Harms: The review found that TRH plus steroid significantly increased the risk of low Apgar score (see glossary, p 1920) at 5 minutes and increased the requirement for assisted ventilation compared with steroids alone (low Apgar; OR 1.80, 95% CI 1.14 to 1.92; assisted ventilation: OR 1.16, CI 1.02 to 1.29).[43] One RCT included in the review found that TRH plus steroids significantly increased motor delay, motor impairment, sensory impairment, and social delay after 12 months compared with steroids alone (motor delay: RR 1.31, 95% CI 1.09 to 1.56; motor impairment: RR 1.51, 95% CI 1.02 to 2.24; sensory impairment: RR 1.97, 95% CI 1.10 to 3.53; social delay: RR 1.25, 95% CI 1.03 to 1.51).[43] TRH plus steroids significantly increased maternal blood pressure compared with steroids alone (1 RCT: risk of an increase of 25 mm Hg in systolic blood pressure; 36/506 [7%] with TRH plus steroids *v* 20/505 [4%] with steroids alone; RR 1.80, 95% CI 1.05 to 3.06; risk of an increase of 15 mm Hg in diastolic blood pressure; 115/506 [23%] with TRH plus steroids *v* 71/505 [14%] with steroids alone; RR 1.62, 95% CI 1.24 to 2.12). The review also found that TRH plus steroids significantly increased other maternal adverse effects including nausea, vomiting, light-headedness, urgency of micturition and facial flushing compared with steroid alone (nausea: 3 RCTs: 303/1175 [26%] with TRH plus steroids *v* 77/1195 [6%] with steroids alone; RR 3.92, 95% CI 3.13 to 4.90; vomiting: 1 RCT: 40/506 [8%] with TRH plus steroids *v* 17/505 [3%] with steroids alone; RR 2.35, 95% CI 1.35 to 4.09; light-headedness: 1 RCT: 139/506 [27%] with TRH plus steroids *v* 80/505 [16%] with steroids alone; RR 1.73, 95% CI 1.36 to 2.20; urgency of micturition (1 RCT: 115/506 [23%] with TRH plus steroids *v* 48/505 [10%] with steroids alone; RR 2.39, 95% CI 1.75 to 3.27; facial flushing: 3 RCTs: 397/1252 [32%] with TRH plus steroids *v* 149/1271 [12%] with steroids alone; RR 2.67, 95% CI 2.26 to 3.16).[43]

Comment: TRH regimens varied in the RCTs identified by the review.[43] Seven of the RCTs analysed by intention to treat.

OPTION ANTIBIOTIC TREATMENT FOR PRETERM LABOUR WITH INTACT MEMBRANES

One systematic review found that antibiotics do not prolong pregnancy and do not reduce perinatal mortality compared with placebo, but they do reduce the incidence of maternal infection.

Benefits: We found one systematic review (search date 2002, 11 RCTs) comparing single or combined antibiotics with placebo or no antibiotic in women in preterm labour (see glossary, p 1920) and with intact membranes.[44] It found no significant difference between antibiotics and no antibiotic in delivery within 48 hours or within 7 days (4 RCTs, 6800 women: 509/4959 [10%] with antibiotics *v* 183/1841 [10%] without antibiotics; OR 1.04, 95% CI 0.89 to 1.23; within 7 days: 7 RCTs, 6957 women: 813/5044 [16%] *v* 337/1913 [18%]; OR 0.98, 95% CI 0.87 to 1.10). It found no significant difference between treatments in neonatal morbidity, respiratory distress syndrome, necrotising enterocolitis, intraventricular haemorrhage or perinatal mortality (respiratory distress syndrome, 8 RCTs, 7104 newborns: 460/5112 [9%] with antibiotics *v* 194/1992 [10%] without antibiotics; RR 0.99, 95% CI 0.84 to 1.16; necrotising enterocolitis, 6 RCTs, 6880 newborns: 62/5004 [1.2%] *v* 25/1876 [1.3%]; RR 1.06, 95% CI 0.64 to 1.73; intraventricular haemorrhage, 4 RCTs, 6717 newborns: 59/4921 [1.2%] *v* 30/1796 [1.7%]; RR 0.76, 95% CI 0.48 to 1.19; perinatal mortality, 9 RCTs, 7208 newborns: 140/5166 [2.7%] *v* 42/2042 [2.1%]; RR 1.22, 95% CI 0.88 to 1.70). It found that antibiotics significantly reduced maternal infection, namely chorioamnionitis and endometritis compared with no antibiotics (9 RCTs, 7242 women: 456/5185 [9%] *v* 230/2057 [11%]; RR 0.74, 95% CI 0.64 to 0.87). It found that β lactams either alone or in combination with a macrolide significantly reduced chorioamnionitis and endometritis (β lactams alone, 3 RCTs: 144/1635 [9%] with β lactams *v* 70/621 [11.3%] no antibiotics; RR 0.75, 95% CI 0.56 to 0.98; β lactam plus macrolide, 4 RCTs: 165/1790 [9%] with β lactam plus macrolide *v* 97/773 [13%] with no antibiotics; RR 0.75, 95% CI 0.59 to 0.95). It found no significant difference between either a macrolide alone or antibiotics used to treat anaerobic bacteria compared with no antibiotic (macrolide alone, 2 RCTs: 157/1653 [9%] with macrolide *v* 64/569 [11%] with no antibiotics; RR 0.81, 95% CI 0.62 to 1.07; antibiotics used to treat anaerobic bacteria, 3 RCTs: 5/155 [3%] with antianaerobic antibiotic *v* 6/139 [4%] with no antibiotic; RR 0.76, 95% CI 0.25 to 2.34).

Harms: There was a trend but not a statistically significant increase in neonatal deaths in the group receiving antibiotics (7 RCTs, 6877 newborns: 99/5005 [2.0%] with antibiotics *v* 24/1872 [1.3%]; RR 1.52, 95% CI 0.99 to 2.34).[44]

Comment: The ORACLE trial[45] dominated the review[44] because it was six times larger than all of the previous RCTs. It differed from the other RCTs because the diagnosis of preterm labour was made by each clinician (as distinct from the other studies, which used similar definitions of preterm labour including uterine contractions and

cervical dilatation) and it was one of only two trials in the review in which antibiotics were administered orally and some women were recruited after 34 weeks. Tocolysis was used in 9 of the 11 RCTs (56% in the ORACLE RCT) and 30–90% of women received corticosteroids.[44,45] Maternal choriomnionitis and endometritis is reduced by the prescription of prophylactic β lactam antibiotics but approximately 88% of women with threatened preterm birth and intact membranes would receive antibiotics unnecessarily for an infection that is easily diagnosed and treated.

GLOSSARY

Apgar score Clinical scoring method that assesses neonatal heart rate, respirations, tone, colour, and reflexes immediately after delivery.

Amnioinfusion Infusion of physiological saline or Ringer's lactate through a catheter transabdominally or transcervically into the amniotic cavity.

Cervical cerclage Insertion of a cervical suture, using non-absorbable suture material, circumferentially around the cervix. May be done transvaginally or transabdominally.

Elective caesarean section When the operation is done at a pre-selected time before the onset of labour, usually after 38 weeks' gestation.

Enhanced antenatal care Includes various programmes of increased medical, midwifery, psychological, social, and nutritional support during pregnancy.

Perinatal Refers to the period after 24 weeks' gestation and includes the first 7 days of postnatal life for the neonate.

Preterm labour Onset of labour (regular uterine contractions with cervical effacement and dilatation) in the preterm period.

Preterm rupture of membranes Leakage of amniotic fluid from the amniotic cavity during the preterm period owing to rupture of the fetal membranes.

Selective caesarean section When the operation is done after the onset of labour.

Tocolytics Pharmacological agents that inhibit uterine contractions.

QUESTIONS

INTERVENTIONS

Key Messages

- **Antibiotics** One systematic review and one subsequent RCT found that antibiotics modestly reduced cough at 1–2 weeks compared with placebo. However, they found no significant difference in quality of life or impairment in normal activity compared with placebo. We found no systematic review or RCTs comparing amoxicillin versus placebo. RCTs found no significant difference in clinical improvement or cure between amoxicillin (amoxycillin) and roxithromycin or cefuroxime. One RCT found that erythromycin reduced the mean number of days of impaired activities compared with placebo. However, RCTs comparing erythromycin versus placebo found no significant difference in other outcomes. RCTs found no significant difference between azithromycin and clarithromycin, among different cephalosporins, or between cefuroxime and amoxicillin plus clavulanic acid. RCTs found that doxycycline reduced the proportion of people with cough at follow up or the mean number of days of cough compared with placebo. Antibiotics increased the risk of adverse events such as nausea, vomiting, rash, headache, and vaginitis compared with placebo. Two RCTs found that adverse effects were less common with cefuroxime than with amoxicillin plus clavulanic acid. Widespread antibiotic use may lead to bacterial resistance to antibiotics.
- **Antihistamines** We found insufficient evidence about the effects of antihistamines compared with placebo in people with acute bronchitis.
- **Antitussives** RCTs found no significant difference in cough severity between codeine or dextromethorphan and placebo in children or adults with acute bronchitis. We found limited evidence from one RCT that moguisteine modestly reduced cough severity compared with placebo in adults, but was associated with more adverse gastrointestinal effects.

Bronchitis (acute)

- **β_2 Agonists** One systematic review found no significant difference in cough or ability to return to work between inhaled or oral β_2 agonists and placebo in people with acute bronchitis. It found limited evidence from one small RCT that β_2 agonists reduced cough compared with erythromycin. The review found that β_2 agonists are more frequently associated with shaking and tremor in adults compared with placebo.
- **Expectorants** We found insufficient evidence about the effects of expectorants in people with acute bronchitis.

DEFINITION

Acute bronchitis is transient inflammation of the trachea and major bronchi. Clinically, it is diagnosed on the basis of cough and occasionally sputum, dyspnoea, and wheeze. This review is limited to episodes of acute bronchitis in people (smokers and non-smokers) with no pre-existing respiratory disease such as a pre-existing diagnosis of asthma or chronic bronchitis, and/or evidence of fixed airflow obstruction, and excluding those with clinical or radiographic evidence of pneumonia. However, using a clinical definition for acute bronchitis implies that people with conditions such as transient/mild asthma or mild chronic obstructive pulmonary disease may have been recruited to some of the reported studies.

INCIDENCE/ PREVALENCE

Acute bronchitis affects 44/1000 adults (> 16 years old) a year, with 82% of episodes occurring in autumn or winter.[1] Acute bronchitis was the fifth most common reason to present to a general practitioner in Australia.[2]

AETIOLOGY/ RISK FACTORS

Infection is believed to be the trigger for acute bronchitis. However, pathogens have been identified in fewer than 55% of people.[1] Community studies that attempted to isolate pathogens from the sputum of people with acute bronchitis found viruses in 8–23%, typical bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*) in 45%, and atypical bacteria (*Mycobacterium pneumoniae*, *Chlamydia pneumoniae*, *Bordetella pertussis*) in 0–25%.[1,3,4] It is unclear whether smoking affects the risk for developing acute bronchitis.

PROGNOSIS

Acute bronchitis is regarded as a mild self limiting illness but there are few data on prognosis and rates of complications such as chronic cough or progression to chronic bronchitis or pneumonia. One prospective longitudinal study reviewed 653 previously well adults who presented to suburban general practices over a 12 month period with symptoms of acute lower respiratory tract infection.[1] It found that within the first month of the illness 20% of people re-presented to their general practitioner with persistent or recurrent symptoms. One prospective study of 138 previously well adults found that 34% had symptoms consistent with either chronic bronchitis or asthma 3 years after initial presentation with acute bronchitis.[5] It is also unclear whether acute bronchitis plays a causal role in the progression to chronic bronchitis or is simply a marker of predisposition to chronic lung disease. Although smoking has been identified as the most important risk factor for chronic bronchitis,[6,7] it is unclear whether the inflammatory effects of cigarette smoke and infection causing acute bronchitis have additive effects in leading to chronic inflammatory airway changes.

AIMS OF INTERVENTION To improve symptoms associated with acute bronchitis; to reduce complications, with minimal adverse effects.

OUTCOMES Duration of symptoms, particularly cough, sputum production, and fever; quality of life scores; adverse effects of treatment; complications, especially chronic cough, pneumonia, and chronic bronchitis.

METHODS *Clinical Evidence* search and appraisal September 2003. We included people of any age or sex with acute bronchitis. We excluded trials conducted in people who had chronic respiratory disease or other acute respiratory diseases. We excluded non-systematic reviews, non-randomised trials, and RCTs of less than 4 days' treatment duration.

QUESTION What are the effects of treatments for acute bronchitis in people without chronic respiratory disease?

OPTION ANTIBIOTICS

One systematic review and one subsequent RCT found that antibiotics modestly reduced cough at 1–2 weeks compared with placebo. However, they found no significant difference in quality of life or impairment in normal activity compared with placebo. We found no systematic review or RCTs comparing amoxicillin versus placebo. RCTs found no significant difference in clinical improvement or cure between amoxicillin (amoxycillin) and roxithromycin or cefuroxime. One RCT found that erythromycin reduced the mean number of days of impaired activities compared with placebo. However, RCTs comparing erythromycin versus placebo found no significant difference in other outcomes. RCTs found no significant difference between azithromycin and clarithromycin; among different cefalosporins; or between cefuroxime and amoxicillin plus clavulanic acid. RCTs found that doxycycline reduced the proportion of people with cough at follow up. Limited evidence suggests that doxycycline may reduce the mean number of days of cough compared with placebo. Antibiotics increased the risk of adverse events such as nausea, vomiting, rash, headache, and vaginitis compared with placebo. Two RCTs found that adverse effects were less common with cefuroxime than with amoxicillin plus clavulanic acid. Widespread antibiotic use may lead to bacterial resistance to antibiotics.

Benefits: We found one systematic review comparing antibiotics versus placebo[8] and eight further RCTs comparing antibiotics versus placebo or each other.[9–16] **Antibiotics versus placebo:** The systematic review (search date 2000, 9 RCTs; 750 people aged 8 to > 65 years, including smokers, but excluding people with chronic bronchitis) compared antibiotics versus placebo.[8] Acute bronchitis was defined by cough, sputum production, or physician diagnosis. The antibiotics used were doxycycline in four RCTs, erythromycin in four RCTs, and sulphamethoxazole plus trimethoprim in one RCT. The review found that antibiotics reduced the proportion of people with cough after 1–2 weeks and mean number of days with reported cough compared with placebo (people with cough, 4 RCTs: 47/143 [33%] with antibiotics *v* 67/132 [51%] with placebo; RR 0.64, 95% CI 0.49 to 0.85; WMD in number of days with cough, 5 RCTs: –0.58 days, 95% CI –1.16 days to –0.009 days). However, it found no

significant difference between antibiotics and placebo in night time cough or productive cough after 1–2 weeks, or for days of impaired activity (night time cough, 3 RCTs: RR for antibiotics *v* placebo 0.76, 95% CI 0.45 to 1.30; productive cough, 7 RCTs: RR for antibiotics *v* placebo 0.97, 95% CI 0.82 to 1.16; WMD in days of impaired activity, 5 RCTs: –0.48 days, 95% CI –0.96 days to +0.01 days). **Amoxicillin versus placebo:** We found no RCTs comparing amoxicillin versus placebo. **Amoxicillin versus macrolides:** We found one RCT (196 adults with clinically diagnosed acute bronchitis and no pre-existing lung disease) comparing amoxicillin 500 mg three times daily versus roxithromycin 150 mg once daily for 10 days.[16] It found no significant difference between amoxicillin and roxithromycin in the proportion with physician assessed improvement or cure (89/96 [93%] with roxithromycin *v* 88/96 [92%] with amoxicillin; P = 0.8). **Amoxicillin versus cephalosporins:** We found one RCT (296 adults with clinically diagnosed acute bronchitis and no pre-existing lung disease) comparing amoxicillin 250 mg three times daily versus cefuroxime 250 mg twice daily for 7 days.[10] It found no significant difference in clinical cure rates between amoxicillin and cefuroxime at 72 hours post-treatment (123/153 [80%] with amoxicillin *v* 109/143 [76%] with cefuroxime; P = 0.8). **Macrolides versus placebo:** We found four RCTs included in the systematic review[8] comparing erythromycin versus placebo and one subsequent RCT comparing azithromycin versus vitamin C (as a placebo).[9] One RCT included in the review (91 people aged ≥8 years) comparing erythromycin versus placebo found a significant reduction in the mean number of days of impaired activities with erythromycin compared with placebo (see web extra table A).[17] However, none of the four RCTs included in the review found significant differences between the treatment and control groups in the number of people with cough, night cough, productive cough, limitation in work/activities, or abnormal lung examination; the number of people who had not improved clinically at follow up; and the mean number of days of cough, productive cough, or feeling ill (see web extra table A).[8,17–19] The subsequent RCT (220 adults with a clinical diagnosis of acute bronchitis and no history of chronic lung disease) comparing azithromycin versus vitamin C (as a placebo) for 5 days found no significant difference between azithromycin and vitamin C in quality of life after 8 days (acute bronchitis specific health related quality of life score, ranging from 0 [not troubled at all] to 6 [extremely troubled]: 0.9 with azithromycin *v* 0.9 with vitamin C; difference adjusted for baseline score +0.03, 95% CI –0.2 to +0.26).[9] **Macrolides versus each other:** We found one RCT (214 adults with clinically diagnosed acute bronchitis and no pre-existing lung disease) comparing azithromycin 500 mg once daily for 2 days then 250 mg once daily for 3 days versus clarithromycin 250 mg once daily for 5 days.[15] It found no significant difference between azithromycin and clarithromycin in clinical cure rates or relapse rates after 6–7 days (cure rate: 55/103 [53%] with azithromycin *v* 70/108 [65%] with clarithromycin; P = 0.4; relapse rate: 2/95 [2.1%] with azithromycin *v* 1/101 [1.0%] with clarithromycin; P = 0.5). **Cephalosporins versus each other:** We found two RCTs.[13,14] The first RCT (465 children < 12 years old with

clinically diagnosed acute bronchitis and no pre-existing lung disease) compared cefuroxime 250 mg twice daily versus cefixime 400 mg once daily for 10 days.[13] It found no significant difference in clinical outcome between cefuroxime and cefixime after 14 days (proportion with satisfactory clinical outcome, as assessed by the treating general practitioner: 130/148 [88%] with cefuroxime *v* 217/238 [91%] with cefixime; P = 0.8). It was not clear how "satisfactory clinical outcome" was defined. The second RCT (196 elderly people with clinically diagnosed acute purulent bronchitis and no pre-existing lung disease) comparing cefuroxime 250 mg twice daily versus cefpodoxime 200 mg twice daily for 5 days found no significant difference in physician rated satisfactory clinical response between cefuroxime and cefpodoxime after 10 days (86/95 [91%] with cefuroxime *v* 87/92 [95%] with cefpodoxime; P = 0.76).[14] It was not clear how "satisfactory clinical outcome" was defined. **Cephalosporins versus amoxicillin plus clavulanic acid:** We found two RCTs.[11,12] The first RCT (312 adults with clinically diagnosed acute bronchitis and no pre-existing lung disease) compared cefuroxime 250 mg twice daily versus amoxicillin 875 mg plus clavulanic acid 125 mg twice daily for 5 days.[11] It found no significant difference between cefuroxime and amoxicillin plus clavulanic acid in self reported clinical improvement at 10–14 days (114/133 [86%] with cefuroxime *v* 128/142 [90%] with amoxicillin plus clavulanic acid; P = 0.27). The second RCT (537 people aged ≥ 12 years with clinically diagnosed acute bronchitis and no pre-existing lung disease) compared cefuroxime 250 mg twice daily for 5 days versus cefuroxime 250 mg twice daily for 10 days versus amoxicillin 500 mg plus clavulanic acid 125 mg three times daily for 10 days.[12] It found no significant difference between the groups in cure rates 1–3 days after completing treatment (84/177 [47%] with cefuroxime for 5 days *v* 100/177 [56%] with cefuroxime for 10 days *v* 116/183 [63%] with amoxicillin plus clavulanic acid; cefuroxime for 5 days *v* cefuroxime for 10 days, P = 0.41; cefuroxime for 5 days *v* amoxicillin plus clavulanic acid, P = 0.91; cefuroxime for 10 days *v* amoxicillin plus clavulanic acid, P = 0.45). **Tetracyclines versus placebo:** We found four RCTs included in the systematic review comparing doxycycline versus placebo (see table A).[8] Two RCTs found that doxycycline significantly reduced the number of people with cough at follow up compared with placebo.[18,19] One RCT found that doxycycline significantly reduced the mean number of days of cough compared with placebo.[18] None of the RCTs found significant effects of doxycycline on the number of people with productive cough, night cough, limitation in work/activities, abnormal lung examination; the number of people who had not improved clinically at follow up; or the mean number of days with productive cough, productive cough, or feeling ill compared with placebo.

Harms:

Antibiotics versus placebo: In the systematic review, adverse events were significantly more common with antibiotics compared with placebo (7 RCTs, adverse events: 60/327 [18%] antibiotics *v* 38/316 [12%] with placebo; RR 1.48; 95% CI 1.02 to 2.14).[8] Adverse events included nausea, vomiting, headache, skin rash, and vaginitis. **Amoxicillin versus placebo:** We found no RCTs. **Amoxicillin versus macrolides:** The RCT gave no information on

adverse effects.[16] **Amoxicillin versus cephalosporins:** The RCT did not report on adverse events.[10] **Macrolides versus placebo:** One RCT included in the review found that significantly more people had adverse effects with erythromycin compared with placebo (18/49 [37%] with erythromycin *v* 6/42 [14%] with placebo; RR 2.57, 95% CI 1.12 to 5.88) (see table A).[17] The other three RCTs included in the review found no significant difference in adverse effects between erythromycin and placebo.[8] **Macrolides versus each other:** The RCT found no significant difference between azithromycin and clarithromycin in adverse effects (17/105 [16%] with azithromycin *v* 13/109 [12%] with clarithromycin; P = 0.56).[15] **Cephalosporins versus each other:** The RCT comparing cefuroxime with cefixime did not report on adverse events.[13] The RCT comparing cefuroxime with cefpodoxime found that the rate of adverse events was similar with cefuroxime and cefpodoxime (4/95 [4.2%] with cefuroxime *v* 6/92 [6.5%] with cefpodoxime; CI not reported).[14] Most of the adverse events were gastrointestinal. **Cephalosporins versus amoxicillin plus clavulanic acid:** The first RCT found that cefuroxime was associated with fewer adverse effects than was amoxicillin plus clavulanic acid (16/133 [12%] with cefuroxime *v* 45/142 [32%] with amoxicillin plus clavulanic acid; P = 0.001).[11] Most of the adverse effects were gastrointestinal. The second RCT found that a significantly lower proportion of people had gastrointestinal symptoms with cefuroxime than with amoxicillin plus clavulanic acid (24/157 [15%] with cefuroxime for 5 days *v* 48/130 [37%] with amoxicillin plus clavulanic acid; P < 0.01).[12] **Tetracyclines versus placebo:** Two RCTs included in the review found no significant difference in adverse effects between doxycycline and placebo (see table A).[8] The other two RCTs included in the review gave no information on adverse effects.

Comment: Physicians may be more likely to prescribe antibiotics for smokers with acute bronchitis than for non-smokers (90% in smokers *v* 75% in non-smokers; P < 0.05).[20] Seven of the trials in the systematic review found that smoking status did not affect response to antibiotics.[8] All trials mentioned above diagnosed acute bronchitis on clinical grounds and commenced treatment independently of sputum culture results. As shown above, there is no evidence that extended spectrum antibiotics are more effective than amoxicillin or doxycycline. Therefore, their use does not seem justified, particularly as widespread antibiotic use in acute bronchitis may lead to bacterial resistance.[21]

OPTION ANTITUSSIVES

RCTs found no difference in cough severity between codeine or dextromethorphan and placebo in children or adults with acute bronchitis. We found limited evidence from one RCT that moguisteine modestly reduced cough severity compared with placebo in adults but was associated with more adverse gastrointestinal effects.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 766 adults, 57 children) of non-prescription medications in people with acute bronchitis[22] and one subsequent RCT,[23] identified by a second systematic review (search date 2000; 1 RCT in 75 children

with acute bronchitis or acute cough).[24] The first review did not perform a meta-analysis because of differences in preparations, outcomes, and durations of follow up. We excluded two of the five RCTs identified by the review because treatment duration was less than 4 days. **In children:** The first review identified one RCT (57 children) that met our inclusion criteria.[25] It compared three treatments: dextromethorphan 15 mg once daily, codeine 10 mg once daily, and placebo at bedtime for 3 nights. It found no significant difference between treatments in mean cough score after 3 days (reduction in mean cough score [range 0–4, higher score indicating more severe cough]: 2.1 with dextromethorphan *v* 2.2 with codeine *v* 2.2 with placebo; dextromethorphan *v* placebo, P = 0.4; codeine *v* placebo, P = 0.7). The subsequent RCT, identified by the second systematic review, compared three treatments: dextromethorphan (7.5 mg once daily for children < 7 years and 15 mg once daily for children ≥ 7 years), dextromethorphan plus salbutamol (albuterol) (1 mg once daily for children < 7 years and 2 mg once daily for children ≥ 7 years), and placebo once daily for 3 days. It found no significance difference in cough symptoms with dextromethorphan compared with placebo (mean cough score day 1: 1.30 with dextromethorphan *v* 1.44 with placebo; day 2: 0.93 with dextromethorphan *v* 1.06 with placebo; day 3: 0.60 with dextromethorphan *v* 0.76 with placebo; differences reported as non-significant for all days) or general condition (mean general condition score day 1: 1.0 with dextromethorphan *v* 1.4 with placebo; day 2: 1.48 with dextromethorphan *v* 1.64 with placebo; day 3: 2.0 with dextromethorphan *v* 2.08 with placebo; difference reported as non-significant for all days) on either of the 3 treatment days.[23] More than half of the people reported some or marked relief by the medication (16/24 [66%] with dextromethorphan *v* 19/26 [73%] with placebo) but the differences between the groups were not significant. **In adults:** The review identified two RCTs that met our inclusion criteria.[26,27] The first (81 adults) compared codeine 30 mg four times daily with placebo for 4 days.[26] It found no significant difference between codeine and placebo in mean cough severity score (higher score indicates worse cough, scale end points unclear) over a 5 day period (mean cough severity score: 17.2 with codeine *v* 18.0 with placebo; P = 0.5). The second RCT (108 adults) compared moguisteine 200 mg three times daily for 5 days versus placebo.[27] It found that moguisteine modestly reduced cough severity score compared with placebo (mean difference in cough score on a scale of 0–9 [higher score indicating more severe cough]: 0.5; P < 0.05).

Harms:

In children: No additional adverse events were recorded with treatment compared with placebo (the event rates for each group were not reported).[25] The subsequent RCT found a low incidence of serious adverse effects in all treatment groups and no significant difference between the dextromethorphan and placebo groups (children with serious adverse effects: 3/24 [13%] with dextromethorphan *v* 1/26 [4%] with placebo, difference reported as

non-significant).[23] **In adults:** The first RCT gave no information on adverse effects.[26] The second RCT found that moguisteine increased nausea, vomiting, and abdominal pain compared with placebo (13/58 [22%] with moguisteine *v* 5/58 [9%] with placebo; $P < 0.05$).[27]

Comment: The first systematic review stated that it examined the effects of treatments in people with "upper respiratory tract infection" rather than "acute bronchitis".[22] However, the clinical criteria used to define this population were consistent with the definition of acute bronchitis used in this topic. Moguisteine is available without prescription only in the UK.

OPTION β_2 AGONISTS

One systematic review found no significant difference in cough or ability to return to work between inhaled or oral β_2 agonists and placebo in people with acute bronchitis. It found limited evidence from one small RCT that β_2 agonists reduced cough compared with erythromycin. The review found that β_2 agonists are more frequently associated with shaking and tremor in adults compared with placebo.

Benefits: We found one systematic review (search date 2000; 2 RCTs in 109 children and 5 RCTs in 418 adults, both smokers and non-smokers, with acute bronchitis or acute cough).[24] People with pre-existing lung disease, with another acute respiratory disorder, or aged under 24 months were excluded. Four of the RCTs included in the systematic review compared an oral β_2 agonist (salbutamol [albuterol]) versus placebo. Three RCTs compared inhaled β_2 agonists (salbutamol [albuterol] and fenoterol) versus placebo. Two RCTs had more than two study arms.[23,28] Results from children and adults were analyzed separately. **Versus placebo:** The review found no significant effect of inhaled or oral β_2 agonists on the proportion of children or adults with cough after 7 days compared with placebo (1 RCT, 59 children: 11/30 [37%] with β_2 agonists *v* 12/29 [41%] with placebo; RR 0.89, 95% CI 0.47 to 1.65; 3 RCTs, 110 adults: RR 0.86, 95% CI 0.63 to 1.18). Similarly, it found no significant difference between β_2 agonists and placebo in the proportion of adults unable to work after 4 days of treatment (2 RCTs, 149 adults: RR for β_2 agonists *v* placebo 0.82, 95% CI 0.28 to 2.34). **Versus antibiotics:** The systematic review[24] identified one small RCT comparing inhaled β_2 agonists versus oral erythromycin for 7 days.[29] It found that β_2 agonists significantly reduced the proportion of adults with cough after 7 days compared with erythromycin (7/17 [41%] with inhaled β_2 agonists *v* 15/17 [88%] with erythromycin; RR 0.47, 95% CI 0.26 to 0.85).

Harms: **Versus placebo:** The systematic review found that in children, shaking and tremor were more frequently associated with β_2 agonists compared with placebo, although the difference was not significant (2 RCTs, 108 children: 6/55 [11%] with β_2 agonists *v* 0/53 [0%] with placebo; RR undefined).[24] In adults, a significantly larger proportion of people reported shaking and tremor with β_2

agonists (both oral and inhaled) compared with placebo (3 RCTs, 211 adults: 58/105 [55%] with β_2 agonists *v* 12/106 [11%] with placebo; OR 7.94, 95% CI 1.17 to 53.94). **Versus antibiotics:** One RCT identified by the review[24] found that tremor and shaking were more frequently associated with β_2 agonists compared with erythromycin (6/17 [35%] with β_2 agonists *v* 0/17 [0%] with erythromycin; RR 13.0, 95% CI 0.8 to 214.0), although the difference was not significant.[29] The RCT found no significant difference between β_2 agonists and erythromycin in other adverse effects (2/23 [8.7%] with β_2 agonists *v* 2/23 [8.7%] with erythromycin; RR 1.0, 95% CI 0.15 to 1.51).

Comment: None.

OPTION EXPECTORANTS

We found insufficient evidence about the effects of expectorants in people with acute bronchitis.

Benefits: We found one systematic review of non-prescription medications for acute cough in people with acute bronchitis (search date 2000).[22] However, the review did not include any RCTs evaluating the effect of expectorants in people with acute bronchitis. We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: The systematic review stated that it examined the effects of treatments in people with "upper respiratory tract infection" rather than "acute bronchitis".[22] However, the clinical criteria used to define this population were consistent with the definition of acute bronchitis used in this topic.

OPTION ANTIHISTAMINES

We found insufficient evidence about the effects of antihistamines in people with acute bronchitis.

Benefits: We found one systematic review of non-prescription medications in people with acute bronchitis (search date 2000).[22] The review identified one RCT (100 adult non-smokers) that met our inclusion criteria.[30] It compared terfenadine 100 mg twice daily versus placebo for 4 or 5 days. It found no significant difference in mean cough score between terfenadine and placebo at day 4 (mean cough score [range 0–3, higher scores indicating worse cough]: 0.80 with terfenadine *v* 0.65 with placebo; P = 0.35).

Harms: The RCT reported a low incidence of adverse events but did not specify these.[30]

Comment: The systematic review stated that it examined the effects of treatments in people with "upper respiratory tract infection" rather than "acute bronchitis".[22] However, the clinical criteria used to define this population were consistent with the definition of acute bronchitis used in this topic.

Community acquired pneumonia

Key Messages

Treatment

- **Antibiotics (amoxicillin, cephalosporins, macrolides, penicillin, quinolones) in hospital** RCTs that compared different oral or intravenous antibiotics in people admitted to hospital found clinical cure or improvement in 73–96% of people. Four RCTs found no significant difference in clinical cure or improvement among different antibiotics. Two RCTs found that quinolones may increase clinical cure compared with co-amoxiclav (amoxicillin plus clavulanic acid) or cephalosporins. However, most trials were small and were designed to show equivalence between treatments rather than superiority of one over another.
- **Antibiotics (amoxicillin, cephalosporins, macrolides, penicillin, quinolones) in outpatient settings** One systematic review that evaluated different oral antibiotics in outpatient settings has found clinical cure or improvement in over 90% of people regardless of antibiotic taken. Another systematic review found that azithromycin reduced clinical failures over 6–21 days compared with other macrolides, cephalosporins, or penicillin. A third systematic review and a subsequent RCT found no significant difference in clinical cure or improvement between quinolones and amoxicillin, cephalosporins, or macrolides. Most trials were designed to show equivalence between treatments rather than superiority of one antibiotic over another.
- **Prompt administration of antibiotics in people admitted to intensive care with community acquired pneumonia (compared with delayed antibiotic treatment)** Two retrospective studies found that prompt administration of antibiotics improved survival. It would probably be unethical to perform an RCT of delayed antibiotic treatment.
- **Bottle blowing** One unblinded RCT in people receiving antibiotics and usual medical care found that bottle blowing physiotherapy plus early mobilisation plus encouragement to sit up regularly and take deep breaths reduced mean hospital stay compared with early mobilisation alone. It found no significant difference in duration of fever.
- **Different antibiotic combinations in intensive care settings** We found no RCTs that compared one combination of antibiotics with another in intensive care units.
- **Guidelines for treating pneumonia (for clinical outcomes)** One systematic review found no significant difference in clinical outcomes between usual care and a guideline based management strategy that incorporated early switch from intravenous to oral antibiotics and early discharge (or both).
- **Intravenous antibiotics in immunocompetent people in hospital without life threatening illness (compared with oral antibiotics)** Two RCTs in immunocompetent people admitted to hospital who did not have life threatening illness found no significant difference in clinical cure or mortality between intravenous and oral antibiotics (co-amoxiclav or cefuroxime). The RCTs found that intravenous antibiotics may increase the length of hospital stay compared with oral antibiotics.

Prevention

- **Pneumococcal vaccine in immunocompetent adults** One systematic review found that pneumococcal vaccination reduced pneumococcal pneumonia in immunocompetent people compared with no vaccination.

- **Influenza vaccine (in elderly people)** We found no RCTs that assessed the effects of influenza vaccine in preventing community acquired pneumonia. Observational studies suggest that influenza vaccine may reduce the incidence of pneumonia and may reduce mortality in the elderly.
- **Pneumococcal vaccine in chronically ill, immunosuppressed, or elderly people** One systematic review found no significant difference between pneumococcal vaccination and no vaccination in the incidence of pneumonia in elderly people or people likely to have an impaired immune system.

DEFINITION

Community acquired pneumonia is pneumonia contracted in the community rather than in hospital. It is defined by clinical symptoms (such as cough, sputum production, and pleuritic chest pain) and signs (such as fever, tachypnoea, and rales), with radiological confirmation.

INCIDENCE/ PREVALENCE

In the northern hemisphere, community acquired pneumonia affects about 12/1000 people a year, particularly during winter and at the extremes of age (incidence: < 1 year old 30–50/1000 a year; 15–45 years 1–5/1000 a year; 60–70 years 10–20/1000 a year; 71–85 years 50/1000 a year).[1–6]

AETIOLOGY/ RISK FACTORS

Over 100 microorganisms have been implicated in community acquired pneumonia, but most cases are caused by *Streptococcus pneumoniae* (see table 1, p 1946).[4–7] Smoking is probably an important risk factor.[8] One large cohort study in Finland (4175 people aged ≥ 60 years) suggested that risk factors for pneumonia in the elderly included alcoholism (RR 9.0, 95% CI 5.1 to 16.2), bronchial asthma (RR 4.2, 95% CI 3.3 to 5.4), immunosuppression (RR 3.1, 95% CI 1.9 to 5.1), lung disease (RR 3.0, 95% CI 2.3 to 3.9), heart disease (RR 1.9, 95% CI 1.7 to 2.3), institutionalisation (RR 1.8, 95% CI 1.4 to 2.4), and increasing age (≥ 70 years *v* 60–69 years; RR 1.5, 95% CI 1.3 to 1.7).[9]

PROGNOSIS

Severity varies from mild to life threatening illness within days of the onset of symptoms. One systematic review of prognosis studies for community acquired pneumonia (search date 1995, 33 148 people) found overall mortality to be 13.7%, ranging from 5.1% for ambulant people to 36.5% for people who required intensive care.[10] The following prognostic factors were significantly associated with mortality: male sex (OR 1.3, 95% CI 1.2 to 1.4); pleuritic chest pain (OR 0.5, 95% CI 0.3 to 0.8, i.e. lower mortality); hypothermia (OR 5.0, 95% CI 2.4 to 10.4); systolic hypotension (OR 4.8, 95% CI 2.8 to 8.3); tachypnoea (OR 2.9, 95% CI 1.7 to 4.9); diabetes mellitus (OR 1.3, 95% CI 1.1 to 1.5); neoplastic disease (OR 2.8, 95% CI 2.4 to 3.1); neurological disease (OR 4.6, 95% CI 2.3 to 8.9); bacteraemia (OR 2.8, 95% CI 2.3 to 3.6); leucopenia (OR 2.5, 95% CI 1.6 to 3.7); and multilobar radiographic pulmonary infiltrates (OR 3.1, 95% CI 1.9 to 5.1).

AIMS OF INTERVENTION

Treatment: To cure infection clinically, to reduce mortality, to alleviate symptoms, to enable return to normal activities, and to prevent recurrence, while minimising adverse effects of treatments.
Prevention: To prevent onset of pneumonia.

OUTCOMES

Treatment: Clinical cure, variably defined but usually defined as return to premorbid health status or complete absence of symptoms such as fever, chills, cough, dyspnoea, or sputum production;

improvement (relief of symptoms); admission to hospital; complications (empyema, endocarditis, lung abscess); death; adverse effects of antibiotics. **Prevention:** incidence of pneumonia, adverse effects of vaccination.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION **What are the effects of interventions in outpatient settings?**

OPTION **ANTIBIOTICS**

One systematic review that evaluated different oral antibiotics in outpatient settings has found clinical cure or improvement in over 90% of people regardless of antibiotic taken. Another systematic review found that azithromycin reduced clinical failures over 6–21 days compared with other macrolides, cephalosporins, or penicillin. A third systematic review and a subsequent RCT found no significant difference in clinical cure or improvement between quinolones and amoxicillin, cephalosporins, or macrolides. Most trials were designed to show equivalence between treatments rather than superiority of one antibiotic over another.

Benefits: We found three systematic reviews[11–13] and one subsequent RCT.[14] The first systematic review (search date not reported, 9 RCTs, 1164 people) compared different oral antibiotics in outpatient settings.[11] Antibiotics evaluated were amoxicillin (amoxycillin) with and without clavulanate, macrolides, cephalosporins, and quinolones. The review did not perform a meta-analysis that directly compared antibiotics. Clinical cure or improvement was reported in over 90% of people regardless of antibiotic taken (no further data reported). **Azithromycin versus other macrolides, cephalosporins, or penicillins:** The second systematic review (search date 2000, 18 RCTs, 2 of which were included in the first review, 1664 people) found that, compared with other macrolides (clarithromycin, erythromycin, or roxithromycin, 13 RCTs); cephalosporins (cefaclor, 2 RCTs), or penicillins (co-amoxiclav [amoxicillin plus clavulanic acid] or penicillin, 3 RCTs), azithromycin significantly reduced clinical failures over 6–21 days (56/928 [6%] with azithromycin *v* 72/736 [10%] with other oral antibiotics; OR 0.63, 95% CI 0.42 to 0.95).[12] These results should be interpreted with caution as most of the RCTs were not blinded. **Quinolones versus amoxicillin, macrolides, or cephalosporins:** The third systematic review (search date 1999, 8 RCTs, none of which were included in the first or second review, 3131 people) found no significant difference in clinical success (cure or improvement) between quinolones (gatifloxacin, levofloxacin, moxifloxacin, sparfloxacin, and trovafloxacin) and high dose amoxicillin, cefaclor, cefpodoxime, ceftriaxone, ceftriaxone plus clarithromycin, cefuroxime axetil, clarithromycin, co-amoxiclav, erythromycin, or roxithromycin (ARR +1.7%, 95% CI −1.4% to +4.8%; no further data reported).[13] The subsequent RCT (299 people) compared oral clarithromycin 1000 mg daily versus oral levofloxacin 500 mg daily.[14] It found no significant difference in clinical cure rates at 7 days between oral clarithromycin and levofloxacin (113/128 [88%] with clarithromycin *v* 107/124 [86%] with levofloxacin; RR 1.02, 95% CI 0.93 to 1.12).[14]

Harms: The first and third reviews gave no information on adverse effects.[11,13] The second review found that azithromycin significantly reduced withdrawals because of adverse effects compared with co-amoxiclav (no further data reported).[12] It also found limited evidence from indirect comparisons that withdrawals because of adverse effects were lower with azithromycin than with clarithromycin, erythromycin, or cefaclor. The subsequent RCT found no significant difference in the proportion of people who had adverse effects (primarily diarrhoea, nausea, and headache) with clarithromycin compared with levofloxacin (26% with clarithromycin *v* 20% with levofloxacin; reported as non-significant; CI not reported), although clarithromycin significantly increased taste disturbance (20/156 [13%] with clarithromycin *v* 1/143 [0.7%] with levofloxacin; $P < 0.001$).[14] Antibiotics can cause allergic reactions (including anaphylaxis), rash, gastrointestinal intolerance (nausea, vomiting, and diarrhoea), vaginal or oral candidiasis, and *Clostridium difficile* diarrhoea (including pseudomembranous colitis). Frequency of adverse effects varies with the antibiotic used.

Comment: Most trials were designed to show equivalence between treatments rather than superiority of one antibiotic over another.

QUESTION What are the effects of treatments in people admitted to hospital?

OPTION ANTIBIOTICS

RCTs that compared different oral or intravenous antibiotics in people admitted to hospital found clinical cure or improvement in 73–96% of people. Four RCTs found no significant difference in clinical cure or improvement among different antibiotics. Two RCTs found that quinolones may increase clinical cure compared with co-amoxiclav (amoxicillin plus clavulanic acid) or cephalosporins. However, most trials were small, and were designed to show equivalence between treatments rather than superiority of one antibiotic over another.

Benefits: We found no systematic review. **Cephalosporins versus penicillin:** We found several RCTs that were too small, too old, or both, to be reliable given the changing sensitivity of organisms to antibiotics. One RCT (378 people) compared intravenous co-amoxiclav (amoxicillin plus clavulanic acid) followed by oral co-amoxiclav with intravenous ceftriaxone followed by intramuscular ceftriaxone.[15] People in both groups also received intravenous erythromycin as decided by their physician (17/184 [9%] people taking co-amoxiclav and 25/194 [13%] people taking ceftriaxone). It found no significant difference in clinical cure at long term follow up, which was not specified (136/184 [73.9%] with co-amoxiclav *v* 144/194 [74.2%] with ceftriaxone; RR 0.99, 95% CI 0.88 to 1.12). **Quinolones versus high dose amoxicillin:** We found two multicentre double blind RCTs.[16,17] The first RCT (329 people in hospital in France, South Africa, or Switzerland) compared sparfloxacin 400 mg on day 1 followed by 200 mg once daily with amoxicillin 1000 mg three times daily.[16] It found no significant difference in clinical cure at 14–21 days (133/159 [84%] with sparfloxacin *v* 144/170 [85%] with amoxicillin; RR 0.99, 95% CI 0.87 to 1.07).[16]

It found that fewer people treated with sparfloxacin discontinued the drug at days 3, 4, or 5 because of a lack of response compared with ampicillin, but the difference did not reach significance (3/126 [2%] with sparfloxacin *v* 11/140 [8%] with amoxicillin; RR 0.30, 95% CI 0.08 to 1.05). The second RCT (411 people with suspected pneumococcal pneumonia, 285 of whom were admitted to hospital) compared oral moxifloxacin 400 mg once daily with oral amoxicillin 1000 mg three times daily.[17] It found no significant difference in clinical cure or improvement at 3–4 weeks after the end of 5–7 days' treatment (154/200 [77.0%] with moxifloxacin *v* 164/208 [78.8%] with amoxicillin; RR 0.97, 95% CI 0.86 to 1.07). **Quinolones versus co-amoxiclav:** We found one multicentre RCT (628 people) that compared moxifloxacin 400 mg once daily (iv followed by oral) with co-amoxiclav 1.2 g intravenously followed by 625 mg orally three times daily with or without clarithromycin for 7–14 days.[18] It found that moxifloxacin significantly increased the clinical cure rate at 5–7 days after treatment compared with co-amoxiclav (225/241 [93%] with moxifloxacin *v* 204/239 [85%] with co-amoxiclav; P = 0.004).[18] **Quinolones versus cephalosporins:** We found one unblinded RCT (590 people, 280 of whom had been admitted to hospital) that compared oral or intravenous levofloxacin or both with intravenous ceftriaxone or oral cefuroxime axetil, or both.[19] It found that levofloxacin significantly increased the proportion of people clinically cured or improved at 5–7 days compared with cephalosporins (96% with levofloxacin *v* 90% with cephalosporins; reported as significant; CI not reported). **Quinolones versus macrolides plus cephalosporins:** We found one multicentre open label RCT (236 people) that compared levofloxacin 500 mg daily (orally or iv) with intravenous azithromycin 500 mg plus intravenous ceftriaxone 1 g for 2 days followed by an optional transition to oral azithromycin 500 mg.[20] It found no significant difference in clinical cure between groups (100/115 [87%] with levofloxacin *v* 97/121 [80%] with azithromycin plus ceftriaxone; RR 1.08, 95% CI 0.97 to 1.21).[20]

Harms:

See also harms of antibiotics, p 1937. **Cephalosporins versus penicillin:** The RCT gave no information on adverse effects.[15] **Quinolones versus high dose amoxicillin:** The first RCT found that fewer people had gastrointestinal disturbances with sparfloxacin compared with amoxicillin (19 with amoxicillin *v* 10 with sparfloxacin; CI not reported).[16] Four people (2.5%) taking sparfloxacin withdrew because of adverse effects compared with two people (1.2%) taking amoxicillin (P value not reported). The second RCT found no significant difference in gastrointestinal adverse effects with moxifloxacin compared with amoxicillin (56/200 [28%] with moxifloxacin *v* 42/208 [20%] with amoxicillin; RR 1.39, 95% CI 0.98 to 1.97).[16] **Quinolones versus co-amoxiclav:** The RCT found similar rates of overall adverse effects (primarily nausea and diarrhoea) between moxifloxacin and co-amoxiclav (39% in both groups; CI not reported).[18] **Quinolones versus cephalosporins:** The RCT found that a similar proportion of people had gastrointestinal adverse effects (primarily nausea and diarrhoea) with levofloxacin compared with cephalosporins (5.8% levofloxacin *v* 8.5% with cephalosporins; absolute numbers and CI not reported).[19] **Quinolones versus macrolides plus cephalosporins:** The RCT

found no significant difference in overall adverse events rates (primarily gastrointestinal adverse effects) between levofloxacin and azithromycin plus ceftriaxone (6/113 [5%] with levofloxacin *v* 11/118 [9%] with azithromycin; RR 0.57, 95% CI 0.22 to 1.49).[20]

Comment: Most trials were small and were designed to show equivalence between treatments rather than superiority of one antibiotic over another. Although detection of penicillin resistant and multidrug resistant *S pneumoniae* is commonly reported, it is hard to enrol people with this infection in randomised studies. One study was carried out in areas with high prevalence of penicillin resistant *S pneumoniae*.[16] It found 8/135 (6.9%) isolates tested were resistant to penicillin,[16] but none showed high level resistance as measured by the minimum inhibitory concentration of penicillin (where pneumococcal strains with minimum inhibitory concentration ≥ 2 μg are termed highly resistant).[21] The trials in uncomplicated pneumonia may not apply to people with comorbidities such as meningitis.[21] There are also concerns about macrolide resistant *S pneumoniae*, but, so far, treatment failure in ambulatory people with community acquired pneumonia is uncommon.[22] In the RCT that compared levofloxacin with cephalosporins, the route of administration was decided by the doctor, and it is unclear whether all participants who received intravenous antibiotics were admitted to hospital.[19] We found one retrospective review (12 945 people ≥ 65 years old in hospital with community acquired pneumonia).[23] It found that initial treatment with a second generation cephalosporin (cefuroxime) plus a macrolide (azithromycin, clarithromycin, or erythromycin), a non-pseudomonal third generation cephalosporin (ceftriaxone, cefotaxime, ceftizoxime) plus a macrolide, or a fluoroquinolone (ciprofloxacin, ofloxacin) reduced mortality at 30 days compared with initial treatment with a β-lactam/β-lactamase inhibitor (ampicillin plus sulbactam, ticarcillin plus clavulanic acid, piperacillin plus tazobactam) plus a macrolide, or an aminoglycoside plus another antimicrobial agent.[23] One retrospective cohort study found that people infected with penicillin resistant compared with non-penicillin resistant *S pneumoniae* were at greater risk of death in hospital (RR 2.1, 95% CI 1.0 to 4.3) and suppurative complications (RR 4.5, 95% CI 1.0 to 19.3).[24] From national surveillance data, penicillin resistant pneumonia was associated with significantly higher mortality after the first 4 days in hospital than non-penicillin resistant pneumonia.[25] These results should be interpreted with caution, however, as they may not account for confounding factors.

OPTION INTRAVENOUS ANTIBIOTICS (COMPARED WITH ORAL ANTIBIOTICS)

Two RCTs in immunocompetent people admitted to hospital who did not have life threatening illness found no significant difference in clinical cure or mortality between intravenous and oral antibiotics (co-amoxiclav [amoxicillin plus clavulanic acid] or cefuroxime). The RCTs found that intravenous antibiotics may increase the length of hospital stay compared with oral antibiotics.

Community acquired pneumonia

Benefits: We found no systematic review. We found two RCTs that compared oral versus intravenous antibiotics in people admitted to hospital with community acquired pneumonia.[26,27] The first RCT (541 people with lower respiratory tract infections, 40% of whom had chest radiographs that were compatible with pneumonia) compared three interventions: oral co-amoxiclav (amoxicillin plus clavulanic acid) for 7 days, intravenous co-amoxiclav for 3 days followed by oral co-amoxiclav for 4 days, and intravenous cefotaxime for 3 days followed by oral cefuroxime for 4 days.[26] People were excluded if they had life threatening infection or were immunocompromised. At discharge from hospital, the RCT found no significant difference between treatments in cure or improvement, or in mortality (cure or improvement: 142/181 [78%] with oral co-amoxiclav *v* 129/181 [71%] iv cefotaxime *v* 122/179 [68%] oral cefuroxime; P = 0.36 for all regimens *v* each other; mortality: 9/181 [5%] oral co-amoxiclav *v* 13/181 [7%] iv cefotaxime *v* 11/179 [6%] oral cefuroxime; P = 0.67 for all regimens *v* each other). However, it found that oral antibiotics significantly reduced hospital stay compared with intravenous antibiotics (proportion of people discharged within 3 days: 36/181 [20%] with oral antibiotics *v* 21/360 [6%] with iv antibiotics; P < 0.005).[26] The second RCT (73 people, no intention to treat analysis) assessed different duration of treatment with intravenous antibiotics.[27] It compared three interventions: 2 days of intravenous cefuroxime followed by 8 days of oral cefuroxime (group 1), 5 days of oral cefuroxime followed by 5 days of intravenous cefuroxime (group 2), or 10 days of intravenous cefuroxime (group 3).[27] People were excluded if they had empyema, septic shock, or respiratory failure. It found no significant difference among groups in the proportion of people with clinical cure after 28 days (18/20 [90%] in group 1 *v* 17/20 [85%] in group 2 *v* 16/17 [94%] in group 3; reported as non-significant, no further data reported). However, it found that people in group 1 had a significantly shorter hospital stay compared with people in either of the other groups (6 days with group 1 *v* 8 days with group 2 *v* 11 days with group 3; reported as significant; CI not reported).[27]

Harms: The RCTs gave no information on adverse effects.[26,27]

Comment: Intravenous antibiotics are used in people who cannot take oral medication because of severe nausea or vomiting. A follow up study (96 people admitted to hospital with community acquired pneumonia) found clinical cure of pneumonia at 30 days in people who were switched from intravenous to oral antibiotics when they had been afebrile for 8 hours, symptoms of cough and shortness of breath were improving, white blood cell counts were returning to normal, and they could tolerate oral medication.[28]

OPTION BOTTLE BLOWING

One unblinded RCT in people who received antibiotics and usual medical care found that bottle blowing physiotherapy plus early mobilisation plus encouragement to sit up regularly and take deep breaths reduced mean hospital stay compared with early mobilisation alone. It found no significant difference in duration of fever.

Benefits: We found no systematic review. We found one RCT (145 people in hospital with community acquired pneumonia) that compared three interventions: early mobilisation alone, early mobilisation plus encouragement to sit up 10 times a day and take 20 deep breaths, and early mobilisation plus encouragement to sit up 10 times a day and blow bubbles through a plastic tube for 20 breaths into a bottle containing 10 cm of water (bottle blowing).[29] Participants concurrently received benzylpenicillin or phenoxymethylpenicillin and usual medical care independently of the study interventions. The RCT found that bottle blowing plus early mobilisation plus encouragement significantly reduced mean hospital stay compared with early mobilisation alone (5.3 with bottle blowing plus early mobilisation plus encouragement *v* 3.9 days with early mobilisation alone; P = 0.01). It found no significant difference among groups in duration of fever (2.3 with early mobilisation alone *v* 1.7 with encouragement to take deep breaths *v* 1.6 with bottle blowing; P = 0.28 for all groups *v* each other; see comment below).

Harms: The RCT gave no information on adverse effects.[29]

Comment: In the RCT, neither participants nor clinicians were blinded to the intervention.[29]

QUESTION What are the effects of treatments in people with community acquired pneumonia receiving intensive care?

OPTION DIFFERENT COMBINATIONS OF ANTIBIOTICS

We found no RCTs that compared one combination of antibiotics with another in intensive care units (see comment below).

Benefits: We found no systematic review and no RCTs that compared one combination of antibiotics with another in intensive care units (see comment below).

Harms: We found no RCTs.

Comment: Use of a combination of antibiotics is regarded as current best practice for ventilator related pneumonia. Choice of antibiotics varies, depending on local guidelines.

OPTION PROMPT VERSUS DELAYED ANTIBIOTIC TREATMENT

Two retrospective studies found that prompt administration of antibiotics improved survival. It would probably be unethical to perform an RCT of delayed antibiotic treatment.

Benefits: We found no systematic review and no RCTs (see comment below). One multicentre retrospective review (medical records of ≥ 14 000 people aged ≥ 65 years admitted to acute [emergency] care hospitals in the USA who were severely ill with community acquired pneumonia) found that antibiotics given within 8 hours of admission to hospital were associated with lower 30 day mortality (OR 0.85, 95% CI 0.75 to 0.96).[30] The review did not specify whether oral or intravenous antibiotics were given. Another retrospective study (39

people with serologically confirmed legionnaires' disease and clinically diagnosed community acquired pneumonia) examined outcome and time to start of treatment.[31] For the 10 people who died, the median delay between diagnosis of pneumonia and start of intravenous erythromycin was 5 days (range 1–10 days), and for those who survived it was 1 day (range 1–5 days; P < 0.001).

Harms: The retrospective studies gave no information on harms.[30,31]

Comment: It would probably be regarded as unethical to perform an RCT of delayed antibiotic treatment.

QUESTION **What are the effects of guidelines on the treatment of community acquired pneumonia?**

OPTION **GUIDELINES**

One systematic review found no significant difference in clinical outcomes between usual care and a guideline based management strategy that incorporated early switch from intravenous to oral antibiotics and early discharge (or both).

Benefits: We found one systematic review (search date 2000, 3 RCTs, 7 cohort studies) that compared a guideline incorporating early switch from intravenous to oral antibiotics and early discharge, or both, with usual care.[32] It found no significant difference between treatments in therapeutic success (not defined), readmission to hospital, admission to intensive care unit, complications, mortality, or any adverse outcome (no further data reported). It also found no significant difference between guideline and usual care in mean length of hospital stay (mean 6.0 days with guideline *v* 7.6 days with usual care; P = 0.05).

Harms: The review found no significant difference in "any adverse outcome" (not specified) between guideline and usual care (no further data reported).[32]

Comment: None.

QUESTION **What are the effects of preventive interventions?**

OPTION **INFLUENZA VACCINE**

We found no RCTs that assessed the effects of influenza vaccine in preventing community acquired pneumonia. Observational studies suggest that influenza vaccine may reduce the incidence of pneumonia and may reduce mortality in the elderly.

Benefits: We found no systematic review or RCTs. See comment below.

Harms: We found no RCTs (see comment below).

Comment: We found one systematic review of cohort studies (search date not stated, 20 studies) that compared influenza vaccine versus no vaccine.[33] It found that influenza vaccine significantly reduced the incidence of pneumonia and significantly reduced mortality (incidence: 24 774 people; ARR 53%, 95% CI 35% to 66%; mortality:

29 928 people; ARR 68%, 95% CI 56% to 76%).[33] Timescales were not reported for any outcomes. Analysis of an administrative database (≥ 25 000 people aged ≥ 64 years) suggested that influenza vaccination reduced the rate of admission to hospital in people with pneumonia or influenza by 48–57% ($P < 0.01$).[34] We found one systematic review (search date 2000,[35] 1 RCT[36]) and one additional RCT that assessed the effects of influenza vaccine in preventing influenza and reducing mortality.[37–39] **Effects in vaccinated people:** The RCT (> 1800 people aged ≥ 60 years) identified by the review[35] compared split virion vaccine with saline solution.[36] It found that vaccine significantly reduced the incidence of clinical influenza at 5 months compared with placebo (AR 17/927 [1.8%] with vaccine *v* 31/911 [3.4%] with placebo; RR 0.53, 95% CI 0.39 to 0.73).[36] The additional RCT (324 elderly residents of nursing homes) compared parenteral trivalent inactivated vaccine plus intranasal live attenuated cold adapted vaccine with parenteral trivalent inactivated vaccine alone. It found that inactivated vaccine plus live attenuated vaccine significantly reduced the incidence of influenza A compared with inactivated vaccine alone (9/162 [5.5%] with inactivated vaccine plus live attenuated vaccine *v* 24/169 [14.2%] with inactivated vaccine alone; RR 0.39, 95% CI 0.18 to 0.81; NNT 12, 95% CI 9 to 38).[37] A reduction in rates of influenza does not necessarily imply a reduction in rates of pneumonia. However, in people with influenza, death is usually caused by pneumonia. Therefore, interventions that reduce influenza mortality have their effects by reducing pneumonia rates. Two RCTs found that adverse effects included pain and tenderness at the site of injection.[38,39] Guillain-Barré syndrome was associated with 1/100 000 influenza vaccinations during the national vaccination programme against swine influenza in the USA in 1976, during which 45 million people were vaccinated.[40]

OPTION PNEUMOCOCCAL VACCINE

One systematic review found that pneumococcal vaccination reduced pneumococcal pneumonia in immunocompetent people compared with no vaccination. The review found no significant difference between pneumococcal vaccination and no vaccination in the incidence of pneumonia in elderly people or people likely to have an impaired immune system.

