreased urinary output is observed. Take mycophenolate on an empty stomach. Take sirolimus 4 hours after the dose of cyclosporine and do not take it with grapefruit juice. All of these drugs should be taken at the same time each day and you should report to the primary care provider if you cannot take the medication as ordered for any reason. Take no other drugs without medical supervision. Take precautions to prevent infection.
- 41-4** Mr. Kinney is at a greatly increased risk of a serious infection and perhaps a life-threatening complication. In addition to the immunosuppressed state putting Mr. Kinney at risk for infection, the immunosuppressant drugs slow the proliferation of lymphocytes and damage rapidly dividing nonimmune cells.

### Chapter 42

- 42-1** The most common adverse effects are bone marrow depression, mucositis, alopecia, and GI ulceration. Julia will need periodic blood tests to determine the degree of bone marrow depression. Nutrition will be important. Julia should have a plan for the alopecia (perhaps including purchasing a wig prior to her hair loss). Be sure to review medications to prevent and treat the adverse effects with Julia.
- 42-2** Although there is some risk, the benefit is that Herceptin will bind with a substance called *human epidermal growth factor receptor(2)*, which is present in excess in 25%- 30% of women with breast cancer.
- 42-3** Tell Julia that every precaution is taken when administering this medication and that she will be medicated before the infusion to reduce the occurrence of a serious allergic reaction.
- 42-4** Ensure that the orders are appropriate; do not accept verbal or telephone orders.

## Chapter 44

- 44-1** The salmeterol in the Advair is long acting and only for prophylaxis of acute bronchoconstriction. The appropriate medication for acute asthma attacks is the albuterol.
- 44-2** Explain to Lynne that she is receiving the same type of medication in her inhaled Advair (contains fluticasone). An inhaled corticosteroid will minimize systemic absorption and adverse effects. Topical application will reduce the inflammation.
- 44-3** Respiratory assessment should consist of observation of the patient's breathing pattern. Observe for a respiratory rate less than 12 or above 24 breaths per minute, dyspnea, cough, or wheezing respirations. Indications of severe respiratory distress include tachypnea, the use of accessory muscles, and hypoxia.

## Chapter 45

- 45-1** Loratadine should be taken on an empty stomach. Do not take both loratadine and diphenhydramine. Wear sunscreen if exposed to sunlight. Inform your physician if you become pregnant, and do not consume alcohol.
- 45-2** First-generation antihistamines such as diphenhydramine are less costly and may provide an alternative to the higher cost of the second-generation antihistamines. Caution Ms. Fisher that if she switches drugs, the first-generation drugs cause more drowsiness.
- 45-3** Since the nurse is unlikely to have an opportunity to teach about individual OTC medications, it is important to advise Ms. Fisher to read the medication label on all OTC medication. She needs to be especially careful when medicating a small child. Loratadine is only approved for use in children 2 years and older.

## Chapter 46

- 46-1** Remind everyone of the need for frequent and thorough hand hygiene. Infected people with viruses on their hands touch objects that uninfected people will touch, thereby transferring the viruses.
- 46-2** Appropriate patient teaching with regard to nasal sprays should include not using a nasal spray for more than 7 days. Rebound nasal swelling can occur with excessive or extended use.
- 46-3** Nonpharmacologic measures would be most appropriate to consider. Intake of adequate fluids, frequent and thorough hand hygiene, and proper disposal of soiled tissues should be reinforced. Chlorpheniramine is an antihistamine. Mr. Hobbs should avoid using an antihistamine; it will dry nasal secretions but it will also dry lower respiratory secretions and

may worsen secretion retention and cough. The use of expectorants, such as guaifenesin, has not clearly been supported by research, and many authorities do not support its use.

## Chapter 48

- 48-1** Digitalization in adults is accomplished by the administration of a total dose of 0.75 to 1.0 mg of digoxin in divided doses over a 24-hour period. Although digitalization engenders a higher risk of toxicity, the maximum drug effect will be reached more rapidly.
- 48-2** The normal digoxin level is 0.5 to 2.0 ng/mL. Toxic serum levels are greater than 2 ng/mL; however, toxicity may occur at any serum level.
- 48-3** When taken orally, the absorption of digoxin depends on the preparation. Capsules have better absorption than the tablets and should not be substituted equally.