Benefits: We found one systematic review (search date 2000, 13 RCTs, > 45 000 people) that compared pneumococcal vaccination with no vaccination.[41] It found that in immunocompetent people (3 RCTs, 21 152 African gold workers and Papua New Guinea highlanders), pneumococcal vaccination significantly reduced all cause pneumonia, pneumococcal pneumonia, pneumococcal bacteraemia and pneumonia related mortality during one winter compared with no vaccination (all cause pneumonia: 3.1% with vaccination *v* 6.5% with no vaccination; RR 0.56, 95% CI 0.47 to 0.66; pneumococcal pneumonia: 0.5% with vaccination *v* 3.1% with no vaccination; RR 0.16, 95% CI 0.11 to 0.23; pneumococcal bacteraemia: 0.7% with vaccination *v* 3.8% with no vaccination; RR 0.18, 95% CI 0.09 to 0.34; pneumonia related mortality: 1.1% with vaccination *v* 1.6% with no vaccination; RR 0.70, 95% CI 0.50 to

0.96). In elderly people or people likely to have an impaired immune system (10 RCTs, 24 074 people), the review found no significant difference between pneumococcal vaccination and no vaccination in all cause pneumonia, pneumococcal pneumonia, pneumococcal bacteraemia, or pneumonia related mortality (all cause pneumonia: 7.0% with vaccination *v* 6.8% with no vaccination; RR 1.08, 95% CI 0.92 to 1.27; pneumococcal pneumonia: 1.7% with vaccination *v* 1.9% with no vaccination; RR 0.88, 95% CI 0.72 to 1.07; pneumococcal bacteraemia: 0.8% with vaccination *v* 1.4% with no vaccination; RR 0.53, 95% CI 0.14 to 1.94; pneumonia related mortality: 1.0% with vaccination *v* 1.1% with no vaccination; RR 0.93, 95% CI 0.72 to 1.20).

Harms: The systematic review found few RCTs that gave information on adverse effects.[41] One RCT in the review found that pneumococcal vaccination was associated with erythema and induration compared with no vaccination. Another RCT in the review found that pneumococcal vaccination increased sore arm, swollen arm, and fever compared with no vaccination.

Comment: A fifth of healthy elderly adults (mean age 71 years) do not have an antibody response to vaccination.[42] New conjugate pneumococcal vaccines are being evaluated. These have been shown to stimulate an antibody response in infants and have decreased the rate of carriage of resistant strains of *S pneumoniae*.[43,44] One retrospective cohort study (1898 elderly members of a staff healthcare organisation) found that pneumococcal vaccination was associated with lower risks of admission to hospital for pneumonia and lower mortality (hospital admission: adjusted RR 0.57, 95% CI 0.38 to 0.84; mortality: adjusted RR 0.71, 95% CI 0.56 to 0.91).[45] The study found evidence of an additive effect for people who received both pneumococcal and influenza vaccinations during the influenza season (RR 0.28, 95% CI 0.14 to 0.58 for admission to hospital for pneumonia and influenza; RR 0.18, 95% CI 0.11 to 0.31 for death).

Spontaneous pneumothorax

Search date August 2003

Abel Wakai

QUESTIONS

INTERVENTIONS

See glossary, p 1954

Key Messages

- We found insufficient evidence to determine whether any intervention is more effective than no intervention for spontaneous pneumothorax.

Treatment

- **Chest tube drainage** We found no RCTs comparing chest tube drainage versus observation. RCTs provided insufficient evidence to compare chest tube drainage versus needle aspiration.
- **Chest tube drainage plus suction** One RCT and one controlled clinical trial found no significant difference in rate of resolution of pneumothorax whether chest tube drainage bottles were connected to suction or not. However, both trials were too small to rule out a clinically important difference.
- **Needle aspiration** RCTs provided insufficient evidence to compare needle aspiration versus observation or chest tube drainage.
- **One way valves on chest tubes** One RCT found no significant difference in rate of resolution between one way valves and drainage bottles with underwater seals, but it is likely to have been too small to detect a clinically important difference. It found that people treated with one way valves used less analgesia and were less likely to be admitted to hospital than people treated with drainage bottles.
- **Small versus standard sized chest tubes** We found no RCTs comparing small versus standard sized chest tubes.

Spontaneous pneumothorax

Preventing recurrence

- **Pleurodesis** Two RCTs have found that adding chemical pleurodesis to chest tube drainage reduces the rate of recurrence of spontaneous pneumothorax compared with chest tube drainage alone. One of the RCTs found that chemical pleurodesis injection was intensely painful. The RCTs found no significant difference in length of hospital stay. One RCT found that thoracoscopic surgery with talc instillation reduced the rate of recurrence at 5 years compared with chest tube drainage. Two RCTs provided insufficient evidence to compare video assisted thorascopic surgery versus thoracotomy. We found no RCTs comparing chemical versus surgical pleurodesis.
- **Optimal timing of pleurodesis (after first, second, or subsequent episodes)** We found no RCTs or high quality cohort studies assessing whether pleurodesis should take place after the first, second, or subsequent episodes of spontaneous pneumothorax.

DEFINITION A pneumothorax is air in the pleural space. A spontaneous pneumothorax occurs when there is no provoking factor, such as trauma, surgery, or diagnostic intervention. It implies a leak of air from the lung parenchyma through the visceral pleura into the pleural space. This review does not include people with tension pneumothorax.

INCIDENCE/ PREVALENCE In a survey in Minnesota, USA, the incidence of spontaneous pneumothorax was 7/100 000 for men and 1/100 000 for women.[1] In England and Wales, the overall rate of people consulting with pneumothorax (in both primary and secondary care combined) is 24/100 000 a year for men and 9.8/100 000 a year for women.[2] The overall annual incidence of emergency hospital admissions for pneumothorax in England and Wales is 16.7/100 000 for men and 5.8/100 000 for women.[2] Smoking increases the likelihood of spontaneous pneumothorax by 22 times for men and eight times for women.[3] A dose–response relationship was observed.[3]

AETIOLOGY/ RISK FACTORS Spontaneous pneumothorax can be primary (typically in young fit people and thought to be because of a congenital abnormality of the visceral pleura) or secondary (caused by underlying lung disease, typically occurring in older people with emphysema or pulmonary fibrosis).

PROGNOSIS Death from spontaneous pneumothorax is rare. Morbidity with pain and shortness of breath is common. Published recurrence rates vary. One cohort study in Denmark found that, after a first episode of primary spontaneous pneumothorax, 23% of people suffered a recurrence within 5 years, most within 1 year.[4] Recurrence rates had been thought to increase substantially after the first recurrence, but one retrospective case control study (147 military personnel) found that 28% of men with a first primary spontaneous pneumothorax had a recurrence; 23% of the 28% had a second recurrence; and 14% of that 23% had a third recurrence, giving a total recurrence rate of 35%.[5]

AIMS OF INTERVENTION To reduce morbidity; to restore normal function as quickly as possible; to prevent recurrence and mortality, with minimum adverse effects.

OUTCOMES Successful resolution of spontaneous pneumothorax after a stated period; time to full expansion of the lung; duration of hospital stay; time off work; harmful effects of treatments (pain, surgical emphysema, wound and pleural space infection); and rate of recurrence.

METHODS *Clinical Evidence* search and appraisal August 2003. The author also performed a hand search for systematic reviews in the Cochrane Library, Issue 4, 2003. Most of the literature consisted of uncontrolled case series.

QUESTION What are the effects of treatments?

OPTION NEEDLE ASPIRATION

RCTs provided insufficient evidence to compare needle aspiration versus observation or chest tube drainage.

Benefits: We found no systematic review. **Versus observation:** We found one RCT (21 people), which found faster resolution with needle aspiration compared with observation (time to full expansion: 1.6 weeks in 8 people successfully treated with needle aspiration *v* 3.2 weeks in 10 people treated conservatively).[6] However, two people randomised to needle aspiration required a chest tube. The RCT did not assess the significance of the difference between groups. **Versus chest tube drainage:** We found three RCTs.[7–9] The first RCT (73 people) found that fewer people had immediate resolution of pneumothorax with needle aspiration compared with chest tube drainage (28/35 [80%] with needle aspiration *v* 38/38 [100%] with chest tube drainage). The people who did not have successful resolution of pneumothorax with needle aspiration were subsequently treated with chest tube drainage.[7] It found that, on average, people receiving needle aspiration spent significantly fewer days in hospital than people receiving chest tube drainage (3.2 days with needle aspiration *v* 5.3 days with chest tube drainage; P = 0.005).[7] It found no significant difference in the rate of recurrence at 1 year (5/30 [17%] with needle aspiration *v* 10/35 [29%] with chest tube drainage; ARR +12%, 95% CI –9% to +32%; RR 0.58, 95% CI 0.22 to 1.52). The second RCT (61 people) found that, at 24 hours, pneumothorax resolved in significantly fewer people with needle aspiration compared with chest tube drainage (22/33 [67%] with needle aspiration *v* 26/28 [93%] with chest tube drainage; ARR 26%, 95% CI 6% to 47%; RR of failure to resolve 0.72, 95% CI 0.55 to 0.93).[8] It found no significant difference in the rate of recurrence at 3 months (6/33 [18%] with needle aspiration *v* 7/28 [25%] with chest tube drainage; ARR +7%, 95% CI –14% to +28%; RR 0.73, 95% CI 0.28 to 1.92). The RCT was not designed to find a difference in duration of hospital stay because chest tube drainage was done on admission, whereas in most people needle aspiration was performed after 3 days of observation in hospital. The third RCT (60 people) found no significant difference between needle aspiration and chest tube drainage in immediate resolution rates (16/27 [59%] with needle aspiration *v* 21/33 [64%] with chest tube drainage; P = 0.9).[9] Resolution was defined for needle aspiration as complete or nearly complete lung

expansion after manual aspiration, and for chest tube drainage as complete lung expansion and chest tube removal within 72 hours. It also found no significant difference between needle aspiration and chest tube drainage in mean hospital stay (3.5 days with needle aspiration *v* 4.5 days with chest tube drainage; P = 0.2) or recurrence rate at 1 year (7/26 [26%] with needle aspiration *v* 9/33 [27%] with chest tube drainage; P = 0.9). The RCT is likely to have been too small to detect a clinically important difference in outcomes.

Harms: **Versus observation:** The RCT gave no information on adverse effects.[6] **Versus chest tube drainage:** The first RCT found that people treated with needle aspiration had significantly less pain on daily pain scores during their hospital stay (mean score: 0.7 with needle aspiration *v* 1.5 with chest tube; P < 0.001).[7] The second RCT found no significant difference in pain or dyspnoea between needle aspiration and chest tube drainage (reported as non-significant; results presented graphically).[8] The third RCT did not assess pain.[9]

Comment: The RCT comparing needle aspiration versus observation was published as a letter.[6] A large case series undertaken in the 1960s reported that 88/119 (74%) people presenting to an outpatient chest clinic with spontaneous pneumothorax were managed successfully without intervention or hospital admission.[10] However, the current clinical relevance of this case series is unclear. A systematic review comparing chest tube drainage versus needle aspiration is underway.[11]

OPTION CHEST TUBE DRAINAGE

We found no RCTs comparing chest tube drainage versus observation. RCTs provided insufficient evidence to compare chest tube drainage versus needle aspiration. We found no RCTs assessing small versus standard sized tubes for chest drainage.

Benefits: We found no systematic review. **Versus observation:** We found no RCTs. **Versus needle aspiration:** See benefits of needle aspiration, p 1949. **Versus surgical pleurodesis:** See glossary, p 1954. See benefits of surgical pleurodesis, p 1952. **Small versus standard sized chest tubes:** We found no RCTs (see comment below). **Versus chest tube drainage plus suction:** See benefits of chest tube drainage plus suction, p 1951.

Harms: **Versus needle aspiration:** See harms of needle aspiration, p 1950. **Small versus standard sized chest tubes:** We found no RCTs (see comment below). **Versus chest tube drainage plus suction:** See harms of chest tube drainage plus suction, p 1957.

Comment: **Small versus standard sized chest tubes:** Small gauge chest tubes are usually easier to insert. One non-randomised trial (44 people) compared small gauge catheters (8 French gauge [see glossary, p 1954]) catheters versus standard chest tubes.[12] It found no significant difference in duration of drainage between groups (5 days *v* 6 days; reported as non-significant, no further data

reported). In people with large pneumothoraces (> 50% lung volume), successful resolution was significantly more likely with standard chest tubes than small gauge (100% with standard tubes *v* 57% with small tubes; $P < 0.05$). No such difference was found in people with small (< 50%) pneumothoraces. The trial found that conventional chest tubes significantly increased the risk of subcutaneous emphysema (9/23 [39%] with conventional tubes *v* 0/21 [0%] with small tubes; $P < 0.05$) and pain compared with small gauge catheters.[12]

OPTION ONE WAY VALVES ON CHEST TUBES

One RCT found no significant difference in rate of resolution between one way valves and drainage bottles with underwater seals, but it is likely to have been too small to detect a clinically important difference. It found that people treated with one way valves used less analgesia and were less likely to be admitted to hospital than people treated with drainage bottles.

Benefits: We found no systematic review. We found one RCT (30 people with spontaneous pneumothorax and respiratory distress) comparing a chest tube (13 French gauge [see glossary, p 1954]) connected to a one way valve versus a chest tube (14 French gauge) connected to a drainage bottle with an underwater seal.[13] It found no significant difference between groups in rate of resolution at 48 hours (complete or nearly complete expansion: 15/17 [88%] with one way valve *v* 11/13 [85%] with drainage bottle; RR 1.04, 95% CI 0.78 to 1.39). It found that one way valves significantly reduced hospital admissions compared with drainage bottles (5/17 [29%] with one way valve *v* 13/13 [100%] with drainage bottle; RR 0.29, 95% CI 0.14 to 0.61).[12] It found that significantly fewer people treated with a one way valve compared with drainage bottle required analgesia (5/17 [29%] with one way valve *v* 10/13 [77%] with drainage bottle; RR 0.38, 95% CI 0.17 to 0.85).[13]

Harms: The RCT found no significant difference in rates of complications between one way valves and drainage bottles with underwater seals (need for a second drain: 3/17 [18%] with one way valve *v* 1/13 [8%] with drainage bottle; skin emphysema: 3/17 [18%] with one way valve *v* 3/13 [23%] with drainage bottle; reported as non-significant, no further data reported).[13]

Comment: None.

OPTION CHEST TUBE DRAINAGE PLUS SUCTION

One RCT and one controlled clinical trial found no significant difference in rate of resolution of pneumothorax whether chest tube drainage bottles were connected to suction or not. However, both trials were too small to rule out a clinically important difference.

Benefits: **Versus chest tube drainage alone:** We found no systematic review, but found one RCT (53 people, 23 with primary spontaneous pneumothorax and 30 with secondary)[14] and one controlled clinical trial (40 people)[15] comparing chest tube drainage using an underwater seal only versus drainage plus suction. The RCT found no

significant difference between chest tube drainage plus suction and chest tube drainage alone in the proportion of people with full lung expansion at 10 days (13/23 [57%] with suction *v* 15/30 [50%] without suction; ARI +7%, 95% CI –21% to +34%; RR 1.13, 95% CI 0.68 to 1.88), but is likely to have been too small to exclude a clinically important difference. Suction pressures ranged from 8–20 cm H_2O.[14] The controlled clinical trial assigned people to chest tube drainage plus suction or chest tube drainage alone by alternate allocation.[15] It also found no significant difference in time taken for lung expansion between adding low pressure suction to chest drainage and chest drainage alone (mean: 5.2 days with suction *v* 6.2 days with no suction; reported as non-significant, CI not reported). The trial did not state whether spontaneous pneumothorax was primary or secondary, or what suction pressure was applied.

Harms: The RCT and controlled clinical trial gave no information on adverse effects.[14,15]

Comment: None.

QUESTION What are the effects of interventions to prevent recurrence?

OPTION PLEURODESIS

Two RCTs have found that adding chemical pleurodesis to chest tube drainage reduces the rate of recurrence of spontaneous pneumothorax compared with chest tube drainage alone. One of the RCTs found that chemical pleurodesis injection was intensely painful. The RCTs found no significant difference in length of hospital stay. One RCT found that thoracoscopic surgery with talc instillation reduced the rate of recurrence at 5 years compared with chest tube drainage. Two RCTs provided insufficient evidence to compare video assisted thorascopic surgery versus thoracotomy. We found no RCTs comparing chemical versus surgical pleurodesis. We found no RCTs or high quality cohort studies assessing whether pleurodesis should take place after the first, second, or subsequent episodes of spontaneous pneumothorax.

Benefits: We found no systematic review. **Adding chemical pleurodesis to chest tube drainage versus chest tube drainage alone:** We found two RCTs.[16,17] The first RCT (unblinded, 229 men with pneumothorax successfully treated by chest tube; mean age 54 years; 55% with chronic obstructive pulmonary disease) found that adding intrapleural instillation of tetracycline significantly reduced recurrence rates over 30 months compared with chest tube alone (26/104 [25%] with tetracycline *v* 44/108 [41%] with chest tube alone; RR 0.61, 95% CI 0.41 to 0.92).[16] It found no significant difference between groups in length of hospital stay (5 days with tetracycline *v* 7 days with chest tube alone) or 5 year mortality (40/113 [35%] with tetracycline *v* 42/116 [36%] with chest tube alone; RR 0.98, 95% CI 0.62 to 1.38). The second RCT (96 people treated with chest tube drainage) compared three groups: no further treatment, tetracycline pleurodesis (see glossary, p 1954), and talc pleurodesis.[17] Mean follow up was 4.6 years. It found that

either type of chemical pleurodesis significantly reduced the pneumothorax recurrence rate over 4.6 years compared with no treatment (2/24 [8%] with talc pleurodesis *v* 3/23 [13%] with tetracycline pleurodesis *v* 9/25 [36%] with no treatment; ARR of recurrence with either form of pleurodesis 25%, 95% CI 6% to 45%; RR 0.64, 95% CI 0.12 to 3.48). It found no significant difference in mean hospital stay (mean 7 days with tetracycline *v* 6 days with talc or with chest tube alone; reported as non-significant, no further data reported). **Thoracoscopic surgery with talc instillation versus chest tube drainage:** We found one multicentre RCT (108 people with large primary spontaneous pneumothorax or primary spontaneous pneumothorax that had failed aspiration) that compared thoracoscopic surgery with talc instillation versus chest tube drainage.[18] It found that thoracoscopic surgery significantly reduced the recurrence rate at 5 years compared with chest tube drainage (3/59 [5%] with surgery *v* 16/47 [34%] with chest tube drainage; $P < 0.01$). It found similar length of hospital stay (mean: 8.0 days with surgery *v* 7.4 days with drainage; no further data reported). **Video assisted thoracoscopic surgery versus thoracotomy:** We found two RCTs.[19,20] The first RCT (60 people with primary spontaneous pneumothorax, either first recurrence or non-resolving first episode) that compared video assisted thoracoscopic surgery versus thoracotomy.[19] It found no significant difference between video assisted thoracoscopic surgery and thoracotomy in recurrence rates after 3 years (3/30 [10%] with video assisted surgery *v* 0/30 [0%] with thoracotomy; ARR +10%, 95% CI −1% to +21%). It found that video assisted surgery significantly reduced the use of analgesia and hospital stay compared with thoracotomy (mean hospital stay: 6.5 days with video assisted surgery *v* 10.7 days with thoracotomy; $P < 0.0001$). The second RCT (60 people, 30 with primary pneumothorax, 30 with secondary, either with recurrence or an air leak persisting for more than 5 days) compared video assisted thoracoscopic surgery versus thoracotomy.[20] It found no significant difference between video assisted thorascopic surgery and thoracotomy in use of analgesia or hospital stay (mean hospital stay: 4 days with video assisted surgery *v* 5 days with thoracotomy; reported as non-significant, CI not reported). It also found no significant difference in recurrence rate at 15 months (2/15 [13%] with video assisted surgery *v* 1/15 [7%] with thoracotomy; reported as non-significant, CI not reported). The RCT is likely to have been too small to detect a clinically important difference. **Chemical versus surgical pleurodesis:** We found no RCTs. **Optimal timing of pleurodesis:** We found no RCTs or high quality cohort studies comparing pleurodesis undertaken at different times (after the first, second, or subsequent episodes of spontaneous pneumothorax; see comment below).

Harms:

Adding chemical pleurodesis to chest tube drainage versus chest tube drainage alone: In the first RCT, 61/105 (58%) people reported intense chest pain on injection of tetracycline.[16] The second RCT found that similar proportions of people reported pain with chemical pleurodesis compared with chest tube alone (17/33 [52%] with tetracycline *v* 14/29 [48%] with talc *v* 18/34 [53%] with chest tube alone; no further data reported).[17] **Thoracoscopic surgery with talc instillation versus chest tube drainage:** The

RCT did not establish a protocol for analgesia; four centres gave postoperative systemic opioids and three did not.[18] It found that thoracoscopic surgery modestly but significantly increased pain during the first 3 days compared with chest tube drainage (results presented graphically). It found no significant difference in pain between groups when people received systemic opioids. **Video assisted thoracoscopic surgery versus thoracotomy:** The first RCT gave no information on adverse effects.[19] The second RCT reported that three people with secondary spontaneous pneumothorax died, one receiving video assisted thorascopic surgery and two receiving thoracotomy, one of whom had previously had unsuccessful video assisted thoracoscopic surgery.[20] **Chemical versus surgical pleurodesis:** We found no RCTs. **Optimal timing of pleurodesis:** We found no RCTs or high quality cohort studies.

Comment: One observational study suggested that the 5 year recurrence rate after a first pneumothorax is about 28%, so there may be little reason to perform pleurodesis after the first episode of pneumothorax.[5] There has been a consensus that pleurodesis is warranted after the second or third episode of pneumothorax. Even though the probability of success with pleurodesis is high, clinicians will have to weigh the likelihood of recurrence against the morbidity associated with the procedure. Chemical pleurodesis may be appropriate for people unfit or unwilling to undergo surgery.

GLOSSARY

French gauge A measure of the size of a catheter or drainage tube defined (in France by JFB Charrière in 1842) to be the outside diameter of the tube in units of 1/3 mm. A 12 French gauge tube has an outer diameter of 4 mm. Sometimes the French gauge is called the Charrière (Ch) gauge.

Pleurodesis The instillation of substances (sclerosants) into the pleural space leading to a sterile inflammatory reaction with formation of dense adhesions. It may be performed non-operatively through a chest tube or thoracoscope (chemical pleurodesis) or operatively (surgical pleurodesis).

Substantive changes

Chest tube drainage plus suction One RCT added;[15] conclusions unchanged.

Pleurodesis Data on chemical and surgical pleurodesis merged. One RCT added.[20] Pleurodesis categorised as Trade-off between benefits and harms.

Upper respiratory tract infection

Search date February 2003

Chris Del Mar and Paul Glasziou

QUESTIONS

INTERVENTIONS

Key Messages

- **Analgesia/anti-inflammatory drugs for symptom relief** One systematic review has found that analgesics or anti-inflammatory drugs reduce sore throat at 1–5 days compared with placebo.
- **Antibiotics for preventing (rare) complications of β haemolytic streptococcal pharyngitis** One systematic review has found that antibiotics prevent non-suppurative complications of β haemolytic streptococcal pharyngitis compared with no antibiotics, but in industrialised countries such complications are rare.
- **Antibiotics for reducing time to recovery in people with proven infection with *Haemophilus influenzae*, *Moraxella catarrhalis*, or *Streptococcus pneumoniae*** In a minority of people, upper respiratory tract infection is found to be caused by *H influenzae*, *M catarrhalis*, or *S pneumoniae*. One RCT found that, in these people, antibiotics increased recovery at 5 days compared with placebo. However, we have no methods currently of easily identifying this subgroup at first consultation.
- **Antihistamines for runny nose and sneezing** One systematic review has found that antihistamines reduce runny nose and sneezing after 2 days compared with placebo, but the clinical benefit is small.

- **Decongestants for short term relief of congestive symptoms** One systematic review found that a single dose of decongestant reduced nasal congestion over 3–10 hours compared with placebo.
- **Vitamin C** One systematic review found that vitamin C slightly reduced the duration of cold symptoms compared with placebo, but the benefit was small and may be explained by publication bias.
- **Antibiotics for reducing time to recovery in people with acute sore throat** One systematic review has found that antibiotics slightly improve symptoms at 6–8 days compared with placebo. Adverse effects (nausea, vomiting, headache, rash, vaginitis) were more common with antibiotics.
- **Echinacea for prevention** One systematic review found that, compared with no treatment, echinacea reduced the proportion of people who had one infection episode, but found insufficient evidence about the effects of echinacea compared with placebo.
- **Echinacea for treatment** Systematic reviews found limited evidence that some preparations of echinacea may improve symptoms compared with placebo, but we found insufficient evidence about the effects of any specific product.
- **Steam inhalation** One systematic review found insufficient evidence about the effects of steam inhalation.
- **Zinc (intranasal gel or lozenges)** Two RCTs found that zinc intranasal gel reduced the mean duration of cold symptoms compared with placebo, but the difference was significant in only one of the RCTs. Two systematic reviews found limited evidence that zinc gluconate or acetate lozenges may reduce duration of symptoms at 7 days, compared with placebo.
- **Antibiotics in people with colds** Systematic reviews found no significant difference between antibiotics and placebo in cure or general improvement at 6–14 days.
- **Decongestants for long term relief of congestive symptoms** One systematic review found insufficient evidence to assess the effects of longer use of decongestants. One case control study found weak evidence that phenylpropanolamine may increase the risk of haemorrhagic stroke.

DEFINITION

Upper respiratory tract infection involves inflammation of the respiratory mucosa from the nose to the lower respiratory tree, but not including the alveoli. In addition to malaise, it causes localised symptoms that constitute several overlapping syndromes: sore throat (pharyngitis), rhinorrhoea (common cold), facial fullness and pain (sinusitis — see acute sinusitis, p 710), and cough (bronchitis — see acute broncitis, p 1923).

INCIDENCE/ PREVALENCE

Upper respiratory tract infections, nasal congestion, throat complaints, and cough are responsible for 11% of general practice consultations in Australia.[1] Each year, children suffer about five such infections and adults two to three infections.[1–3]

AETIOLOGY/ RISK FACTORS

Infective agents include over 200 viruses (with 100 rhinoviruses) and several bacteria. Transmission is mostly through hand to hand contact with subsequent passage to the nostrils or eyes rather than, as commonly perceived, through droplets in the air.[4] A systematic review of the risk factors for developing prolonged illness (especially tiredness) after infectious mononucleosis of five cohort studies of 531 adults showed that this occurred in 2–56% of people. The best

predictor for tiredness was poor physical functioning immediately after the start of the illness; previous psychological factors were identified as unimportant in four studies and predictive in one.[5]

PROGNOSIS Upper respiratory tract infections are usually self limiting. Although they cause little mortality or serious morbidity, upper respiratory tract infections are responsible for considerable discomfort, lost work, and medical costs. Clinical patterns vary and overlap between infective agents. In addition to nasal symptoms, half of sufferers experience sore throat and 40% experience cough. Symptoms peak within 1–3 days and generally clear by 1 week, although cough often persists.[4]

AIMS OF INTERVENTION To relieve symptoms and to prevent suppurative and non-suppurative complications of bacterial infection, with minimal adverse effects from treatments.

OUTCOMES Cure rate; duration of symptoms; incidence of complications; incidence of adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal February 2003. We have excluded RCTs undertaken solely in people with experimentally induced upper respiratory tract infections.

QUESTION What are the effects of treatments?

OPTION ANTIBIOTICS

Systematic reviews found no significant difference between antibiotics and placebo in cure or general improvement at 6–14 days in people with colds. One additional RCT has found that, in people with proven infection with *H influenzae*, *M catarrhalis*, or *S pneumoniae* antibiotics versus placebo increases recovery at 5 days. However, we have no methods currently of easily identifying such people at first consultation. One systematic review has found that antibiotics slightly improve symptoms of sore throat at 6–8 days compared with placebo. One systematic review has found that antibiotics prevent non-suppurative complications of β haemolytic streptococcal pharyngitis compared with no antibiotics, but in industrialised countries such complications are rare. Adverse effects (nausea, vomiting, headache, rash, vaginitis) were more common with antibiotics.

Benefits:

Colds: We found two systematic reviews.[6,7] The first review (search date 2001, 9 RCTs, 2249 people aged 2 months to 79 years with acute upper respiratory infections without complications [naturally acquired colds]) found no significant difference between antibiotics and placebo in general improvement or cure at 7 days (6 RCTs, 168/664 [25%] with antibiotics *v* 170/483 [35%] with placebo; RR 0.89, 95% CI 0.77 to 1.04).[6] The second review (search date not stated, 12 RCTs, 1699 children with naturally acquired upper respiratory tract symptoms in the previous 2 weeks) found no significant difference between antibiotics and placebo in the proportion of children with worse or unchanged clinical outcome at 6–14 days (6 RCTs with adequate data; 309/835 [37%] with antibiotics *v* 280/647 [43%] with placebo; RR 1.01, 95% CI 0.90 to

1.13; raw figures reported from table in paper), or with complications or progression (5 RCTs; 38/549 [6.9%] with antibiotics *v* 28/293 [9.5%] with placebo; RR 0.71, 95% CI 0.45 to 1.12).[7] One additional RCT (314 adults with naturally acquired colds for 1–30 days; < 7 days in 85% of people) comparing amoxicillin/clavulanic acid (co-amoxiclav) (375 mg 3 times daily) versus placebo found no overall difference in "cure" rates at 5 days (P value not reported).[8] However, it found that in the 61 people (20%) with positive sputum cultures for *H influenzae*, *M catarrhalis*, or *S pneumoniae* there was a significant difference in recovery at 5 days (27% with co-amoxiclav *v* 4% with placebo; P = 0.001). If such people could be identified at first consultation, then treating four of these people with antibiotic rather than placebo would result in an average of one more recovery at 5 days (NNT 4; CI not reported). However, we have no methods currently of easily identifying these people at first consultation. **Sore throat:** We found one systematic review (search date 1999, 25 randomised or quasi-randomised trials, 10 863 people with sore throat).[9] It found that, compared with placebo, antibiotics slightly but significantly reduced the proportion of people with symptoms of sore throat at 6–8 days (11 trials; 226/1739 [13%] with antibiotics *v* 199/1079 [18%] with placebo; RR 0.61, 95% CI 0.52 to 0.73), and shortened symptom duration by a mean of about 24 hours at day 3 and 16 hours at 1 week. It found that antibiotics significantly reduced the proportion of people who had developed rheumatic fever at 2 months compared with placebo (7 trials; 37/5287 [0.7%] with antibiotics *v* 74/4059 [1.8%] with placebo; RR 0.29, 95% CI 0.18 to 0.44). It also found that antibiotics significantly reduced otitis media at 14 days (5 trials; 11/2325 [0.5%] with antibiotics *v* 28/1435 [2.0%] with placebo; RR 0.26, 95% CI 0.14 to 0.49) and quincy at 2 months (6 trials; 2/1438 [0.1%] with antibiotics *v* 23/995 [2.3%] with placebo; RR 0.14, 95% CI 0.05 to 0.39). It found too few events to detect any possible protective effect of antibiotics against acute glomerulonephritis (0/2558 [0%] with antibiotics *v* 2/1834 [0.1%] with placebo).

Harms: Adverse effects such as nausea, vomiting, headache, rash, or vaginitis were more common in people taking antibiotics than placebo. For example, one review of antibiotics in people with bronchitis found one extra adverse effect for every 16 people treated.[10] We found no evidence of the size of the risk of antibiotic resistance or pseudomembranous colitis.

Comment: Because most upper respiratory tract infections are viral, the potential benefit from antibiotics is limited. Until rapid identification of those people likely to benefit is possible, the modest effects seen in trials must be weighed against the adverse effects of antibiotics, costs, and potential for inducing antibiotic resistance.

OPTION VITAMIN C

One systematic review found that vitamin C slightly reduced the duration of cold symptoms compared with placebo. However, the beneficial effect is small and may be explained by publication bias.

Upper respiratory tract infection

Benefits: We found one systematic review (search date not stated, 13 RCTs, 17 quasi-randomised or controlled trials identified by two previous systematic reviews[11,12]) that compared vitamin C 1 g or more daily versus placebo for naturally acquired colds.[13] It found that vitamin C reduced the duration of symptoms by about half a day compared with placebo (17 trials; 9365 people; WMD 0.44 days/cold episode, 95% CI 0.23 days/cold episode to 0.64 days/cold episode) representing about 15% fewer symptomatic days per episode.

Harms: The systematic review found no adverse effects associated with vitamin C.[13]

Comment: The beneficial effect reported in the review was small and might be explained by publication bias.

OPTION ZINC

Two systematic reviews found limited evidence that zinc gluconate or acetate lozenges may reduce duration of symptoms at 7 days compared with placebo. Two RCTs found that zinc intranasal gel reduced the mean duration of cold symptoms compared with placebo, but the difference was significant in only one of the RCTs.

Benefits: **Zinc lozenges:** We found two systematic reviews (search date 1997, 7 RCTs;[14] search date 1998, 8 RCTs[15]) comparing zinc lozenges (gluconate or acetate) versus placebo for the treatment of naturally acquired colds. The reviews had different inclusion criteria. Both reviews found that symptoms were unchanged at 3 and 5 days. At 7 days, the first review (7 RCTs, including 2 RCTs excluded from the second review because they were in people with experimentally induced colds, 754 people) found that zinc lozenges significantly reduced continuing symptoms at 7 days compared with placebo (random effects model; 14/93 [15%] with zinc *v* 46/94 [49%] with placebo; RR 0.31, 95% CI 0.18 to 0.52). However, the second review (8 RCTs, including 3 RCTs included in the first review and 1 RCT excluded from the first review on methodological grounds) found no significant difference between zinc lozenges and placebo in continuing symptoms at 7 days (OR 0.52, 95% CI 0.25 to 1.20; results presented graphically). The results at 7 days were statistically heterogeneous, which may be because the RCTs retrieved by the reviews used different zinc formulations; were undertaken in people with different types of virus; or because of other unknown factors. **Zinc intranasal gel:** We found two RCTs comparing intranasal zinc versus placebo.[16,17] The first RCT (213 people with naturally acquired colds of < 24 hours' duration) found that intranasal zinc significantly reduced overall symptom duration compared with placebo (mean duration 2.3 days with intranasal zinc *v* 9.0 days with placebo; $P < 0.05$).[16] The second RCT (160 people with naturally acquired colds of < 24 hours' duration) found no significant difference in overall symptom duration between intranasal zinc and placebo (mean duration 7 days for each group; $P = 0.45$).[17]

Harms: **Zinc lozenges:** The first review stated that, in some of the RCTs, a higher proportion of people had nausea, altered taste, dry mouth, abdominal pain, and headache with zinc lozenges than with placebo, but did not state whether the difference was significant.[14] The

second review gave no information on adverse effects.[15] **Zinc intranasal gel:** The first RCT found that a similar proportion of people experienced a tingling or burning sensation with zinc intranasal gel compared with placebo (45/108 [42%] with zinc *v* 39/105 [37%] with placebo).[16] The second RCT found a similar proportion of people had adverse effects, including nausea, mouth or nasal irritation, abdominal pain, or headache with zinc intranasal gel compared with placebo (any adverse effect; 41/81 [51%] with zinc *v* 40/78 [52%] with placebo).[17]

Comment: None.

OPTION ECHINACEA

Systematic reviews found that some preparations of echinacea may be better than placebo or no treatment for cold treatment and prevention.

Benefits: **Treatment:** We found two systematic reviews (search date 1998, 8 RCTs;[18] search date 2000, 5 additional RCTs[19]) comparing echinacea versus placebo for naturally acquired upper respiratory tract infections. All RCTs included in the first review were double blind except one that was single blind.[18] Quantitative results could be extracted for only two RCTs on duration of illness, three RCTs for runny nose, and five RCTs for a summary symptom score. Results were not combined because of trial heterogeneity. All RCTs compared echinacea versus placebo, and one RCT also compared high versus low dose echinacea. Five RCTs found that echinacea significantly improved symptoms compared with placebo. One RCT found significant results for a subgroup only, and two RCTs found similar improvements in symptoms after treatment with echinacea compared with placebo.[18] The second review identified five further RCTs published after 1997. It also found that RCTs were heterogeneous and of poor quality and it reached the same conclusions as the first review.[19] **Prevention:** The first systematic review identified eight RCTs, with a total of almost 4000 people.[18] The placebo controlled RCTs varied considerably in quality of methods and preparation used, so results were not combined. Of the five placebo controlled RCTs, two found that echinacea significantly reduced the proportion of people who had at least one infection episode compared with placebo. One of these had large loss to follow up. The other placebo controlled RCTs found a non-significant reduction in the rate of infection. Meta-analysis of the three RCTs comparing echinacea versus no treatment found that significantly fewer people had one infection episode after taking echinacea (167/571 [29%] with echinacea *v* 292/566 [52%] with no treatment; RR 0.56, 95% CI 0.48 to 0.65). The three uncontrolled studies identified by the review all found a significant benefit.

Harms: Three of the eight treatment RCTs and four of the eight prevention RCTs reported adverse events. These were generally infrequent and not significantly different between echinacea and placebo. However, outside the trials, anaphylaxis has been reported with echinacea.[20]

Comment: Echinacea is not a single product. There are more than 200 different preparations based on different plants, different parts of the plant (roots, herbs, whole plant), and different methods of

extraction. None of the trials were published in a Medline listed journal. The weakness of trial methods and differences in interventions make it difficult to draw conclusions about effectiveness. Large RCTs may be difficult because echinacea is not patentable and each producer controls a small share of the market. The authors of the systematic review received personal information about several unpublished studies that they were not able to include.

OPTION STEAM INHALATION

One systematic review found insufficient evidence about the effects of steam inhalation.

Benefits: We found one systematic review (search date 1999, 4 RCTs in people with naturally acquired colds, 2 RCTs in people with experimentally induced colds, 319 people) comparing steam inhalation at 40–47 °C versus sham inhalation (air at ≥ 30 °C).[21] The review could not perform a meta-analysis of all of the RCTs because of heterogeneity in populations, methods used to assess symptoms, and poor reporting in some of the RCTs. Pooling of data from two RCTs (146 people with naturally acquired colds) found limited evidence that steam inhalation significantly reduced the proportion of people with symptoms at the end of treatment compared with sham inhalation (29/77 [38%] with steam *v* 46/69 [68%] with control; RR 0.56, 95% CI 0.40 to 0.79). Another RCT that used a different method of assessing symptoms found no significant difference between steam inhalation and control in the proportion of people with improved symptoms at the end of treatment (no improvement in symptom score 23/45 [51%] with steam *v* 26/39 [67%] with control; RR 0.77, 95% CI 0.53 to 1.10), but may have been too small to exclude a clinically important difference.[21]

Harms: The RCTs identified by the review found no evidence of harms.[21] There may be a danger from spilling hot water and from nosocomial infections related to humidifier units.

Comment: None.

OPTION DECONGESTANTS

One systematic review found that, compared with placebo, decongestants reduced nasal congestion over 3–10 hours after a single dose, but found insufficient evidence to assess the effects of longer use of decongestants. One case control study found weak evidence that phenylpropanolamine may increase the risk of haemorrhagic stroke.

Benefits: We found one systematic review (search date 1999, 4 RCTs, 246 adults with naturally acquired colds).[22] It found that, compared with placebo, a single dose of nasal decongestant was moderately effective for the relief of nasal congestion over 3–10 hours (2 RCTs, 155 adults; WMD –0.12, 95% CI –0.19 to –0.16). It found no good evidence on the effects of repeated use over several days.

Harms: Information about harms was not sought actively or reported in the RCTs identified by the review.[22] One case control study compared the use of cold preparations containing phenylpropanolamine

among 702 people with a history of haemorrhagic stroke versus 1376 control people with no history of stroke. The study found a non-significant trend towards increased haemorrhage stroke with phenylpropanolamine (RR 1.50, 95% CI 0.85 to 2.65).[23] However, the study was too small to make definitive conclusions.

Comment: The review found no RCTs in children.

OPTION ANTIHISTAMINES

One systematic review has found that antihistamines reduce runny nose and sneezing after 2 days compared with placebo, but the clinical benefit is small.

Benefits: One systematic review of previously unpublished individual patient data (search date not stated, 7 RCTs in adults with naturally acquired colds, 2 RCTs in adults with experimentally induced colds, 1757 adults) comparing antihistamines versus placebo found that antihistamines reduced the symptoms of runny nose and sneezing for the first 2 days of colds.[24] The effects were small. On a severity scale ranging from 0 (no symptoms) to 3 or 4 (severe symptoms), antihistamines reduced the score by about 0.25 (95% CI 0.10 to 0.40; results presented graphically) for runny nose on days 1 and 2, 0.15 (95% CI 0 to 0.30) for sneezing on day 1, and 0.30 (95% CI 0.15 to 0.45) for sneezing on day 2.

Harms: Harms were not actively looked for in RCTs,[24] but known harms of antihistamines include drowsiness and dry mouth.

Comment: None.

OPTION ANALGESICS OR ANTI-INFLAMMATORY DRUGS

One systematic review has found that analgesics or anti-inflammatory drugs reduce sore throat at 1–5 days compared with placebo.

Benefits: **Sore throat:** We found one systematic review (search date 1999, 12 RCTs of non-steroidal anti-inflammatory drugs [NSAIDs], 3 of paracetamol, 1 of steroids).[25] The RCTs found that all interventions were superior to placebo. Six RCTs (493 people) assessed the effects of NSAIDs only over 24 hours or less. The RCTs found consistently that NSAIDs reduced throat pain. Five RCTs (646 people) assessed the effects of NSAIDs over more than 24 hours. All of the RCTs found a significant reduction in symptoms over 2–5 days with NSAIDs versus placebo ($P < 0.05$ in all RCTs). Two RCTs (158 people) assessed the effects of paracetamol over 24 hours or less. One of these RCTs found a significant reduction in throat pain at 6 hours; the other found no significant difference. One RCT (154 people) assessed the effects of paracetamol over 2 days. It found a significant reduction in sore throat symptoms after 2 days ($P < 0.01$). One RCT comparing corticosteroid injection (dexamethasone 10 mg) versus placebo over 24 hours found a significant reduction in mean throat pain at 24 hours ($P < 0.05$). One RCT (243 adults in a 4 arm RCT) found short term benefits of NSAIDs in people with sore throat treated with flurbiprofen lozenges (3 different strengths: 0.5, 2.5, and 12.5 mg) compared with placebo.[26] Symptom relief scores improved with increasing strength of NSAID.

Harms: NSAIDs may increase the risk of gastrointestinal haemorrhage. One systematic review (search date not stated, 100 RCTs, 12 853 people) found a non-significant tendency towards a higher rate of haemorrhage (ARI for NSAIDs *v* placebo +0.7%, 95% CI –0.1% to +1.5%) and proved ulcer (ARI for NSAIDs *v* placebo +0.05%, 95% CI –0.01% to +0.11%) with NSAIDs compared with placebo (see non-steroidal anti-inflammatory drugs, p 1551).

Comment: None.

Key Messages

In people with chronic asthma

- **Adding long acting inhaled β_2 agonists in people with mild, persistent asthma that is poorly controlled by inhaled corticosteroids** One systematic review and three additional RCTs have found that adding regular doses of long acting inhaled β_2 agonists improves lung function and symptoms and reduces rescue medication compared with increasing the dose of inhaled corticosteroids. However, one further RCT found that increasing inhaled corticosteroid dose reduced exacerbations compared with adding long acting inhaled β_2 agonists. We found insufficient evidence about effects of adding long acting inhaled β_2 agonists on mortality.
- **Adding long acting inhaled β_2 agonists to inhaled corticosteroids in poorly controlled mild to moderate, persistent asthma (for symptom control)** RCTs have found that, in people with asthma that is poorly controlled with inhaled corticosteroids, adding regular long acting inhaled β_2 agonists improves symptoms and lung function compared with adding placebo or a leukotriene antagonist. We found insufficient evidence about effects of adding long acting inhaled β_2 agonists on mortality.
- **Low dose, inhaled corticosteroids in mild, persistent asthma** Systematic reviews and RCTs have found that, in people with mild, persistent asthma, low doses of inhaled corticosteroids improve symptoms and lung function compared with placebo or regular inhaled β_2 agonists.
- **Short acting inhaled β_2 agonists as needed for symptom relief (as effective as regular use) in mild to moderate, persistent asthma** One systematic review and one subsequent RCT found no significant difference between regular and as needed short acting inhaled β_2 agonists for clinically important outcomes.
- **Adding leukotriene antagonists in people with mild to moderate, persistent asthma (likely to be better than adding no treatment, but no clear evidence of benefit over adding inhaled corticosteroids)** RCTs in people taking β_2 agonists alone have found that leukotriene antagonists reduce asthma symptoms and β_2 agonist use compared with placebo. One systematic review and three out of nine subsequent RCTs have found that adding leukotriene antagonists increases exacerbations, reduces lung function, and are less effective for symptom control compared with inhaled corticosteroids. The other six RCTs found no significant difference betweenadding leukotriene antagonists and adding corticosteroids. Two RCTs have found that an inhaled corticosteroid plus a long acting β_2 agonist improved symptoms, lung function, and exacerbations compared with a leukotriene antagonist at 12 weeks.

- **Adding theophylline in people with mild to moderate, persistent asthma poorly controlled by inhaled corticosteroids** One RCT has found that adding theophylline improves peak expiratory flow rate compared with continuing low dose corticosteroids plus placebo after 6 months in people with mild to moderate, persistent asthma that was poorly controlled with inhaled corticosteroids alone. One small RCT found no significant difference in lung function or symptoms between theophylline and formoterol (a long acting β agonist) or between theophylline and zafirlukast (a leukotriene antagonist) after 3 months.
- **Adding leukotriene antagonists plus inhaled corticosteroids in people with mild to moderate, persistent asthma** One systematic review in people taking inhaled corticosteroids found no significant difference between leukotriene antagonists and placebo for exacerbation rates at 4–16 weeks. However, one subsequent RCT in people taking a stable dose of budesonide found that adding montelukast increased asthma free days and decreased nocturnal waking compared with placebo at 16 weeks. One RCT in people taking inhaled corticosteroids found no significant difference between adding montelukast and doubling budesonide in peak expiratory flow rate, daytime symptoms, nocturnal wakening, days with asthma exacerbations, and quality of life.

In people with acute exacerbations of asthma

- **Inhaled corticosteroids for acute asthma (better than placebo)** One systematic review has found that inhaled corticosteroids given in the emergency department reduces hospital admission rates in adults compared with placebo. One systematic review and one subsequent RCT found no significant difference in relapse rates following emergency department discharge between oral and inhaled steroids at 7–10 days. One systematic review found no significant difference in relapse rates between inhaled plus oral corticosteroids and oral corticosteroids alone up to 24 days.
- **Inhaled plus oral corticosteroids for acute asthma (as effective as oral corticosteroid alone)** One systematic review found no significant difference in relapse rates for inhaled plus oral corticosteroid compared with oral corticosteroids up to 24 days.
- **Ipratropium bromide added to β_2 agonists for acute exacerbations** Two systematic reviews and one subsequent RCT have found that ipratropium bromide plus salbutamol improves lung function compared with salbutamol alone and is likely to reduce hospital admission in people with severe acute asthma.
- **Short courses of systemic corticosteroids for acute exacerbations** Two systematic reviews and one subsequent RCT have found that early treatment with systemic corticosteroids reduce admission and relapse rates compared with placebo in people with acute asthma. One systematic review and one small subsequent RCT found no significant difference between oral and inhaled steroids after emergency department discharge in relapse rates at 7–10 days in adults with acute asthma.
- **Spacer devices for delivering inhaled medications from pressurised metered dose inhalers in acute asthma (as good as nebulisers)** One systematic review in people with acute, but not life threatening exacerbations of asthma found no significant difference between β_2 agonists delivered by spacer device compared with nebulisers in rates of hospital admission, time spent in the emergency department, peak expiratory flow rate, or forced expiratory volume in 1 second.

- **Education about acute asthma** One systematic review and one subsequent RCT provided evidence that education to facilitate self management of asthma in adults reduced hospital admission, unscheduled visits to the doctor, and days off work compared with usual care. One subsequent RCT provided insufficient evidence about effects of asthma education on quality of life or social functioning at 6 months.
- **Magnesium sulphate for people with severe acute asthma** We found limited evidence from one systematic review and two subsequent RCTs that intravenous magnesium improved lung function compared with placebo in people with severe acute asthma. One systematic review and three subsequent RCTs found no significant difference between intravenous magnesium sulphate and placebo for hospital admission rates.
- **Mechanical ventilation for people with severe acute asthma** We found no RCTs comparing mechanical ventilation with or without inhaled β_2 agonists versus no mechanical ventilation in people with severe acute asthma. Evidence from cohort studies support its use, although observational studies suggest that ventilation is associated with a high level of morbidity.
- **Oxygen supplementation for acute asthma** We found no systematic review or RCTs of oxygen in acute asthma. However, consensus opinion and pathophysiology suggest that its role is vital in acute asthma.
- **Specialist care for acute exacerbations (more effective than generalist care)** One systematic review found limited evidence that specialist care improved outcomes in people with acute asthma compared with generalist care.
- **Continuous nebulised short acting β_2 agonists for acute asthma (no more effective than intermittent nebulised short acting β_2 agonists)** One systematic review and one subsequent RCT found no significant difference in admission rate between continuous and intermittent nebulised short acting β_2 agonists for hospital admission rates in adults. The subsequent RCT also found no significant difference between continuous and intermittent nebulised short acting β_2 agonists in lung function.
- **Helium–oxygen mixture for acute asthma** One systematic review found no significant difference between helium–oxygen mixture and air or oxygen in pulmonary function tests at 60 minutes for adults and children.
- **Intravenous short acting β_2 agonists for acute asthma (no more effective than nebulised short acting β_2 agonists)** One systematic review found that intravenous delivery of short acting β_2 agonists was no more effective than nebulised delivery in improving peak expiratory flow rate at 60 minutes.

DEFINITION

Asthma is characterised by variable airflow obstruction and airway hyperresponsiveness. Symptoms include dyspnoea, cough, chest tightness, and wheezing. The normal diurnal variation of peak expiratory flow rate (see glossary, p 1991) is increased in people with asthma (see table 1, p 1997). **Chronic asthma** is defined here as asthma requiring maintenance treatment. Asthma is classified differently in the USA and UK (see table 1, p 1997). Where necessary, the text specifies the system of classification used.[1,2] **Acute asthma** is defined here as an exacerbation of underlying asthma requiring urgent treatment.

INCIDENCE/PREVALENCE

Reported prevalence of asthma is increasing worldwide. About 10% of people have suffered an attack of asthma.[3–5] Epidemiological studies have also found marked variations in prevalence in different countries.[6,7]

AETIOLOGY/ RISK FACTORS Most people with asthma are atopic. Exposure to certain stimuli initiates inflammation and structural changes in airways causing airway hyperresponsiveness and variable airflow obstruction, which in turn cause most asthma symptoms. There are a large number of such stimuli; the more important include environmental allergens, occupational sensitising agents, and respiratory viral infections.[8,9]

PROGNOSIS **Chronic asthma:** In people with mild asthma, prognosis is good and progression to severe disease is rare. However, as a group, people with asthma lose lung function faster than those without asthma, although less quickly than people without asthma who smoke.[10] People with chronic asthma can improve with treatment. However, some people (possibly up to 5%) have severe disease that responds poorly to treatment. These people are most at risk of morbidity and death from asthma. **Acute asthma:** About 10–20% of people presenting to the emergency department with asthma are admitted to hospital. Of these, fewer than 10% receive mechanical ventilation.[11,12] Those who are ventilated are at 19-fold increased risk of ventilation for a subsequent episode.[13] It is unusual for people to die unless they have suffered respiratory arrest before reaching hospital.[14] One prospective study of 939 people discharged from emergency care found that 17% (95% CI 14% to 20%) relapsed by 2 weeks.[15]

AIMS OF INTERVENTION To minimise or eliminate symptoms; to maximise lung function; to prevent exacerbations; to minimise the need for medication; to minimise adverse effects of treatment; and to provide enough information and support to facilitate self management of asthma.

OUTCOMES Symptoms (daytime and nocturnal); lung function, in terms of peak expiratory flow rate and forced expiratory volume in 1 second (see glossary, p 1991); need for rescue medication such as inhaled β_2 agonists; variability of flow rates; activities of daily living; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION What are effects of treatments for chronic asthma?

OPTION SHORT ACTING INHALED β_2 AGONISTS AS NEEDED IN ADULTS WITH MILD OR MODERATE ASTHMA

One systematic review and one subsequent RCT found no significant difference between regular and as needed short acting inhaled β_2 agonists for clinically important outcomes.

Benefits: We found one systematic review (search date not reported, 22 crossover RCTs, 8 parallel group RCTs)[16] and one subsequent RCT[17] comparing regular with as needed β_2 agonists. Results from crossover RCTs and parallel group RCTs were analysed separately. Only results from crossover RCTs were suitable for pooling. Most of the included studies did not allow the use of concurrent inhaled corticosteroids. The review found no significant difference between regular and as needed use in morning peak expiratory flow rate (PEFR) (see glossary, p 1991) (5 crossover RCTs, 437 adults: WMD +2.1 L/minute, 95% CI –9.5 L/minute to +13.6 L/minute). Regular

β_2 agonists significantly increased evening PEFR compared with as needed β_2 agonists (6 crossover RCTs, 874 adults: WMD 13.1 L/minute, 95% CI 1.9 L/minute to 24.3 L/minute). As needed β_2 agonists significantly increased diurnal variation (see glossary, p 1991) of PEFR compared with regular use (2 crossover RCTs, 170 adults: 4.4%, 95% CI 4.3% to 4.5%) and pre-bronchodilator forced expiratory volume in 1 second (see glossary, p 1991) obtained at clinic visits (303 people: WMD 157 mL, 95% CI 123 mL to 192 mL). Use of rescue bronchodilator was measured in most of the RCTs that used a short acting β_2 agonist as a rescue agent. Results for an average 24 hour period showed that, when bronchodilators were given regularly, significantly less relief bronchodilator was used (2 crossover RCTs, 45 adults: WMD –0.68 puffs/day, 95% CI –1.30 puffs/day to –0.07 puffs/day). Two crossover RCTs (174 adults) identified by the review measured exacerbation rates.[16] They found no significant difference between regular and as needed use of β_2 agonists (SMD +0.10, 95% CI –0.11 to +0.31). One parallel group RCT (117 adults) identified by the review found that as needed use significantly improved symptom control over a 24 hour period compared with regular use (WMD 0.120 units, 95% CI 0.001 units to 0.239 units). No significant differences were found in quality of life.[16] The subsequent RCT (983 people with asthma in a general practice setting, 90% using regular inhaled corticosteroids) compared as needed versus regular salbutamol (see glossary, p 1991) (400 µg 4 times daily).[17] It found no significant difference between regular and as needed salbutamol in the rate of exacerbations over 1 year (RR 0.96, 95% CI 0.80 to 1.15) or in morning PEFR (see comment below). Evening PEFR was significantly higher with regular salbutamol (WMD 10.7 L/minute, 95% CI 6.7 L/minute to 14.0 L/minute) and diurnal variation of PEFR was also higher (WMD 3.3%, 95% CI 2.5% to 4.1%).[17]

Harms: The systematic review did not find any significant worsening of airways function after stopping regular treatment with β_2 agonists, and concluded that the small increase in lower airways reactivity with regular treatment was unlikely to be of any clinical importance.[16] Non-experimental studies found an association between increased asthma mortality and overuse of short acting inhaled β_2 agonists.[18–23] However, results of these non-randomised studies should be interpreted with caution because of the risk of confounding by factors other than treatment. Other RCTs found that regular use of inhaled β_2 agonists was associated with transient rebound deterioration in airway hyperresponsiveness after stopping the medication[24] and increased allergen induced bronchoconstriction.[25] Tremor was commonly reported, but tolerance developed with more frequent use.[26]

Comment: In the subsequent RCT, 33% (323/983) of people randomised did not complete the RCT, reducing the power of the RCT to detect a significant difference between regular and as needed salbutamol.[17]

OPTION LOW DOSE INHALED CORTICOSTEROIDS IN PEOPLE WITH MILD, PERSISTENT ASTHMA

Systematic reviews and RCTs have found that, in people with mild, persistent asthma, low doses of inhaled corticosteroids improve symptoms and lung function compared with placebo or regular inhaled β_2 agonists.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 6 RCTs, 393 people)[27] and six subsequent RCTs (5 in 1026 adults and adolescents, 1 in 7241 people aged 5–66 years)[28–33] of budesonide. We found one systematic review (search date 1999, 9 RCTs, 1800 people)[34] and one subsequent RCT (304 people aged ≥ 12 years)[35] of fluticasone. We found one systematic review (search date 1999, 6 RCTs, 492 people) of beclometasone (beclomethasone).[36] We found five additional RCTs (2187 adults and adolescents with mild, persistent asthma using the US classification; see table 1, p 1997) of low doses of triamcinolone,[37–40] flunisolide,[41] or mometasone.[42] The systematic reviews and RCTs all found that low dose inhaled corticosteroids significantly improved lung function and symptoms, and reduced the need for short acting bronchodilators compared with placebo. The largest systematic review,[34] which compared fluticasone 100 μg daily or more versus placebo, found that fluticasone significantly improved forced expiratory volume in 1 second, morning peak expiratory flow rate (PEFR) (see glossary, p 1991), use of inhaled β_2 agonists, and the proportion of people who withdrew because of lack of efficiency compared with placebo over 4–12 weeks (forced expiratory volume in 1 second: WMD 0.41 L, 95% CI 0.35 L to 0.47 L; morning PEFR: WMD 30 L/minute, 95% CI 25 L/minute to 35 L/minute; use of inhaled β_2 agonists: WMD 1.36 puffs/day, 95% CI 1.0 puff/day to 1.7 puffs/day; withdrawal because of lack of efficiency: RR 0.32, 95% CI 0.25 to 0.40).[34] The largest subsequent RCT (7241 children and adults aged 5–66 years with mild asthma, no previous steroids) found that budesonide (400 μg once daily for adults and 200 μg once daily for children aged < 11 years) significantly reduced the risk of a severe asthma related event compared with placebo over a period of about 2.4 years (severe asthma related event defined as needing admission or emergency treatment or death owing to asthma: HR 0.56, 95% CI 0.45 to 0.71).[33] **Versus β_2 agonists:** We found one systematic review (search date not reported; 5 RCTs; 3 comparing inhaled corticosteroids *v* placebo; 2 comparing inhaled corticosteroids *v* β_2 agonists; 141 adults with mild, persistent asthma).[43] The review found that regular inhaled corticosteroids (≤ 2 drugs) significantly improved lung function compared with regular β_2 agonists or placebo (overall weighted effect size for PEFR 0.59, 95% CI 0.32 to 0.84).

Harms: We found one systematic review (search date 2001, 2 RCTs) that examined the effects of inhaled corticosteroids on fracture rate.[44] It found no significant difference between conventional doses of inhaled corticosteroids versus placebo for vertebral fracture rates (OR 1.87, 95% CI 0.50 to 7.03). The second review (search date 1998) assessed the harms of inhaled corticosteroids and found that systemic adverse effects increased with dose.[45] It found that,

although posterior subcapsular cataracts occurred more frequently in people taking oral corticosteroids, most studies in adults provided no evidence that inhaled corticosteroids increase the risk once the confounding effect of oral corticosteroid use is removed. The review found no significant effect of inhaled low dose corticosteroids on bruising or skin thickness. The systematic review of fluticasone found that fluticasone significantly increased oral candidiasis compared with placebo (13/653 [2%] with fluticasone *v* 3/645 [0.5%] with placebo; RR 3.45, 95% CI 1.29 to 9.26).[34] The largest subsequent RCT (7241 adults and children) found similar rates of adverse events with budesonide and placebo in adults after about 2.4 years.[33] It found that budesonide significantly restricted growth after 2.4 years compared with placebo in children aged 5–15 years (difference in height increase with budesonide *v* placebo: –0.43 cm/year, 95% CI –0.54 cm/year to –0.32 cm/year).[33]

Comment: Two RCTs have found that inhaled corticosteroids delivered using chlorofluorocarbon free propellants such as hydrofluoroalkane are effective at low doses for people with mild, persistent asthma, but dose equivalence varies with each delivery system.[40,41] The dose of inhaled corticosteroid may need to be adjusted if a chlorofluorocarbon free propellant is used.

OPTION ADDING LONG ACTING INHALED β_2 AGONISTS IN PEOPLE WITH MILD, PERSISTENT ASTHMA THAT IS POORLY CONTROLLED BY INHALED CORTICOSTEROIDS

RCTs have found that, in people with asthma that is poorly controlled with inhaled corticosteroids, adding regular long acting inhaled β_2 agonists improves symptoms and lung function compared with placebo or a leukotriene antagonist. One systematic review and three additional RCTs have found that adding regular doses of long acting inhaled β_2 agonists improves lung function and symptoms, and reduces rescue medication compared with increasing the dose of inhaled corticosteroids. However, one further RCT found that increasing inhaled corticosteroid dose reduced exacerbations compared with adding long acting inhaled β_2 agonists. We found insufficient evidence about effects of adding long acting inhaled β_2 agonists on mortality.

Benefits: **Versus placebo:** We found no systematic review. We found three RCTs (1400 people with moderate, persistent asthma, uncontrolled by inhaled corticosteroids 250–2000 µg daily beclometasone diproprionate or equivalent) comparing regular long acting inhaled β_2 agonists versus placebo.[46–48] The RCTs found that twice daily salmeterol or formoterol (eformoterol) improved quality of life scores, peak expiratory flow rate (PEFR), and forced expiratory volume in 1 second (FEV_1) (see glossary, p 1991) and reduced night wakening compared with placebo. In the largest RCT,[48] salmeterol significantly improved the adjusted mean PEFR and significantly increased the proportion of people who did not awaken at night (PEFR: 398 L/minute with salmeterol *v* 386 L/minute with placebo; $P < 0.001$; no night wakening: 74% with salmeterol *v* 68% with placebo; $P < 0.05$). Exacerbation rates were not significantly different between the two groups in any of the RCTs (AR for severe exacerbations in the largest RCT:[48] 20.8% with salmeterol *v*

20.9% with placebo). **Versus increased use of inhaled corticosteroids:** We found one systematic review (search date 1999, 9 double blind RCTs, 3685 people with symptomatic asthma on their current dose of inhaled steroids, duration 3–6 months)[49] and three additional RCTs.[50–52] The review compared adding salmeterol with increased use of inhaled corticosteroids (at least double the usual dose). It found that morning PEFR was significantly higher with salmeterol (3 months: WMD in PEFR 22 L/minute, 95% CI 15 L/minute to 30 L/minute; $P < 0.001$; 6 months: WMD 28 L/minute, 95% CI 19 L/minute to 36 L/minute). Salmeterol significantly increased days and nights without symptoms (WMD at 6 months: days: 15 days, 95% CI 12 days to 18 days; nights: 5 nights, 95% CI 3 nights to 7 nights). Salmeterol also significantly reduced the need for rescue medication. No increase in asthma exacerbations of any severity was found in the salmeterol group.[49] The first additional RCT (852 people taking low to moderate dose inhaled corticosteroids) compared adding formoterol, increasing the dose of inhaled corticosteroids, and increasing the dose of corticosteroids plus adding formoterol.[50] It found that increased dose of corticosteroids significantly reduced severe exacerbations compared with adding formoterol at 1 year (AR 46% with increased corticosteroid *v* 67% with added formoterol; $P = 0.03$). The second additional RCT (454 people with symptomatic asthma on their current dose of inhaled steroids) compared adding salmeterol 42 μg plus fluticasone 88 μg twice daily versus adding fluticasone 220 μg twice daily.[51] It found that salmeterol plus lower dose fluticasone improved lung function, reduced the use of rescue β_2 agonists, and increased the proportion of symptom free days compared with higher dose fluticasone alone. The third additional RCT (663 symptomatic people aged > 12 years taking low to moderate doses of inhaled corticosteroids) compared budesonide 400 μg plus placebo twice daily versus budesonide 400 μg plus formoterol 9 μg twice daily.[52] It found that adding formoterol significantly improved morning and evening PEFR and improved symptoms at 6 months compared with placebo (morning PEFR difference: 19.0 L/minute, 95% CI 12.3 L/minute to 25.6 L/minute; evening PEFR difference: 15.7 L/minute, 95% CI 9.4 L/minute to 22.1 L/minute; $P < 0.001$; change in symptom score, on a scale from –2 [improvement] to +2 [worsening]: –0.16 with formoterol *v* +0.01 with placebo; $P < 0.001$). It found no difference between formoterol and placebo in the proportion of people with a clinically important improvement in quality of life (Mini Asthma Quality of Life questionnaire score improved > 0.5 points: 51% with formoterol *v* 47% with placebo, P value not reported). **Versus addition of leukotriene antagonists:** We found four RCTs.[53–56] The first RCT (948 adults with symptomatic asthma on their current dose of inhaled steroids) compared adding salmeterol 50 μg twice daily versus adding montelukast 10 mg daily.[53] It found that salmeterol significantly increased the proportion of symptom free days, improved lung function, and reduced the need for rescue medication and night time awakenings compared with montelukast (symptom free days: 24% with salmeterol *v* 16% with montelukast; difference 8%). It found no significant difference in the proportion of people with asthma exacerbations (26/476 [6%] with salmeterol *v*

23/472 [5%] with montelukast; RR 1.12, 95% CI 0.65 to 1.93) over 12 weeks. The second small RCT (65 people with moderate, persistent asthma all using moderate or high dose inhaled steroid) compared three treatments: adding long acting β agonist formoterol 9 μg twice daily; adding leukotriene antagonist zafirlukast 20 mg twice daily; and adding a sustained release theophylline.[54] Additional short acting β agonists were allowed. It found no significant difference between adding formoterol and adding zafirlukast for lung function at 3 months (FEV_1 as % of predicted at 3 months: 89.5% with added formoterol *v* 87.3% with added zafirlukast; $P > 0.05$). However, the study may have lacked power to detect clinically important differences. The third RCT (429 people poorly controlled on inhaled corticosteroids) found no significant difference between adding salmeterol 43 μg twice daily through a metered dose inhaler and adding zafirlukast 20 mg twice daily in FEV_1 at 4 weeks (change from baseline in FEV_1: 0.26 L with salmeterol *v* 0.23 L with zafirlukast).[55] However, it found that salmeterol significantly improved symptom scores and reduced night time wakening compared with zafirlukast at 4 weeks (decrease in symptom scores: 35% with salmeterol *v* 21% with zafirlukast; reduction in nocturnal awakenings: 45% with salmeterol *v* 25% with zafirlukast). The fourth RCT (725 adults poorly controlled on their current dose of inhaled corticosteroids) found that adding a fixed salmeterol 50 μg plus fluticasone 100 μg combination significantly increased morning PEFR, FEV_1, and the chance of a symptom free day or night at 12 weeks compared with fluticasone 100 μg twice daily plus montelukast 10 mg once daily (morning PEFR, mean difference: 15 L/minute, 95% CI 11 L/minute to 20 L/minute; mean difference in FEV_1: 0.11 L, 95% CI 0.06 L to 0.16 L; symptom free day: OR 1.32, 95% CI 1.05 to 1.65; symptom free night: OR 1.28, 95% CI 1.02 to 1.61).[56]

Harms: Several studies have found that people taking regular doses of long acting inhaled β_2 agonists develop tolerance to bronchodilatory effects[57–59] and may develop tremor. Regular use of long acting inhaled β_2 agonists has not been linked to deterioration in asthma control.[48–50]

Comment: We found no RCTs or other studies with sufficient power to assess the effect of regular use of long acting inhaled β_2 agonists on mortality.[60]

OPTION ADDING LEUKOTRIENE ANTAGONISTS ALONE IN PEOPLE WITH MILD TO MODERATE, PERSISTENT ASTHMA

RCTs in people taking β_2 agonists alone have found that leukotriene antagonists reduce asthma symptoms and β_2 agonist use compared with placebo. One systematic review and three out of nine subsequent RCTs have found that adding leukotriene antagonists increases exacerbations, reduces lung function, and are less effective for symptom control compared with inhaled corticosteroids. The other six RCTs found no significant difference between adding leukotriene antagonists and adding corticosteroids in asthma control or lung function. Two RCTs have found that an inhaled corticosteroid plus a long acting β_2 agonist improved symptoms, lung function, and exacerbations compared with a leukotriene antagonist alone at 12 weeks.

Benefits:

Versus placebo: We found no systematic review. We found five RCTs (1400 adults with asthma taking β_2 agonists alone), which compared adding leukotriene antagonists versus adding placebo for 6–13 weeks.[61–65] The first three RCTs all found that the oral leukotriene antagonist zafirlukast 20 mg twice daily significantly reduced daytime and night time asthma symptoms and β_2 agonist use compared with placebo.[61–63] The first and largest of these RCTs (762 people) found that zafirlukast significantly reduced daytime symptoms, night time awakenings, and β agonist use compared with placebo (daytime symptom score: 8.05 with zafirlukast *v* 9.45 with placebo; $P < 0.01$; night time awakenings: 2.05/week with zafirlukast *v* 2.52/week with placebo; $P < 0.05$; β_2 agonist use: 3.1 puffs/day with zafirlukast *v* 3.0 puffs/day with placebo; $P < 0.01$).[61] Morning forced expiratory volume in 1 second (FEV_1) (see glossary, p 1991) was significantly increased in people taking zafirlukast (morning FEV_1 improvement: by 7% with zafirlukast *v* 3% with placebo; $P < 0.01$). The fourth and fifth RCTs (730 people[64] and 782 people[65] aged > 15 years taking as needed short acting β_2 agonists alone) compared three treatments: oral montelukast 10 mg once daily, inhaled beclomethasone, and placebo. Both RCTs found that oral montelukast significantly improved asthma control compared with placebo at 6 weeks (% days with < 2 puffs of salbutamol [see glossary, p 1991], no nocturnal wakening, and no asthma attack; fourth RCT:[64] 50.7% with montelukast *v* 40% with placebo; $P < 0.05$; fifth RCT:[65] 41.4% with montelukast *v* 26.8% with placebo; $P < 0.001$). **Versus inhaled corticosteroids:** We found one systematic review (search date 2002, 12 RCTs in adults, 2 RCTs in children, FEV_1 > 50% predicted)[66] and nine subsequent RCTs.[64,65,67–73] The review compared leukotriene antagonists (montelukast, pranlukast, zafirlukast) versus inhaled corticosteroids (beclomethasone, fluticasone) for 4–37 weeks.[66] It found that leukotriene antagonists increased risk of asthma exacerbations requiring systemic steroids compared with corticosteroids (all leukotriene antagonists: 11 RCTs; significant heterogeneity among trials; RR 1.61, 95% CI 1.15 to 2.25). The review found no significant difference between leukotriene antagonists and inhaled corticosteroids for hospital admission rates for acute asthma (9 RCTs; RR 1.73, 95% CI 0.64 to 4.73). It also found that leukotriene antagonists reduced symptom free days compared with inhaled corticosteroids at 6 weeks (3 RCTs; WMD 9%, 95% CI 5% to 13%).[66] The first subsequent RCT (533 adults with asthma who were symptomatic on β_2 agonists alone) compared fluticasone versus montelukast for 24 weeks.[67] The second subsequent RCT (294 adults and children > 11 years of age previously treated with β_2 agonists alone) compared fluticasone 88 μg twice daily versus zafirlukast 20 μg twice daily.[68] Both RCTs found no significant difference between leukotriene antagonists and inhaled corticosteroids groups for symptom scores. The third subsequent RCT (522 non-smokers with persistent asthma) found that fluticasone propionate 88 μg twice daily increased lung function and quality of life and decreased symptoms compared with oral montelukast 10 mg daily at 24 weeks (mean improvement in FEV_1: 22% with fluticasone *v* 14% with montelukast; $P < 0.001$; mean improvement in

asthma symptom score: 0.91 with fluticasone *v* 0.57 with montelukast; P < 0.001; mean increase in symptom free days: 34% with fluticasone *v* 20% with montelukast; P < 0.001; mean improvement in asthma quality of life questionnaire score: 1.3 with fluticasone *v* 1.0 with montelukast; P < 0.001).[69] The fourth subsequent RCT (440 people aged ≥ 12 years, previously treated with inhaled corticosteroids and short acting β agonists, FEV_1 60–80% of predicted) found that inhaled fluticasone 88 μg twice daily increased lung function and symptom free days at 6 weeks compared with zafirlukast 20 mg twice daily (mean difference in morning FEV_1: 0.16 L, 95% CI 0.08 L to 0.24 L; increase in symptom free days 14%, 95% CI 7% to 21%).[70] The fifth subsequent RCT (45 non-smokers with mild asthma) compared three treatments: budesonide 400 μg twice daily, montelukast 10 mg daily, and budesonide plus montelukast (at the same doses).[71] It found no significant difference between budesonide and montelukast alone for lung function at 16 weeks (increase in FEV_1: 2.1% with budesonide *v* 4.2 with montelukast; increase in forced vital capacity 3.1% with budesonide *v* 5.2% with montelukast; P values not reported). The sixth subsequent RCT (730 adults, aged 15–65 years, baseline FEV_1 50% to 85% of predicted, taking short acting β_2 agonist as needed) compared three treatments: montelukast 10 mg once daily, inhaled beclomethasone 200 μg twice daily, and placebo.[64] It found that beclomethasone significantly improved asthma control compared with montelukast at 6 weeks (% days with < 2 puffs of salbutamol, no nocturnal wakening, and no asthma attack: 50.7% with montelukast *v* 57.9% with beclomethasone; P < 0.05). The seventh additional RCT (51 non-smokers, mean age 26 years, baseline FEV_1 94–99% of predicted across treatment groups, taking short acting β_2 agonist as needed) compared four treatments: montelukast 10 mg daily, budesonide 400 μg twice daily, montelukast 10 mg plus budesonide 400 μg twice daily, and budesonide 800 μg twice daily.[72] It found no significant difference between montelukast alone and either dose of budesonide in FEV_1 at 12 weeks (results as % of predicted FEV_1 for baseline to post-treatment: 94.8% to 96.3% with montelukast *v* 99.9% to 100.4% with budesonide 400 μg *v* 99.2% to 98.9% with budesonide 800 μg; P values not reported). The eighth additional RCT (40 adults, mean age 25 years, baseline FEV_1 94% of predicted) compared montelukast 10 mg daily versus budesonide 400 mg twice daily.[73] It found no significant difference between montelukast and budesonide in FEV_1 at 16 weeks (% of predicted FEV_1 for baseline to post-treatment: 95.2% to 96.0% with montelukast *v* 94.7% to 96.7% with budesonide; P value not reported). The ninth additional RCT (782 adults, mean age 33 years, baseline FEV_1 66% of predicted, mean weekly short acting β_2 agonist use > 2 puffs/day) compared three treatments: montelukast 10 mg daily, beclomethasone 200 μg twice daily, and placebo.[65] It found no significant difference between montelukast and beclomethasone in asthma control (% days with < 2 puffs of salbutamol, no nocturnal wakening, and no asthma attack: 41.4% with montelukast *v* 41.1% with beclomethasone; P = 0.93). **Versus inhaled corticosteroids plus long acting β_2 agonists:** We found no systematic review. We found two RCTs.[74,75] The first RCT (423 adults with symptomatic

asthma taking short acting β_2 agonists) compared montelukast 20 mg once daily versus fluticasone 100 μg plus salmeterol 50 μg twice daily.[74] It found that adding fluticasone plus salmeterol significantly increased symptom free days and reduced exacerbations compared with adding montelukast alone at 12 weeks (increase in symptom free days from baseline: 22% with montelukast *v* 49% with fluticasone plus salmeterol; WMD 27%, 95% CI 20% to 35%; exacerbations: 11 with montelukast *v* 0 with fluticasone plus salmeterol; $P < 0.001$). The second RCT (432 people aged ≥ 15 years with persistent asthma, symptomatic on short acting β agonists) found that fluticasone 100 μg twice daily plus salmeterol 50 μg twice daily significantly increased lung function and reduced symptoms compared with oral montelukast 10 mg once daily at 12 weeks (increase in FEV_1: 27% with fluticasone plus salmeterol *v* 13% with montelukast; $P < 0.001$; increase in symptom free days: 40% with fluticasone plus salmeterol *v* 27% with montelukast; $P < 0.017$).[75]

Harms:

Versus placebo: In the RCT comparing zafirlukast versus placebo, the incidence of adverse effects (predominantly pharyngitis and headache) was similar in both groups (350/514 [68%] with zafirlukast *v* 160/248 [65%] with placebo).[62] **Versus inhaled corticosteroids:** The systematic review found that leukotriene antagonists significantly increased the risk of "withdrawals for any cause" but there was no significant difference between treatments in withdrawal rates owing to adverse effects (12 RCTs; RR 1.2, 95% CI 0.9 to 1.7).[66] One RCT found no significant difference between fluticasone and montelukast in adverse event rate.[69] One RCT found no significant difference between fluticasone and zafirlukast in adverse event rate (7% with fluticasone *v* 4% with zafirlukast; $P = 0.14$).[70] It found that the most common adverse events were headache (2% for both fluticasone and zafirlukast), nausea (1% for fluticasone), and hoarseness (1% for fluticasone). The sixth RCT found similar adverse effects between montelukast and beclomethasone (headache: 10% with montelukast *v* 11% with beclomethasone; upper respiratory infection: 7% with montelukast *v* 10% with beclomethasone; P value not reported).[64] The seventh and eighth RCTs found similar adverse effect rates between montelukast and budesonide.[72,73] The ninth RCT found no difference between montelukast and beclomethasone in upper respiratory infection, headache, or sinusitis (no data reported).[65]

Comment:

One systematic review (search date 2000) identified 22 cases of the Churg–Strauss Syndrome associated with antileukotriene treatment, but the total number of people exposed was not reported.[76]

OPTION ADDING LEUKOTRIENE ANTAGONISTS PLUS INHALED CORTICOSTEROIDS IN PEOPLE WITH MILD TO MODERATE, PERSISTENT ASTHMA

One systematic review in people taking inhaled corticosteroids found no significant difference between leukotriene antagonists and placebo for exacerbation rates at 4–16 weeks. However, one subsequent RCT in people taking a stable dose of budesonide found that adding montelukast increased asthma free days and decreased nocturnal waking compared

with placebo at 16 weeks. One RCT in people taking inhaled corticosteroids found no significant difference between adding montelukast and doubling budesonide in peak expiratory flow rate, daytime symptoms, nocturnal wakening, days with asthma exacerbations, and quality of life.

Benefits: **Versus placebo in people taking inhaled corticosteroids:** We found one systematic review (search date 2001, 12 RCTs in adults, 1 RCT in children with symptomatic asthma on their current dose of inhaled steroids)[77] and one subsequent RCT.[78] The systematic review found no significant different between licensed doses of leukotriene antagonists (montelukast 5 or 10 mg/day, pranlukast 450 mg/day, zafirlukast 80 mg/day) and placebo for exacerbations requiring systemic steroids at 4–16 weeks (2 RCTs: 20/466 [4%] with leukotriene antagonists *v* 33/468 [7%] with placebo; RR 0.61, 95% CI 0.36 to 1.05).[77] The subsequent RCT (639 non-smokers aged 18–70 years, on stable dose of budesonide 400–1600 µg daily or equivalent, baseline forced expiratory volume in 1 second 81% of predicted) compared adding montelukast 10 mg once daily versus placebo for 16 weeks.[78] It found that montelukast significantly increased asthma free days and decreased nocturnal waking compared with placebo (asthma free days: 66.1% with montelukast *v* 42.3% with placebo; difference 23.8%, 95% CI 10.9% to 41.2%; difference in decrease in nocturnal wakening: 6.6%, 95% CI 1.9% to 13.7%). It found no significant difference between montelukast and placebo in daytime asthma symptoms or change in FEV_1 (difference in symptom score, on a scale from 0 [least severe] to 24 [most severe]: –0.09, 95% CI –0.19 to +0.01; difference in change in morning FEV_1: +0.14%, 95% CI –2.47% to +2.75%). **Versus increasing inhaled steroids:** We found one RCT (889 non-smokers, aged 15–75 years, poorly controlled with budesonide 800 µg daily, baseline FEV_1 69% predicted), which compared adding montelukast 10 mg daily versus doubling the dose of budesonide to 1600 µg daily for 12 weeks.[79] It found no significant difference between adding montelukast and doubled budesonide dose in peak expiratory flow rate (see glossary, p 1991), daytime symptoms, nocturnal waking, days with asthma exacerbations, and quality of life (mean increase peak expiratory flow rate: 33.5 L/minute with montelukast *v* 30.1 L/minute with doubled budesonide; difference +3.4 L/minute, 95% CI –12.9 L/minute to +4.8 L/minute; change in daytime symptom score, on a scale from 0 [least severe] to 24 [most severe]: –0.34 with montelukast *v* –0.35 with budesonide; P = 0.91; change in number of nights with nocturnal waking: 12.3% to 2.3% with montelukast *v* 13.8% to 3.9% with budesonide; P = 0.35; median days with exacerbations: 6.7% with montelukast *v* 6.3% with budesonide; P = 0.78; AR for increase in quality of life by ≥ 0.5 points: about 43% with montelukast *v* about 40% with budesonide; P value not reported). **Versus long acting β_2 agonist in people taking inhaled corticosteroids:** See benefits of addition of long acting inhaled β_2 agonists in people with mild, persistent asthma that is poorly controlled by inhaled corticosteroids, p 1973.

Harms: **Versus placebo in people taking inhaled corticosteroids:** The systematic review found that leukotriene antagonists (given at a higher than licensed dose) significantly increased the risk of liver

enzyme elevation compared with placebo (13/280 [5%] with leukotriene antagonists *v* 2/276 [0.7%] with placebo; RR 5.36, 95% CI 1.40 to 20.40).[77] The first subsequent RCT found similar adverse effects between montelukast 10 mg once daily and placebo.[78] The most common adverse effects were influenza (11% with both treatments), headache (9% with montelukast *v* 11% with placebo), upper respiratory tract infection (5% with montelukast *v* 7% with placebo), and worsening asthma (7% with montelukast *v* 5% with placebo). **Versus increasing inhaled steroids:** The RCT comparing added montelukast versus doubled dose of budesonide found no significant difference between treatments in adverse effects at 12 weeks.[79] It found that the most common adverse effects were upper respiratory infection, worsening asthma, and headache (no data reported).

Comment: None.

OPTION THEOPHYLLINE IN PEOPLE WITH MILD TO MODERATE, PERSISTENT ASTHMA POORLY CONTROLLED BY INHALED CORTICOSTEROIDS New

Rodolfo Dennis and Ivan Solarte

One RCT has found that adding theophylline improves peak expiratory flow rate compared with continuing low dose corticosteroids plus placebo after 6 months in people with mild to moderate, persistent asthma that was poorly controlled with inhaled corticosteroids alone. One small RCT found no significant difference in lung function or symptoms between theophylline and formoterol (a long acting β agonist) or between theophylline and zafirlukast (a leukotriene antagonist) after 3 months.

Benefits: **Versus placebo:** We found one RCT (155 people with persistent asthma that was poorly controlled with inhaled corticosteroids) which compared three treatments: continuing low dose inhaled corticosteroids 200 μg twice daily plus placebo, continuing low dose inhaled corticosteroids 200 μg twice daily plus slow release theophylline 200 mg twice daily, and high dose inhaled corticosteroids (500 μg twice daily).[80] It found that continuing low dose corticosteroids plus theophylline improved morning and evening peak expiratory flow rate (PEFR) (see glossary, p 1991) compared with continuing low dose corticosteroids plus placebo after 6 months (mean change in morning PEFR: +4.4 L/minute with corticosteroids plus placebo *v* +21.8 L/minute with corticosteroids plus theophylline; P value not reported; mean change in evening PEFR: 1.9 L/minute with corticosteroids plus placebo *v* 22.5 L/minute with corticosteroids plus theophylline; P value not reported). **Versus leukotriene antagonists:** We found one RCT (64 people with moderate, persistent asthma not well controlled using budesonide daily doses > 800 μg), which compared adding theophylline, zafirlukast, or inhaled formoterol.[54] It found no significant difference between theophylline and zafirlukast in lung function at 3 months (mean improvement in force expiratory volume in 1 second [FEV_1] [see glossary, p 1991] [% predicted]: 20.7% with adding zafirlukast *v* 21.4% with adding theophylline; P value not reported). It found no significant difference between theophylline and zafirlukast in decrease in daily PEFR variability, daytime or night time asthma

symptoms, or in mean number of rescue inhalations after 3 months. The RCT did not present results for asthma exacerbations.
Versus long acting β_2 agonists: We found one RCT (64 people with moderate, persistent asthma that was poorly controlled with inhaled budesonide > 800 μg/day), which compared three added treatments: theophylline, zafirlukast, and inhaled formoterol.[54] It found no significant difference between theophylline and formoterol in improvement in FEV_1, decrease in daily PEFR variability, daytime or night time asthma symptoms, or in mean number or rescue medications after 3 months (mean improvement in % predicted FEV_1: +21.4% with theophylline *v* +22.9% with formoterol; $P > 0.05$, CI not reported). No asthma exacerbations in the study period were reported.

Harms: **Versus placebo:** The RCT found no significant differences between low dose steroids, low dose steroids plus theophylline, and high dose inhaled steroids in any common self reported adverse effect (dyspepsia, nausea, dry mouth, headache, coughing, bronchitis, coryza, pharyngitis; $P > 0.05$ for all between group comparisons).[80]
Versus leukotriene antagonists or long acting β_2 agonists: In the RCT,[54] adverse events, most commonly headache and dyspepsia, were more common with leukotriene than with theophylline (31% with leukotriene antagonists *v* 20% with theophylline, P value not reported), although event rates were the same for theophylline and long acting β_2 agonists (20%). There were no withdrawals because of adverse events in any group.[54]

Comment: The search performed also found two systematic reviews comparing theophylline with long acting β_2 agonists. These reviews included RCTs in people where inhaled steroid use was not required, not well standardised, or not optimally titrated before study randomisation. We, therefore, excluded these reviews. We identified one study comparing oral theophylline versus inhaled formoterol and this will be considered for inclusion when it is translated.[81]

QUESTION What are the effects of treatments for acute asthma?

J Mark FitzGerald

OPTION SPACER DEVICES/HOLDING CHAMBERS FOR DELIVERING β_2 AGONISTS IN ACUTE ASTHMA

One systematic review found no significant difference in forced expiratory volume in 1 second, peak expiratory flow rate, rates of hospital admission, or time spent in the emergency department between nebuliser and spacer devices for delivering β_2 agonists in people with acute but not life threatening asthma.

Benefits: We found one systematic review (search date 1999, 13 RCTs, non-hospitalised adults and children with acute asthma) comparing holding chambers plus metered dose inhalers with nebulisers for delivering β_2 agonists.[82] Results in adults and children were analysed separately (see asthma and other wheezing disorders in children, p 328). In adults, there was no significant difference in rates of hospital admission, length of time spent in the emergency

department, or in peak expiratory flow rate and forced expiratory volume in 1 second (FEV_1) (see glossary, p 1991) (hospital admission: OR 1.12, 95% CI 0.45 to 2.76: time in the emergency department: WMD +0.02 hours, 95% CI –0.40 hours to +0.44 hours). There was still no significant difference when the three RCTs involving the most severely affected people (FEV_1 < 30% predicted) were included (WMD for FEV_1 holding chamber *v* nebuliser –1.5% predicted, 95% CI –8.3% to +5.3%). Symptoms were measured on different scales and findings could not be combined.

Harms: The review found no significant difference in heart rates between holding chambers and nebulisers (WMD with holding chamber *v* nebuliser +1.6% of baseline, 95% CI –2.4% of baseline to +5.5% of baseline).[82]

Comment: The review found no evidence of publication bias.[82] To overcome possible dose confounding, the review was confined to studies that used multiple treatment doses titrated against the individuals' responses. As studies excluded people with life threatening asthma (see glossary, p 1991), results may not generalise to such people.

OPTION SYSTEMIC CORTICOSTEROIDS FOR ACUTE ASTHMA

Two systematic reviews and one subsequent RCT have found that early treatment with systemic corticosteroids reduce admission and relapse rates compared with placebo in people with acute asthma. One systematic review and one small subsequent RCT found no significant difference between oral and inhaled steroids after emergency department discharge in relapse rates at 7–10 days in adults with acute asthma.

Benefits: **Versus placebo:** We found two systematic reviews[83,84] and one subsequent RCT.[85] The first review (search date 1991, 5 RCTs, 422 people) found that early use of systemic corticosteroids (oral, iv, or im) significantly reduced hospital admissions compared with placebo in the emergency department (OR 0.47, 95% CI 0.27 to 0.79; no significant heterogeneity among RCTs; P = 0.72).[83] The second review (search date 2001, 7 RCTs, about 320 people) compared systematic steroids (im and oral) versus placebo after discharge from the emergency department.[84] It found that systemic corticosteroids significantly reduced relapse at 7–10 days and hospital readmissions within 7 days compared with placebo (relapse rates 5 RCTs, 345 people: RR 0.35, 95% CI 0.17 to 0.73; NNT 13, 95% CI 7 to 91; hospital readmissions 4 RCTs, 210 people: RR 0.32, 95% CI 0.11 to 0.94; NNT 16, 95% CI 7 to 125; no significant heterogeneity was found). Corticosteroids significantly reduced the use of β_2 agonists (WMD –3.3 puffs/day, 95% CI –5.5 puffs/day to –1.0 puff/day). The review found no clear difference between intramuscular and oral corticosteroids.[84] The subsequent RCT (259 adults and children, all given nebulised salbutamol [see glossary, p 1991] for 5–20 minutes 1–3 times) compared single dose oral prednisolone (30 mg if aged < 5 years or 60 mg if > 5 years) versus placebo given in the emergency room or outpatient department.[85] It found that oral prednisolone significantly reduced hospital admission rate compared with placebo (37/140 [26%] with prednisolone

v 50/119 [42%] with placebo; P < 0.01). **Versus inhaled steroids:** We found two systematic reviews[86,87] and one small subsequent RCT.[88] The first review (search date 2000) found four RCTs in children but no RCTs in adults (see asthma and other wheezing disorders of childhood, p 328).[86] The second review (search date 2001, 4 RCTs, 772 adults and 22 children) compared oral corticosteroids (prednisone) versus high dose inhaled corticosteroids (≥ 2 mg daily beclomethasone dipropionate or equivalent) in people with acute asthma after emergency department discharge.[87] It found no significant difference between oral and inhaled steroids for relapse rate at 7–10 days (OR relapse 1.00, 95% CI 0.66 to 1.52; no significant heterogeneity among trials; P = 0.88). We found one small subsequent RCT (40 adults aged 18–55 years with asthma exacerbation requiring hospital admission, peak expiratory flow rate [see glossary, p 1991] < 50% of predicted while in emergency department).[88] Treatment for the first 48 hours was with regular nebulised and then inhaled salbutamol plus methylprednisolone 40 mg intravenously every 6 hours for eight doses. Then people were randomised to inhaled flunisolide (8 puffs twice daily, 250 μg/puff) or oral prednisone 40 mg daily for 7 days. It found no significant difference between inhaled and oral steroids in force expiratory volume in 1 second or symptoms (change in force expiratory volume in 1 second [see glossary, p 1991], baseline to 7 days: 1.6 L to 1.3 L with inhaled *v* 1.6 L to 2.3 L with oral steroids; P = 0.33; change in symptoms scores [no details of scoring system reported]: 1.4 to 0.7 with inhaled *v* 1.3 to 0.4 with oral steroids; P = 0.39).

Harms: Systemic corticosteroids can cause the same adverse effects in asthma as in other diseases, even when given for a short time (see asthma and other wheezing disorders of childhood, p 328).

Comment: One RCT (413 adults presenting to general practitioners with acute asthma) found no difference in rates of treatment failure with a short course of oral corticosteroids versus a high dose of inhaled fluticasone.[89] **Stopping treatment:** We found no systematic review but found 1 RCT (35 people admitted to hospital with acute asthma who received 40 mg prednisone for 10 days).[90] It found no significant difference in morning peak expiratory flow rate between tapering of prednisone over 1 week and abrupt stopping (mean increase in peak expiratory flow rate: 45 L/minute with tapering *v* 43 L/minute with abrupt stopping; P = 0.82).[90] **Optimal dose and duration of treatment:** We found no systematic review. One RCT (20 people) compared 1 week with 2 weeks of oral prednisone after a 3 day course of intravenous methylprednisolone and found no difference in peak expiratory flow rate and relapse rates.[91] A second RCT (47 people, 41 analysed) compared 5 versus 10 days of oral prednisolone in people who had been hospitalised with acute asthma.[92] It found no significant difference in lung function. All three RCTs may have been too small to detect a clinically important difference. The optimal duration of treatment is likely to depend on the individual, the severity of the exacerbation, and use of concomitant medications.

OPTION INHALED CORTICOSTEROIDS FOR ACUTE ASTHMA

One systematic review has found that inhaled corticosteroids given in the emergency department reduces hospital admission rates in adults compared with placebo. One systematic review and one subsequent RCT found no significant difference in relapse rates following emergency room discharge between oral and inhaled steroids at 7–10 days. One systematic review found no significant difference in relapse rates between inhaled plus oral corticosteroids and oral corticosteroids alone up to 24 days.

Benefits: **Versus placebo:** We found one systematic review (search date 2001, 3 RCTs, 188 adults).[93] It found that inhaled corticosteroids given in the emergency department significantly reduced admission rates compared with placebo in people with acute asthma (OR 0.38, 95% 0.18 to 0.79). **Versus systemic steroids:** See benefits of systemic corticosteroids, p 1982. **Plus oral corticosteroids versus oral corticosteroids alone:** We found one systematic review (search date 1999, 3 RCTs, 909 adults).[94] It found no significant difference between inhaled plus oral corticosteroids and oral corticosteroids alone in relapse rates at day 7–10 or day 20–24 (day 7–10: OR 0.72, 95% CI 0.48 to 1.10; day 20–24: OR 0.68, 95% CI, 0.46 to 1.02).[94]

Harms: The reviews found no significant differences in adverse effects between the groups, but one review commented that most of the RCTs identified gave little information on adverse effects apart from reporting that they were "rare".[94] See also harms of inhaled corticosteroids under asthma and other wheezing disorders of childhood, p 328.

Comment: None.

OPTION CONTINUOUS NEBULISED SHORT ACTING β_2 AGONISTS FOR ACUTE ASTHMA

One systematic review and one subsequent RCT found no significant difference in admission rates between continuous and intermittent nebulised short acting β_2 agonists for hospital admission rates in adults. The subsequent RCT also found no significant difference between continuous and intermittent nebulised short acting β_2 agonists in lung function.

Benefits: We found one systematic review (search date 2001, 6 RCTs, 393 adults)[95] and one additional RCT.[96] The review found no significant difference in admission rate between 1 hour of continuous and 2 hours of intermittent nebulised salbutamol (see glossary, p 1991) (2.5–16 mg in first hour) after 1–3 hours (2 RCTs, 80 adults, hospital admission rate: RR 0.68, 95% CI 0.33 to 1.38).[95] The included RCTs also used systemic steroids. The subsequent RCT similarly found no significant difference in lung function or rate of hospital admission between continuous and intermittent nebulised salbutamol.[96]

Harms: Commonly reported mild adverse effects associated with frequent dosing include tachycardia, tremor, and headache. Metabolic abnormalities are less common and include hypokalaemia. One

RCT included in the review found the highest rate of adverse effects with high dose intermittent treatment. The most common adverse effect was tremor (24% with intermittent high dose *v* 20% with continuous high dose *v* 9% with hourly standard dose *v* 3% with continuous standard dose).[97]

Comment: We found one RCT (46 adults in hospital), which addressed the slightly different, but related, question of regular nebulised salbutamol (5 mg every 4 hours) versus on demand salbutamol 2.5–5 mg.[98] It found that on demand dosage significantly reduced hospital stay, the proportion of nebulisations and palpitations (hospital stay: 3.7 days with on demand salbutamol *v* 4.7 days with regular salbutamol); proportion of nebulisations: geometric mean 7.0 with on demand salbutamol *v* 14 with regular salbutamol, P = 0.003; palpitations: P = 0.05).

OPTION INTRAVENOUS SHORT ACTING β_2 AGONISTS FOR ACUTE ASTHMA

One systematic review found that intravenous delivery of short acting β_2 agonists was no more effective than nebulised delivery in improving peak expiratory flow rate at 60 minutes.

Benefits: We found one systematic review (search date not reported, 6 RCTs, 337 people) comparing intravenous with inhaled short acting β_2 agonists.[99] Five of the RCTs used nebulised delivery of inhaled β_2 agonists, and one used intermittent positive pressure breathing. It found that intravenous β_2 agonists lowered peak expiratory flow rate (see glossary, p 1991) at 60 minutes compared with inhaled, but the difference was not significant (WMD +24.7 L/minute, 95% CI –2.9 L/minute to +52 L/minute). It found no significant difference in heart rate at 60 minutes between intravenous and inhaled β_2 agonists (WMD +4.5 beats/minute, 95% CI –4.9 beats/minute to +14 beats/minute).

Harms: The systematic review found that intravenous β_2 agonists significantly reduced the proportion of people with autonomic adverse effects (including palpitations, tachycardia, hypertension, tremor, headache, nausea, and vomiting) compared with inhaled β_2 agonists (53/153 [35%] with intravenous *v* 76/144 [53%] with inhaled; OR 0.38, 95% CI 0.22 to 0.65).[99] However the review found significant heterogeneity between the studies for this analysis, so the harms findings should be interpreted with caution.

Comment: One systematic review (search date 2000, 15 RCTs) compared intravenous β_2 agonists with inhaled β_2 agonists or aminophylline but did not compare intravenous with inhaled β_2 agonists alone.[100] It found no significant difference between treatments in peak expiratory flow rate at 6 hours (7 RCTs, WMD: –3.4, 95% CI –21.6 to +14.7).[100]

OPTION IPRATROPIUM BROMIDE ADDED TO β_2 AGONISTS IN ACUTE ASTHMA

Two systematic reviews and one subsequent RCT have found that ipratropium bromide plus salbutamol improves lung function compared with salbutamol alone and is likely to reduce hospital admission in people with severe acute asthma.

Benefits: We found two systematic reviews[101,102] and one subsequent RCT.[103] The first systematic review (search date 1999, 10 RCTs, 1483 people) found that inhaled ipratropium plus salbutamol (see glossary, p 1991) significantly reduced hospital admissions compared with salbutamol alone (5 RCTs, 1186 people; OR 0.62, 95% CI 0.44 to 0.88; NNT 18, 95% CI 11 to 77).[101] Meta-analysis of the four RCTs that evaluated people with severe airflow obstruction (forced expiratory volume in 1 second [FEV_1] [see glossary, p 1991] < 35%) found that additional treatment with ipratropium significantly improved FEV_1 over 90 minutes (effect size: 0.38, 95% CI 0.05 to 0.67). The second systematic review (search date 1997, 10 RCTs, including 8 identified by the later reviews, 1377 people) found that adding ipratropium bromide improved lung function compared with adding salbutamol alone. It also found no significant difference in hospital admissions, when assessing the same three RCTs.[102] The subsequent RCT (180 people with acute asthma, mean FEV_1 < 50%) compared salbutamol plus placebo versus salbutamol plus ipratropium.[103] It found that adding ipratropium significantly improved peak expiratory flow rate (see glossary, p 1991) (difference in improvement with ipratropium *v* placebo: 21%, 95% CI 3% to 38%) and FEV_1 (difference in improvement with ipratropium *v* placebo: 48%, 95% CI 20% to 76%). People taking ipratropium were significantly less likely to require hospital admission at the end of the 3 hour trial period (20% with ipratropium *v* 39% with placebo; P = 0.01).

Harms: The reviews[101,102] and the subsequent RCT[103] found no significant difference in adverse effects with the addition of ipratropium to salbutamol versus salbutamol alone.

Comment: The authors of the second systematic review stated that only three RCTs reported data in sufficient detail to be included in the analysis of hospital admission rates.[102]

OPTION OXYGEN SUPPLEMENTATION FOR ACUTE ASTHMA

We found no systematic review or RCTs of oxygen in acute asthma. However, consensus opinion and pathophysiology suggest that its role is vital in acute asthma. One systematic review found no significant difference between helium–oxygen mixture and air or oxygen in pulmonary function tests at 60 minutes for adults and children.

Benefits: **Oxygen alone:** We found no systematic review or RCTs. **Plus helium versus air or oxygen:** We found one systematic review (search date 2002, 8 RCTs, adults and children aged 16 months to 55 years with acute asthma) that compared any mixture of helium plus oxygen (heliox) versus air/oxygen mixtures.[104] Co-interventions included nebulised bronchodilators with and without steroids. It found no significant difference between helium plus oxygen and air/oxygen in peak expiratory flow rate (see glossary, p 1991) within the first hour (overall WMD, 4 RCTs, 278 people: +3%, 95% CI –2% to +8%). It found no significant difference in peak expiratory flow rate between helium plus oxygen and air/oxygen whether or not nebulised salbutamol (see glossary, p 1991) was used (WMD, 2 RCTs using nebulised salbutamol, 244 people: –0.03, 95% CI

–6.43 to +6.37; WMD in 2 RCTs not using nebulised salbutamol, 34 people: +7.36, 95% CI –1.18 to +15.90). It found that helium plus oxygen slightly improved dyspnoea compared with air/oxygen (WMD in Dyspnoea Index, 2 RCTs, 34 people: 0.60, 95% CI 0.04 to 1.16).

Harms: We found no evidence of adverse effects associated with oxygen alone. **Plus helium versus air or oxygen:** The systematic review (search date 2000) did not report harms.[104] One RCT identified by the review found that one person became hypoxic with 70 : 30 helium : oxygen mixture and another RCT found one person with dizziness with helium.[104]

Comment: The most severe stages of acute asthma are respiratory failure, cardiopulmonary arrest, and death.[12,13] Studies of near fatal asthma suggest that hypoxia rather than arrhythmia account for asthma deaths. It seems reasonable that supplemental oxygen should continue to form a critical part of management even though we found no RCTs providing direct evidence for this. Peak flow readings vary depending on the viscosity of the gas being delivered (helium is less dense than oxygen so non-standardised measures of peak flow will increase relative to air, even if the mixture has no effect on airway narrowing). It was not clear in all RCTs whether peak flow readings were standardised for air and for helium–oxygen mixtures. Evidence for routine use of heliox as a therapeutic option in its own right is currently lacking.

OPTION MAGNESIUM SULPHATE FOR ACUTE ASTHMA

We found limited evidence from one systematic review and two subsequent RCTs that intravenous magnesium improved lung function compared with placebo in people with severe acute asthma. One systematic review and three subsequent RCTs found no significant difference between intravenous magnesium sulphate and placebo for hospital admission rates.

Benefits: **Intravenous magnesium sulphate:** We found one systematic review (search date 1998, 5 RCTs in adults, 2 RCTs in children, 665 people)[105] and three subsequent RCTs.[106–108] The review found no significant difference between intravenous magnesium sulphate and placebo in hospital admission rates (OR 0.31, 95% CI 0.09 to 1.02; significant heterogeneity among trials). Prespecified subgroup analysis of adults with more severe airflow obstruction (5 RCTs, sample size not given; forced expiratory volume in 1 second [FEV_1] (see glossary, p 1991) < 30% at presentation, failure to respond to initial treatment, or failure to improve beyond 60% in FEV_1 after 1 hour) found magnesium sulphate significantly improved peak expiratory flow rate (see glossary, p 1991) and reduced rates of hospital admission compared with placebo (hospital admission rates: OR 0.10, 95% CI 0.04 to 0.27, no significant heterogeneity; P > 0.1).[105] The first subsequent RCT (33 evaluable people) found no significant difference in hospital admissions between intravenous magnesium sulphate and placebo (18% with magnesium sulphate *v* 25% with placebo; RR 0.71, 95% CI 0.19 to 2.67).[106] The second subsequent RCT (42 people with acute

asthma receiving inhaled bronchodilators and iv corticosteroids) found that intravenous magnesium sulphate significantly improved peak expiratory flow rate (PEFR) at 60 minutes compared with placebo. However, it did not reduce the proportion of people admitted to hospital (PEFR: 174 L/minute with placebo *v* 212 L/minute with magnesium sulphate; P = 0.04; hospital admission: 5/18 [28%] with magnesium sulphate *v* 5/24 [21%] with placebo; RR 1.33, 95% CI 0.45 to 3.92).[107] The third subsequent RCT (248 adults, $FEV_1 \leq 30\%$ predicted, all previously treated with methylprednisolone and nebulised salbutamol [see glossary, p 1991]) found that intravenous magnesium sulphate (2 g iv given in the emergency department) significantly improved lung function at 4 hours (mean difference in FEV_1: 4.7% predicted, 95% CI 0.3% to 9.3%; P = 0.045). However, it found no significant difference in hospital admission rates compared with placebo; hospital admission rates (39/122 [32%] with magnesium sulphate *v* 41/126 [32%] with placebo; P value not reported).[108] **Nebulised magnesium sulphate:** We found one RCT (35 people) that compared salbutamol plus 0.9% sodium chloride with salbutamol plus magnesium sulphate through a nebuliser.[109] It found that magnesium sulphate significantly increased PEFR compared with 0.9% sodium chloride (increase in PEFR after 10 minutes: 61% with magnesium sulphate *v* 31% with sodium chloride; difference 30%, 95% CI 3% to 56%; P = 0.03).

Harms: The RCTs did not specifically address harms.

Comment: Further studies are needed to clarify the role of intravenous magnesium sulphate in acute asthma. Two of the studies involved treatment with aminophylline and one with ipratropium, both of which have been found to affect hospital admission rates without affecting the degree of airflow obstruction.[110] The subgroup analysis in the systematic review and larger RCTs involved intergroup and intragroup analyses specified before the trial was conducted, and so provides reasonably strong evidence of an effect.

OPTION MECHANICAL VENTILATION FOR SEVERE ACUTE ASTHMA

We found no RCTs comparing mechanical ventilation with or without inhaled β_2 agonists versus no mechanical ventilation in people with severe acute asthma. Evidence from cohort studies support its use, although ventilation is associated with a high level of morbidity.

Benefits: **Versus no ventilation:** We found no systematic review or RCTs. **Plus inhaled β agonists versus mechanical ventilation:** We found one systematic review (search date 2001) that evaluated the role of inhaled β agonists for asthma in mechanically ventilated people.[111] It found no RCTs.

Harms: Mechanical ventilation is associated with hypotension, barotrauma, infection, and myopathy, especially when prolonged paralysis is required with muscle relaxants and systemic corticosteroids.[112] Adverse effects reported in one retrospective study of 88 episodes of mechanical ventilation were hypotension (20%), pulmonary barotrauma (14%), and arrhythmia (10%).[113]

Comment: Experience suggests that mechanical ventilation is a life saving intervention needed by a small minority of people with severe acute asthma. Cohort studies[114,115] and one case series[116] found fewer deaths with controlled hypoventilation compared with ventilation in which carbon dioxide levels were normalised (for which historical cohorts and case series have reported mortality of 7.5–23.0%).[113,117–119] Non-invasive ventilation has been used in people with acute exacerbations of chronic obstructive lung disease,[120] but requires prospective validation in people with acute asthma. Future research should also focus on delivery of bronchodilators, optimal use of muscle relaxants, and dose of corticosteroids.

OPTION SPECIALIST VERSUS GENERALIST CARE FOR ACUTE ASTHMA

One systematic review found limited evidence that specialist care improved outcomes in people with acute asthma compared with generalist care.

Benefits: We found one systematic review (search date 1995, 2 RCTs in adults and 2 RCTs in children, 10 observational studies).[121] It found limited evidence that specialist care improved outcomes compared with generalist care and that shared care (see glossary, p 1991) is as effective as usual outpatient care.[121] The first RCT of adults in the review (801 people attending a UK outpatient clinic) excluded people with severe asthma.[121] It found no significant difference between integrated care and regular outpatient care for most outcomes at 12 months (use of medication, primary care consultation, hospital admissions, restrictions on normal activity, psychological morbidity, patient satisfaction). The second RCT (245 adults admitted to emergency departments in the USA) found a significant reduction in emergency room visits at 2 weeks when educational information was provided by a nurses who themselves had asthma compared with nurses who did not have asthma.[121]

Harms: The review did not report on harms of specialist compared with generalist care.[121]

Comment: Many of the RCTs and observational studies in the systematic review were small.[121] One non-systematic review of RCTs and observational studies found that "expert based" care improved outcomes compared with general care.[122] One quasi-randomised trial (based on day of attendance) identified by the non-systematic review referred people from the emergency department either to specialist care or routine general medical follow up.[123] It found that people receiving specialist care were significantly less likely to wake at night (OR 0.24, 95% CI 0.11 to 0.52), suffer relapse requiring emergency admission by 6 months (for 1 admission RR 0.56, 95% CI 0.34 to 0.95; for 2 admissions RR 0.30, 95% CI 0.16 to 0.60), or suffer multiple relapses. They were more likely to use inhaled corticosteroids (OR 3.6, 95% CI 1.9 to 6.6) and sodium cromoglycate (RR 2.2, 95% CI 1.9 to 2.5).

OPTION EDUCATION ABOUT ACUTE ASTHMA

One systematic review and one subsequent RCT provided evidence that education to facilitate self management of asthma in adults reduced hospital admission, unscheduled visits to the doctor, and days off work compared with usual care. One subsequent RCT provided insufficient evidence about effects of asthma education on quality of life or social functioning at 6 months.

Benefits: We found one systematic review (search date 2002, 36 RCTs, 6090 people)[124] and two subsequent RCTs.[125,126] The included studies compared the following types of self management with usual care: optimal self management (including a written action plan for self management of medications for exacerbations), plus self monitoring plus regular medical review; self monitoring plus regular review; self monitoring only; regular review only; and written action plan but not optimal self management. Included studies recruited people from hospital, emergency room, outpatient clinic, general practice, and the community. It found that self management education reduced hospital admissions, emergency room visits, unscheduled visits to the doctor, days off work or school, nocturnal asthma, and quality of life (hospital admissions: RR 0.64, 95% CI 0.50 to 0.82; emergency room visits: RR 0.82, 95% CI 0.73 to 0.94; unscheduled visits to the doctor: RR 0.68, 95% CI 0.56 to 0.81; days off work or school: RR 0.79, 95% CI 0.67 to 0.93; nocturnal asthma: RR 0.67, 95% CI 0.56 to 0.79; quality of life: SMD 0.29, 95% CI 0.11 to 0.47). It found that optimal self management that included a written plan significantly reduced hospital admissions (9 RCTs; RR 0.58, 95% CI 0.43 to 0.77). It found no significant difference between self management and usual care in lung function (forced expiratory volume in 1 second [see glossary, p 1991], 7 RCTs: SMD +0.097, 95% CI −0.024 to +0.217). The first subsequent RCT (131 adults admitted to hospital with asthma).[125] It found no significant difference between an education programme (3 group sessions focused on improving self management skills) and waiting list control on 12 out of 13 scales of health and social functioning at 6 months (115 people included in analysis; scales used were SF-36 and the Asthma Quality of Life Questionnaire). The second subsequent RCT (280 adults admitted to hospital with acute asthma) compared two 30 minute education sessions plus a written action plan versus standard care.[126] It found that the educational intervention significantly reduced daytime wheeze and night disturbance 1 month after discharge (no daytime wheeze: OR 2.6, 95% CI 1.5 to 5.3; no night time disturbance: OR 2.0, 95% CI 1.2 to 3.5). However, it found no significant difference in activity limitation (no activity limitation; OR 1.5, 95% CI 0.9 to 2.7). It found that the educational intervention decreased hospital admissions at 12 months compared with usual care, but the difference was not statistically significant (admission: 17% with self management *v* 27% with usual care; OR 0.5, 95% CI 0.3 to 1.0).

Harms: The systematic review[124] and subsequent RCTs[125,126] gave no information on adverse effects.

Comment: The weight of evidence from other published RCTs and systematic overviews supports the role of asthma education among people with asthma.

GLOSSARY

Diurnal variation A characteristic of people with asthma is increased variation in peak flow rates and forced expiratory volume in 1 second during the day. The diurnal variation is sometimes expressed as the difference between maximum and minimum values expressed as a fraction of the maximum value.

Forced expiratory volume in 1 second The volume breathed out in the first second of forceful blowing into a spirometer, measured in litres.

Life threatening asthma An attack of such severity that the person usually requires management in the emergency department. Some people require endotracheal intubation and, usually in the initial stages of resuscitation, cannot inhale bronchodilator treatment.

Peak expiratory flow rate The maximum rate that gas is expired from the lungs when blowing into a peak flow meter or a spirometer. It is measured at an instant, but the units are expressed as litres a minute.

Salbutamol A short acting β_2 agonist known as albuterol in the USA.

Shared care Involves sharing care between outpatient specialist and general practitioner.

Substantive changes

Low dose inhaled corticosteroids in people with mild, persistent asthma One RCT added;[33] categorisation unchanged.

Adding long acting β_2 agonists Two RCTs added;[52,56] categorisation unchanged.

Adding leukotriene antagonists alone in people with mild to moderate, persistent asthma Four RCTs added;[64,65,72,73] categorisation unchanged but benefits data enhanced.

Leukotriene antagonists plus inhaled corticosteroids Two RCTs added;[78,79] categorisation unchanged.

Systemic corticosteroids for acute asthma One RCT added;[88] categorisation unchanged.

Oxygen supplementation for acute asthma One systematic review added;[104] categorisation unchanged.

Education about asthma One RCT added;[126] categorisation unchanged but benefits data enhanced.

Intravenous versus nebulised delivery of short acting β_2 agonists No studies added, but harms data reappraised and enhanced. Categorisation unchanged.

TABLE 1 **Classification of severity for chronic asthma (see text, p 1969).**

In the USA[1]

Asthma is classified by symptoms of severity. Using this system, even people with mild, intermittent asthma can develop severe exacerbations if exposed to appropriate stimuli.

Mild intermittent asthma	Symptoms less than weekly with normal or near normal lung function.
Mild persistent asthma	Symptoms more than weekly but less than daily with normal or near normal lung function.
Moderate persistent asthma	Daily symptoms with mild to moderate variable airflow obstruction.
Severe asthma	Daily symptoms and frequent night symptoms, and moderate to severe variable airflow obstruction.

In the UK[2]

Chronic asthma in ambulatory settings is graded according to the amount of medication required to keep symptoms controlled. People are classified according to whether, for symptom control, they need:

Step 1	Occasional β agonists for symptomatic relief.
Step 2	In addition, regular, inhaled anti-inflammatory agents (such as inhaled corticosteroids, cromoglycate, or nedocromil).
Step 3	In addition, high dose inhaled corticosteroids or low dose inhaled steroids plus long acting inhaled β_2 bronchodilator.
Step 4	In addition, high dose inhaled corticosteroids plus regular bronchodilators.
Step 5	In addition, regular oral corticosteroids.

Bronchiectasis

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Unknown effectiveness

See glossary, p 2002

Key Messages

- **Exercise or physical training** One systematic review found that inspiratory muscle training improved quality of life and exercise endurance compared with no intervention or sham training in people with non-cystic fibrosis bronchiectasis.
- **Inhaled steroids** One systematic review found insufficient evidence from two small RCTs to compare inhaled steroids versus placebo in people with bronchiectasis not due to a specific congenital disease.
- **Long acting β_2 agonists** One systematic review identified no RCTs comparing long acting β_2 agonists versus placebo or other treatments in people with non-cystic fibrosis bronchiectasis.
- **Mucolytics (bromhexine or deoxyribonuclease)** One systematic review found insufficient evidence from three RCTs to compare the effects of bromhexine or recombinant human deoxyribonuclease versus placebo in people with non-cystic fibrosis bronchiectasis.
- **Oral steroids** One systematic review found no RCTs comparing steroids versus placebo, no treatment, or any other pharmacological or non-pharmacological treatment in people with non-cystic fibrosis bronchiectasis.

DEFINITION Bronchiectasis is defined as irreversible widening of medium sized airways (bronchi) in the lung. It is characterised by inflammation, destruction of bronchial walls, and chronic bacterial infection. The condition may be limited to a single lobe or lung segment, or it may affect one or both lungs more diffusely. Clinically, the condition manifests as chronic cough and chronic overproduction of sputum (up to about 500 mL daily), which is often purulent.[1] People with severe bronchiectasis may have life threatening haemoptysis and may develop features of chronic obstructive airways disease, such as wheezing, chronic respiratory failure, pulmonary hypertension, and right sided heart failure.

INCIDENCE/ PREVALENCE We found few reliable data. Incidence has declined over the past 50 years and prevalence is low in higher income countries. Prevalence is much higher in poorer countries and is a major cause of morbidity and mortality.

AETIOLOGY/ RISK FACTORS Bronchiectasis is most commonly a long term complication of previous lower respiratory infections such as measles pneumonitis, pertussis, and tuberculosis. Foreign body inhalation and allergic, autoimmune, and chemical lung damage also predispose to the condition.[2] Underlying congenital disorders such as cystic fibrosis, cilial dysmotility syndromes, α_1 antitrypsin deficiency, and congenital immunodeficiencies may also predispose to bronchiectasis and may be of greater aetiological importance than respiratory infection in higher income countries. Cystic fibrosis is the most common congenital cause.