## Chapter 49

- 49-1** The normal therapeutic serum level of lidocaine is 2 to 5 mcg/mL. The risk of adverse effects is reduced when the drug is administered within the therapeutic range. Lidocaine will also not decrease AV conduction or myocardial contractility with therapeutic doses.
- 49-2** The amiodarone is given to prevent the recurrence of AF and at this low dose it has less toxicity. You should monitor for thyroid dysfunction, pulmonary fibrosis, myocardial depression, hypotension, bradycardia, hepatic dysfunction, CNS disturbances, peripheral neuropathy, bluish discoloration of the skin, and reduced visual acuity.
- 49-3** Bradycardia may indicate impending heart block or cardiovascular collapse. You should stop the IV infusion and report to the physician if there are marked changes in the rate, rhythm, or quality of the pulse.

## Chapter 50

- 50-1** Mr. Gerald should be taught to never take sildenafil or other drugs in this class while on nitroglycerin. The combination can produce life-threatening hypotension.
- 50-2** Beta blockers are used in the treatment of CAD for a number of reasons. They reduce the frequency and severity of anginal attacks. Beta blockers also decrease exercise-induced tachycardia. They additionally are more effective at decreasing the likelihood of silent ischemia and improve the mortality rate after an MI.
- 50-3** Diltiazem is a calcium channel blocker. The drug will improve blood supply to the myocardium and decrease the workload on the heart. In addition, the diltiazem will reduce coronary artery vasospasm,

which is most likely the cause of the pain that Mr. Gerald experiences at rest.

## Chapter 51

- 51-1** The nurse needs to monitor the BP and pulse every 5-15 min. until Mr. Alrashed has a sufficient BP and his BP stabilizes. The nurse needs to also assess the IV site frequently, monitor mental status, distal pulses, urine output and skin temperature closely.
- 51-2** Phentolamine is administered to prevent tissue necrosis in the tissue surrounding the area of infiltration.
- 51-3** All solutions should be clear in color. The brown discoloration indicates the solution is decomposed and no longer safe to use. The solution should be discarded and new solution obtained.

## Chapter 52

- 52-1** Be aware that compliance is a common problem with patients who have hypertension. Explore the reasons for the noncompliance, such as: is the patient unable to make lifestyle changes; is the patient experiencing adverse effects from the medication; is the patient able to afford the cost of the medication; and does the patient understand this asymptomatic disorder and the many complications that hypertension can cause? As always, provide appropriate teaching.
- 52-2** Encourage the patient to reduce weight and sodium intake, to get regular physical activity, to stop smoking, and to moderate alcohol intake. These measures can prevent prehypertension and reduce blood pressure in patients with elevated blood pressure. The patient should also understand antihypertensive drug therapy. Always review other behaviors that may decrease the therapeutic response, such as taking over-the-counter medication.
- 52-3** Due to their efficacy, calcium channel blockers are the drugs of first choice for the treatment of hypertension in African Americans, according to the JNC 7.

## Chapter 53

- 53-1** This provides an opportunity to teach Ms. Bass that avoiding foods high in sodium will help her diuretic to work more effectively. Table salt is an obvious food to avoid, but she should also read the sodium content of food containers and avoid those high in sodium, such as potato chips and other salty snacks.
- 53-2** Spironolactone is a potassium-sparing diuretic. This diuretic will enhance diuresis without depleting potassium like furosemide would. You should observe for hyperkalemia with patients taking a potassium-sparing diuretic.

- 53-3** IV-push furosemide should be given over 1 to 2 minutes, up to a 40-milligram dose. Too-rapid administration may lead to increased ototoxicity.

## Chapter 54

- 54-1** The main reason anticoagulants are used is to prevent the formation of new clots and the extension of clots that are already present. Heparin does not dissolve a clot that is already formed. The main adverse effect is bleeding.
- 54-2** The goal of therapy with heparin is to maintain the aPTT at 1.5 to 2.5 times the baseline value. In most patients, the goal will be 45 to 70 seconds.
- 54-3** Have the blood work evaluated before any warfarin is given. Subsequent assessment of PT/INR should be performed before the second dose of warfarin is given.
- 54-4** Aspirin is used in long-term therapy for the prevention of clot formation in atrial fibrillation and to prevent a future myocardial infarction.