PROGNOSIS Bronchiectasis is a chronic condition with frequent relapses of varying severity. Long term prognosis is variable. Data on morbidity and mortality are sparse.[3] Bronchiectasis frequently coexists with other respiratory disease, making it difficult to distinguish prognosis for bronchiectasis alone.

AIMS OF INTERVENTION To alleviate symptoms; to reduce morbidity and mortality.

OUTCOMES **Primary outcomes:** Quality of life, admission to hospital, days off work, exacerbation and infection rates, haemoptysis, respiratory failure, mortality, and adverse effects of treatment. **Secondary outcomes:** Sputum volume and lung function indices. We reported secondary outcomes only if trials did not include primary outcomes.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION What are the effects of treatments in people with bronchiectasis but without cystic fibrosis?

OPTION EXERCISE OR PHYSICAL TRAINING New

One systematic review found that inspiratory muscle training improved quality of life and exercise endurance compared with no intervention or with sham training in people with non-cystic fibrosis bronchiectasis.

Bronchiectasis

Benefits: We found one systematic review (search date not reported, 2 RCTs published in abstract form only, 43 people with non-cystic fibrosis bronchiectasis).[4] We found no subsequent RCTs. Both RCTs compared inspiratory muscle training (IMT; see glossary, p 2002) versus either no intervention or sham IMT for 8 weeks. The review found that IMT significantly improved exercise endurance and quality of life compared with control (endurance [method of assessment not described]: WMD 264 m, 95% CI 16.4 m to 512 m; quality of life [measured on CRQ scale; see glossary, p 2002]: WMD 12.4, 95% CI 2.38 to 22.48). The review found no RCTs examining other clinical outcomes.

Harms: The two RCTs did not report anything about adverse effects.[4]

Comment: None.

OPTION MUCOLYTICS (BROMHEXINE AND DEOXYRIBONUCLEASE)

One systematic review found insufficient evidence from three RCTs to compare the effects of bromhexine or recombinant human deoxyribonuclease versus placebo in people with non-cystic fibrosis bronchiectasis.

Benefits: We found one systematic review in people with non-cystic fibrosis bronchiectasis (search date 2003, 3 double blind RCTs, total number of people not reported).[5] **Bromhexine:** The review identified one RCT (45 people with acute exacerbation of bronchiectasis [defined as morning cough and > 20 mL sputum]) comparing bromhexine (30 mg 3 times daily) versus placebo. It found that bromhexine significantly reduced sputum volume compared with placebo after about 2 weeks (WMD –21.5%, 95% CI –38.9% to –4.1%). The review found that bromhexine also improved some symptom scores compared with placebo, although the clinical importance of these score changes is uncertain (see comment below). **Recombinant human deoxyribonuclease (rhDNase):** The review identified two RCTs comparing rhDNase aerosol versus placebo. The first RCT (number of people not reported) found no significant difference between rhDNase (2.5 mg in 2.5 mL, once or twice daily) and placebo in lung function or infection rates (time to outcome not stated; infection rates reported for once daily dose: 4/21 [19%] with placebo *v* 0/21 [0%] with rhDNase; P > 0.1; no further numerical data reported). The second RCT also found similar exacerbation rates between rhDNase (twice daily for 24 weeks) and placebo (AR for exacerbation in 168 days: 0.66 with rhDNase *v* 0.56 with placebo; RR 1.17; CI not reported).

Harms: **Bromhexine:** The review did not report on harms.[5] **Recombinant human deoxyribonuclease:** In one included RCT, more people had influenza type symptoms with rhDNase (5 mg daily) than with placebo (4 people with rhDNase *v* 0 with placebo).[5] Other adverse effects were not specifically reported.

Comment: One included RCT found that bromhexine significantly improved symptom scores compared with placebo for "difficulty with expectoration", "cough", and "quality of sputum" after about 2 weeks.[5] The clinical importance of effects on these scores are uncertain.

OPTION INHALED STEROIDS

One systematic review found insufficient evidence from two small RCTs about the effects of inhaled steroids compared with placebo in people with bronchiectasis not due to a congenital disease.

Benefits: We found one systematic review (search date 2001, 2 double blind RCTs, 54 people with bronchiectasis not due to congenital disease or focal airway obstruction).[6] The included RCTs compared inhaled steroids (beclomethasone 1500 μg daily or fluticasone 1000 μg daily) versus placebo. The review found no significant difference between inhaled steroids and placebo in symptom scores (75 mm visual analogue scale for steroids *v* placebo: mean improvement in cough score +5 mm, 95% CI −28 to +38 mm; mean improvement in dyspnoea score +4 mm, 95% CI −33 to +41 mm), lung function indices (improvement in forced expiratory volume in 1 second: +0.4 L/minute, 95% CI −2.2 L/minute to +1.0 L/minute; improvement in forced vital capacity: +0.6 L, 95% CI −0.1 to +1.3 L), or sputum volume (reduction in sputum volume: +0.2 mL daily, 95% CI −0.4 mL daily to +0.7 mL daily) after 4–6 weeks. The review reported that the RCTs lacked power to exclude clinically important effects.

Harms: The review gave no information on harms.[6]

Comment: None.

OPTION ORAL STEROIDS

One systematic review found no RCTs comparing steroids versus placebo, no treatment, or any other pharmacological or non-pharmacological treatment in people with non-cystic fibrosis bronchiectasis.

Benefits: We found one systematic review (search date 2002), which identified no RCTs in people with bronchiectasis without cystic fibrosis.[7] We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION LONG ACTING β_2 AGONISTS

One systematic review identified no RCTs comparing long acting β_2 agonists versus placebo or other treatments in people with non-cystic fibrosis bronchiectasis.

Benefits: We found one systematic review (search date 2002), which identified no RCTs in people with bronchiectasis without cystic fibrosis.[8] We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Inspiratory muscle training (IMT) People are required to breathe through inspiratory orifices of progressively decreasing diameter, with the goal of increasing the load on the respiratory muscles. Another way is to use a threshold loading device that permits inspiration to commence only after a certain threshold mouth pressure is reached. The threshold pressure can be set by means of a weighted plunger. In most programmes, subjects have to train 30 minutes a day, for 5 days a week.

Chronic Respiratory (Disease) Questionnaire (CRQ) A 20 item questionnaire dealing with dimensions of dyspnoea, fatigue, patients' sense of control over disease (mastery), and emotional dysfunction. A trained interviewer needs 20 minutes to complete it. Answers are scored on a seven point scale ranging from 1, which indicates maximum impairment, to 7, which indicates no impairment.

Chronic obstructive pulmonary disease

Key Messages

Maintenance drug

- We found no evidence about effects of most interventions on progression of chronic obstructive pulmonary disease (measured by decline in lung function). However, we found good evidence from RCTs that inhaled corticosteroids do not prevent decline in lung function.
- **Inhaled anticholinergics (improve exacerbation rate, symptoms, and forced expiratory volume in 1 second)** RCTs have found that inhaled anticholinergics improve forced expiratory volume in 1 second (FEV_1), exercise capacity, and symptoms compared with placebo. One large RCT found that adding ipratropium to a smoking cessation programme had no significant impact on decline in FEV_1 over 5 years. RCTs found that inhaled tiotropium (a long acting anticholinergic drug) reduced exacerbation rates compared with placebo or ipratropium.
- **Inhaled anticholinergics plus β_2 agonists (improve forced expiratory volume in 1 second more than either drug alone)** RCTs have found that combining a β_2 agonist with an anticholinergic drug for 2–12 weeks modestly but significantly improves FEV_1 compared with either drug alone. One RCT found that, when combined with an anticholinergic drug, a long acting β_2 agonist improved FEV_1 second and peak expiratory flow rate significantly more than a short acting β_2 agonist. We found no RCTs of long term treatment comparing anticholinergics plus β_2 agonists with placebo.
- **Inhaled β_2 agonists (improve symptoms and forced expiratory volume in 1 second)** RCTs have found that inhaled β_2 agonists for 1 week to 12 months improve FEV_1 and improve symptoms compared with placebo. One RCT found that long acting inhaled β_2 agonists reduced exacerbation rates compared with placebo, although two other RCTs did not find a significant difference in exacerbation rates.
- **Inhaled corticosteroids plus long acting β_2 agonists (improve exacerbation rate, symptoms, quality of life, forced expiratory volume in 1 second)** RCTs have found that the combination of an inhaled corticosteroid plus a long acting β_2 agonist in one inhaler reduced exacerbation rates and improved lung function, symptoms, and health related quality of life compared with placebo. In general, the combination was more effective than inhaled corticosteroid alone or long acting β_2 agonist alone, although this difference was not significant for all outcomes.
- **Inhaled anticholinergics versus β_2 agonists (improve forced expiratory volume in 1 second compared with β_2 agonists)** RCTs have found that 3 months of a short acting inhaled anticholinergic improved FEV_1 compared with short acting β_2 agonists. RCTs have found inconsistent evidence about effects of short acting inhaled anticholinergics compared with long acting β_2 agonists for up to 3 months. Two RCTs found that 6 months of a long acting inhaled anticholinergic significantly improved FEV_1 compared with a long acting inhaled β_2 agonist.
- **Long term domiciliary oxygen (beneficial in people with severe hypoxaemia)** One RCT in people with severe daytime hypoxaemia found that domiciliary oxygen improved survival compared with no domiciliary oxygen. A second RCT in people with severe hypoxaemia found that continuous oxygen reduced mortality compared with nocturnal oxygen. Three RCTs in people with milder hypoxaemia or with nocturnal hypoxaemia only, found no significant difference in mortality between long term domiciliary oxygen and no oxygen.

- **Mucolytics (improve exacerbation rate)** Two systematic reviews found that mucolytics for 3–24 months may reduce the frequency and duration of exacerbations in people with chronic bronchitis compared with placebo. However, it is not clear whether these effects are generalisable to people with chronic obstructive pulmonary disease.
- **Inhaled corticosteroids (improve exacerbation rates, but may have long term harms)** RCTs have found no significant difference between inhaled corticosteroids and placebo in lung function (FEV_1) over 10 days to 10 weeks. However, one systematic review and subsequent RCTs lasting at least 6 months suggested that inhaled steroids increased FEV_1 during the first 3–6 months of use, although we found evidence of no effect on subsequent decline in lung function. One systematic review and subsequent RCTs found that long term inhaled steroids reduced the frequency of exacerbations compared with placebo. Long term inhaled steroids may predispose to adverse effects, including skin bruising, and oral candidiasis.
- **Theophyllines** One systematic review has found that theophyllines slightly improve FEV_1 compared with placebo after 3 months. One large RCT found that theophyllines improved FEV_1 compared with placebo after 12 months' treatment. The usefulness of these drugs is limited by adverse effects and the need for frequent monitoring of blood concentrations.
- **α_1 Antitrypsin infusion** One RCT in people with α_1 antitrypsin deficiency and moderate emphysema found no significant difference between α_1 antitrypsin infusion and placebo in the decline in FEV_1 after 1 year.
- **Deoxyribonuclease** We found no RCTs comparing the long term effects of deoxyribonuclease with placebo.
- **Prophylactic antibiotics** One systematic review found limited evidence of a small reduction in exacerbation rates and days with disability with prophylactic antibiotics. These benefits probably do not outweigh the harms of antibiotics, especially the development of antibiotic resistance. All the identified RCTs were conducted more than 30 years ago, and the results are unlikely to apply to current practice.
- **Oral corticosteroids (evidence of harm but no evidence of long term benefits)** We found no RCTs on long term benefits. One systematic review has found that oral corticosteroids for 2–4 weeks improve FEV_1 compared with placebo. Long term systemic corticosteroids are associated with serious adverse effects, including osteoporosis and diabetes.
- **Oral versus inhaled corticosteroids (evidence of harm but no evidence of long term benefits)** Three RCTs provided insufficient evidence about effects of oral compared with inhaled corticosteroids over 2 weeks. We found no RCTs of long term treatment with oral compared with inhaled corticosteroids. Long term oral corticosteroids are associated with serious adverse effects, including osteoporosis and diabetes.

Smoking cessation interventions

- **Psychosocial plus pharmacological interventions** One large RCT in people with mild chronic obstructive pulmonary disease found that nicotine gum plus a psychosocial smoking cessation and abstinence maintenance programme (with or without ipratropium) slowed the decline of FEV_1, and reduced respiratory symptoms and lower respiratory illnesses, but increased weight gain compared with usual care (without psychosocial intervention). The RCT found no significant difference between treatments in all cause mortality at 5 years.
- **Pharmacological interventions alone** One systematic review found no RCTs in people with chronic obstructive pulmonary disease.

Chronic obstructive pulmonary disease

- **Psychosocial interventions alone** We found no systematic reviews or RCTs in people with chronic obstructive pulmonary disease.

DEFINITION

Chronic obstructive pulmonary disease is characterised by chronic bronchitis or emphysema. Emphysema is abnormal permanent enlargement of the air spaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis. Chronic bronchitis is chronic cough or mucus production for at least 3 months in at least 2 successive years when other causes of chronic cough have been excluded.[1]

INCIDENCE/ PREVALENCE

Chronic obstructive pulmonary disease mainly affects middle aged and elderly people. In 1998, the World Health Organization estimated that chronic obstructive pulmonary disease was the fifth most common cause of death worldwide, responsible for 4.2% of all mortality (estimated 2 249 000 deaths in 1998).[2] Both morbidity and mortality are rising. Estimated prevalence in the USA has risen by 41% since 1982, and age adjusted death rates rose by 71% between 1966 and 1985. All cause age adjusted mortality declined over the same period by 22% and mortality from cardiovascular diseases by 45%.[1] In the UK, physician diagnosed prevalence was 2% in men and 1% in women between 1990 and 1997.[3]

AETIOLOGY/ RISK FACTORS

Chronic obstructive pulmonary disease is largely preventable. The main cause is exposure to cigarette smoke. The disease is rare in lifelong non-smokers (estimated incidence 5% in 3 large representative US surveys from 1971–1984), in whom "passive" exposure to environmental tobacco smoke has been proposed as a cause.[4,5] Other proposed causes include airway hyperresponsiveness, air pollution, and allergy.[6–8]

PROGNOSIS

Airway obstruction is usually progressive in those who continue to smoke, resulting in early disability and shortened survival. Smoking cessation reverts the rate of decline in lung function to that of non-smokers.[9] Many people will need medication for the rest of their lives, with increased doses and additional drugs during exacerbations.

AIMS OF INTERVENTION

To alleviate symptoms; to prevent exacerbations; to preserve optimal lung function; and to improve activities of daily living, quality of life, and survival.[10]

OUTCOMES

Short and long term changes in lung function, including changes in forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026); exercise tolerance; peak expiratory flow rate (see glossary, p 2026); frequency, severity, and duration of exacerbations; symptom scores for dyspnoea; quality of life; and survival. Symptom and quality of life scores include the St George's Respiratory Questionnaire, which is rated on a scale from 0 to 100 (a 4 point change is considered clinically important); the Transitional Dyspnoea Index, which is rated from –9 to +9 (a 1 point change is considered clinically important), and the Chronic Respiratory Disease Questionnaire, which is rated from 1 to 7 (a 0.5 point change is considered clinically important).

QUESTION **What are the effects of maintenance treatment in stable chronic obstructive pulmonary disorder?**

OPTION INHALED ANTICHOLINERGICS

RCTs have found that inhaled anticholinergics improve forced expiratory volume in 1 second, exercise capacity, and symptoms compared with placebo. One large RCT found that adding ipratropium to a smoking cessation programme had no significant impact on decline in forced expiratory volume in 1 second over 5 years. RCTs found that inhaled tiotropium (a long acting anticholinergic drug) reduced exacerbation rates compared with placebo or ipratropium.

Benefits:

Short term short acting anticholinergics: We found no systematic review that assessed effects on lung function. We found many small placebo controlled RCTs. Most found a significant effect in favour of ipratropium.[11–14] We found four larger RCTs comparing ipratropium versus placebo[15–18] and one systematic review comparing any anticholinergic drug versus placebo.[19] The first two of these RCTs (276 people[15] and 405 people[16]) compared ipratropium (36 μg 4 times daily) versus placebo and salmeterol for 12 weeks. In both RCTs, ipratropium significantly improved baseline forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) compared with placebo (results presented graphically). The third RCT (780 people) compared ipratropium (40 μg 4 times daily) versus placebo and versus formoterol (formoterol) for 12 weeks.[17] It found that ipratropium significantly improved FEV_1 compared with placebo (improvement in average FEV_1 over 12 hours after medication 137 mL, 95% CI 88 mL to 186 mL). It found no significant difference in morning premedication peak expiratory flow rate (see glossary, p 2026), symptoms, quality of life scores, or need for rescue bronchodilators. The fourth RCT (183 people with moderate to severe chronic obstructive pulmonary disease [COPD], mean FEV_1 40% of predicted, mean age 64 years) compared three treatments: ipratropium (80 μg 3 times daily), formoterol (18 μg twice daily), and placebo.[18] It found no significant difference between ipratropium and placebo in shuttle walking distance at 12 weeks (mean increase from baseline: 15.3 m with ipratropium *v* 6.1 m with placebo; P not reported, baseline mean distance 325 m). The systematic review (search date 1999) assessed changes in exercise capacity with anticholinergic drugs versus placebo.[19] Meta-analysis was not performed because of heterogeneity in design and outcomes among studies. Sixteen of the 17 RCTs found that anticholinergic drugs improved exercise capacity compared with placebo. **Short term long acting anticholinergics:** We found three RCTs comapring the effects on lung function of tiotropium (a long acting anticholinergic, 18 μg/day) versus placebo or versus ipratropium.[20–22] The first RCT (169 people) compared tiotropium versus placebo for 4 weeks. It found that tiotropium significantly improved FEV_1 during the first 6 hours after treatment compared with placebo and significantly increased trough FEV_1 24 hours after the last dose (mean improvement in post-dose FEV_1: +0.13 L with tiotropium *v* –0.02 L with placebo; $P < 0.05$; mean trough FEV_1: +0.07 L with tiotropium *v* –0.03 L

with placebo, CI not reported; $P < 0.05$).[20] The second RCT (478 people) compared tiotropium versus placebo for 92 days. It found that tiotropium significantly improved FEV_1 during the first 3 hours after treatment ($P < 0.001$), increased the peak response (CI not reported; $P < 0.001$; results presented graphically), and improved symptoms.[21] The third RCT (288 people, average age 65 years) compared tiotropium (18 μg/day) versus ipratropium (40 μg 4 times daily) for 13 weeks.[22] It found that tiotropium significantly increased post-dose FEV_1 and significantly increased mean trough FEV_1 compared with ipratropium (mean FEV_1 6 hours after treatment on first day: 0.24 L with tiotropium *v* 0.18 L with ipratropium; difference 0.06 L, 95% CI 0.02 L to 0.09 L; trough FEV_1: 0.15 L *v* 0.01 L with ipratropium; difference 0.13 L, 95% CI 0.09 L to 0.18 L). **Long term treatment with ipratropium or tiotropium:** We found five RCTs (4 publications).[9,23–25] The first RCT (5887 smokers aged 35–60 years with spirometric signs of early COPD; FEV_1 75% predicted) compared three interventions over a 5 year period: an intensive 12 session smoking cessation programme combining behaviour modification and use of nicotine gum; the same smoking intervention programme plus ipratropium three times daily; or usual care.[9] Although decline in FEV_1 was significantly slower in people in both smoking cessation groups compared with usual care, adding ipratropium had no significant effect (5 year mean cumulative decline in FEV_1 before bronchodilator: usual care 249 mL, 95% CI 236 mL to 262 mL; smoking programme plus ipratropium 188 mL, 95% CI 175 mL to 200 mL; smoking programme plus placebo 172 mL, 95% CI 159 mL to 185 mL). The second RCT (921 people) compared tiotropium (18 μg/day) versus placebo for 1 year.[23] It found that tiotropium significantly improved mean trough FEV_1 compared with placebo 3 and 24 hours after dosing (mean improvement compared with placebo at 3 hours: 140–220 mL; P value not reported; at 24 hours: 120–150 mL; $P < 0.01$). It also found that tiotropium significantly reduced exacerbations and hospital admissions compared with placebo (exacerbations per patient year: 0.76 with tiotropium *v* 0.95 with placebo; $P < 0.05$; admission to hospital for COPD exacerbation: 5.5% with tiotropium *v* 9.4% with placebo; $P < 0.05$).[23] The third RCT found that 1 year of tiotropium (18 μg/day) significantly improved trough FEV_1 and health related quality of life and reduced exacerbations compared with ipratropium (40 μg 4 times daily) at 1 year (improvement in FEV_1 with tiotropium *v* ipratropium: 150 mL; $P < 0.001$; quality of life: AR for 4 unit improvement in the St George's Respiratory Questionnaire 52% with tiotropium *v* 35% with ipratropium; $P = 0.001$; exacerbations in 1 year: 0.73 with ipratropium *v* 0.96 with ipratropium per patient year; $P = 0.006$).[24] It found no significant difference between tiotropium and ipratropium in admissions for COPD exacerbation at 1 year (7.3% with tiotropium *v* 11.7% with ipratropium; $P = 0.11$).[24] The fourth and fifth RCTs were combined in a single report (total of 1207 people, mean age 64 years, mean baseline FEV_1 from 1.07 to 1.12 L across treatment groups) that compared three treatments over 6 months: tiotropium 18 μg once daily; salmeterol 50 μg twice daily; and placebo.[25] The RCTs found that tiotropium significantly increased predose FEV_1 and quality of life and reduced exacerbations compared with placebo, but found

no significant difference between treatments in hospitalisations for exacerbations (increase in FEV_1 compared with placebo: 0.12 L with triotropium; $P < 0.01$; improvement in St George's Respiratory Questionnaire: 4.2 with triotropium *v* 1.5 with placebo; $P < 0.05$; exacerbations per person per year: 1.07 with triotropium *v* 1.49 with placebo; $P < 0.05$; hospitalisations per person per year: 0.15 with tiotropium *v* 0.10 with placebo; P not reported).

Harms: One RCT (233 people with asthma or COPD) found that continuous treatment with bronchodilators (ipratropium plus fenoterol) caused a significantly faster decline in lung function than as needed treatment (144 people, –0.07 L/year with continuous treatment *v* –0.02 L/year with as needed treatment; $P < 0.05$, CI not reported).[26] One RCT comparing ipratropium with placebo found similar rates of adverse events between treatment groups.[18] **Long term treatment with ipratropium or tiotropium:** The first RCT of long term treatment found no significant difference between ipratropium and placebo in serious adverse events (cardiac symptoms, hypertension, skin rashes, and urinary retention: 1.2% with ipratropium *v* 0.8% with placebo), and dry mouth was the most common mild adverse effect.[9] The long term RCT comparing tiotropium versus placebo found similar rates of adverse effects, except for dry mouth (16.0 % with tiotropium *v* 2.7 % with placebo; $P < 0.05$).[23] One RCT found dry mouth was significantly more common with tiotropium compared with ipratropium (12.1% with tiotropium *v* 6.1% with ipratropium; $P < 0.05$).[24] The report of two RCTs found that tiotropium significantly increased dryness of the mouth compared with placebo (8.2% *v* 2.3%; P not reported).[25]

Comment: RCTs of long term treatment found no evidence that people developed tachyphylaxis in response to the bronchodilating effect of ipratropium or tiotropium over a 1–5 year period.[9,23]

OPTION INHALED β_2 AGONISTS

RCTs have found that inhaled β_2 agonists for 1 week to 12 months improve forced expiratory volume in 1 second and improve symptoms compared with placebo. One RCT found that long acting inhaled β_2 agonists reduced exacerbation rates compared with placebo, although two other RCTs found no significant difference in exacerbation rates.

Benefits: **Short term treatment with short acting β_2 agonists:** We found one systematic review (search date 2002, 9 crossover RCTs, 264 people with stable chronic obstructive pulmonary disease [COPD]) comparing short acting β_2 agonists versus placebo for at least 1 week.[27] It found that β_2 agonists delivered by metered dose inhaler slightly but significantly increased forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) compared with placebo (WMD 0.14 L, 95% CI 0.04 L to 0.25 L), and significantly improved daily breathlessness score (results reported as SMD; $P < 0.001$). There was no significant difference between treatments in exercise tolerance (4 RCTs), although the trials were small and the results were heterogeneous. **Short term treatment with long acting β_2 agonists:** We found one systematic review (search date 2001, 8 RCTs of salmeterol, duration 4–16 weeks, 979 people)[28] and five

subsequent RCTs.[16–18,29,30] The review found no significant difference between salmeterol and placebo in FEV_1 (4 RCTs, 717 people; SMD +0.14 L, 95% CI −0.16 L to +0.44 L; see comment below).[28] Other outcomes could not be pooled. The first subsequent RCT (478 people) found that salmeterol (42 μg twice daily) significantly increased FEV_1 throughout the 12 week study period compared with placebo, but results were only presented graphically.[16] The second subsequent RCT (780 people) compared formoterol (12 μg *v* 24 μg twice daily) versus placebo and versus ipratropium for 12 weeks.[17] It found that both doses of formoterol significantly improved FEV_1 compared with placebo (improvement in average FEV_1 over 12 hours after medication with 12 μg formoterol *v* placebo: 223 mL, 95% CI 174 mL to 273 mL; 24 μg formoterol *v* placebo: 194 mL, 95% CI 145 mL to 243 mL). It also found that 12 or 24 μg formoterol significantly improved quality of life compared with placebo (improvement in total score on St George's Respiratory Questionnaire with 12 μg formoterol *v* placebo: 5; $P < 0.001$; with 24 μg formoterol *v* placebo: about 3–4, difference presented graphically; $P = 0.009$). The third subsequent RCT (692 people) compared formoterol (4.5, 9, or 18 μg twice daily) versus placebo for 12 weeks.[29] It found that all doses of formoterol significantly increased FEV_1 compared with placebo (results presented graphically). There was no dose–response effect for FEV_1. The RCT found that the two higher doses of formoterol significantly increased symptom free days compared with placebo (percentage increase in symptom free days compared with placebo +1.4%, 95% CI −2.7% to +5.4% with 4.5 μg formoterol; 4.7%, 95% CI 0.6% to 8.8% with 9 μg formoterol; and 5.7%, 95% CI 1.6% to 9.7% with 18 μg formoterol).[29] The fourth subsequent RCT (34 people, crossover design) compared the effects of three interventions on exercise capacity: formoterol (4.5, 9, or 18 μg twice daily); ipratropium (80 μg 3 times daily); or placebo for 1 week.[30] It found that formoterol or ipratropium slightly but significantly increased time to exhaustion compared with placebo (10.94 minutes with 4.5 μg formoterol; $P < 0.0001$; 10.78 minutes with 9 μg formoterol; $P < 0.01$; 10.59 minutes with 18 μg formoterol; $P < 0.05$; 10.98 minutes with ipratropium; $P < 0.0001$; 10.20 minutes with placebo).[30] The fifth subsequent RCT (183 people with moderate to severe COPD) compared three treatments: formoterol (18 μg twice daily), ipratropium, and placebo.[18] It found no significant difference between formoterol and placebo in the shuttle walking test after 12 weeks' treatment (increase from baseline: 20.4 m with formoterol *v* 6.0 m with placebo; P not reported, baseline mean distance 325 m). **Long term treatment with β_2 agonists:** We found no systematic review of long term treatment with short or long acting β_2 agonists versus placebo. We found six RCTs (5 publications).[25,31–34] The first RCT (623 people) compared salmeterol (50 μg twice daily) versus tiotropium and versus placebo for 6 months.[31] It found that salmeterol significantly improved mean predose morning FEV_1 and average FEV_1 (0–12 hours after dose) compared with placebo (mean improvement in mean predose morning FEV_1 0.085 L; $P < 0.0001$; mean improvement in average FEV_1 0.138 L; $P < 0.0001$). However, the RCT found no significant improvement in symptom score (transition dyspnoea index) or health related

quality of life score (St. George's respiratory questionnaire) compared with placebo. A second article combined results from two RCTs (1207 people) that compared salmeterol (50 μg twice daily); tiotropium (18 μg once daily), and placebo over 24 weeks.[25] It found that salmeterol significantly improved predose FEV_1 compared with placebo (difference: 90 mL; $P < 0.01$). It found no significant difference between treatments in exacerbation rate or quality of life (exacerbations: 1.23 per person per year with salmeterol *v* 1.49 with placebo; P not reported; improvement in St Georges Respiratory Questionnaire: 2.8 with salmeterol *v* 1.5 with placebo; P not reported). The fourth and fifth RCTs compared the same four treatments twice daily: salmeterol 50 μg alone; salmeterol plus fluticasone 500 μg; fluticasone alone; and placebo.[32,33] The fourth RCT (691 people) found that salmeterol significantly increased predose and post-dose FEV_1 compared with placebo at 24 weeks (predose increase: 92 mL; $P < 0.05$; post-dose increase: 191 mL; $P < 0.01$).[32] There was no significant difference between salmeterol and placebo in dyspnoea or quality of life (difference in Transitional Dyspnoea Index: 0.5; Chronic Respiratory Disease Questionnaire: 3.8; P not reported). The fifth RCT (1465 people) found that salmeterol significantly improved predose FEV_1 and significantly reduced the exacerbation rate at 1 year compared with placebo (FEV_1: 1323 mL with salmeterol *v* 1264 mL with placebo; $P < 0.0001$; exacerbation rate: 1.04 per person per year with salmeterol *v* 1.30 with placebo; $P = 0.0003$).[33] It found no significant difference between treatments in quality of life (St George's Respiratory Questionnaire score: 45.2 with salmeterol *v* 46.3 with placebo; P not reported). The sixth RCT (812 people, FEV_1 36% of predicted) compared four treatments twice daily for 1 year: formoterol 12 μg alone; formoterol plus budesonide; budesonide alone; and placebo.[34] It found that formoterol significantly increased post-dose FEV_1 compared with placebo, but found no significant difference in severe exacerbations (increase in FEV_1: 14%, 95% CI 10% to 18%; reduction in exacerbations: 25%, 95% CI −26% to +23%).

Harms:

In people with asthma, β_2 agonists have been linked to increased risk of death, worsened control of asthma, and deterioration in lung function.[35] One crossover RCT (53 people with COPD, $FEV_1 < 70\%$ predicted) compared regular versus as needed treatment with the short acting inhaled β_2 agonist salbutamol for 3 months.[36] It found that regular salbutamol doubled the total daily amount of salbutamol used compared with as needed (13 puffs/day [of which 8 puffs were the allocated regular dose] *v* 6 puffs/day with as needed treatment; significance not reported), with no significant difference in symptoms or lung function. The most common immediate adverse effect is tremor, which is usually worse in the first few days of treatment. High doses of β_2 agonists can reduce plasma potassium, cause dysrhythmia, and reduce arterial oxygen tension.[37] The risk of adverse events may be higher in people with pre-existing cardiac arrhythmias and hypoxaemia.[38] The RCTs comparing salmeterol or formoterol with placebo found no increase in adverse effects.[15,16,18,25,32–34]

Comment: Many people report improvement in symptoms with bronchodilators that is not reflected by a change in FEV_1. Although the systematic review on long acting β_2 agonists showed no significant improvement in FEV_1,[28] two of the four included RCTs (412 people and 97 people) found significant effects, as did the three large subsequent RCTs. Additionally, the generalisability of the systematic review may be limited because RCTs were selected only if they excluded people with 15% or more airflow reversibility to a short acting β_2 agonist, whereas long term studies have found that up to two thirds of people with COPD have at least 15% reversibility with β_2 agonists.[1,39]

OPTION INHALED ANTICHOLINERGICS PLUS β_2 AGONISTS

RCTs have found that combining a β_2 agonist with an anticholinergic drug for 2–12 weeks modestly improves forced expiratory volume in 1 second compared with either drug alone. One RCT found that, when combined with an anticholinergic drug, a long acting β_2 agonist improved forced expiratory volume in 1 second and peak expiratory flow rate more than a short acting β_2 agonist. We found no RCTs of long term treatment with anticholinergics plus β_2 agonists compared with placebo.

Benefits: We found no systematic review. **Short term treatment with anticholinergics plus short acting inhaled β_2 agonists:** We found six RCTs (705, 195, 652, 863, and 357 people with stable chronic obstructive pulmonary disease; 1 report combined the results from 2 RCTs) comparing the addition of ipratropium versus no additional ipratropium in people using standard dose short acting inhaled β_2 agonists for 2 weeks to 3 months.[40–44] All found significant improvements in forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) of about 25% with the combination compared with either drug alone. **Short term treatment with anticholinergics plus long acting inhaled β_2 agonists:** One RCT (94 people) compared the long acting β_2 agonist salmeterol (50 μg twice daily) plus ipratropium (40 μg 4 times daily) versus salmeterol alone (50 μg twice daily) for 12 weeks.[45] It found that the combination significantly improved FEV_1 compared with the β_2 agonist alone (mean improvement as a percentage of predicted FEV_1: 8% with combination *v* 5% with β_2 agonist alone, CI not reported; $P < 0.01$), and evening but not morning peak expiratory flow rate (see glossary, p 2026). It found no significant difference in daytime or night time symptoms.[46] **Short term treatment with anticholinergics plus long acting β_2 agonists versus anticholinergics plus short acting β_2 agonists:** One crossover RCT (172 people) compared ipratropium (40 μg 4 times daily) plus formoterol (12 μg twice daily) versus ipratropium (40 μg 4 times daily) plus salbutamol (200 μg 4 times daily).[47] It found that formoterol plus ipratropium significantly improved FEV_1 and peak expiratory flow rate from baseline after 3 weeks of treatment compared with salbutamol plus ipratropium (improvement in mean morning peak expiratory flow rate from baseline over the previous 7 days with formoterol 12 L/minute, 95% CI 6 L/minute to 19 L/

minute; improvement in premedication FEV_1 from baseline 116 mL, 95% CI 83 mL to 150 mL). **Long term treatment with anticholinergics plus inhaled β_2 agonists:** We found no RCTs of long term treatment with anticholinergics plus β_2 agonists compared with placebo.

Harms: The RCTs found no significant differences in adverse effects between treatments.[40–47]

Comment: None.

OPTION INHALED ANTICHOLINERGICS VERSUS β_2 AGONISTS

RCTs have found that 3 months of a short acting inhaled anticholinergic improved forced expiratory volume in 1 second compared with short acting β_2 agonists. RCTs have found inconsistent evidence about the effects of short acting inhaled anticholinergics compared with long acting β_2 agonists for up to 3 months. Two RCTs found that 6 months of a long acting inhaled anticholinergic significantly improved forced expiratory volume in 1 second compared with a long acting inhaled β_2 agonist.

Benefits: We found no systematic review. **Short term treatment:** We found one non-systematic review (7 RCTs, 1445 people) and three subsequent RCTs comparing ipratropium versus different short acting β_2 agonists for 90 days.[15–17,48] The RCTs in the non-systematic review performed lung function measurements after withholding bronchodilators for at least 12 hours. The review found that ipratropium significantly improved mean forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) compared with β_2 agonists and placebo (28 mL increase with ipratropium *v* 1 mL decrease with β_2 agonist, CI not reported; $P < 0.05$). The first two subsequent RCTs compared ipratropium (36 μg 4 times daily) versus salmeterol (42 μg twice daily).[15,16] The first RCT (411 people) found that salmeterol significantly improved average FEV_1 at 4 and 8 weeks compared with ipratropium (CI not reported; $P < 0.005$), but not immediately after treatment or at 12 weeks.[15] The second RCT (405 people) found no significant difference in FEV_1 between treatments at any time.[16] The third RCT (780 people) compared three treatments: ipratropium, formoterol (12 μg *v* 24 μg twice daily), or placebo for 12 weeks.[17] It found that both doses of formoterol significantly improved FEV_1 compared with ipratropium (improvement in average FEV_1 over 12 hours after medication with 12 μg formoterol *v* with ipratropium: 86 mL, 95% CI 37 mL to 136 mL; with 24 μg formoterol *v* ipratropium: 57 mL, 95% CI 7 mL to 106 mL). Lower dose, but not higher dose, formoterol improved quality of life scores compared with ipratropium (improvement in total score on St George's Respiratory Questionnaire with 12 μg formoterol 3.79; $P < 0.001$; with 24 μg formoterol about 2, difference presented graphically; $P = 0.102$). **Long term treatment:** We found no systematic review comparing long term treatment with anticholinergics versus β_2 agonists. We found two RCTs comparing the same three treatments over 6 months: tiotropium (18 μg/day); salmeterol (50 μg twice daily); or placebo for 6 months.[25,31] The first RCT (total of 623 people) found that tiotropium significantly improved mean predose morning FEV_1, average FEV_1, and health

related quality of life compared with salmeterol (improvement in mean predose morning FEV_1 0.14 L with tiotropium *v* 0.09 L with salmeterol; $P < 0.01$; average FEV_1 [0–12 hours after the dose] 0.08 L greater with tiotropium; $P < 0.001$; AR for 4 unit improvement in health related quality of life [St George's Respiratory questionnaire] 51% with tiotropium *v* 40% with salmeterol; $P < 0.05$). The second RCT (1207 people) found that tiotropium led to a small but significant increase in predose FEV_1 compared with salmeterol (increase in predose FEV_1: 120 mL with tiopropium *v* 90 mL with salmeterol; $P < 0.05$).[25] It found no significant difference between the two active treatments in exacerbation rates, hospitalisations, or quality of life (exacerbations: 1.07 per person per year with triotropium *v* 1.23 with salmeterol; $P = 0.22$; hospitalisation: 0.43 per person per year with iprotropium *v* 0.65 with salmeterol; increase in St George's Respiratory Questionnaire: 4.2 with triotropium *v* 2.8 with salmeterol; P not reported).

Harms: Adverse effects such as tremor and dysrhythmia associated with β_2 agonists seem to be more frequent than the adverse effects associated with anticholinergics, although the review provided no evidence for this.[48] The RCTs comparing salmeterol with ipratropium found no significant difference in the frequency of adverse effects.[15,16] In the first RCT of long term treatment, dry mouth was more frequent with tiotropium than with salmeterol or placebo (experienced by 10% with tiotropium, no further data reported).[31] The second RCT of long term treatment also found that tiotropium significantly increased dryness of the mouth compared with salmeterol (8.2% *v* 1.7%; P not reported).[25] It found no significant difference between the treatments in other adverse effects.

Comment: It has been suggested that older people experience a greater bronchodilator response with anticholinergic drugs than with β_2 agonists, but we found no evidence for this.

OPTION THEOPHYLLINES

One systematic review has found that theophyllines slightly improve forced expiratory flow in 1 second compared with placebo after 3 months. One large RCT found that theophyllines improved forced expiratory flow in 1 second compared with placebo after 12 months' treatment. The usefulness of these drugs is limited by adverse effects and the need for frequent monitoring of blood concentrations.

Benefits: **Short term treatment:** We found one systematic review (search date 2002, 20 small RCTs, 442 people) comparing theophyllines versus placebo for 1 week to 3 months.[49] It found that theophyllines slightly but significantly improved forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) compared with placebo (WMD 100 mL, 95% CI 40 mL to 160 mL). It found no significant difference in maximum walking distance (results presented as SMD).[49] **Long term treatment:** We found one RCT (854 people) comparing three treatments: open label theophylline, double blinded formoterol (12 or 24 μg twice daily), or placebo for 12 months.[50] It found that theophylline significantly improved FEV_1 compared with placebo (mean difference in FEV_1 with theophylline *v* placebo +120 mL, CI not reported; $P < 0.001$).

Harms: The RCTs identified by the review did not report adverse effects.[51] The therapeutic range for theophyllines is small, with blood concentrations of 10–15 mg/L required for optimal effects. Well documented adverse effects include nausea, diarrhoea, headache, irritability, seizures, and cardiac arrhythmias. These may occur within the therapeutic range.[52] One RCT found that people receiving theophylline were twice as likely to discontinue treatment compared with those taking placebo ($P < 0.002$).[50] Nausea was the most frequent adverse effect.

Comment: None.

OPTION ORAL CORTICOSTEROIDS

One systematic review of short term RCTs (usually 2–4 weeks' treatment) has found that oral corticosteroids improve forced expiratory flow in 1 second compared with placebo. We found no RCT of the effects of long term treatment with oral corticosteroids on lung function. Systemic corticosteroids are associated with serious adverse effects, including osteoporosis and induction of diabetes.

Benefits: **Short term treatment:** We found one systematic review (search date 1989, 10 RCTs, 445 people), which compared oral corticosteroids versus placebo in people with stable chronic obstructive pulmonary disease.[53] Treatment usually lasted 2–4 weeks. It found that oral corticosteroids significantly increased the proportion of people with a 20% or greater improvement in baseline forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) compared with placebo (WMD 10%, 95% CI 2% to 18%). When the other five RCTs were included, the difference in effect size was 11% (95% CI 4% to 18%). **Long term treatment:** We found no long term RCTs examining the effects of oral steroids on decline in lung function.

Harms: Many reviews have described the considerable harms of systemic corticosteroids, including osteoporosis and induction of diabetes.[54]

Comment: None.

OPTION INHALED CORTICOSTEROIDS

RCTs have found no significant difference between inhaled corticosteroids and placebo in lung function (forced expiratory volume in 1 second) over 10 days to 10 weeks. However, one systematic review and subsequent RCTs lasting at least 6 months suggested that inhaled steroids increased forced expiratory volume in 1 second during the first 3–6 months of use, although one RCT found no effect on subsequent decline in lung function. One systematic review and subsequent RCTs found that long term inhaled steroids reduced the frequency of exacerbations compared with placebo. Long term inhaled steroids may predispose to adverse effects, including skin bruising, and oral candidiasis.

Benefits: **Short term treatment:** We found no systematic review. We found one non-systematic review that identified 10 RCTs of less than 6 months' duration.[55] Nine short term trials (10 days to 10 weeks,

10–127 people) found no significant difference between inhaled steroids and placebo in improvement in lung function (forced expiratory volume in 1 second [FEV_1]; see glossary, p 2026). **Long term treatment:** We found two systematic reviews and eight subsequent RCTs.[32–34,56–62] The first systematic review (search date 1996, 3 long term placebo controlled RCTs of inhaled steroids, 197 people treated for 2.0–2.5 years) examined lung function.[56] It found that inhaled steroids significantly reduced the rate of deterioration in FEV_1 before bronchodilator compared with placebo (WMD 34 mL/year, 95% CI 5 mL/year to 63 mL/year). It found no significant difference in the rate of deterioration of FEV_1 after bronchodilator or in the frequency of exacerbations (post-dose FEV_1: WMD +39 mL/year, 95% CI –6 mL/year to +84 mL/year). We found five RCTs examining lung function, which were published after the first review[56] (exacerbation rate results from these RCTs were included in the second review, see below[57]).[58–62] The first subsequent RCT (281 people) found that fluticasone significantly improved lung function compared with placebo (adjusted baseline daily peak expiratory flow rate 15 L/minute with fluticasone *v* 2 L/minute with placebo; $P < 0.001$).[58] The second RCT (290 people with mild airways obstruction, FEV_1 86% predicted) found no significant difference between budesonide (800 μg/day plus 400 μg/day for 6 months followed by 400 μg twice daily for 30 months) and placebo for lung function.[59] The third RCT (1277 people, mean FEV_1 77% predicted; 912 people completed the trial) compared budesonide (800 μg/day) with placebo for 3 years.[60] In the first 6 months of the study, FEV_1 improved in the budesonide group but decreased in the placebo group (rate of 17 mL/year with budesonide *v* 81 mL/year with placebo, CI not reported; $P < 0.001$). However, there was no effect on subsequent decline. The fourth RCT (751 people with more severe chronic obstructive pulmonary disease, FEV_1 50% predicted) compared fluticasone (500 μg twice daily for 3 years) versus placebo.[61] It found no effect on decline in lung function. The fifth RCT (1116 people with chronic obstructive pulmonary disease, FEV_1 30–90% predicted) compared inhaled triamcinolone 600 μg twice daily versus placebo.[62] It found no significant difference between triamcinolone and placebo in the rate of decline in FEV_1 after a mean duration of follow up of 40 months (mean 44.2 mL/year with triamcinolone *v* 47.0 mL/year with placebo, CI not reported; $P = 0.50$). The second systematic review (search 2001, 9 RCTs of at least 6 months' duration, 3976 people) examined exacerbation rates.[57] It found that inhaled corticosteroids significantly reduced exacerbations compared with placebo (RR 0.70, 95% CI 0.58 to 0.84).[57] The sixth, seventh, and eighth RCTs were published subsequent to both reviews.[32–34] They compared four treatments: combination therapy with inhaled corticosteroids plus long acting β_2 agonist; inhaled steroids alone; inhaled β_2 agonists alone, and placebo. The sixth RCT (691 people) found that 500 μg fluticasone significantly improved FEV_1 and dyspnoea compared with placebo at 6 months (difference between fluticasone and placebo in FEV_1: 105 mL; $P < 0.05$; difference in Transitional Dyspnoea Index:1.0; $P < 0.05$).[32] The seventh RCT (1465 people) found that fluticasone significantly improved predose FEV_1 and dyspnoea compared with placebo at 1 year (FEV_1:

1302 mL with fluticasone *v* 1264 mL with placebo; P < 0.0001; exacerbation, mean per person per year: 1.05 with fluticasone *v* 1.30 with placebo; P = 0.003).[33] It found no significant difference between fluticasone and placebo in quality of life or symptoms (St George's Respiratory Questionnaire: 45.5 with fluticasone *v* 46.3 with placebo; P not reported). The eighth RCT (812 people) found that budesonide 400 μg twice daily significantly increased FEV_1 compared with placebo at 1 year (difference: 5%, 95% CI 2% to 9%).[34] It found no significant difference between budesonide and placebo in exacerbation rate or quality of life (reduction in exacerbations: +15%, 95% CI −10.3% to + 34.1%; change in St George's Respiratory Questionnaire: −1.9 with budesonide *v* −0.03 with placebo).

Harms: The systematic review of nine RCTs found that inhaled corticosteroids significantly increased risks of oropharyngeal candidiasis and skin bruising compared with placebo (candidiasis: RR 2.1, 95% CI 1.5 to 3.1; skin bruising RR 2.1, 95% CI 1.6 to 2.8).[57] The largest RCT identified by the review found that triamcinolone significantly reduced bone mineral density of the lumbar spine (P = 0.007) and femur (P = 0.001) compared with placebo.[62] The sixth RCT found that fluticasone increased oropharyngeal candidiasis compared with placebo but found that other adverse effects were similar between treatments (candidiasis: 10% with fluticasone *v* < 1% with placebo; P not reported).[32] The seventh RCT found that fluticasone increased oropharyngeal candidiasis compared with placebo but found that other adverse effects were similar between treatments (candidiasis: 7% with fluticasone *v* 2% with placebo; P not reported).[33] The eight RCT found no significant difference between budesonide 400 μg twice daily and placebo in adverse effects.[34]

Comment: The RCTs in the systematic review examined exacerbation rate only as a secondary outcome,[57] but the subsequent RCT examined exacerbation rate as primary outcome variable. The studies of inhaled corticosteroids have been performed in patients with moderate to severe disease (FEV_1 < 50% predicted) and hence apply to that population. The Global Initiative on Obstructive Pulmonary Disease has therefore advocated the use of inhaled corticosteroids only in patients with an FEV_1 < 50% predicted and frequent exacerbations (at least 3 exacerbations in the last 3 years).[63]

OPTION ORAL VERSUS INHALED STEROIDS

Three RCTs provided insufficient evidence about the effects of oral compared with inhaled corticosteroids over 2 weeks. We found no RCTs of long term treatment with oral compared with inhaled corticosteroids. Long term oral corticosteroids are associated with serious adverse effects, including osteoporosis and diabetes.

Benefits: We found no systematic review. **Short term treatment:** We found three RCTs comparing oral prednisolone versus inhaled beclometasone (beclomethasone) (12, 83, and 107 people).[64–66] All were double blind, placebo controlled crossover trials, with treatment periods of 2 weeks. The results of these trials should be interpreted

with caution because treatment effects may persist after crossover. The first small RCT found no significant difference in response rate between treatments.[64] The other two RCTs found greater benefit with oral steroids compared with inhaled steroids. One found that forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) rose from 0.65 L to 1.00 L with prednisolone compared with 0.63 L to 0.80 L with beclometasone (CI not reported; $P < 0.01$). The other found that significantly more people responded to oral treatment (39/107 [36%] *v* 26/107 [24%], CI not reported; $P < 0.05$).[65,66] **Long term treatment:** We found no RCTs.

Harms: None of the RCTs reported on adverse effects.[64–66] Many reviews have described the considerable harms of systemic corticosteroids, including osteoporosis and induction of diabetes.[54]

Comment: One RCT recruited only people known to be responsive to oral steroids, and did not report severity of chronic obstructive pulmonary disease.[65] The other two RCTs included people with chronic obstructive pulmonary disease of more than 5 years' duration and FEV_1 less than 70% predicted.[64,66] All trials excluded people with evidence of reversible airflow obstruction.

OPTION INHALED CORTICOSTEROIDS PLUS LONG ACTING β_2 AGONISTS New

RCTs have found that the combination of an inhaled corticosteroid plus a long acting β_2 agonist reduced exacerbation rates and improved lung function, symptoms, and health related quality of life compared with placebo. In general, the combination was more effective than inhaled corticosteroid alone or long acting β_2 agonist alone, although this difference was not significant for all outcomes.

Benefits: We found three RCTs comparing four treatments: inhaled corticosteroid alone; an inhaled long acting β_2 agonist alone; an inhaled corticosteroid plus a long acting β_2 agonist (combined in one inhaler) and placebo.[32–34] The first RCT (691 people, mean age 64 years, current or former smokers, mean forced expiratory volume in 1 second 40% of predicted) compared a combination of fluticasone (500 μg) plus salmeterol (50 μg) twice daily versus both components separately versus placebo for 24 weeks.[32] It found that combination treatment significantly improved predose FEV_1 compared with placebo, salmeterol alone, and fluticasone alone, and significantly improved post-dose FEV_1 compared with placebo and fluticasone (difference for combination minus other treatment; predose FEV_1: 159 mL *v* placebo; 67 mL *v* salmeterol; 54 mL *v* fluticasone, all $P < 0.05$; post-dose FEV_1: 231 mL *v* placebo; 129 mL *v* fluticasone, both $P < 0.05$; 40 mL *v* salmeterol, $P > 0.05$). It found that the combination significantly improved dyspnoea compared with placebo, salmeterol alone, and fluticasone alone (Transition Dyspnoea Index: difference for combination *v* other treatment: 1.7 *v* placebo; 1.2 *v* salmeterol; 0.7 *v* fluticasone, all $P < 0.05$). It found that the combination significantly improved quality of life compared with placebo and with fluticasone but there was no significant difference between the combination and salmeterol alone (Chronic Respiratory Disease Questionnaire: difference for combination *v* other treatment: 5.3 *v* placebo; 4.8 *v* fluticasone,

both P < 0.05; 1.6 *v* salmeterol, P not reported). The second RCT (1465 people, current or former smokers, mean FEV_1 1245–1308 mL at baseline in the treatment groups) compared the same four treatments (salmeterol, fluticasone, both, and placebo) for 1 year.[33] It found that the combination significantly improved predose and 2 hour post-dose FEV_1 compared with placebo, fluticasone alone, and salmeterol alone (difference for combination *v* other treatment, predose FEV_1: 133 mL, 95% CI 105 to 161 mL *v* placebo; 73 mL, 95% CI 46 to 101 mL *v* salmeterol; 95 mL, 95% CI 67 to 122 mL *v* fluticasone; post-dose FEV_1 difference: 155 mL, 95% CI 106 to 204 mL *v* placebo; 68 mL, 95% CI 20 to 117 mL *v* salmeterol; 94 mL, 95% CI 46 to 142 mL *v* fluticasone). It found that the combination, salmeterol alone, and fluticasone alone significantly reduced the exacerbation rate compared with placebo but there was no significant difference in exacerbation rate between the combination and either salmeterol or fluticasone (exacerbation rate per person per year: 1.30 with placebo; 1.04 with salmeterol alone, 1.05 with fluticasone alone, 0.97 with combination; P < 0.0001 for combination *v* placebo). It found that combination treatment significantly improved quality of life compared with placebo and fluticasone but there was no significant difference between the combination and salmeterol alone (St George's Respiratory Questionnaire: 46.3 with placebo *v* 45.2 with salmeterol *v* 45.5 with fluticasone *v* 44.1 with combination; difference between combination and other treatment: –2.2, 95% CI –3.3 to –1.0 *v* placebo; –1.1, 95% CI –2.2 to +0.1 *v* salmeterol; –1.4, 95% CI –2.5 to –0.2 *v* fluticasone). The third RCT (812 people, mean age 64 years, current or former smokers, mean FEV_1 0.96 to 1.01 L) compared four treatments twice daily over 1 year: a combination of budesonide 320 μg plus formoterol 9 μg twice daily; budesonide alone 200 μg; formoterol alone 4.5 μg; and placebo for 1 year.[34] It found that the combination significantly improved post-dose FEV_1 compared with placebo and budesonide alone but there was no significant difference between combination treatment and formoterol alone (improvement in post-dose FEV_1 for combination *v* placebo: 15%, 95% CI 11% to 19%; combination *v* budesonide: 9%, 95% CI 5.4% to 13%; combination *v* formoterol: +1%, 95% CI –2.2% to +4.9%). It found that combination treatment significantly improved symptoms compared with placebo and budesonide alone but there was no significant difference between combination treatment and formoterol alone (difference in symptoms scored from 0 to 16: combination *v* placebo: –0.77, P < 0.001; combination *v* budesonide: –0.70, P < 0.001; combination *v* formoterol –0.27, P = 0.13). It found that combination treatment significantly improved quality of life compared with placebo (St Georges Respiratory Questionnaire, reduction from baseline: –0.03 with placebo *v* –3.9 with combination, *v* –1.9 with budesonide alone *v* –3.6 with formoterol alone; P = 0.009 for combination *v* placebo; P for combination *v* each active treatment alone not reported).

Harms: The first RCT found that combination treatment and fluticasone alone increased candidiasis compared with placebo (7% with combination *v* 10% with fluticasone *v* < 1% with placebo and salmeterol, P not reported).[32] Other adverse effect rates were similar among treatment groups. The second RCT found a slightly lower

rate of candidiasis (6% with combination *v* 6% with fluticasone *v* 1% with placebo and salmeterol, P not reported).[33] It too found similar rates of other adverse effects among treatment groups. The third RCT found similar rates of adverse effects among treatment groups but did not specifically report candidiasis rate.[34] Two RCTs found no clinically relevant decreases in serum cortisol with fluticasone or combination treatment.[32,33]

Comment: These studies have been performed mainly in people with moderate to severe disease (FEV_1 below 50%) and hence apply to that population. The Global Initiative on Obstructive Pulmonary Disease has, therefore, advocated inhaled corticosteroids and the combination of inhaled corticosteroids plus long acting agonists only in patients with an $FEV_1 < 50\%$ predicted and frequent exacerbations (i.e. at least 3 in the last 3 years).[63]

OPTION MUCOLYTIC DRUGS

Two systematic reviews found that mucolytics for 3–24 months may reduce the frequency and duration of exacerbations in people with chronic bronchitis compared with placebo. However, it is not clear whether these effects are generalisable to people with chronic obstructive pulmonary disease.

Benefits: **Long term treatment:** We found two systematic reviews.[67,68] However, not all included participants had chronic obstructive pulmonary disease (see comment below). The first systematic review (search date 1999, 23 double blind RCTs, 3 RCTs in people with chronic obstructive pulmonary disease, 20 RCTs in people with chronic bronchitis not defined further; > 6000 people) found that mucolytics for 3–6 months significantly reduced the average number of exacerbations and days of disability compared with placebo (exacerbations, WMD: –0.066 exacerbations/month, 95% CI –0.077 exacerbations/month to –0.054 exacerbations/month) and days of disability (disability, WMD: –0.56 days/month, 95% CI –0.77 days/months to –0.35 days/month).[67] The second systematic review (search date 1995, 9 RCTs, 7 of which were included in the first review[67]) compared N-acetylcysteine versus placebo for 3–24 months.[68] It found that N-acetylcysteine reduced exacerbations compared with placebo (overall weighted effect size: 1.37, 95% CI 1.25 to 1.50, 235 reduction).

Harms: The first systematic review found no significant difference between mucolytics and placebo in the total number of adverse events.[67] Adverse effects of N-acetylcysteine were mainly mild gastrointestinal complaints.

Comment: Results of the reviews should be applied with caution.[67,68] It was unclear how many people included in the reviews had chronic obstructive pulmonary disease. In both reviews, there was significant heterogeneity among the RCTs, and symptom scores could not be pooled.[67,68] The effects of N-acetylcysteine are usually not ascribed to its mucolytic properties but rather to its antioxidant properties. The effect of N-acetylcysteine in slowing the decline in lung function is being examined in a large European multicentre study.[69]

OPTION PROPHYLACTIC ANTIBIOTICS

One systematic review found limited evidence of a small reduction in exacerbation rates and days with disability with prophylactic antibiotics. These benefits probably do not outweigh the harms of antibiotics, especially the development of antibiotic resistance. All the identified RCTs were conducted more than 30 years ago, and results are unlikely to apply to current practice.

Benefits: **Short term treatment:** We found no systematic review or RCTs. **Long term treatment:** We found one systematic review (search date not reported, 9 RCTs, 1055 people; see comment below) of prophylactic antibiotics (tetracycline, penicillin, trimethoprim, sulphadimidine, and sulphaphenazole) in people with chronic obstructive pulmonary disease or chronic bronchitis.[70] All trials were performed before 1970. The duration of the RCTs ranged from 3 months to 5 years. It found that antibiotics significantly reduced the risk of any exacerbation during the study compared with placebo (RR 0.91, 95% CI 0.84 to 0.99). It found that antibiotics slightly reduced the number of exacerbations per person per year but the reduction was not statistically significant (WMD: −0.15, 95% CI −0.34 to +0.04). It found that antibiotics significantly reduced the number of days of disability per person per month treated (WMD −0.95, 95% CI −1.89 to − 0.01, 22% reduction).

Harms: In general, there was a poor reporting of possible adverse effects in most trials. Nevertheless, the review found that antibiotics slightly increased adverse effects compared with placebo (number of adverse effects; WMD per person per year treated: 0.01, 95% CI 0.00 to 0.02).[70]

Comment: The results of this review should be interpreted with caution.[70] It was unclear from the descriptions of the original studies how many participants had chronic obstructive pulmonary disease (rather than chronic bronchitis without obstruction). Additionally, the data in the review are over 30 years old, so the pathogens and the pattern of antibiotic sensitivity may have changed, and there is a wider range of antibiotics in use. Most people believe that prophylactic antibiotics do not have a place in routine treatment because of concerns about the development of antibiotic resistance and the possibility of adverse effects.

OPTION DOMICILIARY OXYGEN TREATMENT

One RCT in people with severe daytime hypoxaemia found that domiciliary oxygen improved survival compared with no domiciliary oxygen. A second RCT in people with severe hypoxaemia found that continuous oxygen reduced mortality compared with nocturnal oxygen. Three RCTs in people with milder hypoxaemia or with nocturnal hypoxaemia only found no significant difference in mortality between long term domiciliary oxygen and no oxygen.

Benefits: **Long term treatment:** We found one systematic review (search date 2000, 5 RCTs).[71] The review could not perform a meta-analysis because of differences in trial design and participant selection. The first RCT (87 people), which compared daily oxygen

for at least 15 hours with no oxygen in people with severe daytime hypoxaemia (arterial oxygen tension [PaO_2] between 5.3 and 8 kPa) found that domiciliary oxygen significantly reduced mortality over 5 years.[72] The second RCT (38 people with arterial desaturation at night) comparing nocturnal domiciliary oxygen versus room air found no significant difference in mortality at 3 years (figures not reported).[73] The third RCT (135 people with moderate hypoxaemia [PaO_2 7.4–8.7 kPa] comparing oxygen with no oxygen found no significant difference in survival at 3 years (HR 0.92, 95% CI 0.57 to 1.47; results presented graphically).[74] The fourth RCT (203 people; $PaO_2 < 7.4$ kPa) compared continuous with nocturnal domiciliary oxygen treatment. Continuous oxygen was associated with a significant reduction in mortality over 24 months (22% with continuous *v* 41% with nocturnal oxygen; OR 0.45, 95% CI 0.25 to 0.81).[75] The fifth RCT (76 people with moderate daytime hypoxaemia [PaO_2 7.4–9.2 kPa] and significant nocturnal desaturation) comparing 2 years of nocturnal oxygen treatment with placebo found no significant difference in survival.[76]

Harms: The systematic review did not report adverse effects.

Comment: Only one of the studies was double blinded. Domiciliary oxygen treatment seems to be more effective in people with severe hypoxaemia ($PaO_2 < 8.0$ kPa) than in people with moderate hypoxaemia or those who have arterial desaturation only at night.

OPTION α_1 ANTITRYPSIN INFUSION

We found no RCTs of short term treatment with α_1 antitrypsin. One RCT found no significant difference between α_1 antitrypsin and placebo in the decline in forced expiratory volume in 1 second after 1 year in people with α_1 antitrypsin deficiency and moderate emphysema.

Benefits: We found no systematic review. **Short term treatment:** We found no RCTs. **Long term treatment:** We found one RCT (56 people with α_1 antitrypsin deficiency and moderate emphysema, forced expiratory volume in 1 second (see glossary, p 2026) [FEV_1] 30–80% predicted) comparing α_1 antitrypsin infusions (250 mg/kg) versus placebo infusion (albumin) given monthly for at least 3 years. It found no significant difference in the decline in FEV_1 after 1 year (decline in FEV_1 79 mL with α_1 antitrypsin *v* 59 mL with placebo, CI not reported; $P = 0.25$).[77]

Harms: The RCT reported no adverse effects in people taking α_1 antitrypsin or placebo.[77]

Comment: We found no clear evidence from observational studies on the effect of α_1 antitrypsin. For example, one cohort study (1048 people either homozygous for α_1 antitrypsin deficiency or with an α_1 antitrypsin concentration ≤ 11 µmol/L, with mean FEV_1 49 ± 30% predicted) compared weekly infusions of α_1 antitrypsin 60 mg/kg versus placebo for 3.5–7 years.[78] It found that α_1 antitrypsin significantly reduced mortality after an average of 5 years (RR of death 0.64, 95% CI 0.43 to 0.94). It found no significant difference between treatments in the decline in FEV_1, but in a subgroup of people with a mean FEV_1 of 35–49% predicted, α_1 antitrypsin

significantly reduced the decline in FEV_1 (mean difference in FEV_1 0.08 L/year, 95% CI 0.003 L/year to 0.500 L/year, P = 0.03). A second cohort study (295 people homozygous for α_1 antitrypsin deficiency with FEV_1 < 65% predicted) compared 198 people who received weekly infusions of α_1 antitrypsin 60 mg/kg (duration not reported) versus 97 people who had never received α_1 antitrypsin. It found that α_1 antitrypsin significantly reduced the decline in FEV_1 (0.05 L/year with α_1 antitrypsin *v* 0.08 L/year with no α_1 antitrypsin, CI not reported; P = 0.02).[79]

OPTION DEOXYRIBONUCLEASE

We found no RCTs of deoxyribonuclease in people with chronic obstructive pulmonary disease.

Benefits: We found no systematic review or RCTs of deoxyribonuclease (DNase) specifically in people with chronic obstructive pulmonary disease (see comment below).

Harms: We found no RCTs.

Comment: **Short term treatment:** We found one RCT (349 people with bronchiectasis but not necessarily chronic airway obstruction) comparing DNase versus placebo given twice daily for 24 weeks.[80] It found that DNase significantly reduced forced expiratory volume in 1 second (FEV_1) (see glossary, p 2026) (CI not reported; P ≤ 0.05), but found no significant difference in the frequency of exacerbations over 24 weeks (0.66 in people with DNase) *v* 0.56 in people with placebo; RR 1.70, 95% CI 0.85 to 1.65). In people with cystic fibrosis, DNase treatment is used to degrade DNA that increases the viscosity of pulmonary secretions. However, we found no evidence that this mechanism is useful to people with chronic obstructive pulmonary disease and chronic sputum production.

QUESTION What are the effects of smoking cessation interventions in stable chronic obstructive pulmonary disease? New

OPTION PSYCHOSOCIAL INTERVENTIONS ALONE New

We found no systematic reviews or RCTs in people with chronic obstructive pulmonary disease.

Benefits: We found no systematic reviews or RCTs examining the effects of psychosocial interventions such as professional advice or counselling alone on the outcomes of interest in this review (forced expiratory volume in 1 second (see glossary, p 2026) [FEV_1], peak expiratory flow (see glossary, p 2026) exacerbations, dyspnoea score, quality of life, or survival) specifically in people with chronic obstructive pulmonary disease (see comment below).

Harms: No RCTs were found that reported harms.

Comment: Despite the extensive literature on smoking cessation, we did not identify useful studies because most studies focused on combinations of interventions; continuous abstinence or point prevalence rates of smoking cessation as single outcome measures; healthy people or mixed populations of healthy people and people with disease.

Chronic obstructive pulmonary disease

OPTION PHARMACOLOGICAL INTERVENTIONS ALONE New

One systematic review found no RCTs of pharmacological interventions alone in people with chronic obstructive pulmonary disease.

Benefits: We found one systematic review (search date 2002).[81] It found no RCTs examining the effects of pharmacological smoking cessation interventions alone for the outcomes of interest in this review (forced expiratory volume in 1 second [FEV_1] (see glossary, p 2026), peak expiratory flow, exacerbations, dyspnoea score, quality of life, or survival) specifically in people with chronic obstructive pulmonary disease (see comment below).

Harms: No studies were found of the harms of pharmacological interventions alone.

Comment: The systematic review[81] identified two RCTs, both of which examined pharmacological therapy plus non-pharmacological interventions (see benefits of psychosocial plus pharmacological interventions, p 2025).[82,83] One systematic review (search date May 2001, 157 studies) assessed the clinical effectiveness of bupropion and nicotine replacement therapy for smoking cessation, but did not focus solely on people with COPD.[84,85] It found a low incidence of adverse events with nicotine replacement therapy, irrespective of the type of replacement. The most common adverse effects were localised reactions: skin sensitivity and irritation with patches; throat irritation, nasal irritation, and runny nose with nasal spray; hiccups, burning and smarting sensation in the mouth, sore throat, coughing, dry lips, and mouth ulcers with nicotine sublingual tablets; and hiccups, gastrointestinal disturbances, jaw pain, and orodental problems with nicotine gum. Sleep disturbances and alteration of mood may arise because of nicotine withdrawal. A small number of studies were undertaken with specific subgroups (including smokers with lung disease). Results for individual studies were generally inconclusive but overall results were consistent with the overall pooled results. Results in people with COPD, however, were not reported separately in this systematic review. Regarding the safety of bupropion, the review concluded that seizure is the most significant and important potential adverse effect. However, this review did not identify RCTs that reported any seizures. Common adverse events of bupropion are: rash, pruritis, urticaria, irritability, insomnia, dry mouth, headache, and tremor. The adverse effect profile of slow release bupropion appears to be better than that of immediate release bupropion. The results for specific subgroups (including smokers with pulmonary disease) were generally consistent with the overall pooled results, although results in people with COPD were not reported separately.

OPTION PSYCHOSOCIAL PLUS PHARMACOLOGICAL INTERVENTIONS. New

One large RCT in people with mild chronic obstructive pulmonary disease found that nicotine gum plus a psychosocial smoking cessation and abstinence maintenance programme (with or without ipratropium) slowed the decline of forced expiratory volume in 1 second, reduced respiratory

symptoms, and lower respiratory illnesses, but increased weight gain compared with usual care (without psychosocial intervention). The RCT found no significant difference between treatments in all cause mortality at 5 years.

Benefits: One systematic review (search date 2002[86]) identified two RCTs that examined psychosocial plus pharmacological interventions in people with chronic obstructive pulmonary disease (COPD).[82,83] The first RCT (5887 smokers, aged 35–60 years, with spirometric signs of early COPD, mean prebronchodilator forced expiratory volume in 1 second [FEV_1, see glossary, p 2026] 2.64 L, mean of 30 cigarettes smoked per day) compared three treatments: smoking cessation intervention plus placebo; smoking cessation intervention plus ipratropium; and usual care.[82] The smoking cessation intervention consisted of an intensive 12 session smoking cessation programme combining behaviour modification and use of nicotine gum (nicotine polacrilex 2 mg) with a continuing 5 year maintenance programme that included monitoring of weight gain and nutritional counselling.[87] The RCT found that the smoking cessation intervention (with or without ipratropium) increased the proportion of sustained quitters at 5 years, with a similar proportion remaining abstinent at 11 years, compared with usual care (22% at 5 years and 21.9% at 11 years with smoking cessation-intervention *v* 5% at 5 years and 6% at 11 years with usual care; P not reported).[88] It found that the smoking cessation intervention (with and without ipratropium) significantly improved FEV_1 compared with usual care after 1 and 5 years and that the smoking intervention plus ipratropium significantly improved FEV_1 compared with the smoking cessation intervention alone at 1 and 5 years (change in FEV_1 at 1 year: −34.3 mL with usual care *v* +11.2 mL with smoking cessation intervention *v* +38.8 mL with intervention plus ipratropium; $P < 0.005$ for each between treatment comparison; at 5 years, completer analysis [around 90% of participants]: −267 mL with usual care *v* −208 mL with intervention *v* −184 mL with intervention plus ipratropium; $P \leq 0.002$ for all comparisons).[82] In further analyses, both treatments using a smoking cessation intervention were combined. After 11 years, smoking intervention reduced the decline in FEV_1 compared with usual care (change from baseline: −502 mL with intervention *v* 587 mL with usual care; $P = 0.001$).[89] Smoking cessation intervention significantly reduced self reported lower respiratory illnesses resulting in physician visits compared with usual care at 5 years (results presented graphically; $P = 0.0008$).[90] The smoking cessation intervention significantly reduced cough, phlegm, wheezing, and dyspnoea compared with usual care at 5 years (by intention to treat analysis, cough for ≥3 months/year: 15% with intervention *v* 23% with usual care; phlegm for ≥3 months/year: 12% with intervention *v* 20% with usual care; presence of wheezing: 25% with intervention *v* 31% with usual care; presence of dyspnoea: 19% with intervention *v* 24% with usual care, all $P < 0.0001$).[91] There was no significant difference between the three treatments in all cause mortality at 5 years (2.60% with usual care *v* 2.24% with smoking intervention *v* 2.75% with intervention plus ipratropium; $P = 0.58$).[92] The second RCT (404 people with mild or moderate COPD, smoking an average of 28

cigarettes per day, mean age 54 years) compared bupropion plus counselling versus placebo plus counselling for 12 weeks with 6 months' follow up, but only reported abstinence rates and adverse effects.[83] This study did not provide data about effects on FEV_1 changes, peak expiratory flow, exacerbations, dyspnoea score, quality of life, or survival. It found that bupropion (slow release 150 mg twice daily) plus counselling significantly increased continuous abstinence rates from weeks 4 to 26 compared with counselling alone (16% *v* 9%; P = 0.05; see comments).[83]

Harms: In the first RCT,[82] 31% (about 1216 people) were still using nicotine gum after 1 year. About 25% of these reported at least one adverse effect, but most were minor and transient. The most common adverse effects were: indigestion (5.10% for men and 3.95% for women); mouth irritation (6.2% for men and 6.5% for women); mouth ulcers (4.4% for men and 5.3% for women); nausea (1.8% for men and 3.8% for women); and hiccups (2.8% for men and 3.8% for women).[93] The smoking intervention increased weight gain at 1 and 5 years in both men and women compared with usual care, but the statistical significance was not reported (weight gain, 1 year: 2.61 kg with intervention *v* 0.61 kg with usual care for men and 2.63 kg *v* 1.10 kg for women; 5 years: 3.9 kg with intervention *v* 2.60 kg with usual care for men and 4.75 kg *v* 2.84 kg for women).[94] The second RCT found similar rates of discontinuation due to adverse effects between treatment groups (6% with placebo *v* 7% with bupropion). It found higher rates of serious adverse effects with placebo (2.5% *v* 0.5%).[83]

Comment: None.

GLOSSARY

Forced expiratory volume in 1 second (FEV_1) The volume breathed out in the first second of forceful blowing into a spirometer, measured in litres.

Peak expiratory flow rate The maximum rate that gas is expired from the lungs when blowing into a peak flow meter or a spirometer; the units are expressed as litres per minute.

Substantive changes

Inhaled anticholinergics Two RCTs added;[18,25] categorisation unchanged. Benefits data enhanced.

Inhaled β_2 agonists Five RCTs added;[18,25,32–34] categorisation unchanged. Benefits data enhanced.

Inhaled anticholinergics versus β_2 agonists One RCT added;[25] categorisation unchanged.

Inhaled corticosteroids Three RCTs added;[32–34] categorisation unchanged.

Prophylactic antibiotics One systematic review added;[70] categorisation unchanged.

Key Messages

Non-small cell lung cancer

- **Palliative chemotherapy in stage 4 non-small cell lung cancer** Systematic reviews in people with stage 4 non-small cell lung cancer have found that adding chemotherapy regimens containing cisplatin to best supportive care increases survival at 1 year compared with supportive care alone. Limited evidence from RCTs suggests that adding chemotherapy to best supportive care may improve quality of life compared with best supportive care alone.
- **Thoracic irradiation plus chemotherapy in unresectable stage 3 non-small cell lung cancer (compared with thoracic irradiation alone)** Systematic reviews and two RCTs in people with unresectable stage 3 non-small cell lung cancer have found that adding chemotherapy to irradiation improves survival at 2–5 years compared with irradiation alone. One RCT found no significant difference in median survival between radical radiotherapy plus chemotherapy and radiotherapy alone. Observational evidence suggests that, in people aged over 70 years with unresectable stage 3 non-small cell lung cancer, chemotherapy plus radiotherapy may reduce quality adjusted survival compared with radiotherapy alone. We found insufficient evidence about effects on quality of life.
- **Hyperfractionated radiation treatment in unresectable stage 3 non-small cell lung cancer** One systematic review found no clear evidence that altered fractionation regimens, accelerated, hyperfractionated, or hyperfractionated split course regimens are any more effective than conventional radiotherapy. One RCT identified by the review has found that continuous, hyperfractionated, accelerated radiotherapy reduces mortality at 2 years compared with conventional radiotherapy in people with stage 3A, 3B, 1, or 2 non-small cell lung cancer.
- **Palliative single drug chemotherapy in stage 4 non-small cell lung cancer (not clearly better than combination chemotherapy)** One systematic review and subsequent RCTs in people with stage 3 and 4 non-small cell lung cancer found inconclusive evidence on the effects of single agent chemotherapy compared with combined chemotherapy. One systematic review and subsequent RCTs provided insufficient evidence to compare first line platinum based version non-platinum based chemotherapy.
- **Preoperative chemotherapy in people with resectable stage 3 non-small cell lung cancer** One systematic review of small, weak RCTs and one subsequent RCT provided inconclusive evidence about the effects of preoperative chemotherapy in people with resectable stage 3 non-small cell lung cancer.
- **Postoperative chemotherapy in people with resected stage 1–3 non-small cell lung cancer** Systematic reviews and subsequent RCTs in people with completely resected stage 1–3 non-small cell lung cancer found no significant difference in survival at 5 years between postoperative cisplatin based chemotherapy and surgery alone with or without concomitant radiotherapy, although subgroup analysis in one RCT suggests that postoperative chemotherapy may increase survival in people with stage 3 disease. One systematic review has found that postoperative alkylating agents increase mortality compared with no postoperative chemotherapy.

Small cell lung cancer

- **Chemotherapy plus thoracic irradiation in limited stage small cell lung cancer** Two systematic reviews in people with limited stage small cell lung cancer have found that adding thoracic irradiation to chemotherapy improves survival at 3 years and improves local control. However, one of these reviews has found that chemotherapy plus thoracic irradiation increases deaths related to treatment.
- **Prophylactic cranial irradiation for people in complete remission from limited or extensive stage small cell lung cancer** One systematic review in people with small cell lung cancer in complete remission has found that prophylactic cranial irradiation improves survival at 3 years and reduces the risk of developing brain metastases compared with no irradiation. While long term cognitive dysfunction after cranial irradiation has been described in non-randomised studies, RCTs have not found a cumulative increase in neuropsychological dysfunction.
- **Dose intensification of chemotherapy** One systematic review found limited evidence that intensifying chemotherapy dose by either increasing the number of chemotherapy cycles, increasing chemotherapy dose, or increasing dose intensity per cycle may modestly improve survival compared with standard chemotherapy. However, additional RCTs have found inconclusive evidence about the effects of dose intensification on survival.
- **Oral etoposide in extensive stage small cell lung cancer** Two RCTs in people with extensive stage small cell lung cancer found that oral etoposide reduced survival compared with combination chemotherapy at 1 year. One RCT, in people with extensive stage small cell lung cancer who had not responded to induction combination chemotherapy, found no significant difference between oral etoposide and no further treatment in mortality at 3 years, although overall mortality was lower in people taking etoposide. RCTs found that etoposide may reduce nausea, alopecia, and numbness in the short term compared with combination chemotherapy. They found no evidence that it offered better quality of life overall.

DEFINITION Lung cancer (bronchogenic carcinoma) is an epithelial cancer arising from the bronchial surface epithelium or bronchial mucous glands. It is broadly divided into small cell and non-small cell lung cancer. For a description of the stages of lung cancer see table 1, p 2053.

INCIDENCE/ PREVALENCE Lung cancer is the leading cause of cancer death in both men and women annually, affecting about 100 000 men and 80 000 women in the USA and about 40 000 men and women in the UK. Small cell lung cancer constitutes about 20–25% of all lung cancers, the remainder being non-small cell lung cancers of which adenocarcinoma is now the most prevalent form.[1]

AETIOLOGY/ RISK FACTORS Smoking remains the major preventable risk factor, accounting for about 80–90% of all cases.[2] Other respiratory tract carcinogens have been identified that may enhance the carcinogenic effects of tobacco smoke, either in the workplace (e.g. asbestos and polycyclic aromatic hydrocarbons) or in the home (e.g. indoor radon).[3]

PROGNOSIS Lung cancer has an overall 5 year survival rate of 10–12%.[4] At the time of diagnosis, 10–15% of people with lung cancer have localised disease. Of these, half will have died at 5 years despite potentially curative surgery. Over half of people have metastatic

disease at the time of diagnosis. People with non-small cell cancer who have surgery have a 5 year survival of 60–80% for stage 1 disease and 25–50% for stage 2 disease.[4] In people with small cell cancer, those with limited stage disease who have combined chemotherapy and mediastinal irradiation have a median survival of 18–24 months, whereas those with extensive stage disease who are given palliative chemotherapy have a median survival of 10–12 months.[4] About 5–10% of people with small cell lung cancer present with central nervous system involvement, and half develop symptomatic brain metastases by 2 years. Of these, only half respond to palliative radiation, and their median survival is less than 3 months.[4]

AIMS OF INTERVENTION To prolong life; to improve quality of life; and to provide palliation of symptoms, with minimum adverse effects of treatment.

OUTCOMES Survival; clinical response rates; disease related symptoms; adverse effects of treatment; quality of life. Despite recent progress in the development of valid instruments, measuring quality of life in people with lung cancer remains a serious challenge.[5,6]

METHODS *Clinical Evidence* search and appraisal September 2003. Unless stated otherwise, we have used the term stage 3 non-small cell lung cancer to refer to both stage 3A and stage 3B (see table 1, p 2053).

QUESTION What are the effects of treatments for non-small cell lung cancer?

OPTION PRE- AND POSTOPERATIVE CHEMOTHERAPY IN PEOPLE WITH RESECTABLE NON-SMALL CELL LUNG CANCER

One systematic review of small, weak RCTs and one subsequent RCT provide inconclusive evidence about the effects of preoperative chemotherapy in people with resectable stage 3 non-small cell lung cancer. Systematic reviews and subsequent RCTs in people with completely resected stage 1–3 non-small cell lung cancer found no significant difference in survival at 5 years between postoperative cisplatin based chemotherapy and surgery alone with or without concomitant radiotherapy, although subgroup analysis in one RCT suggests that postoperative chemotherapy may increase survival in people with stage 3 disease. One systematic review has found that postoperative alkylating agents increase mortality compared with no postoperative chemotherapy.

Benefits: **Preoperative chemotherapy versus no chemotherapy:** We found one systematic review,[7] one non-systematic review,[8] and one subsequent RCT.[9] The systematic review (search date 1997, 4 RCTs, 204 people with technically resectable stage 3A non-small cell lung cancer) compared preoperative cisplatin based chemotherapy with no chemotherapy.[7] It found that preoperative chemotherapy significantly reduced mortality at 2 years compared with no preoperative chemotherapy (2 fully reported RCTs; AR 34/58 [59%] with preoperative chemotherapy *v* 54/62 [87%] with no chemotherapy; RR 0.67, 95% CI 0.42 to 0.89; NNT 4, 95% CI 2 to 11). The non-systematic review, which identified the same RCTs, suggested that this evidence is limited because the trials were small,

staging was clinical rather than pathological, and treatment groups were not balanced for prognostic factors such as K-Ras mutations.[8] The subsequent RCT (355 people with resectable stages 1 [except T1N0] to 3A non-small cell lung cancer) compared preoperative chemotherapy (2 cycles of ifosfamide plus mitomycin plus cisplatin) versus primary surgery alone.[9] It found no significant difference in survival after 4 years follow up between preoperative chemotherapy and surgery alone in people with any disease stage or in people with stage 3 disease (median survival for any disease stage 37 months, 95% CI 26.7 months to 48.3 months with preoperative chemotherapy *v* 26.0 months, 95% CI 19.8 months to 33.6 months; P = 0.15; RR for survival in people with stage 3 disease 1.04, 95% CI 0.68 to 1.60; P = 0.85). **Postoperative chemotherapy versus surgery alone:** We found one systematic review[10] and two subsequent RCTs.[11,12] The review (search date 1991, 14 RCTs, 1394 people with resected stage 1–3 non-small cell lung cancer) found no significant difference between postoperative cisplatin based chemotherapy compared with surgery alone in mortality at 5 years (8 RCTs; ARR +5%, 95% CI –1% to +10%; HR 0.87, 95% CI 0.74 to 1.02; P = 0.08).[10] However, it found that postoperative alkylating agents significantly increased mortality compared with surgery alone (5 RCTs; HR 1.15; CI not reported; P = 0.005; ARI of death at 5 years +5%, CI not reported). The first subsequent RCT (70 people, stage 1–3B resected non-small cell lung cancer) compared postoperative chemotherapy (4 cycles of iv cyclophosphamide, vincristine, adriamycin, and lomustine, followed by oral ftorafur) versus no chemotherapy for 1 year.[11] It found no significant difference in survival at 5 years between postoperative chemotherapy and no postoperative chemotherapy (49% with postoperative chemotherapy *v* 31% with no chemotherapy; P > 0.05, absolute numbers not reported).[11] A subgroup analysis in people with stage 3 non-small cell lung cancer (40 people with stage 3A, 9 with stage 3B) found that postoperative chemotherapy significantly increased survival at 5 years compared with no postoperative chemotherapy (44% with postoperative chemotherapy *v* 21% with no chemotherapy; P < 0.025, absolute numbers not reported). Results for people with stage 3A and 3B non-small cell lung cancer were not reported separately.[11] The second subsequent RCT (221 people, stage 1–2 resected non-small cell lung cancer) compared uracil plus tegafur for 2 years versus no postoperative chemotherapy.[12] It found no significant difference in 5 year survival or 5 year disease free survival between chemotherapy and no chemotherapy (survival: 79% with postoperative chemotherapy *v* 75% with no chemotherapy; HR 1.13, 95% CI 0.65 to 1.97; disease free survival: 78% with postoperative chemotherapy *v* 71% with no chemotherapy; HR 1.37, 95% CI 0.81 to 2.32). **Postoperative chemotherapy plus radiotherapy versus postoperative radiotherapy alone:** We found one systematic review (search date 1991, 7 RCTs, 807 people)[10] and one subsequent RCT.[11] The review found no significant difference in overall survival between adding postoperative chemotherapy to postoperative radiotherapy and postoperative radiotherapy alone (overall survival: HR 0.98; CI not reported, P = 0.76; HR for 6 RCTs that used cisplatin based chemotherapy HR 0.94; CI not reported, P = 0.46; ARR for death at

5 years +2%, 95% CI −3% to +8%).[10] The subsequent RCT (488 people with completely resected stage 2 or 3A non-small cell lung cancer) compared postoperative radiotherapy with or without cisplatin plus etoposide.[13] It found no significant difference between postoperative chemotherapy plus radiotherapy and radiotherapy alone in median survival (37.9 months with postoperative chemotherapy plus radiotherapy *v* 38.8 months with radiotherapy alone; P = 0.56).

Harms:

Preoperative chemotherapy: One RCT identified by the review, which compared preoperative chemotherapy versus no chemotherapy, found that chemotherapy was associated with grade III or IV neutropenia (80% of people), nausea and vomiting, diarrhoea, hypomagnesaemia, and alopecia (no further data reported).[7] **Postoperative chemotherapy:** The systematic review of postoperative cisplatin based chemotherapy gave no information on adverse effects.[10] One RCT (269 people) identified by the review, which compared four postoperative courses of cyclophosphamide plus adriamycin plus cisplatin versus no postoperative chemotherapy, found that only 53% of people allocated to postoperative chemotherapy completed all four courses.[14] Mild to severe gastrointestinal toxicity was reported in 88% of people receiving postoperative chemotherapy. A second RCT identified by the review reported similar toxicity.[15] Many adjuvant chemotherapy studies were published before serotonin receptor antagonist antiemetics were available. The second subsequent RCT (221 people) reported grade 3–4 toxicity in 0.9% (1/110) of people and grade 1 or more toxicity in 59.8% (64/110) of people with postoperative uracil plus tegafur.[12]

Comment:

The systematic review examining effects of preoperative chemotherapy[7] identified one interim report[16] of an RCT in 27 people, which was unsuitable for inclusion in the meta-analysis. The RCT found that preoperative chemotherapy significantly improved median survival after about 30 months' follow up compared with no preoperative chemotherapy (median survival: 28.7 months with preoperative chemotherapy *v* 15.6 months with no chemotherapy; P = 0.095).[17] Larger trials of preoperative chemotherapy in people with stage 3A non-small cell lung cancer are needed. Most of the chemotherapy regimens in the postoperative RCTs identified by the reviews are no longer used, and more trials examining newer agents are needed.

OPTION THORACIC IRRADIATION FOR UNRESECTABLE STAGE 3 NON-SMALL CELL LUNG CANCER (COMPARED WITH THORACIC IRRADIATION ALONE)

Systematic reviews and subsequent RCTs in people with unresectable stage 3 non-small cell lung cancer have found that adding chemotherapy to irradiation improves survival at 2–5 years compared with irradiation alone. One RCT found no significant difference in median survival between radical radiotherapy plus chemotherapy and radiotherapy alone. Observational evidence suggests that, in people aged over 70 years with

unresectable stage 3 non-small cell lung cancer, chemotherapy plus radiotherapy may reduce quality adjusted survival compared with radiotherapy alone. We found insufficient evidence about effects on quality of life.

Benefits: We found three systematic reviews[10,17,18] and three subsequent RCTs.[19–21] The first review (search date 1991, 22 RCTs, 3033 people with unresected stage 3 non-small cell lung cancer) found that chemotherapy plus thoracic irradiation significantly reduced mortality compared with radiotherapy alone, with an absolute survival benefit of 3% with combined treatment compared with radiotherapy alone at 2 years (mortality: HR 0.90, 95% CI 0.83 to 0.97).[10] The second review (search date 1995, 14 RCTs, including 9 RCTs identified by the first review and 1 RCT excluded from the first review because of poor methodology, 1887 people) found that a cisplatin based regimen plus radiotherapy significantly reduced mortality at 2 years compared with radiotherapy alone (OR 0.7, 95% CI 0.5 to 0.9).[17] The third review (search date 1995, 14 RCTs, including 11 RCTs identified by the first or second review, 2589 people) found that chemotherapy (primarily cisplatin based) plus radiotherapy significantly reduced mortality at 3 years compared with radiotherapy alone (RR 0.83, 95% CI 0.77 to 0.90).[18] The first subsequent RCT (458 people) compared 2 months of cisplatin plus vinblastine followed by standard radiotherapy with either standard or hyperfractionated radiotherapy alone.[19] It found that combined treatment significantly improved 5 year survival compared with radiotherapy alone (AR 8% with combined treatment *v* 5% with standard radiotherapy *v* 6% with hyperfractionated radiotherapy; $P = 0.04$ for combined *v* either comparison). The second subsequent RCT (446 people) compared radical radiotherapy plus four cycles of mitomycin plus ifosfamide plus cisplatin with radical radiotherapy alone.[20] It found no significant difference in median survival between groups (11.7 months with combined treatment *v* 9.7 months with radiotherapy alone; $P = 0.14$). The third subsequent RCT (506 people randomised, 460 analysed, stage 3A or 3B) compared radiotherapy (60 Gy) plus neoadjuvant cisplatin plus ifosfamide plus and mitomycin for three 21 day cycles versus radiotherapy alone.[21] It found that chemotherapy increased survival at 2 years, but the statistical significance was not reported (20.0% with adjuvant chemotherapy *v* 7.4% with no adjuvant treatment). We found insufficient evidence about the effects of combining thoracic irradiation with chemotherapy on quality of life.

Harms: The reviews and RCTs gave no information on long term adverse effects of treatment.[10,17–21]

Comment: Radioprotector drugs and three-dimensional conformal radiotherapy are being investigated to reduce the toxicities of combined modality treatment.[22] One meta-analysis (6 prospective phase II or III studies) found that, in people aged over 70 years with unresectable stage 3 non-small cell lung cancer, chemotherapy plus radiotherapy significantly reduced quality adjusted survival compared with radiotherapy alone (10.8 months with chemotherapy plus radiotherapy *v* 13.1 months with standard radiotherapy; $P < 0.01$).[23]

OPTION HYPERFRACTIONATED RADIATION TREATMENT FOR UNRESECTABLE STAGE 3 NON-SMALL CELL LUNG CANCER

One systematic review found no clear evidence that altered fractionation regimens, accelerated, hyperfractionated, or hyperfractionated split course regimens were more effective than conventional radiotherapy. One RCT identified by the review found that continuous, hyperfractionated, accelerated radiotherapy reduced mortality at 2 years compared with conventional radiotherapy in people with stage 3A, 3B, 1, or 2 non-small cell lung cancer.

Benefits:

Hyperfractionation: We found one systematic review (search date 2001, 7 RCTs, 1369 people, 4 altered fractionation regimens; accelerated, hyperfractionated, hyperfractionated and split course, and continuous, hyperfractionated, accelerated radiotherapy (CHART; see glossary, p 2049).[24] It found that of all the regimens examined, only CHART was clearly more effective than standard regimens. **Accelerated radiotherapy:** The review (search date 2001, 1 RCT, 99 people randomised, 77 people with stage 3 analysed) found no significant difference in survival between accelerated radiotherapy and standard radiotherapy (median survival: 14.4 months with accelerated *v* 13.8 months with standard; HR 0.93, 95% CI 0.67 to 1.28).[24] **Accelerated radiotherapy plus chemotherapy:** The review (search date 2001, 1 RCT, 81 people analysed) found no significant difference in survival between accelerated radiotherapy plus chemotherapy and standard radiotherapy alone (median survival: 15.0 months with accelerated plus chemotherapy *v* 13.8 months with standard; HR 0.99, 95% CI 0.73 to 1.32).[24] **Hyperfractionated radiotherapy:** The review (search date 2001, 3 RCTs, 361 people) identified one large RCT (306 people) and two small RCTs.[24] Overall, the review found no significant difference in survival between hyperfractionated radiotherapy and standard radiotherapy, although results were heterogeneous (HR 0.94, 95% CI 0.80 to 1.09, heterogeneity P = 0.025).[24] The large RCT found no significant difference in survival. One small RCT found that hyperfractionated radiotherapy increased survival. The second small RCT found that hyperfractionated radiotherapy decreased survival. **Hyperfractionated radiotherapy plus chemotherapy:** The review (search date 2001, 1 RCT, 17 people) found no significant difference in survival between hyperfractionated radiotherapy plus chemotherapy and standard radiotherapy alone (median survival: 14.5 months with radiotherapy plus chemotherapy *v* 6.0 months with radiotherapy alone; HR 1.72, 95% CI 0.51 to 5.74).[24] **Split-course hyperfractionated radiotherapy plus chemotherapy:** The review (search date 2001, 2 RCTs, 126 people) found that split-course hyperfractionated radiotherapy plus chemotherapy significantly improved survival compared with standard radiotherapy alone (HR 0.48, 95% CI 0.33 to 0.70).[24] However, there was significant heterogeneity among RCTs. One RCT found no significant difference in survival and the other RCT (considered to be of poor quality because of inadequate reporting) found that combined treatment significantly improved survival. **Continuous hyperfractionated accelerated**

radiotherapy (CHART): See glossary, p 2049. We found no systematic review or RCTs exclusively in people with stage 3 non-small cell lung cancer. The systematic review (search date 2001, 1 RCT, 563 people with non-small cell lung cancer; 61% with stage 3A or 3B, 39% with stage 1 or 2)[24] found that CHART significantly reduced mortality and improved local tumour control compared with standard radiotherapy at 2 years (mortality: AR 71% with CHART *v* 80% with standard radiotherapy, HR 0.78, 95% CI 0.65 to 0.94; P = 0.008; local tumour control: HR 0.79, 95% CI 0.63 to 0.98; P = 0.03).[22]

Harms: **Accelerated radiotherapy:** The review (search date 2001, 1 RCT, 77 people analysed) found that accelerated radiotherapy significantly increased grade 3 and 4 oesophageal toxicity compared with standard radiotherapy (number for each treatment group: 15 people with accelerated *v* 6 people with standard; P value not reported in review).[24] **Accelerated radiotherapy plus chemotherapy:** The review (search date 2001, 1 RCT, 104 people, 78% of people analysed) found that accelerated radiotherapy plus chemotherapy significantly increased grade 3 and 4 oesophageal toxicity compared with standard radiotherapy (24/51[47%] with accelerated *v* 6/53 [11%] with standard, P value not reported in review).[24] **Hyperfractionated radiotherapy:** The large RCT identified by the systematic review (search date 2001) found three treatment related deaths with hyperfractionated radiotherapy.[24] **CHART:** The systematic review (search date 2001)[24] found information on the adverse effects of CHART in further reports.[22,25] It found that CHART significantly increased pain on swallowing, heartburn (both of which were of brief duration), cough (P = 0.01), shortness of breath (P = 0.03), and dizziness (P = 0.03) compared with conventional radiotherapy over the first 3 months. It found no symptoms with a greater than 20% difference between treatment groups at 1 year.[25] The review found that CHART increased pulmonary fibrosis at 2 years (16% with CHART *v* 4% with standard, P value not reported).[24]

Comment: None.

OPTION PALLIATIVE CHEMOTHERAPY IN STAGE 4 NON-SMALL CELL LUNG CANCER

Systematic reviews in people with stage 4 non-small cell lung cancer have found that adding chemotherapy regimens containing cisplatin to supportive care increases survival at 1 year compared with supportive care alone. Limited evidence from RCTs suggests that chemotherapy plus best supportive care may improve quality of life compared with best supportive care alone. Two systematic reviews and subsequent RCTs in people with advanced non-small cell lung cancer found inconclusive evidence on the effects of single agent chemotherapy compared with combined chemotherapy. One systematic review and additional RCTs provided insufficient evidence to compare first line platinum based versus non-platinum based chemotherapy.

Benefits: **First line chemotherapy versus supportive care:** We found three systematic reviews.[10,26,27] The most recent systematic review (search date 1998, 4 earlier systematic reviews)[26] did not fully describe the four earlier systematic reviews it identified, three of

which included the same RCTs. The review did not perform a meta-analysis. The first review that performed a meta-analysis (search date 1991, 11 RCTs, 1190 people with advanced non-small cell lung cancer) compared supportive care plus chemotherapy versus supportive care alone.[10] It found that, in trials from the 1970s, long term alkylating agents plus supportive care did not significantly improve survival compared with supportive care alone (HR 1.26, 95% CI 0.96 to 1.66; P = 0.095). However, cisplatin containing regimens plus supportive care significantly increased survival at 1 year (HR 0.73; P < 0.0001) and increased median survival compared with supportive care alone (5.5 months with cisplatin containing regimens plus supportive care *v* 4 months with supportive care alone). It is not possible to deduce from these RCTs to what extent the observed effects are because of the cisplatin or to all the other drugs in the combinations studied. The second review[26] that performed a meta-analysis (search date not reported, 8 RCTs, 7 of which were included in the first review,[10] 712 people with advanced non-small cell lung cancer) comparing chemotherapy plus best supportive care versus best supportive care alone found that chemotherapy significantly reduced mortality at 6 months (OR 0.44, 95% CI 0.32 to 0.59).[26] The third review[27] identified four RCTs, which compared single agent chemotherapy plus best supportive care versus best supportive care alone, and assessed effects on quality of life.[28–31] Overall, the trials consistently found that chemotherapy plus best supportive care improved quality of life compared with best supportive care alone. The difference between groups was not significant in most trials, but they are likely to have been underpowered to detect a clinically important difference. The first RCT (207 people with stage 3B or 4 non-small cell lung cancer) found that adding vinorelbine to supportive care significantly improved emotional functioning (assessed by European Organization for Research and Treatment of Cancer QLQ-C30 questionnaire P = 0.01, absolute numbers not reported), nausea and vomiting (P = 0.04), pain (P < 0.01), and dyspnoea (P = 0.02) compared with supportive care alone.[28] It found no significant difference between groups in other measures of quality of life, although all scores, except those for diarrhoea, were improved in people taking vinorelbine.[28] The second RCT (300 people with symptomatic locally advanced or metastatic non-small cell lung cancer, Karnofsky performance status (see glossary, p 2049) 60–90) compared gemcitabine plus best supportive care versus best supportive care alone.[29] It found that people receiving gemcitabine had improved quality of life (assessed by European Organization for Research and Treatment of Cancer QLQ-C30 questionnaire) compared with people receiving best supportive care alone.[29] The RCT did not assess the significance of the difference between groups. The third RCT (157 people with stage 3B or 4 non-small cell lung cancer) found no significant difference in overall quality of life between paclitaxel plus supportive care and supportive care alone (assessed by the Rotterdam symptom checklist; lower scores indicate worse symptoms: –0.019 with paclitaxel *v* –0.017 with supportive care alone; P = 0.242), although scores improved in people taking paclitaxel.[31] The fourth RCT (191 people aged ≥ 70 years with stage 3B or 4 non-small cell lung cancer) found no

significant difference in global health status between adding vinorelbine to supportive care and supportive care alone, although functional scale scores were higher in people taking vinorelbine (global health status assessed by European Organization for Research and Treatment of Cancer QLQ-C30 questionnaire, higher score indicates better function, mean difference in score +4.58, 95% CI −0.26 to +9.43).[28] Toxicity scores were also higher in people receiving vinorelbine compared with supportive care alone, but the difference was not significant. **First line single agent versus combined chemotherapy:** We found two systematic reviews[32,33] and five subsequent RCTs.[34–38] The first systematic review (search date 1995–1996, 25 RCTs, 5156 people with stage 4 non-small cell lung cancer) found no significant difference between platinum analogue or vinorelbine containing combination chemotherapy and platinum analogue or vinorelbine alone in 1 year survival (RR 1.10, 95% CI 0.94 to 1.43).[32] The second systematic review (search date 2002, 3 RCTs) compared the single agent gemcitabine versus combination treatment.[33] The review did not pool results. It found that none of the RCTs found any significant difference between treatments in survival (results from the 3 RCTs for gemcitabine *v* combination: 7.9 months with gemcitabine *v* 6.1 months with combination; P = 0.13; 6.6 months with gemcitabine *v* 7.6 months with combination; P reported as not significant; 8.5 months with gemcitabine *v* 11.1 months with combination; P = 0.65). Two subsequent RCTs compared vinorelbine plus gemcitabine versus monotherapy and found different results.[34,37] The first subsequent RCT (120 people with advanced non-small cell lung cancer aged > 70 years) found that gemcitabine plus vinorelbine significantly improved survival at median 14 months compared with vinorelbine alone (median survival: 29 weeks with combined treatment *v* 18 weeks with single treatment; P < 0.01).[34] The second subsequent RCT (698 people aged 63–86 years with stage 3B or 4 disease) found no significant difference in survival between vinorelbine plus gemcitabine and either vinorelbine alone or gemcitabine alone (median survival: 30 weeks with combination *v* 36 weeks with vinorelbine *v* 28 weeks with gemcitabine; HR 1.17, 95% CI 0.95 to 1.44 for combination *v* vinorelbine; HR 1.06, 95% CI 0.86 to 1.29 for combination *v* gemcitabine).[37] The third subsequent RCT (522 chemotherapy naive people with stage 3 or 4 non-small cell lung cancer) found that gemcitabine plus cisplatin significantly improved survival compared with cisplatin alone (median survival: 9.1 months with combination *v* 7.6 months with cisplatin alone; P = 0.004).[35] The fourth subsequent RCT (415 with histologically or cytologically confirmed stage 3 or 4 non-small cell lung cancer) found that cisplatin plus vinorelbine significantly improved survival compared with cisplatin alone (median survival: 8 months with combination *v* 6 months with cisplatin alone; P = 0.002).[36] The fifth subsequent RCT (398 people with stage 3B or 4 non-small cell lung cancer) compared three treatments: irinotecan alone, cisplatin plus vindesine, and cisplatin plus irinotecan.[38] It found no significant difference in survival between irinotecan alone and irinotecan plus cisplatin (median survival time: 46 weeks with irinotecan alone *v* 45.6 weeks with cisplatin plus vindesine *v* 50 weeks with cisplatin plus irinotecan; 2 year survival:

21.9% with irinotecan alone *v* 18.7% with cisplatin plus vindesine *v* 19.4% with cisplatin plus irinotecan; P = 0.089 for irinotecan alone *v* cisplatin plus vindesine). **First line platinum based versus non-platinum based chemotherapy:** We found one systematic review of "new" chemotherapy agents (search date 2001, 4 RCTs)[40] and five additional RCTs[39,41–44] that compared platinum based versus non-platinum treatment. The systematic review identified two RCTs that compared cisplatin plus etoposide versus gemcitabine.[40] Neither RCT found any significant difference in survival (median survival in 1 RCT, 146 people; 7.6 with cisplatin plus etoposide *v* 6.6 months with gemcitabine; P > 0.9; second RCT, 53 people: 48 weeks with cisplatin plus etoposide *v* 37 weeks with gemcitabine; P = 0.65).[45,46] The systematic review identified two RCTs that compared vinorelbine alone versus vinorelbine plus cisplatin.[40,47,48] The studies used different doses of vinorelbine (50% dose difference) and found different results for survival. One RCT (231 people) found no significant difference between vinorelbine alone (80 mg/m^2) and vinorelbine plus cisplatin (median survival: 32 weeks with vinorelbine alone *v* 33 weeks with vinorelbine plus cisplatin; P = 0.48).[47] The other RCT (412 people) found that vinorelbine plus cisplatin significantly increased survival compared with vinorelbine alone (median survival: 31 weeks with vinorelbine alone *v* 40 weeks with vinorelbine plus cisplatin; P = 0.045).[48] The first additional RCT (441 people with stage 3 or 4 non-small cell lung cancer) compared docetaxel plus cisplatin versus docetaxel plus gemcitabine and found no significant difference in survival at 1 year (86/205 [42%] with docetaxel plus cisplatin *v* 78/201 [39%] with docetaxel plus gemcitabine; RR 1.08, 95% CI 0.84 to 1.33).[39] The second additionalRCT (509 people with stage 3 or 4 non-small cell lung cancer) comparing paclitaxel plus carboplatin versus paclitaxel plus gemcitabine found no significant difference in median survival (10.4 months with paclitaxel plus carboplatin *v* 9.8 months with paclitaxel plus gemcitabine; P = 0.32).[41] The third additional RCT (90 people with stage 3 or 4 non-small cell lung cancer) found similar median survival time between paclitaxel plus carboplatin and paclitaxel plus gemcitabine (14.1 months with paclitaxel plus carboplatin *v* 12.6 months paclitaxel plus gemcitabine; CI not reported).[42] The fourth additional RCT (267 people with stage 3B or 4 non-small cell lung cancer) compared four regimens: paclitaxel plus carboplatin plus gemcitabine, paclitaxel plus carboplatin plus vinorelbine, paclitaxel plus gemcitabine, and gemcitabine plus vinorelbine.[43] It found no significant difference in survival at 1 year among groups (range 38–44%, reported as non-significant, no further data reported), but it is likely to have been too small to detect a clinically important difference among regimens. The fifth additional RCT (284 people with stage 4 non-small cell lung cancer) compared three regimens: cisplatin plus carboplatin plus ifosfamide, cisplatin plus carboplatin plus gemcitabine, and ifosfamide plus gemcitabine.[44] It found no significant difference in median survival among groups, although people taking ifosfamide plus gemcitabine had longer median survival time compared with people taking a cisplatin containing regimen (P = 0.2). The RCT is likely to have been underpowered to detect a clinically important difference among regimens. **Any second line chemotherapy:** We found one

systematic review (search date not reported, 34 single agent studies and 24 combination regimen studies, 30 published only as an abstract).[49] The review found that results from studies were conflicting and was unable to draw conclusions because of the heterogeneity of participant selection in the studies, and the different definitions of people considered sensitive or refractory to treatment. **Second line single agent docetaxel:** We found one systematic review (search date 2000, 2 RCTs, 477 people resistant to platinum based combination chemotherapy).[50] Results of the RCTs were not combined because of trial heterogeneity. The first RCT identified by the review found that docetaxel 75 mg/m^2 significantly improved survival at 1 year compared with best supportive care (37% with docetaxel *v* 11% with best supportive care; P = 0.003).[51] The second RCT identified by the review found that docetaxel significantly improved survival at 1 year compared with vinorelbine or ifosfamide (32% with docetaxel *v* 19% with vinorelbine or ifosfamide; P = 0.025).[52]

Harms:

Over 50% of people with advanced lung cancer treated with chemotherapy reported alopecia, and gastrointestinal and haematological toxicity.[48] One non-systematic review found greater toxicity in people with Eastern Cooperative Oncology Group (ECOG) scale performance status 3 or 4 (see glossary, p 2049).[53] Subgroup analysis (64 people with ECOG scale performance status 2) from an RCT comparing four cisplatin based chemotherapy regimens found high rates of haematological and gastrointestinal toxicity and low response rates after 1 year; as a result the enrolment of people with ECOG performance status 2 was discontinued (proportion of people who had any grade 3–4 toxicity: 30–60% of people taking paclitaxel plus cisplatin; 8–67% of people taking gemcitabine plus cisplatin; 12–59% of people taking docetaxel plus cisplatin; 27–33% of people taking paclitaxel plus carboplatin; response rate with any type of chemotherapy 14%, 95% CI 5.6% to 22.6%; median survival 4.1 months, 95% CI 0.2 months to 31.0 months).[54] **First line single agent versus combined chemotherapy:** The second subsequent RCT (698 people) found that vinorelbine plus gemcitabine significantly increased thrombocytopenia and liver toxicity compared with vinorelbine alone and significantly increased neutropenia, vomiting, fatigue, extravasation effects, cardiac toxicity, and constipation compared with gemcitabine alone.[37] The fifth subsequent RCT (398 people with stage 3B or 4 non-small cell lung cancer) found that platinum plus vindesine increased overall major adverse effects compared with irinotecan alone.[38] However, irinotecan significantly increased diarrhoea (grade 3 or 4 nausea or vomiting: 23% with platinum plus vindesine *v* 9% with irinotecan alone; P = 0.001; grade 3 or 4 diarrhoea: 3% with platinum plus vindesine *v* 15% with irinotecan alone; P = 0.008). **First line platinum based versus non-platinum based chemotherapy:** The first additional RCT, which compared docetaxel plus cisplatin with docetaxel plus gemcitabine, found that docetaxel plus cisplatin significantly increased neutropenia (P = 0.01), nausea and vomiting (P = 0.001), and diarrhoea (P = 0.001).[39] The RCTs[41,42] comparing paclitaxel plus carboplatin versus paclitaxel plus gemcitabine found similar levels of haematological toxicity between groups,

although one RCT[42] found that paclitaxel plus carboplatin significantly increased grade 3 thrombocytopenia compared with paclitaxel plus gemcitabine. The fourth additional RCT found that gemcitabine plus vinorelbine significantly reduced non-haematological toxicity (neuropathy, alopecia, nausea/emesis, diarrhoea, myalgia/arthralgia) compared with paclitaxel plus carboplatin plus gemcitabine, paclitaxel plus carboplatin plus vinorelbine, or paclitaxel plus gemcitabine ($P < 0.05$ for gemcitabine plus vinorelbine *v* any other regimen).[43]

Comment: For people with stage 4 non-small cell lung cancer, treatment options consist of either chemotherapy or symptomatic care, including palliative radiation. People with Eastern Cooperative Oncology Group (ECOG) scale performance status 3 or 4 have usually been excluded from RCTs of lung cancer chemotherapy. One non-systematic review has found that carboplatin has comparable response rate to, but a better toxicity profile than, cisplatin in people with stage 4 non-small cell lung cancer.[55] One RCT (408 people with stage 3B or 4 non-small cell lung cancer) comparing carboplatin plus paclitaxel versus vinorelbine plus cisplatin found no significant difference in survival at 1 year (36% with carboplatin plus paclitaxel *v* 38% with vinorelbine plus cisplatin; reported as non-significant). It found that vinorelbine plus cisplatin significantly increased withdrawal owing to toxicity (15% with carboplatin plus paclitaxel *v* 28% with vinorelbine plus cisplatin; $P = 0.001$).[56] Newer agents such as vinorelbine, gemcitabine, irinotecan, paclitaxel, and docetaxel produce objective responses in more than 20% of people with advanced lung cancer,[55] and combinations of some of these agents may be as effective and may cause less toxicity than platinum based regimens. Measuring quality of life in people with lung cancer remains a serious challenge.[40] In the first subsequent RCT comparing first line single agent versus combined chemotherapy, median survival with vinorelbine alone was much shorter than in the second subsequent RCT (18 weeks[34] *v* 36 weeks[37]). The second subsequent RCT speculates that this may be because either the higher doses of vinorelbine used in the first subsequent RCT may be toxic in the elderly based on phase I evidence or there may have been biases in patient selection. The systematic review comparing second line chemotherapy versus supportive care recommended that RCTs of second line chemotherapy report and analyse details of patient characteristics, response to first line treatment, and interval between last chemotherapy and recurrence.[49]

QUESTION What are the effects of treatments for small cell lung cancer?

OPTION DOSE INTENSIFICATION OF CHEMOTHERAPY VERSUS STANDARD CHEMOTHERAPY

One systematic review found limited evidence that intensifying chemotherapy dose by increasing the number of chemotherapy cycles, increasing chemotherapy dose, or increasing dose intensity per cycle may modestly improve survival compared with standard chemotherapy. However, additional RCTs have found inconclusive evidence about the effects of dose intensification on survival.

Benefits: We found one systematic review (search date 2001, 20 RCTs, 5490 people, most with extensive stage small cell lung cancer)[57] and three additional RCTs[58–60] assessing dose or dose intensity of chemotherapy. Methods of dose intensification differed among RCTs. The review identified eight RCTs comparing an increased (12–14) with a standard (5–6) number of cycles of chemotherapy; five RCTs comparing higher with lower doses of chemotherapy; four RCTs comparing higher with lower intensity chemotherapy, and three RCTs comparing changes in both dose per cycle and number of cycles of chemotherapy with standard dose chemotherapy for standard number of cycles (see comment below). The review found that the median survival time was higher in people receiving dose intensification compared with standard chemotherapy (9.8 months with dose intensification *v* 11.5 months with standard chemotherapy, significance not reported). The difference in median survival was increased if the two RCTs (of the 3 that altered both the dose per cycle and the total number of cycles of chemotherapy) that reduced the number of treatment cycles were excluded (11.5 months with dose intensification *v* 8.7 months with standard chemotherapy, significance not reported). The first additional RCT (229 people with extensive stage small cell lung cancer) comparing dose intensive (cisplatin plus vincristine plus doxorubicin plus etoposide) with standard chemotherapy (alternating cyclophosphamide, doxorubicin, vincristine plus cisplatin) found no significant difference in progression free survival (median 0.66 years in each group) or overall survival (0.98 with dose intensive *v* 0.91 years with standard chemotherapy, reported as non-significant, no further data reported).[58] The second additional RCT (59 people with limited stage and 74 people with extensive stage small cell lung cancer) found no significant difference between paclitaxel plus cisplatin plus etoposide and cisplatin plus etoposide in survival at 1 year (AR 38.2% with paclitaxel plus cisplatin plus etoposide *v* 37% with cisplatin plus etoposide; P = 0.09).[59] The third additional RCT (233 people with extensive disease) found no significant difference in survival over 2 years with three different schedules of epirubicin, vindesine, and ifosfamide (6 cycles every 3 weeks; 6 accelerated cycles every 2 weeks with granulocyte macrophage colony stimulating factor [GM-CSF] support, and 6 accelerated cycles every 2 weeks with oral co-trimoxazole) (2 year survival 5–6%; P = 0.86).[60]

Harms: The review gave no information on adverse effects.[57] The additional RCTs found that, except in people with widespread extensive stage small cell lung cancer, adverse effects of chemotherapy were of short duration.[50,58,61] However, the first RCT found that dose intensive chemotherapy significantly increased deaths related to toxicity compared with standard chemotherapy (9/110 [8%] with dose intensive *v* 1/109 [1%] with standard chemotherapy; RR 8.9, 95% CI 1.1 to 69.0; NNH 14, 95% CI 7 to 60).[58] The second RCT also found that paclitaxel plus cisplatin plus etoposide significantly increased deaths related to toxicity compared with cisplatin plus etoposide (8/62 [13%] with paclitaxel plus cisplatin plus etoposide *v* 0/71 [0%] with cisplatin plus etoposide; P = 0.001).[58]

Comment: Dose escalation and intensification may modestly improve survival; however, the only review of dose intensification available included four different variations of dose and cycle across 20 studies, making comparisons difficult. More research on alternative approaches to the treatment of small cell lung cancer is needed.

OPTION ADDING THORACIC IRRADIATION TO CHEMOTHERAPY IN LIMITED STAGE SMALL CELL LUNG CANCER

Two systematic reviews in people with limited stage small cell lung cancer have found that adding thoracic irradiation to chemotherapy improves survival at 3 years and local control compared with chemotherapy alone. However, one of these reviews has found that thoracic radiation plus chemotherapy increases death related to treatment compared with chemotherapy alone. One systematic review and six additional RCTs found insufficient evidence on the best timing, dose, and fractionation of radiation.

Benefits: We found two systematic reviews.[62,63] The first review (search date not reported, 13 RCTs, 2573 people with limited stage small cell lung cancer) found that radiation plus chemotherapy significantly increased 3 year survival compared with chemotherapy alone (AR 15% with radiation plus chemotherapy *v* 10% with chemotherapy alone; P = 0.001).[62] The second review (search date not reported, 11 RCTs, 10 of which were included in the first review, 1911 people with limited stage small cell lung cancer) pooled data from nine of the RCTs (1521 people) and found that thoracic radiation plus chemotherapy significantly improved local control compared with chemotherapy alone (50% with radiation plus chemotherapy *v* 25% with chemotherapy alone; ARI of improved local control 25%, 95% CI 17% to 34%).[63] **Timing of radiation:** We found one systematic review (search date 2000, 4 RCTs, 927 people with limited stage small cell lung cancer),[64] one additional RCT,[65] and two subsequent RCTs,[66,67] which compared early with late addition of thoracic radiotherapy to chemotherapy. The review found no significant difference between early and late addition of radiotherapy in 5 year survival (AR 66/455 [14.5%] with early addition *v* 63/472 [13.2%] with late addition; RR 1.09, 95% CI 0.78 to 1.48).[65] The additional RCT, included in the review but not in the meta-analysis, found that early radiotherapy significantly increased 5 year survival compared with late addition of radiotherapy (30% with early addition *v* 15% with late addition; P = 0.03).[65] The first subsequent RCT (81 people with limited stage small cell lung cancer) compared early radiotherapy (given with the first cycle of chemotherapy) with late radiotherapy (given with the fourth cycle of chemotherapy).[66] It found no significant difference between early and late radiotherapy in survival after median follow up of 35 months (median 17.5 months with early radiotherapy *v* 17.0 months with late radiotherapy; P = 0.6). The second subsequent RCT (231 people with limited stage small cell lung cancer receiving 4 cycles of cisplatin plus etoposide) compared early addition of thoracic radiotherapy (with the first cycle of chemotherapy [concurrent]) versus late (after the fourth cycle of chemotherapy [sequential]).[67] It found no significant difference in survival at 2, 3, or 5

years between concurrent and sequential radiotherapy (5 year survival: 24% with concurrent *v* 18% with sequential; P = 0.097). Adjustments for prognostic factors, performance status (see glossary, p 2049), age and stage suggested that overall there was a significantly lower risk of death in people receiving concurrent rather than sequential radiotherapy (HR 0.70, 95% CI 0.52 to 0.94; P = 0.02).[67] **Dose:** One RCT (333 people with limited stage small cell lung cancer) found no significant difference between standard dose radiotherapy (25.0 Gy over 2 weeks) and high dose radiotherapy (37.5 Gy over 3 weeks) in overall survival over 3 years (P = 0.18; results presented graphically).[68] **Fractionation:** We found two RCTs.[69,70] The first RCT (417 people) found that hyperfractionation (twice daily treatment) compared with conventional fractionation (once daily treatment) significantly improved 5 year survival (26% with hyperfractionation *v* 16% with conventional fractionation; P = 0.04).[69] The second RCT (353 people) comparing once daily irradiation with twice daily irradiation found no significant difference in 3 year survival (34% with 50.4 Gy in 28 fractions daily *v* 29% with 48.0 Gy in 32 fractions twice daily; P = 0.46).[70]

Harms: The second systematic review found that thoracic radiation plus chemotherapy significantly increased death related to treatment compared with chemotherapy alone (29/884 [3.3%] with radiation plus chemotherapy *v* 12/841 [1.4%] with chemotherapy alone; OR 2.54, 95% CI 1.90 to 3.18).[63] **Fractionation:** One RCT found that hyperfractionation increased the incidence of oesophagitis compared with conventional fractionation.[69]

Comment: Interest in adding thoracic irradiation to chemotherapy derives from the observation that local recurrence in the chest is a major cause of first treatment failure and carries an extremely poor prognosis. One non-systematic review suggested that chest irradiation reduced local failure rates and increased 3 year survival by 50%.[71] The reasons for this improvement have not been established but may include the early use of radiation plus chemotherapy rather than improvements in either modality alone.[72] The RCTs of early versus late addition of radiotherapy used different methods and do not provide strong evidence.[64–66] The different results may be explained by different rates of early toxicity from treatment and different rates of relapse in the central nervous system.