## Chapter 55

- 55-1** Inform Mr. Watkins that he will need to have blood analysis performed in 4 to 6 weeks. He will need to be without food for the triglyceride level. In addition to lipid levels, the physician will check liver function.
- 55-2** Although this group of drugs is usually well tolerated, potential adverse effects include nausea, constipation, diarrhea, abdominal cramps or pain, headache, and skin rash. Tell Mr. Watkins to notify his health care provider if he notices **unexplained muscle pain or tenderness**: This can be a warning sign of rhabdomyolysis, a destruction of the muscle. Patients at higher risk are the elderly; those on a high dose of a statin; those with a small body frame; and those concurrently taking gemfibrozil, such as Mr. Watkins.
- 55-3** Gemfibrozil must be administered at least 30 minutes before food and on an empty stomach.

## Chapter 57

- 57-1** Include the administration of a multivitamin with her daily nourishment. The undernourished frequently have deficiencies in vitamins A, D, B<sub>12</sub>, folic acid, riboflavin, and thiamine.
- 57-2** In the elderly, the most common mineral-electrolyte deficiencies are of calcium and iron. Excess states are also possible. Serum levels of minerals and electrolytes should be monitored carefully and measures taken to prevent both deficiency and excess.
- 57-3** Iron preparations are to be administered before meals for best absorption. When given with coffee, tea, or dairy products, absorption is decreased.

## Chapter 58

- 58-1** Orlistat works by blocking the fat absorbed from the intestine. This drug will block approximately 30% of the fat ingested in a meal. It is important to teach that increasing the dose will not increase the percentage of fat blocked. This drug also blocks the absorption of fat-soluble vitamins, so you should advise Ms. Vargas to take a multivitamin at a different time than the orlistat.
- 58-2** Strategies should include the practice of a healthy lifestyle by eating a variety of foods daily and by eating a diet rich in whole grains, vegetables, and low-fat dairy products. Limit the intake of saturated fat, trans fat, cholesterol, added sugars, salt, and alcohol. Ms. Vargas must also include some regular physical activity.
- 58-3** The initial goal of weight-loss therapy should be to reduce body weight by about 10 percent from baseline weight at a rate of one to two pounds per week for the first 6 months. Assist Ms. Vargas to set a realistic and healthy goal.
- 58-4** The dose of orlistat should not be taken if the patient misses a meal. Teach Ms. Vargas to omit the dose if a meal is missed.

## Chapter 59

- 59-1** Teach Ms. Daniels to avoid cigarette smoking, alcohol, caffeine, aspirin, and NSAIDs.
- 59-2** Acid reflux can be reduced by avoiding stomach distention. Eating small meals will reduce gastric distention. Teach Ms. Daniels not to lie down for at least 1 to 2 hours after eating. Foods and drinks that can increase acid reflux include fats, chocolate, citric juices, coffee, and alcohol. Take medication with 8 oz of water. Control obesity, constipation, or other causes of increased intra-abdominal pressure. It may also be helpful to elevate the head of the bed to reduce acid reflux.
- 59-3** When providing patient teaching about drug therapy, include the reasons why each medication has been selected. Make sure to encourage the patient to ask questions. Teach Ms. Daniels that the reason she is to take Mylanta is because it contains simethicone; Maalox does not. Although simethicone will not reduce gastric acid, it does relieve gas and reflux.

## Chapter 60

- 60-1** Ms. Campbell is elderly, has hemorrhoids and has chronic disease and should not strain when having a bowel movement. Docusate sodium is most likely the drug of choice. This drug has little laxative effect. Docusate sodium will work by decreasing the surface tension of the fecal mass, thereby allowing

water to enter the stool. It will also act as a detergent to facilitate the addition of fat and water to the stool, thereby making it easier to expel.

- 60-2** Assess for the number of stools, the appearance of the fecal mass, any abdominal distention or discomfort, or flatulence. Evaluate the drugs Ms. Campbell is taking because they may reduce intestinal function. Also, assess risk factors such as decreased activity and a diet with minimal fiber intake and low fluid intake.
- 60-3** Ms. Campbell has taken much more medication than needed. The psyllium preparation will usually act in 12 to 24 hours but may take as long as 2 to 3 days to exert the full effect. Milk of magnesia is a saline cathartic that will usually have an effect in 0.5 to 6 hours. Ms. Campbell did not allow either of these medications enough time to work. She also administered a stimulant cathartic that should not be used in older patients. Teach Ms. Campbell about drug actions, including how long before each drug takes effect. Also, provide guidance on appropriate drug selection.