OPTION PROPHYLACTIC CRANIAL IRRADIATION FOR PEOPLE IN COMPLETE REMISSION FROM SMALL CELL LUNG CANCER

One systematic review in people with small cell lung cancer in complete remission has found that prophylactic cranial irradiation improves survival at 3 years and reduces the risk of developing brain metastases compared with no irradiation. Although long term cognitive dysfunction after cranial irradiation has been described in non-randomised studies, RCTs have not found a cumulative increase in neuropsychological dysfunction.

Benefits: We found one systematic review (search date 2000, 7 RCTs, 987 people with small cell lung cancer in complete remission) comparing cranial radiation with no cranial radiation.[73] Of the people in the

RCTs, 12% in the irradiation group and 17% in the no irradiation group had extensive stage small cell lung cancer at presentation. It found that cranial irradiation significantly improved survival and increased disease free survival compared with no cranial irradiation (survival: RR of death at 3 years 0.84, 95% CI 0.73 to 0.97, corresponding to a 5.4% increase in survival; disease free survival: RR of recurrence or death at 3 years 0.75, 95% CI 0.65 to 0.86). The review found that cranial irradiation significantly reduced the cumulative incidence of brain metastases compared with no cranial irradiation (RR 0.46, 95% CI 0.38 to 0.57). Larger doses of radiation significantly reduced brain metastases ($P = 0.02$), but did not significantly improve survival ($P = 0.89$).

Harms: Non-randomised studies suggest that prophylactic cranial irradiation may lead to neuropsychological sequelae but the review was unable to assess this because adequate assessments were carried out in only two of the seven RCTs.[73] These two RCTs found no cumulative increase in neuropsychological dysfunction in individuals receiving prophylactic cranial irradiation. These RCTs and other non-randomised studies found that 24–60% of participants may have neuropsychological problems before treatment, and other studies have not accounted for potential confounding factors such as age, tobacco use, paraneoplastic syndromes, and neurotoxic chemotherapy effects.

Comment: The clinical importance of cognitive impairment after prophylactic cranial irradiation remains unclear. Differences in survival benefiting those people receiving prophylactic cranial irradiation are small, reflecting the impact of other events not influenced by prophylactic cranial irradiation, e.g. other metastases or thoracic relapse.[74]

OPTION ORAL ETOPOSIDE IN EXTENSIVE STAGE SMALL CELL LUNG CANCER

Two RCTs in people with extensive stage small cell lung cancer found that oral etoposide reduced survival compared with combination chemotherapy at 1 year. One RCT, in people with extensive stage small cell lung cancer who had not responded to induction combination chemotherapy, found no significant difference between oral etoposide and no further treatment in mortality at 3 years, although overall mortality was lower in people taking etoposide. RCTs found that etoposide may reduce nausea, alopecia, and numbness in the short term compared with combination chemotherapy, but found no evidence that it offered better quality of life overall.

Benefits: We found no systematic review but found three RCTs.[75–77] **Versus combination chemotherapy:** The first RCT (155 people with extensive stage small cell lung cancer) compared oral etoposide 100 mg daily for 5 days with combination chemotherapy.[75] It found that etoposide significantly reduced survival at 1 year compared with combined chemotherapy (9.8% with etoposide *v* 19.3% with combined chemotherapy; $P < 0.05$). It found similar median survival rates with etoposide compared with combination chemotherapy (4.8 months with etoposide *v* 5.9 months with combined chemotherapy; CI not reported) and found inconclusive results on quality of life. Acute nausea was significantly worse with combination chemotherapy ($P < 0.01$), but pain, appetite, general well

being, and mood were worse with oral etoposide ($P < 0.001$). Palliation of lung cancer symptoms was of significantly shorter duration with etoposide than with combination chemotherapy ($P < 0.01$).[75] The second RCT (339 people with extensive stage small cell lung cancer) comparing oral etoposide with combination chemotherapy found that etoposide significantly reduced survival at mean 21 months (HR 1.35, 95% CI 1.03 to 1.70; $P = 0.03$; absolute numbers not reported).[76] **Versus no further treatment:** The third RCT (233 people with extensive stage small cell lung cancer and Karnofsky performance status (see glossary, p 2049) ≥ 50 who had not responded after 4 cycles of intravenous cisplatin, etoposide, and ifosfamide) compared oral etoposide 50 mg/m^2 versus no further treatment for 3 months.[77] It found that oral etoposide significantly increased median progression free survival compared with no treatment (8.2 months with etoposide *v* 6.5 months with no treatment; $P = 0.0018$). It found no significant difference in overall survival at 3 years, although mortality was lower in people taking etoposide (9.1% with etoposide *v* 1.9% with no treatment; $P = 0.0704$).

Harms: **Versus combination chemotherapy:** The first RCT found that etoposide significantly reduced nausea in the short term (assessed by daily diary card; $P < 0.01$) compared with combination chemotherapy.[75] However, it found that combination chemotherapy significantly improved general well-being (assessed by daily diary card; $P < 0.01$) and overall quality of life (assessed by Rotterdam Symptom Checklist; $P < 0.01$) compared with etoposide.[75] The second RCT found that etoposide reduced alopecia and numbness compared with combination chemotherapy, but increased haematological adverse effects, particularly anaemia.[76] **Versus no further treatment:** The third RCT found that oral etoposide was associated with alopecia and grade 3–4 toxicities, including myelosuppression (40% of people), anaemia (20%), and granulocytopenia (42%).[77] The RCT gave no comparative information about adverse effects in people receiving no treatment.

Comment: Treatment of extensive stage disease is palliative and, because age has been identified as a prognostic factor in small cell lung cancer, studies have looked at outcomes in elderly people with limited and extensive stage disease and in people of all ages with a poor prognosis. Although small cell lung cancer is relatively sensitive to chemotherapy, extensive stage disease remains incurable. Median survival with treatment is 10–12 months, and as yet has been unaffected by high dose combination chemotherapy. Because of its lower acute toxicity, etoposide may be considered for elderly people with extensive stage disease or people with a poor prognosis.

GLOSSARY

Continuous hyperfractionated accelerated radiotherapy (CHART) Radiotherapy given at a rate of two or more radiation fractions a day (each of smaller dose than conventionally fractionated doses). The number of fractions a week is gradually increased to shorten overall duration of treatment.

Performance status Expression used to describe functional status or wellness of participants in studies of cancer. There are two widely accepted scales: the Eastern Cooperative Oncology Group (ECOG) scale (0 = no symptoms; 1 = symptomatic

but no extra time in bed; 2 = in bed less than 50% of the day, no work, can care for self; 3 = in bed more than 50% of day, not bedridden, minimal self care; 4 = completely bedridden), and the Karnofsky Scale of symptoms and disability (from 100% = no symptoms to 0% = dead).

Split-course, hyperfractionated radiotherapy Radiotherapy using two or more fractions daily of smaller than conventional fraction size, where the total dose is split into at least two separate courses with an interruption of 10–14 days.

Substantive changes

Pre- and postoperative chemotherapy in people with resectable non-small cell lung cancer One RCT added;[12] categorisation unchanged.

Adding chemotherapy to thoracic irradiation for unresectable stage 3 non-small cell lung cancer One RCT added;[21] categorisation unchanged.

Hyperfractionation (stage 3) One systematic review added;[24] categorisation unchanged, but benefits and harms data enhanced.

Chemotherapy in stage 4 non-small cell lung cancer One systematic review and two RCTs added;[33,37,38] categorisation unchanged but benefits and harms data enhanced.

QUESTIONS

INTERVENTIONS

TREATMENT IN SYMPTOMATIC NON-PREGNANT WOMEN

Beneficial

Antibacterial treatment 2057

TREATMENT IN PREGNANT WOMEN

Likely to be beneficial

Antibacterial treatment (except intravaginal clindamycin) in pregnant women who have had a previous preterm birth 2059

Unknown effectiveness

Antibacterial treatment (except intravaginal clindamycin) in low risk pregnancy 2059

Likely to be ineffective or harmful

Intravaginal clindamycin cream. 2059

TREATING MALE SEXUAL PARTNER

Likely to be ineffective or harmful

Treating a woman's male sexual partner with metronidazole or clindamycin (does not reduce the woman's risk of recurrence) 2061

TREATMENT BEFORE GYNAECOLOGICAL PROCEDURES

Likely to be beneficial

Oral or intravaginal antibacterial treatment before surgical abortion 2061

Unknown effectiveness

Antibacterial treatment before gynaecological procedures other than abortion 2061

To be covered in future updates

Recurrent bacterial vaginosis

Key Messages

- Bacterial vaginosis may resolve spontaneously.

In symptomatic non-pregnant women

- **Antibacterial treatment** One systematic review found that antibacterial treatment (intravaginal clindamycin or metronidazole) increased cure rate compared with placebo. One systematic review found no significant difference between oral and intravaginal antibacterial drugs in cure rates after 5–10 days or at 4 weeks. Another systematic review has found that a 7 day course of twice daily oral metronidazole increases cure rates at 3–4 weeks compared with a single 2 g dose. Limited evidence from RCTs found no significant difference in cure rates with oral clindamycin versus oral metronidazole twice daily for 7

days, and no significant difference between once and twice daily dosing with intravaginal metronidazole gel. One RCT found no significant difference in cure rates at 35 days between intravaginal clindamycin ovules for 3 days and intravaginal clindamycin cream for 7 days. We found no evidence on long term outcomes. One small RCT found that more than 50% of women had recurrent bacterial vaginosis 2 months after antibacterial treatment.

In pregnant women

- **Antibacterial treatment (except intravaginal clindamycin) in pregnant women who have had a previous preterm birth** One systematic review found that antibiotics reduced the risk of low birth weight in women with bacterial vaginosis who had a previous preterm delivery, although results for preterm delivery were heterogeneous. Subgroup analysis of one subsequent RCT found that oral clindamycin given early in the second trimester reduced miscarriages or preterm deliveries compared with placebo.
- **Antibacterial treatment (except intravaginal clindamycin) in low risk pregnancy** One systematic review in general populations of pregnant women found no significant difference between antibiotics (oral or vaginal) and placebo in the risk of preterm delivery, low birth weight, neonatal sepsis, or perinatal death. However, one subsequent RCT found that oral clindamycin given early in the second trimester reduced miscarriages or preterm deliveries compared with placebo.
- **Intravaginal clindamycin cream** Three RCTs found that treating pregnant women with intravaginal clindamycin cream was associated with an increased risk of preterm delivery and low birth weight compared with placebo, but the increase was not significant.

Treating male sexual partner

- **Treating a woman's male sexual partner with metronidazole or clindamycin** One systematic review has found that, in women receiving antibacterial agents, and who have one steady male sexual partner, treating the partner with oral metronidazole or clindamycin does not reduce the woman's risk of recurrence.

Treatment before gynaecological procedures

- **Oral or intravaginal antibacterial treatment before surgical abortion** Three RCTs consistently found that oral or intravaginal antibacterial treatment in women with bacterial vaginosis about to have surgical abortion was associated with a lower risk of pelvic inflammatory disease compared with placebo, but the difference was only significant in the largest RCT.
- **Antibacterial treatment before gynaecological procedures (other than abortion)** We found no RCTs on the effects of antibacterial treatment in women with bacterial vaginosis about to have gynaecological procedures other than abortion.

DEFINITION Bacterial vaginosis is a microbial disease characterised by an alteration in the bacterial flora of the vagina from a predominance of *Lactobacillus* species to high concentrations of anaerobic bacteria. The condition is asymptomatic in 50% of infected women. Women with symptoms have an excessive white to grey, or malodorous vaginal discharge, or both; the odour may be particularly noticeable during sexual intercourse. Diagnosis requires three out of four

Bacterial vaginosis

features: the presence of clue cells; a homogenous discharge adherent to the vaginal walls; pH of vaginal fluid greater than 4.5; and a "fishy" amine odour of the vaginal discharge before or after addition of 10% potassium hydroxide.

INCIDENCE/ PREVALENCE Bacterial vaginosis is the most common infectious cause of vaginitis, being about twice as common as candidiasis.[1] Prevalences of 10–61% have been reported among unselected women from a range of settings.[2] Data on incidence are limited but one study found that, over a 2 year period, 50% of women using an intrauterine contraceptive device had at least one episode, as did 20% of women using oral contraceptives.[3] Bacterial vaginosis is particularly prevalent among lesbians.[4]

AETIOLOGY/ RISK FACTORS The cause of bacterial vaginosis is not fully understood. Risk factors include new or multiple sexual partners[1,3,5] and early age of sexual intercourse,[6] but no causative microorganism has been shown to be transmitted between partners. Use of an intrauterine contraceptive device[3] and douching[5] have also been reported as risk factors. Infection seems to be most common around the time of menstruation.[7]

PROGNOSIS The course of bacterial vaginosis varies and is poorly understood. Without treatment, symptoms may persist or resolve in both pregnant and non-pregnant women. Recurrence after treatment occurs in about a third of women. The condition is associated increased rates of complications of pregnancy: low birth weight; preterm birth (pooled OR from 10 cohort studies: 1.8, 95% CI 1.5 to 2.6);[8] preterm labour; premature rupture of membranes; late miscarriage; chorioamnionitis (48% *v* 22%; OR 2.6, 95% CI 1.0 to 6.6);[9] endometritis after normal delivery (8.2% *v* 1.5%; OR 5.6, 95% CI 1.8 to 17.2);[10] endometritis after caesarean section (55% *v* 17%; OR 5.8, 95% CI 3.0 to 10.9);[11] and surgery to the genital tract. Women who have had a previous preterm delivery are especially at risk of complications in pregnancy, with a sevenfold increased risk of preterm birth (24/428 [5.6%] in all women *v* 10/24 [41.7%] in women with a previous preterm birth).[12] Bacterial vaginosis can also enhance HIV acquisition and transmission.[13]

AIMS OF INTERVENTION To alleviate symptoms and to prevent complications relating to childbirth, termination of pregnancy, and gynaecological surgery, with minimal adverse effects; to reduce adverse neonatal outcomes.

OUTCOMES Preterm delivery; other complications in pregnancy; puerperal and neonatal morbidity and mortality; clinical or microbiological cure rates, usually at 1–2 weeks or 4 weeks after completing treatment; recurrence rates.

METHODS *Clinical Evidence* search and appraisal July 2003. In addition, the authors used information obtained from drug manufacturers.

QUESTION **What are the effects of different antibacterial regimens in non-pregnant women with symptomatic bacterial vaginosis?**

OPTION **ANTIBACTERIAL TREATMENT**

One systematic review found that antibacterial treatment (intrvaginal clindamycin or metronidazole) increased cure rate compared with placebo. One systematic review found no significant difference in cure rates at 5–10 days or 4 weeks between oral and intravaginal antibacterial drugs. Another systematic review has found that a 7 day course of twice daily oral metronidazole increases cure rates compared with a single 2 g dose. Limited evidence from RCTs found no significant difference in cure rates between oral clindamycin and oral metronidazole, and no significant difference between once and twice daily dosing with intravaginal metronidazole gel. One RCT found no significant difference in cure rates at 35 days between 3 day treatment with intravaginal clindamycin ovules and 7 day treatment with intravaginal clindamycin cream. We found no evidence on long term outcomes. One small RCT found that more than 50% of women had recurrent bacterial vaginosis 2 months after antibacterial treatment.

Benefits:

Antibacterial versus placebo treatment: We found one systematic review (search date 1996) that summarised the results of four RCTs comparing antibacterial treatment versus placebo.[14] The systematic review found that the cumulative cure rate 25–39 days after completion of treatment was 82% with intravaginal clindamycin cream compared with 35% with placebo. The cumulative cure rates for intravaginal metronidazole gel 4–16 days after completion of treatment was 81% compared with 17–27% with placebo. The relatively high cumulative cure rates with placebo treatment suggest that bacterial vaginosis could resolve spontaneously without treatment. **Oral versus intravaginal antibacterial treatment:** We found one systematic review (search date 1996, 5 RCTs) comparing oral and intravaginal formulations of metronidazole and clindamycin,[14] and one subsequent RCT.[15] Three RCTs were conducted in symptomatic non-pregnant women and two were conducted in symptomatic and asymptomatic non-pregnant women.[14] There was no significant difference in cumulative cure rates 5–10 days after completing treatment (86% with oral metronidazole 500 mg twice daily for 7 days *v* 85% with clindamycin vaginal cream 5 g at bedtime for 7 days *v* 81% for metronidazole vaginal gel 5 g twice daily for 5 days; P values and CI not reported). Four weeks after completing treatment, the cumulative cure rates were 78% for oral metronidazole, 82% for clindamycin vaginal cream, and 71% for metronidazole vaginal gel. The subsequent RCT (399 women) comparing clindamycin vaginal cream versus oral metronidazole also found no significant difference in cure rates (68% for clindamycin cream *v* 67% for oral metronidazole; $P = 0.81$).[15] However, a large number of women were not included in the efficacy analysis, making interpretation of the results difficult (results reported on 233 women, many exclusions for different reasons). **Different oral antibacterial regimens:** We found one systematic review

(search date 1996, 4 RCTs) comparing metronidazole 500 mg twice daily for 7 days versus a single 2 g dose of metronidazole,[14] and two additional RCTs comparing metronidazole 500 mg twice daily for 7 days versus clindamycin 300 mg twice daily for 7 days.[16,17] The systematic review found significantly higher cumulative cure rates at 3–4 weeks after completing treatment with 7 day metronidazole than with single dose metronidazole (82% with 7 days of metronidazole *v* 62% with single dose metronidazole; $P < 0.05$). The first additional RCT (143 symptomatic non-pregnant women) found no significant difference in cure rates within 7–10 days of starting treatment (women cured: 46/49 [94%] with clindamycin *v* 48/50 [96%] with metronidazole; RR 0.98, 95% CI 0.89 to 1.07).[16] A quarter of women were lost to follow up. The second RCT (96 non-pregnant women) found no significant difference in cure rates (39/41 [95%] with clindamycin *v* 41/44 [93%] with metronidazole; ARI 2%; RR 1.00, 95% CI 0.92 to 1.14).[17] **Different intravaginal antibacterial regimens:** We found two RCTs.[18,19] The first RCT (514 women) found no significant difference in effectiveness between once daily versus twice daily dosing of intravaginal metronidazole gel (118/207 [57%] with once daily gel *v* 129/209 [62%] with twice daily gel; RR 0.92, 95% CI 0.79 to 1.08).[18] The second RCT (662 women) compared 3 day treatment with intravaginal clindamycin ovules versus 7 day treatment with intravaginal clindamycin cream.[19] It found no significant difference in cure rates at 35 day assessment (134/238 [56%] with 3 day regimen *v* 113/224 [50%] with 7 day regimen; ARI 6%; RR 1.10, 95% CI 0.94 to 1.30).

Harms: The review of different oral antibacterial regimens found that adverse effects occurred in between a quarter and two thirds of women taking oral metronidazole, including mild to moderate nausea/dyspepsia, unpleasant metallic taste, headache, and dizziness.[14] Infrequent adverse effects from oral clindamycin included heartburn, nausea, vomiting, diarrhoea, constipation, headache, dizziness, and vertigo; the trials gave no data on frequency. Intravaginal clindamycin has been associated, rarely, with mild to severe colitis[20] and vaginal candidiasis. The RCT of once versus twice daily intravaginal metronidazole gel found no significant difference in frequency of adverse effects.[18] Comparison of results across RCTs found that yeast vulvovaginitis might be less common with intravaginal metronidazole than with oral metronidazole (4% for intravaginal[21] *v* 8–22% for oral[22]).

Comment: Intravaginal administration reduces systemic absorption and systemic adverse effects. Some women may prefer oral medication because it is more convenient. We found one RCT (61 women, 19 withdrew) that followed up women who had been treated for bacterial vaginosis with either clindamycin vaginal cream or oral metronidazole.[23] It found that more than 50% of women in both groups had recurrent bacterial vaginosis 2 months after treatment (exact figures and statistical analysis not reported).

QUESTION **What are the effects of antibacterial treatments in pregnant women with bacterial vaginosis?**

OPTION **TREATMENTS FOR PREGNANT WOMEN**

One systematic review in general populations of pregnant women found no significant difference between antibiotics (oral or vaginal) and placebo in the risk of preterm delivery, low birth weight, neonatal sepsis, or perinatal death. The review found that antibiotics reduced the risk of low birth weight in women with bacterial vaginosis who had a previous preterm delivery, although results for preterm delivery were heterogeneous. One subsequent RCT found that oral clindamycin given early in the second trimester reduced miscarriages or preterm deliveries compared with placebo, both among all women and in the subgroup of women with previous late miscarriage or preterm delivery. Three RCTs that compared intravaginal clindamycin cream versus placebo found a non-significant increase in preterm birth and low birth weight in women with bacterial vaginosis treated with clindamycin cream compared with placebo.

Benefits: We found one systematic review (search date 2002, 10 RCTs, 4249 women) comparing antibacterial treatment versus placebo,[24] and one subsequent RCT.[25] **In all pregnant women, regardless of risk:** Overall, the review found no significant difference between antibiotic and placebo in the risk of preterm delivery, low birth weight, perinatal death, or neonatal sepsis in the general population of pregnant women with bacterial vaginosis (preterm delivery < 37 weeks' gestation: OR 0.95, 95% CI 0.82 to 1.10; low birth weight: OR 0.97, 95% CI 0.76 to 1.23; perinatal death: OR 2.17, 95% CI 0.72 to 6.54; neonatal sepsis: 0.95, 95% CI 0.06 to 15.28).[24] It similarly found no significant difference in these outcomes with oral antibiotics versus placebo or no treatment, and with vaginal antibiotics versus placebo or no treatment. The subsequent RCT (485 asymptomatic women with bacterial vaginosis) found that treatment with oral clindamycin early in the second trimester significantly decreased the rate of miscarriage or preterm delivery compared with placebo (13/244 [5.3%] with clindamycin *v* 38/241 [15.8%] with placebo; ARR 10.4%, 95% CI 5.0% to 15.8%).[25] **In women with previous preterm birth:** The review found that antibiotics significantly reduced the risk of low birth weight compared with placebo (OR 0.31, 95% CI 0.13 to 0.75). However, it did not significantly reduce the risk of preterm delivery or perinatal death (preterm delivery: OR 0.83, 95% CI 0.59 to 1.17; perinatal death: OR 3.64, 95% CI 0.86 to 15.45), although results for preterm delivery were heterogeneous among studies (see comment below). Subgroup analysis of the subsequent RCT found that oral clindamycin reduced the rate of late miscarriage and preterm delivery in women who had previous late miscarriage or preterm delivery (7/36 [19%] with clindamycin *v* 16/38 [42%] with placebo; RR 0.46, 95% CI 0.22 to 0.99; calculated by *Clinical Evidence*).[25]

Harms: Overall, the systematic review found that adverse effects of antibiotics were uncommon.[24] It found no significant difference between antibiotics and placebo or no treatment in the risk of adverse effects

(adverse effects sufficient to stop treatment: OR 1.30, 95% CI 0.69 to 2.47; adverse effects not sufficient to stop treatment: OR 1.33, 95% CI 0.73 to 2.42). Three included RCTs found an increase in preterm birth or low birth weight in women with bacterial vaginosis who received intravaginal clindamycin cream compared with placebo.[26–28] However, in all RCTs, the increase was not significant. One large RCT (1953 women) included in the review found significantly more adverse effects with oral metronidazole compared with placebo, particularly gastrointestinal symptoms (20.0% with metronidazole *v* 7.5% with placebo; CI not reported).[29]

Comment: The average quality of the trials in the systematic review was good. All trials reported loss to follow up between 1–17% for the various treatment groups.[24] In addition to an increased risk of preterm birth and neonatal sepsis with intravaginal clindamycin treatment, one included RCT found an alteration of normal vaginal flora to flora consistent with bacterial vaginosis among women at high risk of preterm birth who were treated with clindamycin cream.[30] The review found two different clusters of results for oral treatment of bacterial vaginosis among high risk women. Different effects may be because of differences in dose and type of treatment regimen or in the timing of treatment.[24] **Difference in treatment regimen:** Three included RCTs found that antibiotics reduced preterm birth, of which two[31,32] used the US Centers for Disease Control and Prevention recommended treatment of bacterial vaginosis in pregnancy (metronidazole 250 mg three times daily for 7 days). The other RCT[12] used a lower dose of metronidazole (400 mg twice daily for 2 days), but found a reduction in preterm birth in a small subgroup analysis (17 women in each group). One included RCT, which found no reduction in preterm birth, used a lower dose of metronidazole (2 g single dose, repeated 48 hours later).[29] The subsequent RCT, which also found a benefit from treatment, used oral clindamycin, which has broader activity compared with metronidazole against bacterial vaginosis organisms (especially *Mobiluncus* species). **Differences in timing of treatment:** Differences in timing of treatment (early *v* late gestational age) may also have contributed to different results among studies. The two included RCTs[29,33] that found no reduction in preterm birth initiated antibiotic treatment at about 24 weeks of gestation, but the subsequent RCT, which found a reduction of preterm birth, initiated antibiotic treatment earlier in the pregnancy (at about 16 weeks).[25] To a lesser degree, differences in study population (symptomatic *v* asymptomatic) and diagnosis of bacterial vaginosis (clinical *v* Gram stain diagnosis) may also have contributed to the differing results. **Diagnostic criteria and screening:** Bacterial vaginosis is a condition of altered vaginal flora. There is a continuum of degrees of alteration of vaginal flora that women may have, and bacterial vaginosis may be defined differently according to the diagnostic criteria being used. Given this uncertainty, screening for bacterial vaginosis may result in the treatment of some women who do not have bacterial vaginosis. Thus, it is important to evaluate the harms of treatment among women who have equivocal bacterial vaginosis. Subgroup analyses of RCTs suggest that likely harms of antibiotics in this group include an increase in preterm birth and neonatal sepsis.[31,34]

QUESTION **Does treating male partners prevent recurrence?**

OPTION **TREATMENTS FOR PARTNERS TO PREVENT RECURRENCE**

One systematic review has found that, in women receiving antibacterial agents, and who have one steady male sexual partner, treating the partner with an oral antibacterial agent does not reduce the woman's risk of recurrence.

Benefits: We found one systematic review (search date not reported, 5 RCTs) evaluating the effect of treating male sexual partners of women with bacterial vaginosis on recurrence rates.[35] The review found that treatment of a sexual partner with metronidazole or clindamycin had no significant effect on recurrence rates in women with bacterial vaginosis receiving the same treatment. The RCTs identified by the review assessed a variety of treatment regimens and populations but excluded women who were pregnant or who had coexistent vaginal infections. The systematic review did not attempt to test for heterogeneity between RCTs or to pool the results.

Harms: No harmful effects were reported.[35]

Comment: The lack of evidence of effectiveness of both metronidazole and clindamycin suggests that anaerobes are unlikely to be the sole pathogenic agents linking bacterial vaginosis with sexual intercourse.

QUESTION **What are the effects of treatment before gynaecological procedures?**

OPTION **ANTIBACTERIAL TREATMENT BEFORE GYNAECOLOGICAL PROCEDURES**

Three RCTs found a lower rate of pelvic inflammatory disease with oral or intravaginal antibacterial treatment compared with placebo in women with bacterial vaginosis who are about to have surgical abortion, but the difference was only significant in the largest RCT. We found no RCTs on the effects of treatment before other gynaecological procedures, including abdominal hysterectomy, caesarean section, or insertion of an intrauterine contraceptive device.

Benefits: We found no systematic review. **Before surgical abortion:** We found three RCTs.[36–38] The first RCT (174 women with bacterial vaginosis) compared oral metronidazole 500 mg three times daily for 10 days versus placebo in women about to have surgical abortion.[36] Fewer women taking metronidazole developed pelvic inflammatory disease than those taking placebo, although the result did not reach significance (3/84 [4%] with metronidazole *v* 11/90 [12%] with placebo; RR 0.29, 95% CI 0.08 to 1.01). The second RCT (1655 women) compared intravaginal clindamycin cream versus placebo in women about to have surgical abortion.[37] It found that significantly fewer women treated with clindamycin had an infection after abortion (recalculation by *Clinical Evidence*: infection after abortion 3/181 [2%] with clindamycin cream *v* 12/181 [7%] with placebo; RR 0.25, 95% CI 0.07 to 0.87; NNT 20,

95% CI 11 to 409). The third RCT compared a single dose metronidazole suppository 2 mg versus placebo.[38] It found that metronidazole suppository was associated with a non-significantly lower rate of postoperative upper genital tract infection (12/142 [8%] with metronidazole *v* 21/131 [16%] with placebo; RR 0.52, 95% CI 0.27 to 1.02). **Before gynaecological surgery:** Bacterial vaginosis is associated with an increased risk of endometritis after caesarean section and vaginal cuff cellulitis after abdominal hysterectomy,[11,39] but we found no RCTs of antibacterial treatment in women before such surgery. **Before insertion of an intrauterine contraceptive device:** Bacterial vaginosis has been associated with pelvic inflammatory disease (see pelvic inflammatory disease, p 2121) in women using intrauterine contraceptive devices,[3] but we found no RCTs of antibacterial treatment in women with bacterial vaginosis before insertion of these devices.

Harms: The RCTs provided no information on adverse effects.[36–38]

Comment: None.

Substantive changes

Treatment in pregnancy One systematic review[24] and one RCT added;[25] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Key Messages

In men and non-pregnant women

- Short term microbiological cure is the outcome used in most RCTs, but this may not mean eradication of *Chlamydia trachomatis*. Long term cure rates have not been studied extensively because of high default rates and difficulty in distinguishing persistent infection from reinfection due to re-exposure.
- **Azithromycin (single dose)** A systematic review of 12 blinded and unblinded RCTs found no significant difference in microbiological cure of *Chlamydia trachomatis* between a single dose of azithromycin and a 7 day course of doxycycline. Rates of adverse effects were similar.

- **Doxycycline, tetracycline (multiple dose regimens)** Small RCTs with short term follow up and high withdrawal rates found that multiple dose regimens of tetracyclines (doxycycline, tetracycline) achieve microbiological cure in at least 95% of people with genital chlamydia. A systematic review of 12 blinded and unblinded RCTs found no significant difference in microbiological cure of *C trachomatis* between a 7 day course of doxycycline and a single dose of azithromycin. Rates of adverse effects were similar. Meta-analysis of two RCTs found that doxycycline significantly reduced microbiological failure compared with ciprofloxacin.
- **Erythromycin (multiple dose regimens)** Three small RCTs found that erythromycin achieved microbiological cure in 77–100% of people, with the highest cure rate with a 2 g compared with a 1 g daily dose.
- **Amoxicillin, ampicillin, clarithromycin, lymecycline, minocycline, ofloxacin, pivampicillin, rifampicin, rosarimicin, roxithromycin, sparfloxacin, trovafloxacin (multiple dose regimens)** We found limited evidence on the effects of these regimens.
- **Ciprofloxacin (multiple dose regimens)** Two RCTs found that ciprofloxacin cured 63–92% of people. Meta-analysis found that ciprofloxacin significantly increased microbiological failure compared with doxycycline.

In pregnant women

- **Azithromycin (single dose)** One systematic review found that a single dose of azithromycin significantly increased microbiological cure and decreased the risk of an adverse effect, sufficient to stop treatment, when compared with a 7 day course of erythromycin. Two subsequent unblinded RCTs found no significant difference in cure rate between single dose azithromycin and multiple dose amoxicillin.
- **Erythromycin, amoxicillin (multiple dose regimens)** One small RCT identified in a systematic review found that erythromycin versus placebo significantly increased microbiological cure. Other RCTs in the review found high cure rates with erythromycin and amoxicillin and no significant difference in microbiological cure between the two drugs.
- **Clindamycin (multiple dose regimens)** One small RCT found no significant difference in cure rates between clindamycin and erythromycin.

DEFINITION Genital chlamydia is a sexually transmitted infection of the urethra in men, and of the endocervix, urethra (or both) in women. It is defined as **uncomplicated** if it has not ascended to the upper genital tract. Infection in women is asymptomatic in up to 80% of cases, but may cause non-specific symptoms, including vaginal discharge and intermenstrual bleeding. Infection in men causes urethral discharge and urethral irritation or dysuria, but may also be asymptomatic in up to half of cases.[1] **Complicated** chlamydial infection includes spread to the upper genital tract (causing pelvic inflammatory disease in women [see pelvic inflammatory disease, p 2121] and epididymo-orchitis in men) and extra genital sites, such as the eye. Interventions for complicated chlamydial infection are not included in this chapter.

INCIDENCE/ PREVALENCE Genital chlamydia is the most commonly reported bacterial sexually transmitted infection in developed countries [1] and reported rates increased by 10% in the UK and USA between 2000 and 2001.[2,3] In women, infection occurs most commonly between the ages of 16

Chlamydia (uncomplicated, genital)

and 19 years. In this age group, about 1000/100 000 new infections are reported each year in the UK,[2] compared with 1900/100 000 in Sweden,[4] and 2536 per 100 000 in the USA.[3] The peak age group for men is 20–24 years, with about 650/100 000 new infections per year in the UK and USA and 1200/100 000 in Sweden.[2–4] Rates decline markedly with increasing age. Reported rates are highly dependent on the level of testing. The population prevalence of uncomplicated genital chlamydia in 18–44 year olds in the UK in 1999 was 2.2% (95% CI 1.5% to 3.2%) in men and 1.5% (95% CI 1.1% to 2.1%) in women.[5]

AETIOLOGY/RISK FACTORS

Infection is caused by the bacterium *C trachomatis* serotypes D–K. It is transmitted primarily through sexual intercourse, but also perinatally and through direct or indirect oculogenital contact.[1]

PROGNOSIS

In women, untreated chlamydial infection that ascends to the upper genital tract causes pelvic inflammatory disease (see pelvic inflammatory disease topic, p 2121) in an estimated 30–40% of cases.[6] Tubal infertility has been found to occur in about 11% of women after a single episode of pelvic inflammatory disease, and the risk of ectopic pregnancy is increased six- to sevenfold.[7] Ascending infection in men causes epididymitis, but evidence that this causes male infertility is limited.[8] Maternal to infant transmission can lead to neonatal conjunctivitis and pneumonitis in 30–40% of cases.[1] Chlamydia may coexist with other genital infections and may facilitate transmission and acquisition of HIV infection.[1] Untreated chlamydial infection persists asymptomatically in most women for at least 60 days and for a shorter period in men.[9] Spontaneous remission also occurs at an estimated rate of 5% per month.[10]

AIMS OF INTERVENTION

To eradicate *C trachomatis*; to prevent the development of upper genital tract infection; to prevent further sexual transmission; and to prevent perinatal transmission, with minimal adverse effects of treatment.

OUTCOMES

The primary outcome is short term microbiological cure rate (calculated as the percentage of people attending a follow up visit at least 1 week after the end of antibiotic treatment who had a negative test for *C trachomatis*). This may not mean eradication of *C trachomatis* because of the prolonged life cycle of the organism. Long term cure rates have not been studied extensively because of high default rates and difficulty in distinguishing persistent infection from reinfection. However, studies have found no persistent infection up to 20 weeks after successful antibiotic treatment.[9] Other outcomes include adverse effects of treatment, including effects on the fetus and incidence of pelvic inflammatory disease and infertility. We present cure rates for pregnant women separately from those for men and non-pregnant women because two important drug groups, tetracyclines and quinolones, are contra-indicated in pregnancy.

METHODS

Clinical Evidence search and appraisal May 2003. All relevant systematic reviews and masked clinical RCTs were included. RCTs of treatment for genital chlamydia usually compare a new antibiotic versus an existing regimen because placebo controlled RCTs would be considered unethical. Single trials usually have insufficient statistical power to establish equivalence but meta-analysis is often

inappropriate because of differences in the antibiotics used. Therefore, where appropriate, we present the absolute cure rates for individual antibiotics, combining results across trials. We present the range of cure rates (with exact binomial CIs) or, if there was no evidence of statistical heterogeneity between RCTs, the summary cure rate (95% CIs) weighted by the standard error. Summary rates do not include cure rates of 100% because the standard error cannot be computed if there are no treatment failures. In one instance (ciprofloxacin), two RCTs compared the same regimen with no evidence of statistical heterogeneity and we used a fixed effects meta-analysis to calculate the summary odds ratio with 95% confidence intervals. Trial quality was assessed in terms of randomisation, blinding, and numbers of withdrawals from analysis.[11] RCTs with methodological limitations have been included but relevant problems are mentioned in the text. **Categorising interventions:** We considered a regimen beneficial if the summary cure rate from two or more RCTs was 95% or greater, as previously suggested,[12] and if the lower confidence limit was also above 90%. We found insufficient data to differentiate reinfections from persistent infections. We considered regimens to be likely (or unlikely) to be beneficial on the basis of positive (or negative) results from two or more RCTs, and of unknown effectiveness if there was only one RCT or if results were conflicting.

QUESTION **What are the effects of antibiotic treatment in men and non-pregnant women with uncomplicated genital chlamydial infection?**

OPTION SINGLE DOSE ANTIBIOTICS

A systematic review of 12 blinded and unblinded RCTs found no significant difference in microbiological cure of *C trachomatis* between a single dose of azithromycin and a 7 day course of doxycycline. Rates of adverse effects were similar.

Benefits: **Versus placebo:** We found no systematic reviews and no RCTs. **Versus other single dose antibiotics:** We found no systematic reviews and no RCTs. **Versus multiple dose antibiotics:** We found one systematic review (search date 2001, 12 blinded and unblinded RCTs, 1543 people) comparing azithromycin (1 g as a single dose) versus doxycycline (100 mg twice daily for 7 days).[13] It found no significant difference in microbiological cure of *C trachomatis* (cure rates for single dose azithromycin ranging from 81–100%, for multiple dose doxycycline from 92–100%; pooled efficacy difference for microbiological cure with azithromycin versus doxycycline +0.008, 95% CI −0.007 to +0.022; P = 0.296).

Harms: Short term adverse effects of both azithromycin and doxycycline were reported to be mild and similar.[13]

Comment: When taken as a directly observed treatment, azithromycin has the advantage over multiple dose antibiotics that adherence to therapy can be guaranteed.

OPTION MULTIPLE DOSE ANTIBIOTICS

Small RCTs with short term follow up and high withdrawal rates found that multiple dose regimens of tetracyclines (doxycycline, tetracycline) achieve microbiological cure in at least 95% of people with genital chlamydia. A systematic review of 12 blinded and unblinded RCTs found no significant difference in microbiological cure of *C trachomatis* between a 7 day course of doxycycline and a single dose of azithromycin. Rates of adverse effects were similar. Three small RCTs found that erythromycin achieved microbiological cure in 77–100% of people, with the highest cure rate with a 2 g rather than a 1 g daily dose. Two RCTs found that ciprofloxacin cured 63–92% of people. Meta-analysis found that ciprofloxacin significantly increased microbiological failure compared with doxycycline. We found limited evidence on the effectiveness of other macrolides, quinolones, and penicillins. The RCTs had short term follow up and high withdrawal rates.

Benefits:

Versus placebo: We found one small RCT that found trimethoprim-sulphadiazine to be superior to placebo (see comment below).[14] **Versus single dose antibiotics**: See single dose antibiotics in men and non-pregnancy, p 2067. **Versus each other:** We found no systematic review comparing multiple dose antibiotics with each other. We found 22 RCTs reported to be double blind or with blinded outcome assessment comparing 19 different multiple dose antibiotic regimens. Four RCTs included comparison with single dose azithromycin but only the data on multiple dose antibiotics are presented in this section (see table A on web extra).[15–35] Results were similar in men and women and in populations with proven and presumed infection, so data were combined. **Doxycycline:** We found 11 RCTs (1434 men and women, comparing doxycycline with another antibiotic.[15–17,19–26] The cure rate was 100% in six and the weighted average 98% (95% CI 96% to 99%) in the other five. We found no RCTs comparing different regimens for doxycycline, but the most frequent schedule (in 6 RCTs) was 100 mg twice daily for 7 days. **Tetracycline:** The summary cure rate in four RCTs (201 men and women) comparing tetracycline hydrochloride (500 mg 4 times daily for 7 days) versus another antibiotic was 97% (95% CI 94% to 99%).[27] **Erythromycin:** Cure rates with erythromycin stearate 1 g daily for 7 days (3 RCTs, 191 people) ranged from 77–95%,[33–35] and with erythromycin 2 g daily for 7 days (2 RCTs, 40 people) from 94–100%.[32,35] **Ciprofloxacin:** In two RCTs (190 men and women) the cure rate for ciprofloxacin ranged from 63–92%.[23,24] Meta-analysis by *Clinical Evidence* found that failure of microbiological cure was significantly more frequent with ciprofloxacin than with doxycycline (OR 5.0, 95% CI 1.2 to 10.0). **Other antibiotics:** Ofloxacin, sparfloxacin, trovafloxacin, minocycline, lymecycline, clarithromycin, ampicillin, pivampicillin, and rifampicin were studied in single RCTs (see table A on web extra). No RCT measured the effect of antibiotics on pelvic inflammatory disease or infertility.

Harms:

Reported adverse effects varied widely between RCTs but were mostly gastrointestinal (see table A on web extra). Adverse effects, severe enough to stop treatment, were infrequent. Photosensitivity, which is particularly associated with tetracyclines, was also reported to occur with sparfloxacin.[22]

Comment: **Versus placebo:** The single placebo controlled trial was conducted in 1978, when the value of treating non-gonococcal urethritis was disputed.[14] This trial was halted because of the high incidence of complications in the placebo group. **Versus each other:** Most RCTs were conducted in sexually transmitted diseases clinics, where follow up is difficult; in 7/14 RCTs with available data, more than 15% of randomised participants were not included in the analysis.[14,18,25,32–35] Most RCTs were small (3 had fewer than 40 people with chlamydia)[19,27,32] and many antibiotic regimens were compared, so it is difficult to draw conclusions about relative efficacy. Only five RCTs reported that sexual partners of participants were offered treatment. Amoxicillin (amoxycillin) and ampicillin have not been adequately assessed in the treatment of genital chlamydia infection (see table A on web extra) because *in vitro* studies suggest that amoxicillin does not eradicate *C trachomatis*,[36] raising the concern that infection may persist and recrudesce *in vivo*. A similar effect is presumed for ampicillin.

QUESTION What are the effects of treatment for pregnant women with uncomplicated genital chlamydial infection?

OPTION SINGLE DOSE ANTIBIOTICS

One systematic review found that a single dose of azithromycin increased microbiological cure rate and decreased the risk of an adverse effect sufficient to stop treatment, compared with a 7 day course of erythromycin. Two subsequent unblinded RCTs found no significant difference in cure rates between single dose azithromycin and multiple dose amoxicillin.

Benefits: **Versus placebo:** We found no systematic reviews and no RCTs. **Versus other single dose antibiotics:** We found no systematic reviews and no RCTs. **Versus multiple dose antibiotics:** We found one systematic review (search date 1998, 4 non-blinded RCTs, 290 pregnant women),[37] and two subsequent RCTs.[38,39] The review compared a single dose of azithromycin 1 g versus erythromycin 500 mg 4 times daily for 7 days.[37] At first follow up visit 2–3 weeks after treatment, failure of microbiological cure was significantly less frequent with azithromycin than with erythromycin (failure to cure 11/145 [8%] with azithromycin *v* 27/145 [19%] with erythromycin; RR 0.42, 95% CI 0.22 to 0.80).[37] There was no significant difference in the rate of premature delivery in one RCT (OR 0.75, 95% CI 0.28 to 2.04). The two subsequent unblinded RCTs both compared a single dose of azithromycin 1 g versus 7 days of amoxicillin 500 mg.[38,39] The first RCT (39 women) found no significant difference in microbiological cure rate (failure to cure: 1/19 [5.2%] with azithromycin *v* 3/15 [20%] with amoxicillin [amoxycillin]; OR 0.26, 95% CI 0.005 to 3.79).[38] The second RCT (110 women) found no significant difference in the combined outcome of negative microbiological test and completion of all medication (32/55 [58%] with amoxicillin *v* 35/55 [63%] with azithromycin; RR 0.9, 95% CI 0.7 to 1.2).[39]

Harms: The systematic review found that azithromycin decreased the risk of an adverse effect, sufficient to stop treatment, compared with erythromycin (4/254 [1.6%] with azithromycin *v* 40/249 [16.6%]

with erythromycin; RR 0.11, 95% CI 0.04 to 0.28).[36] Fetal anomaly (not further specified) was reported in one infant in each group. The first subsequent RCT found that a non-significantly greater proportion of women reported adverse events with azithromycin compared with amoxicillin (10/19 [52.6%] with azithromycin *v* 5/17 [29.4%] with amoxicillin; RR 1.8, 95% CI 0.8 to 4.2).[38] Similarly, the second subsequent RCT found non-significantly more adverse effects with azithromycin compared with amoxicillin (6/55 with azithromycin *v* 3/55 [5.5%] with amoxicillin; RR 0.5, 95% CI 0.1 to 1.9).[39] We found little good evidence on the effects of azithromycin on pregnancy outcomes.

Comment: Erythromycin is more likely than azithromycin to be discontinued because of its gastrointestinal side effects. Furthermore, azithromycin as a single dose antibiotic is suitable for directly observed treatment where compliance can be guaranteed. However, azithromycin is not yet licensed for use in pregnancy.

OPTION MULTIPLE DOSE ANTIBIOTICS

One small RCT identified in a systematic review found that erythromycin or clindamycin significantly increased microbiological cure compared with placebo. Other RCTs in the review found no significant difference between erythromycin and amoxicillin in microbiological cure rate, and high cure rates with both drugs. One small RCT in the review found no significant difference in cure rates between clindamycin and erythromycin.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 1 RCT, 135 women).[37] It found that treatment with erythromycin or clindamycin was more effective than placebo (OR for failure of cure 0.06, 95% CI 0.03 to 0.12). No other information reported. **Versus single dose antibiotics:** >. **Versus each other:** We found one systematic review (search date 1998, 11 blinded and unblinded RCTs, 1449 people).[37] The review found three RCTs comparing microbiological cure rates with amoxicillin (amoxycillin) 1.5 g daily for 7 days and erythromycin 2 g daily for 7 days. The RCTs found high rates of microbiological cure with both drugs and a non-significantly higher rate of microbiological cure with amoxicillin (amoxycillin) compared with erythromycin (182/199 [91%] with amoxicillin *v* 163/191 [85%] with erythromycin; RR for failure of cure with amoxicillin compared with erythromycin 0.59, 95% CI 0.34 to 1.03). The review found one small RCT, which found no significant difference in cure rates between clindamycin and erythromycin (cure rate 38/41 [93%] *v* 31/37 [84%]; RR for failure of cure 0.45, 95% CI 0.12 to 1.7).[37]

Harms: Rates of adverse effects were similar for clindamycin and erythromycin, but adverse effects, sufficient to stop treatment, were less frequent with amoxicillin than erythromycin (OR 0.16, 95% CI 0.09 to 0.30).[37] None of the RCTs gave information on adverse clinical outcomes in the offspring.

Comment: Out of three RCTs conducted between 1982 and 1997, which compared the effects of antibiotic therapy with placebo, only one reported cure rates in women.[37]

Substantive changes

Azithromycin (single dose) in men and non-pregnant women One systematic review added;[13] categorisation changed to Beneficial.

QUESTIONS

INTERVENTIONS

*Categorisation based on observational or non-randomised evidence in the context of practical and ethical problems of performing RCTs

Genital herpes

Key Messages

Preventing transmission of herpes simplex virus

- **Male condom use to prevent sexual transmission from infected men to non-infected sexual partners** Limited evidence from a prospective cohort study suggests that condom use by men infected with genital herpes may reduce transmission of herpes simplex virus type 2 (HSV-2) to their non-infected sexual partners.
- **Antiviral treatment to prevent sexual transmission** We found no systematic review or RCTs on the effects of antiviral treatments to prevent sexual transmission.
- **Caesarean delivery in women with genital lesions at term** We found no systematic review or RCTs on the effects of caesarean delivery on mother to baby transmission of genital herpes in patients with genital lesions at term. The procedure carries the risk of increased maternal morbidity and mortality.
- **Daily oral antiviral treatment in late pregnancy (36 or more weeks of gestation) in women with a history of genital herpes** One systematic review and two subsequent RCTs found that aciclovir reduced the rate of genital lesions at term in women with first or recurrent episodes of genital herpes simplex virus during pregnancy. The review and the RCTs provided insufficient evidence to assess the effect of oral antiviral treatment during pregnancy on neonatal infection.
- **Female condoms** We found no systematic review or RCTs on the effects of female condoms to prevent sexual transmission.
- **HSV-2 glycoprotein-D-adjuvant vaccine in HSV-1- and HSV-2-seronegative women** Limited evidence from one RCT comparing recombinant HSV-2 glycoprotein-D-adjuvant vaccine versus placebo showed protection of the vaccine against new genital herpes infection in women who had been seronegative for HSV-1 and HSV-2 at baseline.
- **HSV-2 glycoprotein-D-adjuvant vaccine in men and HSV-1-seropositive women** Limited evidence from one RCT comparing recombinant HSV-2 glycoprotein-D-adjuvant vaccine with placebo showed no protection of the vaccine against new genital herpes infection in women who had been seropositive for HSV-1 at baseline or in men.
- **Male condom use to prevent transmission from infected women to non-infected men** Limited evidence from a prospective cohort study suggests that male condom use may provide no protection from transmission of HSV-2 to non-infected men from their infected female partners.
- **Other forms of vaccination** We found no good evidence on other forms of vaccination.
- **Serological screening and counselling in late pregnancy** We found no systematic review or RCTs on the effects of interventions to prevent maternal infection in late pregnancy (such as serological screening and counselling).
- **Recombinant glycoprotein vaccines (gB2 and gD2)** One RCT found no significant difference between recombinant glycoprotein vaccine (gB2 plus gD2) and placebo in the prevention of herpes simplex virus type 2 infection.

Treatments for a first episode of genital herpes

- **Oral antiviral versus placebo treatment in first episodes** RCTs found that oral antiviral treatment versus placebo decreases the duration of lesions, symptoms, and viral shedding, and reduces neurological complications in people with first episode genital herpes. Two small RCTs provided insufficient evidence to assess time to recurrence and frequency of recurrence compared with placebo.
- **Different routes of antiviral administration in first episodes** We found no systematic reviews or RCTs comparing different routes of administration in antiviral treatment. A non-randomised comparison of results of different trials from one institution suggests that systemic (oral or iv) antiviral treatment may be more effective and associated with fewer reported side effects than topical medication.
- **Different types of oral treatment in first episodes** RCTs found no difference in clinical outcomes among oral aciclovir, valaciclovir, and famciclovir in people with a first episode of genital herpes.

Treatments to reduce the impact of recurrance

- **Daily oral antiviral treatment in people with high rates of recurrence** RCTs have found that daily maintenance treatment with oral antiviral agents reduces the frequency of recurrences and improves psychosocial morbidity in people with frequent recurrence compared with placebo.
- **Oral antiviral treatment taken at the start of recurrence** One systematic review and one subsequent RCT found that oral antiviral treatment taken at the start of recurrence reduced the duration of lesions, episode duration, and viral shedding and increased the rate of aborted recurrences compared with placebo in people with recurrent genital herpes. RCTs found no difference among different antiviral agents. All antiviral agents were found to be similarly effective in reducing the duration of symptoms and viral shedding compared with placebo. One RCT found no difference between valaciclovir taken for 3 days versus 5 days.
- **Psychotherapy to reduce recurrence** One systematic review found insufficient evidence on the effects of psychotherapy on genital herpes recurrence.

Treatments in people with HIV infection

- **Oral antiviral treatment in people immunocompromised with HIV infection** We found no systematic review or RCTs evaluating antiviral treatment for genital herpes in people immunocompromised with HIV infection. However, evidence from other settings suggests that antiviral agents may be effective treatments of genital herpes in immunocompromised people.

DEFINITION Genital herpes is an infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) causing ulceration in the genital area. Herpes simplex virus infections can be confirmed on the basis of virological and serological findings. Types of infection include **first episode primary infection**, which is defined as herpes simplex virus confirmed in a person without prior findings of HSV-1 or HSV-2 antibodies; **first episode non-primary infection**, which is HSV-2 confirmed in a person with prior findings of HSV-1 antibodies or vice versa; **first recognised recurrence**, which is HSV-1 (or HSV-2) confirmed in a person with prior findings of HSV-1 (or HSV-2) antibodies; and **recurrent genital herpes**, which is caused by reactivation of latent herpes simplex virus. HSV-1 can also cause

gingivostomatitis and orolabial ulcers; HSV-2 can also cause other types of herpes infections, such as ocular herpes; and both virus types can cause infection of the central nervous system (e.g. encephalitis).

INCIDENCE/ PREVALENCE

Genital herpes infections are among the most common sexually transmitted diseases. Seroprevalence studies showed that 22% of adults in the USA had HSV-2 antibodies.[1] A UK study found that 23% of adults attending sexual medicine clinics and 7.6% of blood donors in London had antibodies to HSV-2.[2] Seroprevalence of HSV-2 increased by 30% (95% CI 15.8% to 45.8%) between the periods 1976–1980 and 1988–1994.[1] However, it should be noted that although antibody levels prove the existence of present or past infections, they do not differentiate between possible manifestations of HSV-2 infections (e.g. genital/ocular). Thus, the figures have to be treated with caution when applied to genital herpes only.

AETIOLOGY/ RISK FACTORS

Both HSV-1 and HSV-2 can cause a first episode of genital infection, but HSV-2 is more likely to cause recurrent disease.[3] Most people with HSV-2 infection have only mild symptoms and remain unaware that they have genital herpes. However, these people can still pass on the infection to sexual partners and newborns.[4,5]

PROGNOSIS

Sequelae of herpes simplex virus infection include neonatal herpes simplex virus infection, opportunistic infection in immunocompromised people, recurrent genital ulceration, and psychosocial morbidity. HSV-2 infection is associated with an increased risk of HIV transmission and acquisition.[6] The most common neurological complications are aseptic meningitis (reported in about 25% of women during primary infection) and urinary retention (reported in up to 15% of women during primary infection).[5] The absolute risk of neonatal infection is high (41%, 95% CI 26% to 56%) in babies born to women who acquire infection near the time of labour and low (< 3%) in women with established infection, even in those who have a recurrence at term.[7,8] About 15% of neonatal infections result from postnatal transmission from oral lesions of relatives or hospital personnel.[5]

AIMS OF INTERVENTION

To prevent transmission; to reduce the morbidity of the first episode; to reduce the risk of recurrent disease after a first episode, with minimal adverse effects of treatment.

OUTCOMES

Rates of transmission (demonstrated either clinically, virologically or serologically, depending on the study); seroconversion, severity, and duration of symptoms; healing time; duration of viral shedding (intermediate outcome reflecting the risk of transmitting the infection, although a direct link between the duration of viral shedding and risk of transmission has not been demonstrated); recurrence rates; psychosocial morbidity; adverse effects of treatment.

METHODS

Clinical Evidence search and appraisal July 2003. We also included preliminary results of clinical trials published in the abstracts of the Interscience Conference on Antimicrobial Agents and Chemotherapy and International Society for STD Research.

QUESTION What are the effects of interventions to prevent transmission of herpes simplex virus?

OPTION VACCINATION

One RCT found no significant difference between recombinant glycoprotein vaccine (gB2 plus gD2) and placebo in the prevention of herpes simplex virus type 2 infection. Limited evidence from one RCT comparing recombinant herpes simplex virus type 2 glycoprotein-D-adjuvant vaccine versus placebo showed protection of the vaccine against new genital herpes infection in women who had been seronegative for herpes simplex virus type 1 and herpes simplex virus type 2 at baseline. No protection was demonstrated in women who had been seropositive for herpes simplex virus type 1 or in men. We found no systematic reviews or RCTs on other forms of vaccination.

Benefits: We found no systematic review but we found two RCTs (5107 people) comparing vaccination versus placebo in the prevention of herpes simplex virus infection.[9,10] One RCT (2393 people seronegative for recombinant herpes simplex virus type 2 [HSV-2] and HIV at high risk of exposure to genital herpes) compared recombinant glycoprotein vaccine (gB2 plus gD2) versus placebo.[9] It found no significant difference in the number of people with herpes simplex virus seroconversion or positive genital herpes simplex virus culture (4.2 cases per 100 person years with glycoprotein vaccine *v* 4.6 cases per 100 person years with placebo; P = 0.58). Similarly, it found no significant difference in the duration of initial genital herpes (7.1 days with glycoprotein vaccine *v* 6.5 days with placebo, P = 0.45) or in the frequency of subsequent recurrences in people who acquired genital HSV-2 infection (rate of recurring lesions 13/24 [54%] with glycoprotein vaccine *v* 21/33 [64%] with placebo, P = 0.47). A second RCT (2 studies; 847 HSV-1 and HSV-2 seronegative people in study 1 and 1867 HSV-2 seronegative people in study 2 but at risk from a regular sexual partner with clinically confirmed genital herpes) compared the efficacy of recombinant HSV-2 glycoprotein-D-adjuvant vaccine versus placebo.[10] Vaccine efficacy was defined in terms of the number of people with genital lesions or symptoms and positive genital herpes simplex virus culture, or herpes simplex virus polymerase chain reaction and seroconversion. Both study arms demonstrated that the vaccine was effective in women who were seronegative for HSV-1 and HSV-2 at baseline (study 1: 73% efficacy, 95% CI 19% to 91%, P = 0.01; study 2: 74% efficacy, 95% CI 9% to 93%, P = 0.02). No protection was demonstrated in women who were seropositive for HSV-1 (study 2: −106% efficacy, 95% CI −723% to +49%, P = 0.3) or in men (study 1: −11% efficacy, 95% CI −161% to +53%, P = 0.81; study 2: −10% efficacy, 95% CI −127% to +47%, P = 0.8).