## Chapter 61

- 61-1** Determine the number of stools each day and the amount, consistency, color, odor, and presence of abnormal components in each stool. Ask Mr. Mendoza what measures he has initiated to relieve the diarrhea and if he has any other symptoms, such as nausea and vomiting or fever. The most obvious cause of Mr. Mendoza's diarrhea is his recent trip to Mexico; however, also consider chronic inflammatory diseases of the bowel, use of laxative or other drugs, and food intake.
- 61-2** The drug of choice to treat diarrhea is loperamide. Mr. Mendoza should be instructed to take no more than 8 mg per day: 4 mg initially then 2 mg after each loose stool. If his symptoms persist for more than 48 hours, Mr. Mendoza should consult his physician.
- 61-3** Mr. Mendoza should discontinue the use of loperamide. Antidiarrheal agents are contraindicated in diarrhea caused by microorganisms. In these circumstances, antidiarrheal agents that slow peristalsis may aggravate and prolong diarrhea.

## Chapter 62

- 62-1** Assess for headache, diarrhea or constipation, dizziness, fatigue, and muscle aches.
- 62-2** Encourage Ms. Snyder to minimize activity during acute nausea and vomiting. Avoid oral intake of food, fluids, and drugs, because this may increase vomiting. Encourage Ms. Snyder to take antiemetics 30 to 60 minutes before meals or a nausea-producing event such as radiation or chemotherapy. Avoid

exposure to stimuli as much as possible; this includes unpleasant sights and odors, alcohol, and excessive ingestion of food or drugs that irritate the gastric mucosa.

**62-3** Diphenhydramine is given with metoclopramide to decrease metoclopramide's extrapyramidal effects.

**62-4** You should follow the patient's wishes whenever possible; however, Ms. Snyder needs to understand that the antiemetic medication will work much better when given to prevent nausea and vomiting rather than to treat it. Convey to her that the pre-treatment approach will increase her comfort and allow the use of lower doses of the drugs.

### Chapter 63

**63-1** Instruct Mrs. Molnar to avoid activities that increase IOP. She should avoid straining at stool, heavy lifting, bending over, coughing, and vomiting when possible.

**63-2** Wash hands before applying the medications. To decrease the systemic absorption of eye drops, instruct Mrs. Molnar to close the eye and apply pressure to the tear duct for 3 to 5 minutes after instillation. When multiple eye drops are prescribed, there should be an interval of 5 to 10 minutes between the medications.

**63-3** The nurse should observe for bradycardia, arrhythmias and bronchoconstriction.

### Chapter 64

**64-1** The drug of choice for Ginger is most likely a low-potency, topical hydrocortisone.

**64-2** Teach Ginger that dry skin and pruritus are aggravated by hot water and harsh soap, so she should take warm baths and use a gentle cleanser. Patting

the skin dry with a towel and using a lotion will reduce the irritation. She may also take a colloidal-oatmeal bath to help relieve the pruritus.

**64-3** Apply hydrocortisone sparingly, in a thin layer. Ginger may apply it twice daily until the itch and redness are resolved. If she experiences relief with less frequent application, she should use the drug less often.

**64-4** The most appropriate nursing diagnosis based on these data is Disturbed Body Image related to visible skin lesions.

### Chapter 65

**65-1** Instruct Mrs. Blevins to begin to take 400 to 600 micrograms of folic acid daily. Folic acid supplementation can prevent neural-tube birth defects.

**65-2** Tell Mrs. Blevins that constipation is a common occurrence during pregnancy. The best treatment is to increase amount of exercise and intake of fluids and high-fiber foods. If a laxative is needed, a bulk-producing agent is recommended because it is safest for both mother and fetus.

**65-3** All systemically absorbed drugs in the mother's blood-stream will reach the fetus. Drugs are listed with an FDA pregnancy risk category based on the amount of risk to the fetus. Drugs categorized as risk category X should not be used at all during pregnancy. Most drugs are risk category C and should be discussed with the physician. These drugs should only be used when the potential benefit to the mother outweighs the risk to the fetus.

**65-4** Mrs. Blevins needs a new prescription for birth control without estrogen. Ortho Tri-Cyclen contains estrogen; estrogen is contraindicated while she is breast-feeding.