Harms: The first RCT reported the vaccine to be safe and well tolerated, with frequencies of local and systemic reactions similar to those stated in the literature.[9] In the second RCT, the frequency of soreness at the injection site severe enough to prevent people from engaging in

normal actions was higher with vaccine (5%) than with placebo (study 1: 3% and study 2: 1%, no P value reported).[10] The study found no major differences between the two groups in the frequency and type of reported symptoms or dropout rates (no statistical values reported).

Comment: Glycoprotein vaccines differ not only in the choice of recombinant HSV molecules but also in the use of adjuvants (i.e. substances used to stabilise vaccine components). The use of different adjuvants may explain the inconsistent efficacy results of otherwise similar glycoprotein vaccines.

OPTION CONDOMS

Limited evidence from a prospective cohort study suggests that condom use by men infected with genital herpes may reduce transmission of herpes simplex virus type 2 to their non-infected sexual partners. However, the cohort study found no evidence that condoms protected non-infected men from infection from infected female partners. We found no systematic review or RCTs on the effects of female condoms to prevent sexual transmission.

Benefits: We found no systematic review or RCTs. In a prospective cohort study (528 couples [98% heterosexual] discordant for herpes simplex virus type 2 infection and followed for 18 months) men infected with genital herpes who used condoms in more than 25% of sexual acts were at lower risk of infecting their sexual partners with herpes simplex virus type 2 (adjusted HR 0.09, 95% CI 0.01 to 0.67), but non-infected men wearing a condom were not protected against transmission from their infected female partners (adjusted HR 2.02, 95% CI 0.32 to 12.50).[11]

Harms: The study gave no information on adverse effects.

Comment: Only 61% of couples ever used condoms during the study and only 8% used them consistently.[11] Controlled trials of condoms for prevention of herpes simplex virus type 2 transmission are impractical. Even with routine counselling, many couples do not regularly use condoms. Trials of different methods of advising people to use condoms or providing condoms could be performed.

OPTION ANTIVIRAL TREATMENT TO PREVENT SEXUAL TRANSMISSION

We found no good evidence on the effects of antiviral treatments on rates of sexual transmission.

Benefits: We found no systematic review or RCTs examining the effects of antiviral treatments on sexual transmission rates.

Harms: See individual antiviral drugs (see harms of daily maintenance antiviral treatment, p 2085).

Comment: RCTs have shown that daily antiviral treatment decreases the frequency of clinical and subclinical viral shedding (see antiviral treatment at the start of recurrence, p 2083 and outcomes section, p 2076).

OPTION ANTIVIRAL TREATMENT DURING PREGNANCY

One systematic review and two subsequent RCTs found that aciclovir reduced the rate of genital lesions or the detection of herpes virus at term in women with first or recurrent episodes of genital herpes simplex virus during pregnancy. The review and the RCTs provided insufficient evidence to assess the effects of oral antiviral agents during pregnancy on neonatal transmission.

Benefits: We found one systematic review (search date 1996;[8] 2 RCTs and 1 controlled study;[12–14] 210 pregnant women near term with genital herpes) of daily aciclovir versus placebo and two subsequent RCTs.[15,16] **Rate of recurrent genital herpes at term:** All three studies in the review found lower rates of recurrent genital herpes at term in women treated with aciclovir, although in one study the effect was not significant (frequency of recurrent genital herpes at labour 0/21 [0%] with aciclovir *v* 9/25 [36%] with placebo, P = 0.002;[12] 2/32 [6%] with aciclovir *v* 6/33 [18%] with placebo; OR 0.3, 95% CI 0.03 to 1.9;[13] frequency of recurrent genital herpes within 10 days before delivery or at labour 0/46 [0%] with aciclovir *v* 12/46 [26%] with no treatment, P < 0.001[14]).[8] The first subsequent RCT (231 women with genital herpes diagnosed either by positive culture or clinical diagnosis) found that aciclovir (400 mg 3 times daily) given from 36 weeks of gestation until delivery reduced clinically evident genital herpes at delivery compared with placebo (7/116 [6%] with aciclovir *v* 16/115 [14%] with placebo; P = 0.046; OR 0.40, 95% CI 0.13 to 1.08).[15] The second subsequent RCT (162 women) comparing aciclovir 400 mg three times daily versus placebo given from 36 weeks of gestation until delivery found that genital lesions at term were less frequent with aciclovir compared with placebo, although this difference was not significant (4/84 [5%] with aciclovir versus 11/78 [14%] with placebo, P = 0.08).[16] Fewer women on aciclovir had detectable viral shedding (by polymerase chain reaction) near term compared with those on placebo (2% with aciclovir versus 43% with placebo, P < 0.01). **Rate of caesarean delivery for genital herpes:** See comment below. All three studies in the review found lower rates of caesarean delivery for genital herpes in women treated with aciclovir, although in one study the effect was not significant (AR of caesarean delivery for genital herpes 0/21 [0%] with aciclovir *v* 9/25 [36%] with placebo, P = 0.002;[12] AR of caesarean delivery for genital herpes 4/31 [13%] with aciclovir *v* 8/32 [25%] with placebo; OR 0.44, 95% CI 0.09 to 1.94;[13] AR of caesarean delivery for genital herpes 0/46 with aciclovir [0%] *v* 9/46 [20%] with no treatment, P < 0.001[14]).[8] The first subsequent RCT found no significant difference in rates of caesarean delivery for maternal herpes simplex infection between aciclovir and placebo (8/116 [7%] with aciclovir *v* 14/115 [12%] with placebo; OR 0.53, 95% CI 0.19 to 1.44).[15] The second subsequent RCT found that aciclovir reduced rates of caesarean delivery for genital herpes compared with placebo, although the difference was not significant (3/84 [4%] with aciclovir *v* 8/78 [10%]

with placebo, P = 0.17).[16] **Prevalence of neonatal herpes:** Neither the three studies in the review[8] nor the subsequent RCTs found any cases of neonatal transmission in either intervention or control groups.[12–16] The second subsequent RCT found no difference in neonatal outcome between the intervention and control groups.[16]

Harms: Most RCTs gave no information on adverse effects on the women. One RCT found no evidence of haematological or biochemical toxicity with aciclovir and reported no difference in adverse effects between treatment and control groups.[13] The controlled study found no maternal adverse effects.[14] On short term follow up, two RCTs and the controlled study found no apparent adverse effects on any of the neonates who had had prenatal exposure to aciclovir or were treated prophylactically with aciclovir after delivery.[12,14,15] One RCT found no difference in neonatal outcome between the maternal treatment and control groups.[16] However, the studies were underpowered to detect rare adverse events, such as an increase in aciclovir related obstructive uropathy in the newborns.

Comment: The trials in the review were heterogeneous in terms of the dose and duration of aciclovir and the populations enrolled.[12–14] The studies were underpowered to detect rare effects, such as an increase in asymptomatic viral shedding or neonatal infection. The indication for caesarean delivery for maternal herpes simplex infection was mainly based on clinical diagnosis (presence of prodromal symptoms or genital lesions suspicious for genital herpes) at term. However, in one of the RCTs in the review, delivery by elective caesarean section was performed if a woman experienced a herpes recurrence later than 38 weeks of gestation.[13] In the first subsequent RCT, one woman had caesarean delivery for genital herpes without a clinical recurrence at term and two women with genital lesions delivered vaginally.[15] In the second subsequent RCT, three women in the placebo group and one woman in the aciclovir group did not undergo caesarean delivery because their lesions were distant from the birth canal.[16]

OPTION SEROLOGICAL SCREENING AND COUNSELLING TO PREVENT ACQUISITION OF HERPES SIMPLEX VIRUS DURING LATE PREGNANCY

We found insufficient evidence on the effects of serological screening and counselling during pregnancy on maternal infection rates.

Benefits: We found no systematic review or RCTs that assessed either serological screening with type specific assays to identify women at risk for acquisition of herpes simplex virus infection in late pregnancy, or counselling to avoid genital–genital and oral–genital contact in late pregnancy.

Harms: We found no RCTs.

Comment: None.

OPTION CAESAREAN DELIVERY TO PREVENT NEONATAL HERPES

We found insufficient evidence for the effect of caesarean delivery on the risk of neonatal herpes. The procedure carries a risk of increased maternal morbidity and mortality.

Benefits: We found no systematic review or RCTs that assessed the effects of caesarean delivery on the risk of mother to child transmission of herpes simplex virus.

Harms: Caesarean delivery is associated with significant maternal morbidity and mortality. A study pooling data from different studies estimated that, for every two neonatal deaths from herpes simplex virus, a policy of caesarean delivery might cause one maternal death.[17]

Comment: The absolute risk of neonatal infection is high (AR 41%, 95% CI 26% to 56%) in babies born to women who acquire infection near the time of labour and low (AR < 3%) in women with established infection, even in those who have recurrence at term.[7,8] Most women who acquire infection toward the end of pregnancy are undiagnosed, and most cases of neonatal herpes simplex virus infection are acquired from women without a history of genital herpes. Case studies indicate that the transmission of herpes simplex virus type 2 can occur, despite caesarean delivery.[16] The available evidence suggests that efforts to prevent neonatal herpes simplex virus infection should focus on preventing infection in late pregnancy. Countries vary in their approach to obstetric management of women with recurrent genital herpes at term. In the USA and the UK, these women are advised to have a caesarean delivery, with its attendant risks to the mother. In the Netherlands, women with recurrent genital herpes at delivery have been allowed vaginal birth since 1987. This policy has not resulted in an increase in neonatal herpes (26 cases from 1981–1986 and 19 cases from 1987–1991).[8]

QUESTION What are the effects of antiviral treatment in people with a first episode of genital herpes?

OPTION ORAL ANTIVIRAL TREATMENT VERSUS PLACEBO

RCTs have found that oral antiviral treatment decreases the duration of lesions, symptoms, and viral shedding, and reduces neurological complications in people with first episode genital herpes compared with placebo. Two small RCTs provided insufficient evidence to assess time to recurrence and frequency of recurrence compared with placebo.

Benefits: We found no systematic review but we found seven RCTs (411 men and women) of oral aciclovir for the treatment of first episode genital herpes.[18–23] **Viral shedding, symptoms, and complications:** The largest RCT (180 people) compared aciclovir 200 mg five times daily versus placebo. Subgroup analysis of those with primary herpes (119 people) found that aciclovir decreased the duration of viral shedding (median 2 days with aciclovir *v* 9 days with placebo, $P < 0.001$), pain (5 days with aciclovir *v* 7 days with placebo, $P = 0.05$), time to complete healing of lesions (12 days with aciclovir *v* 14 days with placebo, $P = 0.005$), and reduced formation of new lesions after 48 hours on therapy (18% with aciclovir *v* 62% with placebo, $P = 0.001$).[20] Other RCTs found

similar results.[18,19,21,22] Neurological complications (aseptic meningitis and urinary retention) were also reduced. **Recurrence rates:** A meta-analysis of two small placebo controlled RCTs (61 people) found no significant difference in time to recurrence or frequency of recurrence between people given oral aciclovir and those given placebo.[23]

Harms: Adverse effects (mostly headache and nausea) were rare, and frequency was similar for aciclovir and placebo.

Comment: No precise estimates of effectiveness were available due to small numbers. The largest RCT excluded 30/180 people before analysis: 10 people for not completing the study protocol, 12 because of suspected past infection, and eight because herpes simplex virus was not isolated.[20]

OPTION DIFFERENT ROUTES OF ANTIVIRAL ADMINISTRATION New

We found no systematic reviews or RCTs comparing different routes of administration in antiviral treatment. A non-randomised study comparing the results of different trials from one institution suggests that oral or intravenous antiviral treatment may be more effective and associated with fewer reported side effects than topical medication.

Benefits: We found no systematic reviews or RCTs comparing the different routes by which antiviral treatment can be administered.

Harms: We found no RCTs. A non-randomised study comparing the results of different trials from one institution suggests that systemic treatment may be associated with fewer reported side effects than topical medication.[24]

Comment: A non-randomised comparison of results of different trials from one institution suggests that systemic treatment may be more effective than topical medication.[24]

OPTION DIFFERENT TYPES OF ORAL ANTIVIRAL TREATMENT New

RCTs found no difference in clinical outcomes among oral aciclovir, valaciclovir, and famciclovir in people with a first episode of genital herpes.

Benefits: We found no systematic reviews but we found two RCTs.[25,26] The first RCT (643 otherwise healthy adults) compared oral valaciclovir 1000 mg twice daily versus oral aciclovir 200 mg five times daily for 10 days.[25] It found no difference between the two medications in any clinical or virological variables. The second RCT (951 adults) compared three doses of oral famciclovir (125, 250, or 500 mg 3 times daily) versus oral aciclovir 200 mg five times daily.[26] It similarly found no difference among treatments.

Harms: Adverse effects (mostly headache and nausea) were rare and frequency was similar for aciclovir, valaciclovir, and famciclovir.

Comment: None.

QUESTION What interventions reduce the impact of recurrence?

OPTION ORAL ANTIVIRAL TREATMENT TAKEN AT THE START OF RECURRENCE

One systematic review and one subsequent RCT found that oral antiviral treatment taken at the start of recurrence reduced the duration of lesions, episode duration, and viral shedding and increased the rate of aborted recurrences compared with placebo in people with recurrent genital herpes. RCTs found no difference among different antiviral agents. All antiviral agents were found to be similarly effective in reducing the duration of symptoms and viral shedding compared with placebo. One RCT found no difference between valaciclovir taken for 3 days versus 5 days.

Benefits: We found no systematic review. **Aciclovir versus placebo:** We found one non-systematic review of several RCTs (more than 650 healthy adults) and one subsequent RCT.[27,28] The RCTs in the review evaluated 5 days of oral aciclovir (200 mg 5 times daily or 800 mg twice daily), started at the first sign of recurrence. Aciclovir versus placebo reduced the period of viral shedding (1 day with aciclovir *v* 2 days with placebo) and duration of lesions (5 days with aciclovir *v* 6 days with placebo).[27] The subsequent RCT (131 people with ≥3 recurrences in the previous 12 months, observed for ≥1 recurrence).[28] It found that oral aciclovir (800 mg 3 times daily) versus placebo for 2 days significantly reduced the median duration of lesions, episodes, and viral shedding (median duration of lesions: 4 days with aciclovir *v* 6 days with placebo, P = 0.001; median duration of episodes: 4 days with aciclovir *v* 6 days with placebo, P < 0.001; median duration of viral shedding: 25 hours with aciclovir *v* 58.5 hours with placebo, P = 0.04).[28] **Famciclovir versus placebo:** We found one RCT (467 people) identified in a systematic review (search date 1997) comparing famciclovir versus placebo.[29] It found that oral famciclovir (125–500 mg twice daily) significantly reduced the duration of lesions (5 days with famciclovir *v* 4 days with placebo, P value not reported) and viral shedding (3 days with famciclovir *v* 2 days with placebo, P value not reported). **Valaciclovir versus placebo:** We found one RCT (986 people) identified in a systematic review (search date 1997) comparing valaciclovir versus placebo.[29] It found that self initiated oral valaciclovir (500 or 1000 mg twice daily) for 5 days versus placebo decreased the episode duration (4 days with valaciclovir *v* 6 days with placebo, P value not reported) and viral shedding (2 days with valaciclovir *v* 4 days with placebo, P value not reported), and increased the rate of aborted recurrences (31% with valaciclovir *v* 21% with placebo, P value not reported). RCTs found no difference among different antiviral agents. **Famciclovir versus aciclovir:** We found one RCT (204 people), which found no significant difference in time to healing between oral famciclovir and aciclovir (mean lesion healing time 5.1 days with famciclovir *v* 5.4 days with acyclovir; mean difference +0.3 days, 95% CI –0.3 days to +0.8 days).[30] **Valaciclovir versus aciclovir:** We found one systematic review (search date 1997, 2 RCTs, 1939 people) comparing oral valaciclovir and aciclovir.[29] It found no significant difference in

clinical outcomes between the two antiviral agents. One RCT found that a prolonged course of valaciclovir had no added benefit compared to a 3 day treatment. **Valaciclovir 3 days versus 5 days:** One RCT (531 people with 6 or more recurrences of genital herpes/year) found no difference between 3 or 5 days of treatment with valaciclovir (500 mg twice daily) in episode duration (median 4.7 *v* 4.6 days) or aborted recurrences (27% *v* 21%). People initiating treatment within 6 hours of first symptoms or signs were more likely to have an aborted episode than those starting treatment after 6 hours (OR 1.93, 95% CI 1.28 to 2.9).[31]

Harms: Adverse effects (mostly headache and nausea) were rare, and frequency was similar for aciclovir, valaciclovir, famciclovir, and placebo.[29]

Comment: The benefit was found to be greater if the person with recurrent herpes initiated treatment at the first symptom or sign of a recurrence.[31,32]

OPTION DAILY ORAL ANTIVIRAL TREATMENT

RCTs have found that daily maintenance treatment with oral antiviral agents reduces the frequency of recurrences and improves psychosocial morbidity in people with frequent recurrence compared with placebo.

Benefits: We found one systematic review of valaciclovir and famciclovir in the treatment of people with frequently recurring genital herpes (search date 1997, 4 placebo controlled RCTs).[29] Two of the four RCTs in the review evaluated treatment for 1 year, one for 4 months, and one for 16 months. **Valaciclovir versus placebo:** The first RCT (1479 people) compared valaciclovir 250 mg 4 times daily; valaciclovir 250 mg twice daily; valaciclovir 500 mg 4 times daily; valaciclovir 1000 mg 4 times daily; aciclovir 400 mg twice daily; and placebo. It found a dose–response effect across the valaciclovir regimen on freedom from recurrence compared with placebo (freedom from recurrence 48–50% with valaciclovir 1000 mg 4 times daily and aciclovir 400 mg twice daily; 40% with valaciclovir 500 mg 4 times daily; 22% with valaciclovir 250 mg 4 times daily *v* 5% with placebo).[33] **Famciclovir versus placebo:** The second RCT (455 people) compared famciclovir 250 mg twice daily; famciclovir 125 mg 3 times daily; famciclovir 250 mg 3 times daily; and placebo. It found that famciclovir significantly increased median time to first recurrence compared with placebo (11 months with famciclovir 250 mg twice daily; 10 months with famciclovir 250 mg 3 times daily; 8 months with famciclovir 125 mg 3 times daily *v* 1.5 months with placebo).[34] **Aciclovir versus placebo:** One non-systematic review identified two small RCTs comparing aciclovir and placebo for 1 year or more (107 people with a history of frequent recurrence ≥ 6/year).[27] The first RCT (32 people) comparing aciclovir 800 mg daily and placebo found that aciclovir reduced recurrence over 2 years (freedom from recurrence at 2 years: 5/18 [28%] with aciclovir *v* 0/14 [0%] with placebo; ARR 28%, 95% CI 1% to 51%). The second RCT similarly found that aciclovir 400 mg twice daily reduced recurrence compared with placebo over 1 year (freedom from recurrence at 1 year: 21/48 [44%] with

aciclovir *v* 0/28 [0%] with placebo; ARR 44%, 95% CI 26% to 56%). We found one subsequent double blind, placebo controlled RCT (1146 adults), which also found that aciclovir reduced recurrence compared with placebo over 1 year (recurrence rate 1.7% with aciclovir *v* 12.5% with placebo; $P < 0.0001$).[35] Of 210 adults in the trial who completed 5 years of continuous treatment with aciclovir 400 mg twice daily, 53–70% were free of recurrence each year. **Viral shedding (aciclovir versus placebo):** We found one RCT (34 women with recently acquired genital herpes simplex virus type 2 infection) of daily maintenance, which compared aciclovir treatment versus placebo and assessed viral shedding in women.[36] Women obtained swabs for viral cultures daily for 70 days while receiving aciclovir 400 mg twice daily or placebo. It found that aciclovir reduced viral shedding by 95% on days with reported lesions and by 94% on days without lesions, compared with placebo. **Psychosocial morbidity:** We found two RCTs. **Daily oral antiviral treatment:** One RCT (1479 people) evaluated the effect of daily oral antiviral treatment (once and twice daily valaciclovir and aciclovir) on a genital herpes quality of life scale.[37,38] A second RCT (202 people) evaluated treatment preference and quality of life during episodic and suppressive therapy with valaciclovir.[39] People receiving daily aciclovir or valaciclovir had significantly greater mean improvements from baseline than those receiving placebo[38] and significantly greater treatment satisfaction and quality of life than those receiving episodic treatment.[39]

Harms: Daily treatments with aciclovir, famciclovir, and valaciclovir were well tolerated.[40] People taking aciclovir were followed for up to 7 years, and those taking famciclovir and valaciclovir for up to 1 year. Nausea and headache were infrequent, and participants rarely discontinued treatment because of adverse effects. We found no studies evaluating whether daily maintenance treatment increases high risk sexual behaviour. We found no evidence that daily treatment with aciclovir results in emergence of aciclovir resistant herpes simplex virus during or after stopping treatment in healthy adults.[40]

Comment: None.

OPTION PSYCHOTHERAPY

One systematic review found that the effects of psychotherapy on the rate of genital herpes recurrence have not yet been adequately studied.

Benefits: We found one systematic review (search date 1991), which identified six poor quality studies of psychotherapeutic interventions in 69 people (4 studies had < 10 participants).[41] Interventions varied from hypnotherapy and progressive muscle relaxation to cognitive therapy and multifaceted intervention. The largest RCT (31 people with > 4 recurrences/year) compared psychosocial intervention versus social support or waiting list. Participants receiving psychosocial intervention had significantly lower recurrence rates (6 recurrences/year) compared with the pretreatment frequency (11 recurrences/year, $P < 0.001$) or with the other groups (11 recurrences/year, $P < 0.001$).[42]

Genital herpes

Harms: The review and the RCT gave no information on adverse effects.[41,42]

Comment: Small numbers of people, inadequate controls, and subjective and retrospective assessment of recurrence frequency at baseline limit the usefulness of these studies.[41] Controlled studies that include prospective clinical evaluation of disease activity are needed.

QUESTION **What are the effects of treatments in people with genital herpes and HIV infection?**

OPTION **ANTIVIRAL TREATMENTS**

We found no RCTs evaluating antiviral treatment for genital herpes in people immunocompromised with HIV infection. However, evidence from other settings suggests that antiviral agents may be effective treatments of genital herpes in immunocompromised people.

Benefits: We found no systematic review and no RCTs on the treatment of first episode genital herpes in people with HIV infection. We found no systematic reviews but we found several RCTs comparing different antiviral agents for prevention or treatment of recurrent genital herpes infections. **Prevention of recurrence:** We found two RCTs.[43,44] **Famciclovir versus placebo:** One crossover RCT (48 people with antibodies to HIV and herpes simplex virus; 38 with a history of genital herpes) compared famciclovir and placebo over 8 weeks but its results were difficult to interpret.[44] **Valaciclovir versus aciclovir:** The other RCT (1062 people with a median CD4 count of 320/mm^3) compared valaciclovir (500 mg twice daily) or valaciclovir (1000 mg once daily) versus aciclovir (400 mg twice daily) over 1 year.[43] It found no significant difference between either dose of valaciclovir and aciclovir, although recurrence was less likely with the lower dose of valaciclovir given twice daily than with the higher dose given once daily (recurrence free at 48 weeks 82% with 500 mg twice daily *v* 71% with 1000 mg once daily; $P < 0.05$). **Treatment of recurrence:** We found two RCTs.[43,45] **Famciclovir versus aciclovir:** One RCT (193 people on stable antiretroviral treatment) compared famciclovir (500 mg twice daily) versus aciclovir (400 mg 5 times daily) for 1 week.[45] It found no difference between the two drugs in mucocutaneous recurrence of herpes simplex virus. **Valaciclovir versus aciclovir:** The other RCT (467 people) compared valaciclovir (1000 mg twice daily) versus aciclovir (200 mg 5 times daily) for 5 days.[43] It found no significant differences between the two drugs.

Harms: Adverse effects (mostly headache and nausea) occurred with similar frequencies in all regimens.

Comment: Only one of the RCTs[43] had a placebo control; most studies compared new treatments rather with the standard treatment, aciclovir. The crossover trial of famciclovir versus placebo was difficult to interpret because of a high withdrawal rate.[44] Although we found only limited evidence of an effect of antiviral agents for treatment of genital herpes in people with HIV infection, there was a consensus that antiviral treatment may be helpful, based on evidence from immunocompromised people who do not have HIV.

Aciclovir has been found to be effective in immunocompromised populations. With the availability of effective treatments for HIV, trials of antiviral (antiherpes simplex virus) agents versus placebo may now be conducted. In HIV infected people, there is a markedly increased rate of herpes simplex virus shedding.[46] HIV has been recovered from genital herpes lesions.[47] We found no evidence on the effect of daily antiviral treatment on transmission of HIV to sexual partners.

Substantive changes

There has been major restructuring of this chapter since the last update:

Vaccination One RCT added.[10] Glycoprotein-D-adjuvant vaccine showed protection of the vaccine against new genital herpes infection in women who had been seronegative for herpes simplex virus type 1 (HSV-1) and HSV-2 at baseline compared with placebo. No protection was demonstrated in women who had been seropositive for HSV-1, and men. HSV-2 glycoprotein-D-adjuvant vaccine categorised as Unknown effectiveness.

Antiviral treatment during pregnancy One RCT added;[16] categorisation unchanged.

Antiviral treatment at the start of recurrence One RCT added;[31] categorisation unchanged.

Daily maintenance antiviral treatment One RCT added;[39] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Key Messages

- **Cryotherapy (as effective in clearing warts as trichloroacetic acid, electrosurgery, or podophyllin)** We found no RCTs comparing cryotherapy versus placebo or no treatment. Two RCTs found no significant difference between cryotherapy and trichloroacetic acid in clearance of warts after 6–10 weeks' treatment. One of the RCTs found no significant difference in recurrence of warts at 2 months after the end of treatment. One RCT found limited evidence that cryotherapy was less effective for clearance than electrosurgery after 6 weeks' treatment. However, follow up of the people with successful wart clearance found no significant difference in the proportion of people who had warts at 3–5 months. Another RCT found no significant difference in wart clearance at 3 months between cryotherapy and electrosurgery. One RCT found that cryotherapy increased clearance after 6 weeks' treatment compared with podophyllin, and follow up of the people with successful wart clearance found that fewer people receiving cryotherapy had warts at 3–5 months.

Genital warts

- **Electrosurgery (as effective as cryotherapy or podophyllin, more effective than intramuscular or subcutaneous interferon in clearing warts)** We found no RCTs comparing electrosurgery versus no treatment. One RCT found that electrosurgery improved clearance after 6 weeks' treatment compared with cryotherapy. However, follow up of the people with successful wart clearance found no significant difference in the proportion of people who had warts at 3–5 months after treatment. It also found that electrosurgery improved clearance after 6 weeks' treatment compared with podophyllin, and follow up of the people with successful wart clearance found that the difference was maintained at 3–5 months after treatment. Another RCT found no significant difference in wart clearance at 3 months between electrosurgery and cryotherapy. One RCT found limited evidence that electrosurgery was more effective than intramuscular or subcutaneous interferon in clearing warts at 3 months.
- **Imiquimod in people without HIV** One systematic review and one subsequent RCT have found that imiquimod cream increases wart clearance and reduces recurrence compared with placebo in people without HIV. One RCT in women without HIV found that twice daily doses of imiquimod 5% did not increase wart clearance over 20 weeks compared with once daily or three times weekly doses but found that it increased skin erythema.
- **Interferon, topical** Three RCTs have found that topical interferon increases wart clearance at 4 weeks after treatment compared with placebo. One of the RCTs also found that topical interferon increased wart clearance at 4 weeks after treatment compared with podophyllotoxin.
- **Laser surgery (as effective as surgical excision in clearing warts)** We found no RCTs comparing laser surgery versus no treatment. One RCT found no significant difference in wart clearance or recurrence rates over 36 weeks between laser and surgical excision.
- **Podophyllin (as effective as podophyllotoxin or surgical excision in clearing warts but less effective than cryotherapy and electrosurgery, less effective than surgical excision in preventing recurrence)** We found no RCTs comparing podophyllin versus placebo. RCTs have found that podophyllin resin is as effective in clearing warts as podophyllotoxin and surgical excision. One RCT found that podophyllin was less effective than cryotherapy or electrosurgery in clearing warts at 6 weeks, and follow up of the people with successful wart clearance found that more people receiving podophyllin had warts at 3–5 months. One RCT found that podophyllin was more effective than systemic interferon in clearing warts at 3 months. Another RCT found that podophyllin was less effective than surgical excision in preventing recurrence at 6–12 months. One RCT found no significant difference in wart clearance at 3 months between podophyllin plus trichloroacetic acid and podophyllin alone.
- **Podophyllotoxin** RCTs have found that podophyllotoxin increases wart clearance within 16 weeks compared with placebo. They found no significant difference in wart clearance between podophyllotoxin and podophyllin. One RCT found that podophyllotoxin was less effective than topical interferon in clearing warts at 4 weeks.
- **Surgical excision (as effective as laser surgery or podophyllin in clearing warts, more effective than podophyllin in preventing recurrence)** We found no RCTs comparing surgical excision versus no treatment. RCTs found no significant difference between surgical (scissor) excision and laser surgery or podophyllin in wart clearance. However, they have found that surgical excision is more effective than podophyllin in preventing recurrence.

- **Bi- and trichloroacetic acid (as effective as cryotherapy in clearing warts)** We found no RCTs comparing bi- and trichloroacetic acid versus placebo. Two RCTs found no significant difference between trichloroacetic acid and cryotherapy in clearance of warts after 6–10 weeks' treatment, and one of the RCTs found no significant difference in recurrence of warts at 2 months after the end of treatment. One RCT found no significant difference in wart clearance at 3 months between trichloroacetic acid plus podophyllin and podophyllin alone.
- **Condoms to prevent transmission of human papillomavirus or external genital warts** Observational studies provided insufficient evidence to assess the effects of condom use on transmission of human papillomavirus. Penetrative intercourse is not required for spread as this can occur with external genital–genital or hand–genital touching. One case control and one cross-sectional study suggested that people who always used condoms were less likely to have genital warts than people who never or occasionally used them.
- **Imiquimod in people with HIV** One RCT in people with HIV identified by a systematic review found no significant difference in wart clearance over 16 weeks between imiquimod cream and placebo.
- **Interferon, systemic** RCTs found that systemic interferon improved wart clearance at 2–3 months compared with placebo but was associated with flu-like symptoms, including blood disorders, headache, chills, fever, nausea, and vomiting. One RCT found that systemic interferon was less effective than podophyllin in clearing warts at 3 months.

DEFINITION External genital warts are benign epidermal growths on the external perigenital and perianal regions. There are four morphological types: condylomatous, keratotic, papular, and flat warts.

INCIDENCE/ PREVALENCE In 1996, external and internal genital warts accounted for over 180 000 initial visits to private physicians' offices in the USA: about 60 000 fewer than were reported for 1995.[1] In the USA, 1% of sexually active men and women aged 18–49 years are estimated to have external genital warts.[2] It is believed that external and cervical lesions caused by the human papillomavirus (HPV) are the most prevalent sexually transmitted disease among persons 18–25 years of age. In the USA, 50–60% of women aged 18–25 years test positive for HPV DNA, but no more than 10–15% ever have genital warts.[3]

AETIOLOGY/ RISK FACTORS External genital warts are caused by HPV and are sexually transmitted. They are more common in people with impaired immune function.[3] Although more than 100 types of HPV have been identified, most external genital warts in immunocompetent people are caused by HPV types 6 and 11.[4,5]

PROGNOSIS The ability to clear and remain free of external genital warts is a function of cellular immunity.[6] In immunocompetent people, the prognosis in terms of clearance and avoiding recurrence is good,[7] but people with impaired cellular immunity (e.g. people with HIV and AIDS) have great difficulty achieving and maintaining wart clearance.[3] Without treatment, external genital warts may remain unchanged, may increase in size or number, or may resolve completely. Clinical trials have found that recurrences may occur and may necessitate repeated treatment. External genital warts rarely, if ever, progress to cancer.[8] Juvenile laryngeal papillomatosis, a rare

and sometimes life threatening condition, occurs in children of women with a history of genital warts. Its rarity makes it hard to design studies that can evaluate whether treatment in pregnant women alters the risk.[9,10]

AIMS OF INTERVENTION To eliminate warts from the external genitalia; to prevent recurrence; and to avoid sequelae, with minimal adverse effects.

OUTCOMES Wart clearance, generally accepted as complete eradication of warts from the treated area, rather than elimination of HPV; recurrence; sequelae; adverse effects of treatment; quality of life; transmission.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION What are the effects of treatments for external genital warts?

OPTION BI- AND TRICHLOROACETIC ACID

We found no RCTs comparing bi- and trichloroacetic acid versus placebo. Two RCTs found no significant difference between trichloroacetic acid and cryotherapy in clearance of warts after 6–10 weeks' treatment, and one of the RCTs found no significant difference in recurrence of warts at 2 months after the end of treatment. One RCT found no significant difference in wart clearance at 3 months between trichloroacetic acid plus podophyllin and podophyllin alone.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus cryotherapy:** Two RCTs found no significant difference between trichloroacetic acid and cryotherapy in wart clearance after 6 weeks' treatment (1 RCT; 86 people; 21/33 [64%] with trichloroacetic acid *v* 37/53 [70%] with cryotherapy; RR 0.91, 95% CI 0.67 to 1.25),[11] or after 10 weeks' treatment (1 RCT; 130 men; 43/49 [89%] with trichloroacetic acid *v* 46/57 [81%] with cryotherapy; RR 1.08, 95% CI 0.92 to 2.82).[12] One of the RCTs found no significant difference in recurrence at 2 months after the end of 10 weeks' treatment (14/39 [36%] with trichloroacetic acid *v* 15/38 [40%] with cryotherapy; RR 0.91, 95% CI 0.51 to 1.61).[12] **Plus podophyllin versus podophyllin alone:** One RCT (73 people) found no significant difference in wart clearance at 3 months between trichloroacetic acid plus podophyllin and podophyllin alone (10/35 [28%] with trichloroacetic acid plus podophyllin *v* 9/38 [24%] with podophyllin alone; P value reported as non-significant, CI not reported).[13] **Versus other treatments:** We found no RCTs.

Harms: Safety during pregnancy is unknown. **Versus placebo:** We found no RCTs. **Versus cryotherapy:** The first RCT gave no information on adverse effects.[11] The second RCT found no significant difference in discomfort, ulceration, and scabbing between cryotherapy and trichloroacetic acid (29/57 [51%] with trichloroacetic acid *v* 19/43 [44%] with cryotherapy; reported as non-significant, CI not

reported).[12] **Plus podophyllin versus podophyllin alone:** The RCT found that trichloroacetic acid plus podophyllin was associated with ulceration at site of treatment in three people and soreness in two people.[13] It found no adverse effects in people taking podophyllin alone.

Comment: Small numbers of people and inadequate study designs make it difficult to evaluate effectiveness. In pregnant women, only case series are available: 31/32 (97%) pregnant women treated with trichloroacetic acid had wart clearance, and 2/31 (6%) had recurrence.[14]

OPTION CRYOTHERAPY

We found no RCTs comparing cryotherapy versus placebo or no treatment. Two RCTs found no significant difference between cryotherapy and trichloroacetic acid in clearance of warts after 6–10 weeks' treatment. One of the RCTs found no significant difference in recurrence of warts at 2 months after the end of treatment. One RCT found limited evidence that cryotherapy was less effective for clearance than electrosurgery after 6 weeks' treatment, but follow up of the people with successful wart clearance found no significant difference in the proportion of people who had warts at 3–5 months. Another RCT found no significant difference in wart clearance at 3 months between cryotherapy and electrosurgery. One RCT found that cryotherapy increased clearance after 6 weeks' treatment compared with podophyllin, and follow up of the people with successful wart clearance found that fewer people receiving cryotherapy had warts at 3–5 months.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs comparing cryotherapy versus placebo or no treatment. **Versus bi- and trichloroacetic acid:** See benefits of bi- and trichloroacetic acid, p 2092. **Versus electrosurgery:** We found two RCTs.[15,16] The first RCT (450 people) compared three interventions: cryotherapy, electrosurgery, and podophyllin (see comment below).[15] It found that cryotherapy was significantly less effective in clearing warts after 6 weeks' treatment compared with electrosurgery (68/86 [79%] with cryotherapy *v* 83/88 [94%] with electrosurgery; P = 0.003).[15] The RCT followed up people who had successful wart clearance after 6 weeks' treatment (177 people), and found no significant difference in the proportion of people who had warts at 3–5 months after treatment (9/42 [21%] with cryotherapy *v* 10/46 [22%] with electrosurgery; P = 0.09).[15] The second RCT (42 people) compared cryotherapy versus electrosurgery given at 2 weekly intervals as necessary until warts were completely cleared.[16] It found no significant difference in wart clearance at 3 months' follow up between cryotherapy and electrosurgery (10/18 [56%] with cryotherapy *v* 10/24 [42%] with electrosurgery; RR 1.33, 95% CI 0.71 to 2.50). **Versus podophyllin:** We found one RCT (450 people) that compared three interventions: cryotherapy, electrosurgery, and podophyllin (see comment below).[15] It found that cryotherapy significantly increased wart clearance after 6 weeks' treatment compared with podophyllin (68/86 [79%] with cryotherapy *v* 26/63 [41%] with podophyllin; P < 0.0001).[15] The RCT followed up people who had successful wart clearance after 6 weeks' treatment

(177 people) and found that cryotherapy significantly reduced the proportion of people who had warts at 3–5 months after treatment compared with podophyllin (9/42 [22%] with cryotherapy *v* 7/16 [44%] with podophyllin; $P < 0.0001$).[15] **Versus other treatments:** We found no RCTs.

Harms: **Versus placebo:** We found no RCTs. One case series of 34 pregnant women who received three or fewer treatments of cryotherapy found no subsequent infection or premature rupture of membranes.[17] **Versus bi- and trichloroacetic acid:** See harms of bi- and trichloroacetic acid, p 2092. **Versus electrosurgery or podophyllin:** One RCT reported local infection in 1/86 (1%) people receiving cryotherapy compared with 0/149 (0%) people receiving electrosurgery or podophyllin.[15]

Comment: The results of the RCT comparing cryotherapy versus electrosurgery or podophyllin should be interpreted with caution as no intention to treat analysis was performed and 213/450 (47%) of people withdrew from the trial.[15]

OPTION ELECTROSURGERY

We found no RCTs comparing electrosurgery versus no treatment. One RCT found that electrosurgery improved clearance after 6 weeks' treatment compared with cryotherapy. However, follow up of the people with successful wart clearance found no significant difference in the proportion of people who had warts at 3–5 months after treatment. It also found that electrosurgery improved clearance after 6 weeks' treatment compared with podophyllin, and follow up of the people with successful wart clearance found that the difference was maintained at 3–5 months after treatment. Another RCT found no significant difference in wart clearance at 3 months between electrosurgery and cryotherapy. One RCT found limited evidence that electrosurgery was more effective than intramuscular or subcutaneous interferon in clearing warts at 3 months.

Benefits: We found no systematic review. **Versus no treatment or sham treatment:** We found no RCTs versus no treatment or sham treatment. **Versus cryotherapy:** See benefits of cryotherapy, p 2093. **Versus interferon, systemic:** One RCT (203 people) found that electrosurgery was more effective than intramuscular interferon (RR for electrosurgery *v* intramuscular 3.3, 95% CI 1.8 to 5.9) or subcutaneous interferon (RR for electrosurgery *v* subcutaneous 6.9, 95% CI 2.8 to 17.1).[18] **Versus podophyllin:** We found one RCT (450 people) that compared three interventions: electrosurgery, podophyllin resin, and cryotherapy (see comment below).[15] It found that electrosurgery significantly increased wart clearance after 6 weeks' treatment compared with podophyllin (83/88 [94%] with electrosurgery *v* 26/63 [41%] with podophyllin; $P < 0.05$).[15] The RCT followed up people who had successful wart clearance after 6 weeks' treatment (177 people), and found that electrosurgery significantly increased the proportion of people who had no warts at 3–5 months (10/46 [22%] with electrosurgery *v* 7/16 [44%] with podophyllin; $P < 0.0001$).[15] **Versus other treatments:** We found no RCTs.

Harms: **Versus cryotherapy:** See harms of cryotherapy, p 2094. **Versus interferon, systemic:** The RCT found that electrosurgery was associated with local oedema, pain and dyspareunia.[18] See also harms of interferon, systemic, p 2096. **Versus podophyllin:** The first RCT found that pain and local irritation were reported in 17% of treated people given electrosurgery.[15]

Comment: **Versus podophyllin:** The results of the RCT should be interpreted with caution as no intention to treat analysis was performed and 213/450 (47%) of people withdrew from the trial.[15]

OPTION IMIQUIMOD

One systematic review and one subsequent RCT have found that imiquimod cream increases wart clearance and reduces recurrence compared with placebo in people without HIV. One RCT in people with HIV identified by the review found no significant difference in wart clearance over 16 weeks between imiquimod cream and placebo. One RCT in women without HIV found that twice daily doses of imiquimod 5% did not increase wart clearance over 20 weeks compared with once daily or three times weekly doses but found that it increased skin erythema.

Benefits: **Versus placebo:** We found one systematic review[19] (search date 2000, 5 RCTs in 588 people with genital warts without HIV infection, 1 RCT in 100 people with HIV) and one subsequent RCT.[20] The review found that, in people without HIV, imiquimod cream (1–5%) significantly increased clearance rates over 16 weeks compared with placebo (5 RCTs, AR for clearance 51% with imiquimod *v* 6% with placebo; RR 8.3, 95% CI 5.2 to 13.0; NNT 3, 95% CI 2 to 3).[19] The subsequent RCT (60 men without HIV) found similar results (AR for clearance at 4 weeks 70% with imiquimod *v* 10% with placebo; P = 0.0001).[20] The review found that in people without HIV, imiquimod 1% or 5% significantly increased the proportion of people with no recurrence at 10–16 weeks after treatment compared with placebo (AR of no recurrence after clearance 37% with imiquimod 5% *v* 28% with imiquimod 1% *v* 4–5% with placebo; RR for imiquimod 5% *v* placebo 9.0, 95% CI 4.9 to 17.0; NNT 3, 95% CI 3 to 4; RR for imiquimod 1% *v* placebo 2.9, 95% CI 1.5 to 5.9; NNT 10, 95% CI 3 to 91).[19] One RCT (100 people with HIV) included in the review found no significant difference in clearance at 16 weeks between imiquimod cream 5% and placebo (11% with imiquimod *v* 6% with placebo; P = 0.48).[19] **Different doses of imiquimod:** We found one open label RCT (90 women without HIV) comparing topical imiquimod 5% given either twice daily, once daily, or three times weekly.[21] It found no significant difference among groups in clearance rates over 20 weeks (63% with twice daily *v* 72% with once daily *v* 62% with 3 times weekly; P > 0.3).[21] **Versus other treatments:** We found no RCTs.

Harms: **Versus placebo:** The systematic review found no significant difference between imiquimod and placebo in withdrawal from treatment because of adverse effects (4 RCTs; AR 1.8% with imiquimod *v* 0% with placebo; RR 1.7, 95% CI 0.4 to 9.9).[19] The largest included RCT found that moderate to severe erythema, erosion, excoriation, oedema, and scabbing were more common with imiquimod 5%

than with imiquimod 1% or placebo (erythema: 40% *v* 4% *v* 3%; erosion: 10% *v* 1% *v* 2%; excoriation: 7% *v* 0% *v* 0%; oedema: 2% *v* 0% *v* 0%; scabbing: 5% *v* 2% *v* 0%: no further data reported).[19] The subsequent RCT found that 18% of people taking imiquimod had mild erythema, erosion, or oedema.[20] **Different doses of imiquimod:** The RCT found that imiquimod twice daily significantly increased the proportion of people with severe erythema compared with imiquimod once daily or three times weekly (25% with twice daily *v* 10% with once daily *v* 4% with 3 times weekly; $P = 0.01$).[21]

Comment: A secondary analysis of one of the RCTs identified by the review[19] (209 people without HIV) found that imiquimod significantly increased wart clearance compared with placebo regardless of gender, initial wart size, duration of current outbreak of warts, previous wart treatment, and tobacco use of participants.[22]

OPTION INTERFERON, SYSTEMIC

RCTs found that systemic interferon improved wart clearance at 2–3 months compared with placebo but was associated with flu-like symptoms, including blood disorders, headache, chills, fever, nausea, and vomiting. One RCT found that systemic interferon was less effective than podophyllin in clearing warts at 3 months.

Benefits: We found no systematic review. **Versus placebo:** We found seven RCTs.[18,23–28] Five of the RCTs found a significant difference in rates of wart clearance at 3 months between systemic interferon and placebo.[18,24–26,28] One of the RCTs (100 people) found that systemic interferon for 10 days significantly increased wart clearance at 8 weeks compared with placebo (25/49 [51%] with interferon *v* 13/45 [29%] with placebo; $P < 0.05$).[27] It found that a similar proportion of responders remained free of warts at 12 months (100% with systemic interferon *v* 92% with placebo). **Versus podophyllin:** One RCT (154 people with condylomata acuminata of < 6 months' duration) found that systemic interferon was significantly less effective than podophyllin in clearing warts at 3 months (AR for clearance 23% with interferon *v* 45% with podophyllin; $P = 0.003$).[29] **Versus other treatments:** We found no RCTs.

Harms: Flu-like symptoms were reported at variable frequencies. Headache, fatigue and malaise, myalgia, nausea and vomiting, fever, chills, and dizziness were reported in 0.5–100% of people taking systemic interferon.[23–31] Anaphylactic reaction occurred in 2% of people in one RCT;[18] leukopenia occurred in 6–28% and thrombocytopenia in 3–4% of people in another RCT;[25] and raised liver enzymes in 3% of people in two RCTs.[25,30]

Comment: None.

OPTION INTERFERON, TOPICAL

Three RCTs have found that topical interferon increases wart clearance at 4 weeks after treatment compared with placebo. One of the RCTs also found that topical interferon increased wart clearance at 4 weeks after treatment compared with podophyllotoxin.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs (223 people). The RCTs found that more people taking interferon had complete wart clearance 4 weeks after treatment than people taking placebo (6% with interferon *v* 3% with placebo, CI not reported;[32] 73% with interferon *v* 10% with placebo, $P < 0.0001$;[33] 90% with interferon *v* 20% with placebo, CI not reported[34]). About a third of people in each group in the first RCT had cleared their warts by 16 weeks.[32] Recurrence rates were not evaluated. **Versus podophyllotoxin:** One of the RCTs also compared topical interferon versus podophyllotoxin.[34] It found that topical interferon significantly increased wart clearance at 4 weeks after treatment compared with podophyllotoxin (18/20 [90%] with topical interferon *v* 12/20 [60%] with podophyllotoxin; $P = 0.0285$).[34] **Versus other treatments:** We found no RCTs.

Harms: **Versus placebo:** One RCT reported local burning and itching in 39% of people using topical interferon.[32] **Versus podophyllotoxin:** One RCT reported fever, headache, and itching in 18% of people using topical interferon.[34]

Comment: Differences in the clearance rates in the RCTs may be attributable to the preparations used; one preparation was incorporated into a methylcellulose aqueous base[32] and the other two were instilled into a cream base.[33,34]

OPTION SURGICAL EXCISION

We found no RCTs comparing surgical excision versus no treatment. RCTs found no significant difference between surgical (scissor) excision and laser surgery or podophyllin in wart clearance. However, they have found that surgical excision is more effective than podophyllin in preventing recurrence.

Benefits: We found no systematic review. **Versus no treatment:** We found no RCTs comparing surgical excision versus no treatment. **Versus laser surgery:** We found one RCT comparing surgical excision versus carbon dioxide laser.[35] It found no significant difference in clearance between laser and surgical excision (RR 1.2, 95% CI 0.6 to 2.4) and found no significant difference in recurrence rates between the two treatments.[35] **Versus podophyllin:** We found two RCTs (97 people).[36,37] They found no significant difference between surgical excision and podophyllin in wart clearance (16/18 [89%] with surgical excision *v* 15/19 [79%] with podophyllin; RR 1.13, 95% CI 0.85 to 1.50;[36] 28/30 [93%] with surgical excision *v* 23/30 [77%]; $P = 0.20$[37]). However, they found that surgical excision significantly reduced recurrence rates over 6–12 months compared with podophyllin (19% with surgical excision *v* 60% with podophyllin; $P = 0.105$;[36] 29% with excision *v* 65% with podophyllin; $P < 0.01$[37]). **Versus other treatments:** We found no RCTs.

Harms: All surgically treated people experienced pain.[36,37] **Versus laser surgery:** The RCT found no significant difference in scar formation between surgical excision and laser surgery, although fewer people having surgical excision developed scars (9% had scars with surgical excision *v* 28% with laser surgery; $P > 0.2$).[35] Postoperative pain was reported equally in both groups. **Versus podophyllin:**

Both RCTs found that more people receiving surgical excision had pain than people receiving podophyllin (11/18 [61%] with excision *v* 5/19 [26%] with podophyllin;[36] 25/30 [83%] with excision *v* 7/30 [23%] with podophyllin[37]). The second RCT also found that more people receiving surgical excision had bleeding than people receiving podophyllin (13/30 [43%] with excision *v* 11/30 [37%] with podophyllin).[37] The RCTs did not assess the significance of the differences between groups.[36,37]

Comment: None.

OPTION LASER SURGERY

We found no RCTs comparing laser surgery versus no treatment. One RCT found no significant difference in wart clearance or recurrence rates over 36 weeks between laser and surgical excision.

Benefits: We found no systematic review. **Versus no treatment:** We found no RCTs comparing laser surgery versus no treatment. **Versus surgical excision:** See benefits of surgical excision, p 2097. **Versus other treatments:** We found no RCTs.

Harms: **Versus surgical excision:** See harms of surgical excision, p 2097.

Comment: We found two case series of laser surgery, which included 47 pregnant women.[14,38] These reported premature rupture of membranes (2/32 [6%] women), prolonged rupture of membranes (1/32 [3%]), the need for postoperative suprapubic catheterisation (7/32 [22%]), pyelonephritis (1/32 [3%]), prolonged healing time (1/52 [2%]), and rectal perforation with secondary abscess (1/52 [2%]).

OPTION PODOPHYLLOTOXIN

RCTs have found that podophyllotoxin increases wart clearance within 16 weeks compared with placebo. They found no significant difference in wart clearance between podophyllotoxin and podophyllin. One RCT has found that podophyllotoxin was less effective than topical interferon in clearing warts at 4 weeks.

Benefits: We found no systematic review. **Versus placebo:** We found eight RCTs (1035 people) comparing podophyllotoxin versus placebo.[34,39–45] All found that, within 16 weeks of treatment, podophyllotoxin was more effective for clearance than placebo (RRs of clearance *v* placebo ranged between 2.0, 95% CI 0.9 to 4.3 and 48.0, 95% CI 3.0 to 773.0). RCTs of 0.5% cream or solution found recurrence rates ranging from 4%[45] to 33%.[40] One RCT (57 people) of 0.5% podophyllotoxin solution as prophylaxis against recurrence of external genital warts (initially treated in an open label study) found fewer recurrences among people taking placebo.[46] **Versus interferon, topical:** See benefits of interferon, topical, p 2097. **Versus podophyllin:** Five RCTs compared podophyllotoxin versus podophyllin.[47–51] They found no significant difference in wart clearance (RR values for podophyllin *v* podophyllotoxin ranging between 0.7, 95% CI 0.4 to 1.1[48] and 1.7, 95% CI 0.9 to 3.2).[50] One RCT used a 2% solution in a limited study of self treatment for penile warts and found no significant difference in clearance between podophyllotoxin and podophyllin (RR for podophyllin *v* podophyllotoxin 0.6, 95% CI 0.3 to 1.3).[51]

Harms: Safety during pregnancy is unknown. Cohort studies have reported rare cases of balanoposthitis.[52,53] **Versus placebo:** Local inflammation or irritation, erosion, burning, pain, and itching are reported in most trials. Dyspareunia, bleeding, scarring, and insomnia are reported rarely.[39] **Versus interferon, topical:** See harms of interferon, topical, p 2097. **Versus podophyllin:** One large RCT reported burning and inflammation in 75% and bleeding in 25% of people treated with podophyllotoxin.[42] Eight RCTs reported pain, erythema, irritation, and tenderness in 3–17% of people treated with podophyllin.[15,29,36,37,47,48,50] Skin burns (1–3%),[36] bleeding (4%),[37] and erosion or ulcerations (1%[48] to 11%[17]) were also reported. Faecal incontinence (4%)[37] and preputial tightening (1%)[47] were reported rarely.

Comment: RCTs examined the efficacy of podophyllotoxin solutions more often than cream preparations, but cream or gel preparations may be easier to apply than solutions. This and other differences may cause variable efficacy. Podophyllotoxin does not contain the mutagenic flavonoid compounds, quercetin and kaempherol, which are contained in podophyllin resin preparations.[54]

OPTION PODOPHYLLIN

We found no RCTs comparing podophyllin versus placebo. RCTs have found that podophyllin resin is as effective in clearing warts as cryotherapy, podophyllotoxin, and surgical excision. One RCT found that podophyllin was less effective than cryotherapy or electrosurgery in clearing warts at 6 weeks, and follow up of the people with successful wart clearance found that more people receiving podophyllin had warts at 3–5 months. One RCT found that podophyllin was more effective than systemic interferon in clearing warts at 3 months. Another RCT found that podophyllin was less effective than surgical excision in preventing recurrence at 6–12 months. One RCT found no significant difference in wart clearance at 3 months between podophyllin plus trichloroacetic acid and podophyllin alone.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Different doses of podophyllin:** One RCT (140 men with anogenital warts) found no significant difference in clearance rates at 3 months between podophyllin 10% and podophyllin 25% (AR 22% in both groups).[55] **Versus cryotherapy:** See benefits of cryotherapy, p 2093. **Versus electrosurgery:** See benefits of electrosurgery, p 2094. **Versus interferon, systemic:** See benefits of interferon, systemic, p 2096. **Versus podophyllotoxin:** See benefits of podophyllotoxin, p 2098. **Versus surgical excision:** See benefits of surgical excision, p 2097. **Plus trichloroacetic acid versus podophyllin alone:** See benefits of bi- and trichloroacetic acid, p 2092.

Harms: Safety during pregnancy is unknown. **Different doses of podophyllin:** The RCT stated that podophyllin 10% or 25% was not associated with hypersensity or ulceration.[55] **Versus cryotherapy:** See harms of cryotherapy, p 2094. **Versus electrosurgery:** See harms of electrosurgery, p 2095. **Versus interferon, systemic:**

Genital warts

See harms of interferon, systemic, p 2096. **Versus podophyllotoxin:** See harms of podophyllotoxin, p 2099. **Versus surgical excision:** See harms of surgical excision, p 2097. **Plus trichloroacetic acid versus podophyllin alone:** See harms of bi- and trichloroacetic acid, p 2092.

Comment: Podophyllin may contain the mutagenic flavonoid compounds, quercetin and kaempherol.[54]

QUESTION **What are the effects of interventions to prevent transmission of human papillomavirus or external genital warts?**

OPTION CONDOMS

Observational studies provided insufficient evidence to assess the effects of condom use on transmission of human papillomavirus. Penetrative intercourse is not required for spread as this can occur with external genital–genital or hand–genital touching. One case control and one cross-sectional study suggested that people who always used condoms were less likely to have genital warts than people who never or occasionally used them.

Benefits: **Condoms:** We found one systematic review (search date 2000, 1 cohort, 2 cross-sectional, 5 case control studies) comparing the effects of condom use versus no or occasional condom use on transmission of subclinical human papillomavirus (HPV) or transmission of external genital warts.[56] The review could not perform a meta-analysis because of heterogeneity of populations in the studies retrieved. The review was unable to draw firm conclusions about the effects of condom use on transmission of HPV but suggested that condoms use may reduce the risk of developing external genital warts. It identified six studies (479 women) assessing the effects of condom use on transmission of subclinical HPV, one of which found that condom use reduced the incidence of HPV. One cross-sectional study (182 women sex workers) identified by the review found that women who always used condoms were significantly less likely to have HPV than women who occasionally or never used condoms (OR 0.2, 95% CI 0.1 to 0.6). However, two case control studies and one cohort study (2638 women) found no significant difference between regular condom use and no use in the proportion of women who had HPV. Another two case control studies (1659 women) found that women who always used condoms were significantly more likely to have HPV than women who never used them (OR 3.8, 95% CI 1.2 to 11.6 in the first study; OR 1.5, 95% CI 1.1 to 2.0 in the second study). One cross-sectional study (432 male military recruits) identified by the review found that men who always used condoms were significantly less likely to have genital warts or HPV compared with men who occasionally or never used condoms (OR 0.3, 95% CI 0.2 to 0.5). One case control study (1298 people attending a sexually transmitted disease clinic) also found that people who always used condoms were significantly less likely to have genital warts than people who never used them (adjusted OR for men: 0.3, 95% CI 0.2 to 0.4; women: 0.6, 95% CI 0.4 to 0.9).[56]
Other treatments: We found no RCTs.

Harms: **Condoms:** The review gave no information on adverse effects.[56]

Comment: Penetrative intercourse is not required for spread as this can occur with external genital–genital or hand–genital touching. It is believed that for transmission the virus must be in the form of a virion, which occurs only in lesions. Viable transmission does not occur with contact with the HPV without a lesion.

Substantive changes

Bi- and trichloroacetic acid Two RCTs found no significant difference between trichloroacetic acid and cryotherapy in clearance of warts after 6–10 weeks' treatment, and one of the RCTs found no significant difference in recurrence of warts at 2 months after the end of treatment.[11,12] Evidence reassessed. Recategorised as Likely to be beneficial.

Imiquimod One RCT comparing imiquimod versus placebo[20] and another RCT[21] comparing twice daily doses of imiquimod 5% versus once daily or three times weekly doses added; categorisation unchanged.

Preventing transmission One systematic review of case-control and cross-sectional studies assessing condom use added;[56] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Beneficial

Likely to be beneficial

Unknown effectiveness

*Based on comparisons of results across arms of different trials.
†Based on non-RCT evidence and consensus.

See glossary, p 2110

Key Messages

- **Single dose antibiotic regimens using selected cephalosporins or spectinomycin in uncomplicated infection in pregnant women** One systematic review has found that antibiotic treatment (amoxicillin [amoxycillin] plus probenecid, spectinomycin, ceftriaxone, and cefixime) is effective for curing gonorrhoea in pregnant women. We found no reports of serious adverse effects.
- **Single dose antibiotic regimens using selected fluoroquinolones, selected cephalosporins, or spectinomycin in uncomplicated infection in men and non-pregnant women** One systematic review found limited evidence that single dose regimens (ceftriaxone, ciprofloxacin, gatifloxacin, spectinomycin, azithromycin, ofloxacin, cefixime) achieve cure rates of 95% or higher in urogenital or rectal infection. Cure rates were lower (≤ 80%) for pharyngeal infection. Resistance to penicillins, tetracyclines, and sulphonamides is now widespread, and resistance to fluoroquinolones has become common in some geographic areas.

- **Multidose antibiotic regimens using selected injectable fluoroquinolones or selected injectable cephalosporins in disseminated infection** We found no RCTs assessing treatments for disseminated gonococcal infection published, but there is strong consensus that multidose regimens using injectable cephalosporins or quinolones (except where quinolone-resistant *Neisseria gonorrhoeae* have been reported) are the most effective treatment. We found no reports of treatment failures with these regimens.
- **Dual antibiotic treatment for gonorrhoea and chlamydia infections in all people diagnosed with gonorrhoea** Dual treatment for gonorrhoea and chlamydia infections is based on theory and expert opinion rather than on evidence from RCTs. The balance between benefits and harms will vary with the prevalence of co-infection in each population.

DEFINITION Gonorrhoea is caused by infection with *Neisseria gonorrhoeae*. In men, uncomplicated urethritis is the most common manifestation, with dysuria and urethral discharge. Less typically, signs and symptoms are mild and indistinguishable from those of chlamydial urethritis. In women, the most common manifestation is cervicitis, which produces symptoms (e.g. vaginal discharge, lower abdominal discomfort, and dyspareunia) in only half of the women. Co-infection with chlamydia is reported in 20–40% of people.[1–3]

INCIDENCE/ PREVALENCE Between 1975 and 1997, the incidence of reported gonorrhoea in the USA fell by 74%, reaching a nadir of 122/100 000 people. Since 1997, between 125 and 133 cases have been reported per 100 000 people each year.[4] Rates are highest in younger people. In 2002, the incidence was highest in women aged 15–19 years (676/100 000) and men aged 20–24 years (538/100 000). In England, Wales, and Northern Ireland, diagnoses of gonorrhoea have increased since 1994, reaching 296/100 000 for 20–24 year old men and 214/100 000 for 16–19 year old women in 2002.[5]

AETIOLOGY/ RISK FACTORS Most infections result from penile–vaginal, penile–rectal, or penile–pharyngeal contact. An important minority of infections are transmitted from mother to child during birth, which can cause ophthalmia neonatorum. Less common are ocular infections in older children and adults as a result of sexual exposure, poor hygiene, or the medicinal use of urine.

PROGNOSIS The natural history of untreated gonococcal infection is spontaneous resolution after weeks or months of unpleasant symptoms.[6] During this time, there is a substantial likelihood of transmission to others and of complications developing in the infected individual.[6] In many women, the lack of readily discernible signs or symptoms of cervicitis means that infections go unrecognised and untreated. An unknown proportion of untreated infections causes local complications, including lymphangitis, periurethral abscess, bartholinitis, and urethral stricture; epididymitis in men; and in women involvement of the uterus, fallopian tubes, or ovaries causing pelvic inflammatory disease (see pelvic inflammatory disease, p 2121). Gonorrhoea is associated with pelvic inflammatory disease. One review found *N gonorrhoeae* was cultured from 8–32% of women with acute pelvic inflammatory disease in 11 European studies and from 27–80% of women in eight US studies.[7] The proportion of *N gonorrhoeae* infections in women that lead to pelvic inflammatory disease has not been well studied. However, one study of 26

women exposed to men with gonorrhoea found that 19 women were culture positive and of these, five women had pelvic inflammatory disease and another four had uterine adnexal tenderness.[8] Pelvic inflammatory disease may lead to infertility (see pelvic inflammatory disease, p 2121). In some people, localised gonococcal infection may disseminate. A US study estimated the risk of dissemination to be 0.6–1.1% among women, whereas a European study estimated it to be 2.3–3.0%.[9,10] The same European study found a lower risk in men, estimated to be 0.4–0.7%.[10] When gonococci disseminate, they cause petechial or pustular skin lesions; asymmetrical arthropathies, tenosynovitis or septic arthritis; and, rarely, meningitis or endocarditis.

AIMS OF INTERVENTION To relieve symptoms; avoid complications; and prevent further transmission, with minimal adverse effects of treatment.

OUTCOMES Microbiological cure rates (number of infected people or infected sites culture-negative 1–14 days after treatment, divided by number of infected people or infected sites cultured 1–14 days after treatment).

METHODS *Clinical Evidence* search and appraisal September 2003. Additional Pubmed search conducted by author in October 2003. Key words: gonorrhoea and *N gonorrhoeae* infections, plus a search of references of key articles and books. Studies were excluded if they defined possible treatment failures as "reinfections", if they did not use end points based on microbiological cure, or if they were based on drug regimens unlikely to be of general use (e.g. those using antibiotic regimens that are toxic or to which resistance is now widespread).[11] The authors have not searched for, or included, papers published before 1981 as the susceptibility of *N gonorrhoea* changes over time. The results of particularly old clinical trials may be misleading because of intervening changes in susceptibility.

QUESTION What are the effects of treatments for uncomplicated infections in men and non-pregnant women?

OPTION SINGLE DOSE ANTIBIOTIC REGIMENS

One systematic review found limited evidence that single dose regimens (ceftriaxone, ciprofloxacin, gatifloxacin, spectinomycin, azithromycin, ofloxacin, cefixime) achieve cure rates of 95% or higher in urogenital or rectal infection. Cure rates were lower (≤ 80%) for pharyngeal infection. Resistance to penicillins, tetracyclines, and sulphonamides is now widespread, and resistance to fluoroquinolones has become common in some geographic areas.

Benefits: **Uncomplicated urogenital, rectal, and pharyngeal infections:** We found one systematic review (search date 1993).[11] The results were updated to 2002 by the author of the review using the original methods (see table 1, p 2111) (Moran JS, personal communication, 2003). The original review identified studies (both RCTs and other clinical trials) published from 1981–1993 that used a single dose regimen based on an antimicrobial other than a β-lactamase sensitive penicillin or a tetracycline.[11] The search retrieved studies with a total of 24 383 evaluable people. Combining results across

arms of trials, 97% were cured on the basis of culture results. Sites of infection, when specified, included the cervix, urethra, rectum, and pharynx. Comparison of cure rates by site of infection found that cure rates were over 95% for all sites except the pharynx, for which they were about 80% (see table 1, p 2111).[14] **Eye infections:** We found no systematic review or RCTs (see comment below).

Harms: Single dose regimens using fluoroquinolones, third generation and extended spectrum cephalosporins, or spectinomycin are generally safe and well tolerated. The most important adverse effects are rare hypersensitivity reactions. Minor adverse effects are most troublesome for the cefixime 800 mg regimen[15,16] and the azithromycin 2 g regimen;[17] both cause frequent gastrointestinal upset. All the other effective doses are associated with a low incidence of adverse outcomes. One large observational cohort study of azithromycin, cefixime, ciprofloxacin, and ofloxacin "in everyday use" found few serious adverse effects.[18] Quinolones may cause arthropathy in animals. One systematic review of harms (search date 2000) found no irreversible fluoroquinolone induced cartilage pathology after 0.3–10.0 months of follow up in 201 adolescents treated for between 7 and 270 days.[19]

Comment: There is good agreement between antigonococcal activity of antimicrobials *in vitro* and their efficacy in clinical trials. A large number of people were evaluated in a range of settings, suggesting that the results can be generalised. However, comparative results from different settings were not reported. Single dose regimens may make adherence more likely. The ceftriaxone and spectinomycin regimens require intramuscular injection. Resistance is now widespread for all penicillins, sulphonamides, and tetracyclines, and is becoming common for fluoroquinolones in many parts of the world.[5,20–22] Resistance to third generation and extended spectrum cephalosporins or spectinomycin is rarely reported (see table 2, p 2112). **Eye infections:** We found two small cohort studies of single dose ceftriaxone for gonococcal eye infections.[26,27] In the first study (12 adults with conjunctivitis), all people responded well to a single 1 g dose of ceftriaxone.[26] In the second study (21 neonates with gonococcal ophthalmia), eye swabs from all neonates were negative 24 hours after a single intramuscular 62.5 mg dose of ceftriaxone.[27]

QUESTION What are the effects of treatments for uncomplicated infections in pregnant women?

OPTION SINGLE DOSE ANTIBIOTIC REGIMENS

One systematic review has found that antibiotic treatment (amoxicillin [amoxycillin] plus probenecid, spectinomycin, ceftriaxone, and cefixime) is effective for curing gonorrhoea in pregnant women. We found no reports of serious adverse effects.

Benefits: We found one systematic review (search date 2001, 2 RCTs) of treatments of gonococcal infection during pregnancy.[28] One of the RCTs (267 pregnant women with positive cultures for gonorrhoea)

compared amoxicillin (amoxycillin) plus probenecid versus spectinomycin versus ceftriaxone. Overall, it found no significant difference between regimens (failure to achieve cure 9/84 [10.7%] with amoxicillin *v* 4/84 [4.8%] with spectinomycin; RR 2.25, 95% CI 0.72 to 7.02; 9/84 [10.7%] with amoxicillin *v* 4/84 [4.8%] with ceftriaxone; RR 2.25, 95% CI 0.72 to 7.02). However, the study may have lacked the power to detect clinically important effects. By site of infection, amoxicillin 3 g plus probenecid 1 g cured 91% of cervical infections, 85% of rectal infections and 80% of pharyngeal infections; single dose ceftriaxone 250 mg cured 95% of rectal and cervical infections and 100% of pharyngeal infections; spectinomycin 2 g cured 97% of rectal and cervical infections and 83% of pharyngeal infections.[29] The second RCT (95 women with positive cultures for gonorrhoea) compared a single dose of ceftriaxone intramuscularly versus a single dose of cefixime orally.[28] It found that eradication rates were similar in the two groups: ceftriaxone 125 mg eradicated 96.8% (95% CI 89.0% to 99.6%) of cervical and rectal infections and 100% (95% CI 47.8% to 100%) of pharyngeal infections; and cefixime 400 mg eradicated 96.0% (95% CI 88.8% to 99.6%) of cervical and rectal infections and 100% (95% CI 54.1% to 100%) of pharyngeal infections.

Harms: The systematic review reported vomiting after treatment in 1/267 (0.4%) women included in one trial.[28] The second RCT reported soreness at the injection site among women receiving ceftriaxone and some "minor" malformations among their children, generally cosmetic (e.g. nevus, café au lait spots, skin tag: 10/60 [16.7%] with ceftriaxone *v* 7/62 [11.3%] with cefixime).[30] Because quinolones cause arthropathy in animals, their use is not recommended in pregnancy, although we found no reports of adverse effects of quinolones on pregnancy outcome in humans. One multicentre, prospective, controlled study (200 exposed women) found no evidence of adverse effects.[31] We found no evidence that the non-quinolone regimens listed above are less safe or less well tolerated by pregnant women than by men or non-pregnant women.

Comment: None.

QUESTION What are the effects of treatments for disseminated gonococcal infection?

OPTION MULTIDOSE ANTIBIOTIC REGIMENS

We found no RCTs assessing treatments for disseminated gonococcal infection, but there is strong consensus that multidose regimens using injectable cephalosporins or quinolones (except where quinolone-resistant *N gonorrhoeae* have been reported) are the most effective treatment. We found no reports of treatment failures with these regimens.

Benefits: We found no systematic review and no RCTs of the treatment of disseminated gonococcal infection published since 1981.

Harms: We found no reports of adverse effects of multidose regimens using injectable cephalosporins or quinolones in this context.

Comment: More than 100 clinical trials involving over 20 000 people have found that many single dose antimicrobial regimens cure uncomplicated infections more than 90% of the time.[11] Given the protracted natural history without treatment, this evidence suggests that treatment with these antimicrobial regimens is beneficial. Which regimens are most beneficial cannot be determined precisely because direct randomised comparisons of the best different regimens have not been performed. However, analysis of available trials supports the consensus that the most effective regimens are those using selected third generation or expanded spectrum cephalosporins and, except where resistance is common, those using selected fluoroquinolones or spectinomycin. Although we found no published data establishing the efficacy of these treatments, we found no reports of treatment failures.

QUESTION What are the effects of dual treatment for gonorrhoea and chlamydia infection?

OPTION DUAL ANTIBIOTIC TREATMENT

Dual treatment with an antimicrobial effective against *Chlamydia trachomatis* is based on theory and expert opinion rather than evidence from RCTs. The balance between benefits and harms from controlled trials will vary with the prevalence of co-infection in each population.

Benefits: We found no systematic review or RCTs.

Harms: We found no good evidence on the harms of dual treatment (see glossary, p 2110). Treatment for chlamydia can cause mild gastrointestinal distress, and there is the possibility that using a second drug could stimulate the emergence or spread of resistance in *N gonorrhoeae* or other bacteria.

Comment: Routine dual treatment has been advocated and implemented for the past 19 years, and is believed to have two potential benefits. Firstly, it is believed by some to have contributed to the decline in the prevalence of chlamydia infection observed in some populations. We found no evidence for any direct effect of dual treatment on chlamydia prevalence. Other factors may have contributed to reduced chlamydia prevalence (including widespread screening for asymptomatic chlamydia infection and changes in sexual behaviour), making it difficult to attribute decreases in the prevalence of chlamydia infection to any specific cause. Secondly, routine dual treatment may retard the spread of resistant gonococcal strains. Limited data from case reports support this belief. In the past, chlamydia testing was often unavailable, expensive, time consuming, and not highly sensitive, whereas dual treatment with a tetracycline, such as doxycycline, was safe and inexpensive. Chlamydia testing has now become more widely available, more affordable, quicker, and more sensitive, and the prevalence of chlamydia has fallen in some populations. Nevertheless, chlamydia is still found in 20–40% of people with gonorrhoea in many clinics.[1–3]

Gonorrhoea

GLOSSARY

Dual treatment the routine treatment of people with gonorrhoea with an antimicrobial regimen effective against genital *Chlamydia trachomatis* infection in addition to a regimen effective against gonorrhoea (sometimes called dual therapy or co-treatment).

TABLE 1 **Effectiveness of selected single dose regimens in published clinical trials[10] and updated to 2003 (see text, p 2111).**

	Pharyngeal infections	Urogenital and rectal infections
Drug and dose	**% cured (95% CI)**	**% cured (95% CI)**
Ceftriaxone 250 mg	98.9 (94.0 to 100)	99.2 (98.8 to 99.5)
Ciprofloxacin 500 mg*	97.2 (85.5 to 99.9)	99.8 (98.7 to 100)
Ciprofloxacin 250 mg	88.5 (88.8 to 95.2)	98.7 (98.0 to 99.4)
Ceftriaxone 125 mg	94.1 (85.6 to 98.4)	98.9 (97.9 to 99.8)
Gatifloxacin 600 mg	100 (82.3 to 100)	99.6 (97.7 to 100)
Spectinomycin 2 g	51.8 (38.7 to 64.9)	98.2 (97.6 to 99.9)
Azithromycin 2 g	100 (82.3 to 100)	99.2 (97.2 to 99.9)
Ofloxacin 400 mg	88.7 (68.8 to 97.8)	98.6 (97.8 to 99.4)
Gatifloxacin 400 mg	100 (63.1 to 100)	99.2 (97.1 to 99.9)
Cefixime 800 mg	80.0 (51.9 to 95.7)	98.4 (95.9 to 99.6)
Cefixime 400 mg	92.3 (74.9 to 99.1)	97.4 (95.9 to 98.6)
Cefuroxime axetil 1 g	56.9 (43.3 to 70.5)	96.2 (94.8 to 97.5)
Cepodoxime proxetil 200 mg	78.9 (54.5 to 94.0)	96.5 (94.3 to 98.5)

*Excludes two published clinical trials among people known to be at high risk of harbouring fluoroquinolone resistant strains; ciprofloxacin 500 mg cured only 48/72 (67%) of cervical infections in one trial [12] and 41/66 (62%) in the other.[13]

TABLE 2 **Reported resistance of *N gonorrhoeae* to antimicrobials (see text, p 2112).**

Drug	Resistance
Sulphonamides	Widespread
Penicillins	Widespread
Tetracyclines	Widespread
Third generation cephalosporins (e.g. ceftriaxone, cefixime)	One report from China[21]
Spectinomycin	Rare
Quinolones	Asia: becoming very common, especially in the Far East (e.g. 80% in China, 64% in Japan, 54% in the Phillippines;[20] there are few data from the Middle East, but a high prevalence of resistance (61%) has been reported in Israel.[23]
	USA: in 2002, resistance to ciprofloxacin was reported in 2.2% of 5367 isolates. In the five states boring the Pacific Ocean, 8.3% of isolates were resistant. In the remaining sates, 0.2% were resistant.[22]
	UK: among 2204 gonorrhoeae isolates from England and Wales tested in 2002, 9.8% were flouroquinolone resistant.[24]
	Australia and New Zealand; 13% and 10%, respectively.[20]
	South America: one fluoroquinolone resistant isolate reported.[25]

Partner notification

Search date July 2003

Catherine Mathews, Nicol Coetzee, Merrick Zwarenstein, and Sally Guttmacher

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Unknown effectiveness

See glossary, p 2119

Key Messages

- We found no good evidence on the effects of partner notification on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.
- We found no studies comparing the effects of an intervention across different groups, such as people with different diseases or combinations of diseases, or people from different settings.
- **Contract referral (as effective as provider referral in people with syphilis)** One systematic review of one large RCT comparing different partner notification strategies in people with syphilis found no significant difference in the proportion of partners notified between provider referral and contract referral, when people receiving the contract referral option were given 2 days to notify their partners.
- **Offering a choice between provider and patient referral (*v* patient referral) in people with HIV** One systematic review of one RCT comparing different partner notification strategies found that, in people with HIV, offering a choice between provider referral (where the identity of the index patient was not revealed) and patient referral improved notification rates compared with offering patient referral alone.
- **Provider referral or contract referral (*v* patient referral) in people with gonorrhoea or non-gonococcal urethritis (mainly chlamydia)** One systematic review has found that, for people with gonorrhoea, contract versus patient referral increased the rate of partners presenting for treatment. For people with non-gonococcal urethritis, one systematic review found that provider versus patient referral increased the proportion of partners notified and of positive partners detected per patient.

Partner notification

- **Adding telephone reminders and contact cards to patient referral; educational videos; information pamphlets; patient referral by different types of healthcare professionals; patient referral in HIV** We found insufficient evidence about the effects of these interventions in improving partner notification.

DEFINITION Partner notification is a process whereby the sexual partners of people with a diagnosis of sexually transmitted infection are informed of their exposure to infection. The main methods are patient referral, provider referral, contract referral, and outreach assistance (see glossary, p 2119).

INCIDENCE/ PREVALENCE A large proportion of people with sexually transmitted infections will have neither symptoms nor signs of infection. For example, 22–68% of men with gonorrhoea who were identified through partner notification were asymptomatic.[1] Partner notification is one of the two strategies to reach such individuals, the other strategy being screening. Managing infection in people with more than one current sexual partner is likely to have the greatest impact on the spread of sexually transmitted infections.[2]

PROGNOSIS We found no studies showing that partner notification results in a health benefit, either to the partner or to future partners of infected people. Obtaining such evidence would be technically and ethically difficult. One RCT in asymptomatic women compared identifying, testing, and treating women at increased risk for cervical chlamydial infection versus usual care. It found these reduced incidence of pelvic inflammatory disease (RR 0.44, 95% CI 0.20 to 0.90).[3] This evidence suggests that partner notification, which also aims to identify and treat people who are largely unaware of infection, would provide a direct health benefit to partners who are infected.

AIMS OF INTERVENTION To prevent complications of infection in the partner; to prevent transmission to others; to prevent reinfection; and to identify social networks of people practising risky sexual behaviours.

OUTCOMES Partners identified; partners notified; partners presenting for care; partners testing positive; partners treated; rates of reinfection in the patient; incidence of sexually transmitted diseases in the population; harms to patient or partner, such as domestic violence and abuse; ethical outcomes (patient autonomy *v* beneficence). The main outcome presented in each option is the ratio of the number of partners notified to the number of index patients.

METHODS *Clinical Evidence* search and appraisal July 2003. We included RCTs comparing at least two alternative partner notification strategies. The outcome used in this summary was the absolute difference between the ratio of partners identified, notified, presenting for care, testing positive, or treated per index case. Assuming a Poisson distribution for the outcomes, the 95% confidence intervals were calculated using the normal approximation to the Poisson distribution. We excluded studies that did not allow us to extract data on people with specific sexually transmitted diseases, rather than on one of a range of sexually transmitted diseases.

QUESTION **What are the effects of different partner notification strategies in different groups of people?**

OPTION IN PEOPLE WITH HIV INFECTION

One systematic review of one RCT found that, for people with HIV infection, offering index patients a choice between provider referral (where the identity of the index patient is not revealed to the partner) and patient referral resulted in more partners being notified than offering patient referral alone. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Benefits: We found one systematic review (search date 2001, 1 RCT, 162 people who tested positive for HIV).[4] **Offering a choice between provider and patient referral versus patient referral:** The RCT (162 people who tested positive for HIV) compared offering a choice between provider referral and patient referral versus patient referral (see glossary, p 2119). It was conducted at three public health departments in North Carolina, USA. Of those approached, the 46% who agreed to participate in the study were mostly men (69%), of whom most were homosexual or bisexual (76%). The choice between provider referral and patient referral significantly increased the likelihood that partners would be notified (rate of number of partners notified to number of index patients 78/39 [2.00] for the group with choice *v* 10/35 [0.29] for the patient referral group; rate increase 1.71, 95% CI 1.35 to 2.07). Thus, for every person offered provider referral compared with using patient referral there will be more than one additional partner notified (see figure A on web extra). **Contract referral:** We found no RCTs assessing contract referral (see glossary, p 2119) in people with HIV infection. **Outreach assistance:** The systematic review found one RCT, comparing patient referral versus outreach assistance (see glossary, p 2119) in people with HIV who were injecting drug users, the findings of which have yet to be reported fully.[4,5]

Harms: People's reluctance to disclose their HIV status to partners (see comment below) suggests expectation of harms from doing so. These and other potential harms are poorly understood. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Comment: The number of partners notified is an intermediate outcome. The number of infections in partners that are prevented or treated has not been assessed. Thus, the true benefits and harms of HIV partner notification are unknown. **Rates of disclosure:** One descriptive study (276 people attending for initial primary care for HIV infection in the USA) found that 40% of the respondents had not disclosed their HIV status to all partners over the preceding 6 months.[6] Individuals with more than one partner were significantly less likely to disclose to all partners. Only 42% of the non-disclosers reported that they used condoms all the time, which indicates that

many partners were at risk of HIV infection. Another descriptive study conducted in the USA found that, even after repeated individual counselling of people with HIV infection and a 6 month opportunity to disclose HIV status, 30% had not informed any of their past partners and 29% had not informed any of their present partners.[7] **Patient preferences:** The RCT (162 people) comparing offering people a choice between provider and patient referral versus patient referral alone found that, in the group with the choice, most partners (90%) were notified by the provider and only eight people by the index patient.[4] The RCT comparing patient referral versus outreach assistance[5] found, among people allocated to a choice, 82% chose to have the outreach team notify at least one partner, and the team was asked to notify 71% of all partners named by this group. One group in the USA attempted to compare contract referral with provider referral, but cross over between comparison groups made this impossible.[8] The results were therefore analysed as a series without comparison groups, where all patients were assigned to provider referral. The study included 1070 people, who reported having had 8633 partners in the past year. Of these partners, 1035 were successfully located, of whom 248 had previously tested positive for HIV, 560 were tested by the disease intervention specialist, 69 refused testing, and 158 were located by record search only. Of the 560 partners tested, 122 tested positive.

OPTION IN PEOPLE WITH GONORRHOEA OR CHLAMYDIA

One systematic review has found that, for people with gonorrhoea, contract versus patient referral increases the rate of partners presenting for treatment. One RCT also found that contract referral increased the rate of positive partners detected compared with patient referral. For people with non-gonococcal urethritis, one RCT found that provider versus patient referral increased the proportion of partners notified and of positive partners detected per patient. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Benefits: We found one systematic review (search date 2001, 2 RCTs of partner notification in people with gonorrhoea and 1 RCT in people with non-gonococcal urethritis).[4] **Gonorrhoea:** The two RCTs (2085 people with gonorrhoea) compared patient referral with contract referral (see glossary, p 2119). The first RCT (1898 people) found that contract referral significantly increased the number of partners assessed per index patient (392/632 [0.62 partners per index patient] with contract referral *v* 469/1266 [0.37] with patient referral; rate difference 0.25 partners per index patient, 95% CI 0.18 to 0.32). Positive gonorrhoea culture was significantly more likely in the contract referral group than in the patient referral group (233/632 [0.37 positive partners per index patient] with contract referral *v* 315/1266 [0.25] with patient referral; rate difference 0.12, 95% CI 0.06 to 0.18).[4] The second RCT (187 index patients) found contract referral was associated with a non-significantly higher proportion of partners assessed per index patient (119/94 [1.27] with contract referral *v* 107/93 [1.15] in the patient referral

group; rate difference +0.12, 95% CI –0.2 to +0.44), and found no significant difference in the number of partners with positive gonorrhoea cultures per index patient.[4] (See figure B on web extra.)
Chlamydia: One RCT (678 people with non-gonococcal urethritis) compared patient referral with provider referral (see glossary, p 2119). It found that provider referral significantly increased the proportion of partners assessed per patient (159/221 [0.72] with provider referral *v* 91/457 [0.20] with patient referral; rate difference 0.52, 95% CI 0.40 to 0.64). In this study, provider referral also significantly increased the proportion of partners with positive culture per index patient (20/221 [0.09] with provider referral *v* 14/457 [0.03] with patient referral; rate difference 0.06, 95% CI 0.02 to 0.10). Provider referral would have to be offered to two index patients with non-gonococcal urethritis for one additional partner to be assessed, and to 17 index patients to identify one additional partner with a positive culture. These findings are likely to over estimate the difference, as partners referred by index patients may have been assessed elsewhere.[4] (See figure C on web extra).

Harms: These are poorly understood. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Comment: One cohort study (265 urban, adolescent girls attending a clinic in Alabama, USA) found that, given the choice, people with gonorrhoea or chlamydia are about as likely to choose provider referral as patient referral.[9] Non-gonococcal urethritis is an old term used when gonorrhoea has been excluded but a positive diagnosis not made. The most common causative agent would be chlamydia.

OPTION IN PEOPLE WITH SYPHILIS

One systematic review of one large RCT found no significant difference between provider referral versus contract referral, when people receiving the contract referral option were given only 2 days in which to notify their partners. We found no RCTs assessing patient referral. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Benefits: We found one systematic review (search date 2001, 1 RCT, 1966 people diagnosed with syphilis in 3 US states).[4] It compared the proportion of partners per patient who were located, tested, tested positive, and treated, using three types of referral process: contract referral (see glossary, p 2119) (patients were given 2 days to notify partners themselves, before disease intervention specialists would notify them); provider referral (see glossary, p 2119) (immediate notification by an intervention specialist); and provider referral with the option of a blood test (immediate notification by an intervention specialist who had the option of performing a blood test if he or she thought that the partner would not seek medical attention despite being notified of exposure). There were no significant differences between the three groups: 1.2, 1.1, and 1.1 partners per patient were located; 0.92, 0.87, and 0.86 were tested; and 0.67, 0.61, and 0.62 were treated (CI not provided).[4]

Harms: These are poorly understood. The systematic review found no good evidence on the effects of these strategies on relationships between patients and partners and, in particular, on the rate of violence, abuse, and abandonment of patient or partner.

Comment: In the RCT, the investigators had no way of determining whether disease intervention specialists began actively seeking partners in the contract referral group before waiting 2 days, and they found some evidence of this.[4] Furthermore, the investigators speculated that people may have been allocated to groups not according to the randomisation schedule. These problems may compromise the validity of the study. The use of disease intervention specialists is an approach that may not be generalisable to other settings.

QUESTION What can be done to improve the effectiveness of patient referral?

OPTION COUNSELLING PLUS CONTACT REFERRAL CARDS AND TELEPHONE FOLLOW UP COMPARED WITH COUNSELLING ALONE

One systematic review found one small RCT, which found no significant difference between counselling plus contact referral cards and telephone follow up versus counselling alone.

Benefits: We found one systematic review (search date 2001, 1 RCT).[4] One RCT (38 students from a university clinic in the USA) compared the use of counselling plus contact referral cards and telephone follow up of the index patient with counselling alone. It found no difference between the strategies in the rate of partners presenting for care. The trial also assessed adding a US$3 incentive to the referral card. Charges for clinic visits for patients and partners would be waived after successful recruitment of partners for treatment. This had no effect on the number of partners presenting for care.[4]

Harms: None reported.

Comment: None.

OPTION DIFFERENT HEALTH PROFESSIONALS

One systematic review found one RCT, which found no difference in the effects of patient referral by different healthcare professionals.

Benefits: We found one systematic review (search date 2001, 1 RCT).[4] One RCT (678 index patients) found that there was no difference between patient referral (see glossary, p 2119) using nurses who did not ask for partners' names and gave referral letters, and disease intervention specialists who took partners' names but no contact details, in terms of the number of partners with positive cultures who were identified (rate difference 0, 95% CI –0.03 to +0.03).[4]

Harms: None reported.

Comment: None.

OPTION INFORMATION PAMPHLETS

One RCT found insufficient evidence on information pamphlets compared with routine counselling.

Benefits: We found one systematic review (search date 2001, 1 unpublished RCT).[4] The unpublished RCT (1898 index patients), conducted in the USA, investigated the use of information pamphlets compared with a routine counselling interview alone. Providing patients with information pamphlets was as effective as the interview alone (rate difference 0, 95% CI −0.07 to +0.07). The two strategies were also equally effective in terms of the number of partners identified with a positive culture per index patient. However, the RCT combined two interventions: different health professionals and asking for partners' names, either of which may have affected the results.[4]

Harms: None reported.

Comment: None.

OPTION EDUCATIONAL VIDEOS

One RCT found no significant difference between educational videos versus standard care, but the outcome reported was potentially inappropriate.

Benefits: We found one systematic review (search date 2001, 1 RCT).[4] The RCT (902 people in the USA) compared a video taped story promoting partner notification versus standard care. No differences in the number of partners assessed were reported (figures not provided).[4] The RCT counted returned contract cards as the main outcome, which has not been shown to be a sensitive enough surrogate indicator for partners presenting for assessment.[10]

Harms: None reported.

Comment: None.

GLOSSARY

Contract referral Also known as conditional referral. Index patients are encouraged to inform their partners, with the understanding that health service personnel will notify those partners who do not visit the health service within a contracted time period.

Outreach assistance At the request of patients, partners are notified by members of an outreach team indigenous to the community, who do not disclose the name of the patient to the partners.

Patient referral Health service personnel encourage index patients to inform partners directly of their possible exposure to sexually transmitted infections.

Provider referral Third parties (usually health service personnel) notify partners identified by index patients, without disclosing the name of the patient to the partners.

Pelvic inflammatory disease

Search date August 2003

Jonathan Ross

QUESTIONS

INTERVENTIONS

Key Messages

- **Antibiotics (for symptoms and microbiological clearance in women with confirmed pelvic inflammatory disease)** There is consensus that antibiotic treatments are more effective than no treatment for women with confirmed pelvic inflammatory disease. One systematic review of observational studies and RCTs has found that several different antibiotic regimens (including parenteral clindamycin plus parenteral aminoglycoside; parenteral cephalosporin with or without probenecid plus oral doxycycline; and oral ofloxacin) are similarly effective in relieving the symptoms of pelvic inflammatory disease, and achieve high rates of clinical and microbiological cure.
- **Oral antibiotics (*v* parenteral antibiotics)** Two RCTs found no significant difference between oral ofloxacin and parenteral cefoxitin plus doxycycline.
- **Outpatient (*v* inpatient) antibiotic treatment** One RCT found no significant difference between outpatient treatment with intramuscular cefoxitin plus probenecid plus oral doxycycline versus inpatient treatment with parenteral antibiotics for outcomes of recurrence of pelvic inflammatory disease, infertility, or ectopic pregnancy at 35 months.
- **Different durations of antibiotic treatment** We found no good evidence on the optimal duration of treatment.

Pelvic inflammatory disease

- **Empirical antibiotic treatment versus treatment guided by test results** We found no RCTs comparing empirical antibiotic treatment (before receiving results of microbiological tests) versus treatment that is guided by test results.
- **Routine antibiotic prophylaxis before intrauterine device insertion in women at high risk** We found no good evidence about antibiotic prophylaxis before intrauterine device insertion in women at high risk.
- **Routine antibiotic prophylaxis before intrauterine device insertion in women at low risk** One systematic review found no significant difference between routine prophylaxis with doxycycline versus placebo before intrauterine contraceptive device insertion in pelvic inflammatory disease in women at low risk of pelvic inflammatory disease.

DEFINITION

Pelvic inflammatory disease (PID) is inflammation and infection of the upper genital tract in women, typically involving the fallopian tubes, ovaries, and surrounding structures.

INCIDENCE/PREVALENCE

The exact incidence of PID is unknown because the disease cannot be diagnosed reliably from clinical symptoms and signs.[1–3] Direct visualisation of the fallopian tubes by laparoscopy is the best single diagnostic test, but it is invasive and not used routinely in clinical practice. PID is the most common gynaecological reason for admission to hospital in the USA, accounting for 49/10 000 recorded hospital discharges. A diagnosis of PID is made in 1/62 (1.6%) women aged 16–45 years attending their primary care physician in England and Wales.[4] However, because most PID is asymptomatic, this figure underestimates the true prevalence.[1,5] A crude marker of PID in developing countries can be obtained from reported hospital admission rates, where it accounts for 17–40% of gynaecological admissions in sub-Saharan Africa, 15–37% in Southeast Asia, and 3–10% in India.[6]

AETIOLOGY/RISK FACTORS

Factors associated with PID mirror those for sexually transmitted infections: young age, reduced socioeconomic circumstances, lower educational attainment, and recent new sexual partner.[2,7,8] Infection ascends from the cervix, and initial epithelial damage caused by bacteria (especially *Chlamydia trachomatis* and *Neisseria gonorrhoeae*) allows the opportunistic entry of other organisms. Many different microbes, including *Mycoplasma hominis* and anaerobes, may be isolated from the upper genital tract.[9] The spread of infection to the upper genital tract may be increased by vaginal douching and instrumentation of the cervix, but reduced by the barrier method, levonorgestrel implants, and oral contraceptives compared with other forms of contraception.[10–14]

PROGNOSIS

PID has a high morbidity; about 20% of affected women become infertile, 20% develop chronic pelvic pain, and 10% of those who conceive have an ectopic pregnancy.[2] Uncontrolled observations suggest that clinical symptoms and signs resolve in a significant proportion of untreated women.[15] Repeated episodes of PID are associated with a four to six times increase in the risk of permanent tubal damage.[16] One case control study (76 cases and 367 controls) found that delaying treatment by even a few days is associated with impaired fertility (OR 2.6, 95% CI 1.2 to 5.9).[17]

AIMS OF INTERVENTION To alleviate the pain and systemic malaise associated with infection; to achieve microbiological cure; to prevent development of permanent tubal damage with associated sequelae, such as chronic pelvic pain, ectopic pregnancy, and infertility; and to prevent the spread of infection to others.

OUTCOMES Incidence and severity of acute symptoms and signs; microbiological cure of the upper genital tract; incidence of chronic pelvic pain, ectopic pregnancy, infertility; and rate of transmission to others.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION What are the effects of empirical treatment versus treatment delayed until the results of microbiological investigations are known?

OPTION EMPIRICAL ANTIBIOTIC TREATMENT

We found no RCTs comparing empirical antibiotic treatment (before receiving results of microbiological tests) versus treatment that is guided by test results.

Benefits: We found no systematic review or RCTs comparing empirical versus delayed treatment.

Harms: We found no reliable evidence on harms.

Comment: Because there are no reliable clinical diagnostic criteria for pelvic inflammatory disease, early empirical treatment is common.[3] The positive predictive value of a clinical diagnosis is 65–90% compared with laparoscopy.[1–3] The absence of infection from the lower genital tract, where samples are usually taken, does not exclude pelvic inflammatory disease[2] and so may not influence the decision to treat. One case control study (76 cases and 367 controls) found that delaying treatment is associated with impaired fertility (OR 2.6, 95% CI 1.2 to 5.9).[17]

QUESTION How do different antimicrobial regimens compare?

OPTION DIFFERENT ANTIMICROBIAL REGIMENS

There is consensus that antibiotic treatments are more effective than no treatment for women with confirmed pelvic inflammatory disease (PID). One systematic review of observational studies and RCTs has found that several different antibiotic regimens (including parenteral clindamycin plus parenteral aminoglycoside; parenteral cephalosporin with or without probenecid plus oral doxycycline; and oral ofloxacin) are similarly effective in relieving the symptoms of PID, and achieve high rates of clinical and microbiological cure. We found no good evidence on the optimal duration of treatment. Two RCTs found no significant difference between oral ofloxacin versus parenteral cefoxitin and doxycycline. One RCT found no significant difference between outpatient treatment with intramuscular cefoxitin–probenecid and oral doxycycline versus parenteral antibiotics for outcomes of recurrence, infertility, or ectopic pregnancy at 35 months.

Pelvic inflammatory disease

Benefits: We found one systematic review (search date 1992, 21 studies),[18] aspects of which were subsequently updated (search date 1997, 26 studies, 1925 women).[19] The earlier review examined all antimicrobial regimens whereas the second review focused on anti-anaerobic treatment. The reviews evaluated 16 different antimicrobial regimens. The identified studies included case series, and it is not possible to ascertain how many studies were RCTs from the aggregated data published in the reviews. Inclusion criteria were a diagnosis of PID (clinical, microbiological, laparoscopic, or by endometrial biopsy) and microbiological testing for *C trachomatis* and *N gonorrhoeae*. The reviews found that antibiotics were effective in relieving the symptoms associated with PID, with clinical and microbiological cure rates of 88–100% (see table 1, p 2127). The only regimen that appeared to perform less well was oral metronidazole with doxycycline (see table 1, p 2127). However, the studies were of low power and apparent differences in efficacy may have been confounded by differences in disease severity among studies.
Duration of treatment: We found no RCTs examining the optimal duration of treatment**.** The duration of treatment was not addressed in the systematic review, although the most common treatment period was 14 days.[19] **Oral versus parenteral treatment:** The reviews did not analyse outcomes by the oral or parenteral route of administration. Most regimens started with parenteral treatment and continued with oral treatment at different points. Two subsequent RCTs (249 and 72 women) compared oral ofloxacin versus parenteral cefoxitin and doxycycline. The RCTs found no significant difference in cure rates between groups (first RCT: RR 1.03, 95% CI 0.97 to 1.1; second RCT: RR 0.97, 95% CI 0.88 to 1.07).[20,21]
Outpatient versus inpatient treatment: We found one RCT (831 women with mild to moderate PID) published after the review, which compared a single intramuscular dose of cefoxitin with oral probenecid followed by oral doxycycline given to outpatients versus inpatient admission for parenteral antibiotics.[22] It found no significant difference in incidence between treatments for tenderness, gonorrhoeal or chlamydial infection, or endometritis at 30 days (tenderness: 20.6% with outpatient treatment *v* 18.4% with inpatient treatment; P = 0.50; gonorrhoeal infection: 3.9% with outpatient treatment *v* 2.4% with inpatient treatment; P = 0.44; chlamydial infection: 2.7% with outpatient treatment *v* 3.6% with inpatient treatment; P = 0.52; endometritis 45.9% with outpatient treatment *v* 37.6% with inpatient treatment; P = 0.09). At 35 months (mean follow up), the study found no significant difference between treatments for PID recurrence, chronic pelvic pain, infertility, or ectopic pregnancy (recurrence: 12.4% with outpatient treatment *v* 16.6% with inpatient treatment; P = 0.11; chronic pelvic pain: 33.7% with outpatient treatment *v* 29.8% with inpatient treatment; P = 0.27; infertility: 18.4% with outpatient treatment *v* 17.9% with inpatient treatment; P = 0.85; ectopic pregnancy: 1.0% with outpatient treatment *v* 0.3% with inpatient treatment; P = 0.37).[22]

Harms: The harms associated with treatment were not specifically addressed by the systematic reviews.[18,19] In two RCTs reporting adverse effects, withdrawal from treatment was uncommon (2/20 for doxycycline/metronidazole; 0/20 for pefloxacin/metronidazole;

0/16 for ciprofloxacin; reason for withdrawal not reported).[23,24] The RCT comparing outpatient treatment with inpatient parenteral treatment found no significant difference between treatments for adverse drug reactions (1.7% with outpatient treatment *v* 1.5% with inpatient treatment; event type not specified).[22]

Comment: We found no RCTs comparing antibiotics versus placebo or no treatment. However, such trials would be considered unethical, because there is strong consensus that antibiotic treatments are more effective than no treatment in women with PID. We found little evidence about treatment of PID of differing severity, the effect of ethnicity, or the effects of tracing sexual contacts (see partner notification, p 2113). The risks of tubal occlusion and subsequent infertility relate to the severity of PID before starting treatment,[25] and clinical improvement may not translate into preserved fertility.[26,27] The inclusion of observational studies in the systematic review without a sensitivity analysis may compromise the validity of the conclusions. In the review, reliable comparison of different drugs may be confounded by possible differences in disease severity among the included studies.

QUESTION **What are the effects of routine antibiotic prophylaxis to prevent pelvic inflammatory disease before intrauterine contraceptive device insertion?**

OPTION **ROUTINE ANTIBIOTIC PROPHYLAXIS BEFORE INTRAUTERINE CONTRACEPTIVE DEVICE INSERTION**

One systematic review found that routine prophylaxis with doxycycline versus placebo before intrauterine device insertion did not reduce the risk of pelvic inflammatory disease (PID) in women at low risk of PID. We found no good evidence on the effects in women likely to be at high risk.

Benefits: We found one systematic review (search date 2002, 4 RCTs, 3598 women requesting intrauterine device insertion).[28] The RCTs compared a single dose of doxycycline (200 mg) versus placebo 1 hour before intrauterine device insertion. Meta-analysis in the review found no significant difference in the incidence of PID (doxycycline *v* placebo OR 0.89, 95% CI 0.53 to 1.51). The rate of PID in all women was low (0.5–1.6%), whether or not they received antibiotics, suggesting that this was a low risk group. We found no RCTs on the effects of routine antibiotic prophylaxis in women at high risk of PID.

Harms: The harms associated with treatment were not specifically addressed by the systematic review.[28] Nausea and vomiting has been reported with 17–28% of healthy volunteers on doxycycline, depending on the formulation administered.[29] See harms of antimicrobial regimens, p 2129.

Comment: In the populations included in the systematic review, the risk of PID after intrauterine device insertion was low.[28] The occurrence of PID in this group usually reflects the introduction of infection into the

uterus during intrauterine device insertion and therefore will vary with the prevalence of sexually transmitted infections in the population. The confidence intervals of results were wide, suggesting that the study may have lacked power to rule out a clinically important difference.

Substantive changes

Which antibiotic Oral antibiotics (*v* parenteral antibiotics): categorisation changed from Unknown effectiveness to Likely to be beneficial after re-evaluating the evidence.

Which antibiotic Outpatient antibiotic treatment (*v* inpatient antibiotic treatment): categorisation changed from Unknown effectiveness to Likely to be beneficial after re-evaluating the evidence.

Key Messages

- **Topical allylamines** One systematic review and four subsequent RCTs have found that allylamines are more effective than placebo for curing fungal skin infections. The review found insufficient evidence comparing different allylamines versus one another. We found no evidence on recurrence rates after clinical cure.
- **Topical azoles** One systematic review has found that azole creams administered for 4–6 weeks increase cure rates compared with placebo. We found no RCTs evaluating differences between individual azoles. We found no evidence on recurrence rates after clinical cure.
- **Improved foot hygiene, including socks, and hosiery** We found no systematic review or RCTs on the effects of foot hygiene and hosiery.

DEFINITION Athlete's foot is a cutaneous fungal infection caused by dermatophyte infection. It is characterised by itching, flaking, and fissuring of the skin. It may manifest in three ways: the skin between the toes may appear mascerated (white) and soggy; the soles of the feet may become dry and scaly; and the skin all over the foot may become red and vesicular eruptions may appear.[1] It is conventional in dermatology to refer to fungal skin infections as superficial in order to distinguish them from systemic fungal infections.

INCIDENCE/ PREVALENCE Epidemiological studies have produced various estimates of the prevalence of athlete's foot. Studies are usually conducted in populations of people who attend dermatology clinics, sports centres or swimming pools, or who are in the military. UK estimates suggest that athlete's foot is present in about 15% of the general population.[2] Studies conducted in dermatology clinics in Italy[3] and China (1014 people)[4] found prevalences of 25% and 27%, respectively. A population based study conducted in Israel found the prevalence among children to be 30%.[5]

AETIOLOGY/ RISK FACTORS Swimming pool users and industrial workers may be at increased risk of fungal foot infection. However, one survey identified fungal foot infection in only 9% of swimmers, with the highest prevalence (20%) being in men aged 16 years and older.[2]

PROGNOSIS Fungal infections of the foot are not life threatening in people with normal immune status, but in some people they cause persistent itching and, ultimately, fissuring. Other patients are apparently unaware of persistent infection. The infection can spread to other parts of the body and to other individuals.

AIMS OF INTERVENTION To control symptoms and prevent recurrence, with minimal adverse effects.

OUTCOMES Rates of fungal eradication, shown by negative microscopy and culture, and resolution of clinical signs and symptoms at follow up. We have chosen mycological cure as a primary outcome. Clinical cure is not coherently reported in superficial mycology trials.[6] Like many other diagnostic tests, microscopy and culture are not absolutely accurate. There are several reasons why fungal infections can be missed in laboratory tests.[7] Microscopy and culture are the most frequently used outcomes in athlete's foot research to establish the effect of an intervention.

METHODS *Clinical Evidence* search and appraisal April 2003. We initially searched Medline, Embase, and the Cochrane Controlled Trials Register to May 2003 for systematic reviews and subsequent RCTs (all languages). Studies were excluded if foot specific data could not be extracted. We excluded studies that did not use microscopy and culture (skin infections) or culture (nail infections) for diagnosis and as an outcome measure.

Athlete's foot

QUESTION What are the effects of topical treatments for athlete's foot? New

OPTION TOPICAL ALLYLAMINES (NAFTIFINE, TERBINAFINE)

One systematic review and four subsequent RCTs have found that allylamines are more effective than placebo for curing fungal skin infections. The review found insufficient evidence comparing different allylamines versus one another. We found no evidence on recurrence rates after clinical cure.

Benefits: **Versus placebo:** We found one systematic review (search date 1997),[8,9] and four subsequent RCTs.[10–13] The systematic review (12 RCTs, 1433 people with fungal infections of the foot) found that topical allylamines for 1–4 weeks significantly increased the cure rate, as assessed by culture or microscopy after 6–8 weeks, compared with placebo (at 6 weeks: 532/724 [73%] with allylamines *v* 139/709 [20%] with placebo; RR 3.7, 95% CI 3.2 to 4.4).[8,9] The first subsequent RCT (70 people with interdigital tinea pedis and positive fungal culture) found increased cure rates at 7 weeks after 7 days of treatment with 1% terbinafine cream compared with placebo (mycological cure: 91% with terbinafine *v* 37% with placebo; CI not reported; $P < 0.001$).[10] The second subsequent RCT (60 people with moccasin type tinea pedis [see glossary, p 2132]) compared two different treatments, 1% terbinafine cream and 1% butenafine (a benzylamine derivative) cream, versus placebo.[11] People receiving butenafine applied the cream for 1 week, whereas terbinafine and placebo were applied for 2 weeks. The RCT found higher cure rates after 2 weeks with butenafine or terbinafine than with placebo (18/20 [90%] with butenafine *v* 16/20 [80%] with terbinafine *v* 2/20 [10%] with placebo; active treatment *v* placebo $P < 0.001$). The third subsequent RCT (153 people with interdigital tinea pedis) found significantly higher cure rates with a 1% solution of terbinafine than with placebo after 8 weeks (35/54 [65%] with terbinafine *v* 1/23 [4%] with placebo; RR 14.9, 95% CI 2.2 to 102.3; NNT 2, 95% CI 1.3 to 2.2; figures calculated from graph data).[12] The fourth subsequent RCT (70 people with interdigital tinea pedis) compared 1% terbinafine emulsion gel applied for 7 days versus placebo.[13] It found significantly higher cure rates with 1% terbinafine gel than with placebo at 8 weeks (25/31 [80%] with terbinafine *v* 7/21 [33%] with placebo; RR 2.14, 95% CI 1.3 to 4.5; NNT 3, 95% CI 2 to 5). **Different allylamines:** The systematic review identified one small RCT (60 people), which found no significant difference in cure rates between naftifine and terbinafine (75% with naftifine *v* 81% with terbinafine; ARR +5%, 95% CI −17% to +21%).[8,9] **Versus topical azoles:** See benefits of topical azoles, p 2131.

Harms: None were reported in the systematic review.[8,9] The first subsequent RCT comparing terbinafine versus placebo reported six adverse events, three in the placebo group and three in the terbinafine group.[10] The second RCT did not describe adverse effects.[11] The third RCT found that adverse effects did not significantly differ between terbinafine and placebo (adverse effects:

16/105 [15%] with terbinafine *v* 5/48 [10%] with placebo; RR 1.46, 95% CI 0.57 to 3.76).[12] The nature of these adverse effects was not described in those reports. The fourth subsequent RCT comparing terbinafine versus placebo concluded that both were well tolerated, but some mild to moderate skin reactions and rashes were reported.[13]

Comment: One of the subsequent RCTs included multiple comparisons between groups.[11] No apparent adjustment for multiple comparisons was made to reduce the risk of false positive findings.

OPTION TOPICAL AZOLES (CLOTRIMAZOLE, MICONAZOLE NITRATE, TIOCONAZOLE, SULCONAZOLE NITRATE, BIFONAZOLE, ECONAZOLE NITRATE)

One systematic review has found that azole creams administered for 4–6 weeks increase cure rates compared with placebo. We found no RCTs evaluating differences between individual azoles. We found no evidence on recurrence rates after clinical cure.

Benefits: We found one systematic review (search date 1997).[8,9] **Versus placebo:** The review identified 17 RCTs (1259 people with fungal skin infections of the foot).[8,9] Interventions lasted for 4–6 weeks. The review found that treatment with azoles resulted in a significant increase in cure rate, as determined by culture or microscopy, compared with placebo after 6–10 weeks (cure: 538/664 [81%] with azoles *v* 233/595 [39%] with placebo; RR 2.1, 95% CI 1.85 to 2.3). **Different azoles:** The review found no significant difference between individual azoles administered for 3–4 weeks.[8,9] **Versus topical allylamines:** The review identified 12 RCTs (1487 people with fungal infections of the foot).[8,9] We found two additional RCTs.[14,15] The review found a significant increase in cure rates after 3–12 weeks in the risk of treatment failure with 1–6 weeks of topical allylamine compared with at least 4 weeks of topical azole (627/773 [81%] with topical allylamine *v* 490/714 [69%] with topical azole; RR 2.6, 95% CI 2.3 to 2.9). No significant difference was found in cure rates between a 1 week course of allylamine and a 4 week course of azole (411/464 [85%] with 1 week of allylamine *v* 377/448 [84%] with 4 weeks of azole; RR 1.0, 95% CI 0.99 to 1.10).[8,9] The first additional RCT (429 people with interdigital athlete's foot) found no significant difference in cure rates after 8 weeks with twice daily application of 1% terbinafine solution followed by 3 weeks of placebo compared with 4 weeks of 1% clotrimazole solution (73% with terbinafine *v* 72% with clotrimazole; ARR +1%, 95% CI –5% to +8%).[14] The second additional RCT (48 people) also found no significant difference in numbers of treatment failures after 10 weeks between 1 week of treatment with 1% terbinafine cream and 4 weeks of treatment with 2% clotrimazole cream (ARR +2%, 95% CI –33% to +28%).[15]

Harms: The second additional RCT found similar adverse events with 1% terbinafine solution and 1% clotrimazole solution.[15] About 5% of the people experienced mild to moderate local skin reactions, such as itching, erythema, or scaling.

Athlete's foot

Comment: Clinical equivalence between azoles was not established in the systematic review.[8,9] Wide confidence intervals and variations in follow up make it difficult to establish clinical equivalence between different azoles.

OPTION SOCKS, STOCKINGS, FOOT HYGIENE

We found no systematic reviews or RCTs on the effects of foot hygiene and hosiery.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: Evidence from the placebo arms of RCTs suggests that improved foot hygiene can produce mycological cure in some patients.[16]

GLOSSARY

Moccasin type tinea pedis A skin fungal infection causing the entire sole of the foot to appear dry and scaly.

Cellulitis and erysipelas

Search date October 2003

Andrew Morris

QUESTIONS

INTERVENTIONS

Key Messages

- **Antibiotics** We found no RCTs comparing antibiotics versus placebo. RCTs comparing different antibiotic regimens found clinical cure in 50–100% of people.
- **Comparative effects of different antibiotic regimens** RCTs provided insufficient information on differences between regimens. However, most of the RCTs included only a small number of people with cellulitis or erysipelas, and were designed to test equivalence rather than to detect a clinically significant difference in cure rates between antibiotics.
- **Oral versus intravenous antibiotics** We found no satisfactory RCTs comparing oral antibiotics versus intravenous antibiotics.
- **Short versus long courses of antibiotics** We found no RCTs comparing different durations of antibiotics.
- **Treatment of predisposing factors to prevent recurrence** We found no RCTs or observational studies on the effects of treating predisposing factors for recurrence of cellulitis or erysipelas.

Cellulitis and erysipelas

DEFINITION **Cellulitis** is a spreading bacterial infection of the dermis and subcutaneous tissues. It causes local signs of inflammation such as warmth, erythema, pain, lymphangitis, and frequently systemic upset with fever and raised white blood cell count. **Erysipelas** is a form of cellulitis and is characterised by pronounced superficial inflammation. The lower limbs are by far the most common sites, but any area can be affected. The term erysipelas is commonly used when the face is affected.

INCIDENCE/ PREVALENCE We found no specific data on the incidence of cellulitis, but cellulitis and abscess infections were responsible for 158 consultations per 10 000 person years in the UK in 1991.[1] In 1985 in the UK, skin and subcutaneous tissue infections resulted in 29 820 hospital admissions and a mean occupancy of 664 hospital beds each day.[2]

AETIOLOGY/ RISK FACTORS The most common infective organisms for cellulitis and erysipelas in adults are streptococci (particularly *Streptococcus pyogenes*) and *Staphylococcus aureus*.[3] In children, *Haemophilus influenzae* was a frequent cause prior to the introduction of the HiB vaccination. Several risk factors for cellulitis and erysipelas have been identified in a case control study (167 cases and 294 controls): lymphoedema (OR 71.2, 95% CI 5.6 to 908.0), leg ulcer (OR 62.5, 95% CI 7.0 to 556.0), toe web intertrigo (OR 13.9, 95% CI 7.2 to 27.0), and traumatic wounds (OR 10.7, 95% CI 4.8 to 23.8).[4]

PROGNOSIS Cellulitis can spread through the bloodstream and lymphatic system. A retrospective case study of people admitted to hospital with cellulitis found that systemic symptoms such as fever and raised white blood cell count were present in up to 42% of cases at presentation.[5] Lymphatic involvement can lead to obstruction and damage of the lymphatic system that predisposes to recurrent cellulitis. Recurrence can occur rapidly or after months or years. One study found that 29% of people with erysipelas had a recurrent episode within 3 years.[6] Local necrosis and abscess formation can also occur. It is not known whether the prognosis of erysipelas differs from that of cellulitis. We found no evidence about factors that predict recurrence, or a better or worse outcome. We found no good evidence on the prognosis of untreated cellulitis.

AIMS OF INTERVENTION To reduce the severity and duration of infection; to relieve pain and systemic symptoms; to restore the skin to its premorbid state; to prevent recurrence; to minimise adverse effects of treatment.

OUTCOMES Duration and severity of symptoms (pain, swelling, erythema, and fever); clinical cure (defined as the absence of pain, swelling, and erythema); recurrence; adverse effects of treatment. We found no standard scales of severity in cellulitis or erysipelas.

METHODS *Clinical Evidence* search and appraisal October 2003. Where we found no RCTs, we included observational studies retrieved by the contributor's own search in June 1999.

QUESTION What are the effects of treatments?

OPTION ANTIBIOTICS

We found no RCTs comparing antibiotics versus placebo or different durations of treatment, and no satisfactory RCTs comparing oral versus intravenous antibiotics. RCTs comparing different antibiotic regimens found clinical cure in 50–100% of people but provided insufficient information on differences between regimes. However, most of the RCTs included only a small number of people with cellulitis or erysipelas, and were designed to test equivalence rather than to detect a clinically significant difference in cure rates between antibiotics.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Oral versus intravenous antibiotics:** We found no satisfactory RCTs (see comment below). **Different antibiotic regimens:** We found nine RCTs comparing different antibiotic regimens in people with various skin infections (see table 1, p 2138).[7–15] Two of the RCTs were conducted solely in people with cellulitis (192 people with moderate to severe cellulitis);[7,8] one RCT was conducted solely in people with erysipelas (69 people);[9] the other six RCTs were conducted in people with a range of skin infections and provided subgroup analysis of people with cellulitis or erysipelas.[10–15] One of the RCTs conducted solely in people with cellulitis (58 people with moderate to severe cellulitis) found that intravenous ceftriaxone significantly increased clinical cure after 4–6 days compared with intravenous flucloxacillin. The results of this study should be treated with caution since only 45 people (78%) completed the study, and it would not appear that an intention to treat analysis was performed.[7] The other RCTs and the subgroup analyses found no significant difference between different antibiotics in clinical cure after 4–30 days.[7,9–15] However, most of the RCTs included only small numbers of people with cellulitis or erysipelas and were designed to test equivalence rather than to detect a clinically significant difference in cure rates between antibiotics. **Short versus long courses of antibiotics:** We found no RCTs comparing different durations of antibiotics.

Harms: **Oral versus intravenous antibiotics:** In a quasi-randomised trial (73 people with erysipelas, see comment) comparing oral with intravenous penicillin, adverse events occurred in 15 people taking oral penicillin (rash 4, diarrhoea 7, abscess 4) and in 10 people taking intravenous penicillin (rash 2, diarrhoea 4, cannula phlebitis 4).[16] The RCT comparing flucloxacillin with ceftriaxone (58 people with moderate to severe cellulitis) found no significant difference in the proportion of people experiencing adverse effects including diarrhoea, nausea and vomiting, abdominal pain, and vaginal candidiasis (6/22 [27%] with flucloxacillin *v* 3/22 [14%] with ceftriaxone; RR 2.00, 95% CI 0.57 to 7.00).[7] **Different antibiotic regimens:** The RCTs found no evidence of a difference in rates of adverse events with different antibiotic regimens. The RCT comparing cefazolin plus probenecid versus ceftriaxone plus placebo (134 people with moderate to severe cellulitis) found no significant difference in the proportion of people who experienced adverse

effects, including nausea and vomiting, diarrhoea, headache, and dizziness (14/67 [21%] with cefazolin plus probenecid *v* 7/67 [10%] with ceftriaxone plus placebo; RR 2.00, 95% CI 0.86 to 4.64).[8] The RCT comparing penicillin versus roxithromycin (69 people with erysipelas) found no significant difference in the proportion of people experiencing drug related rashes (2/38 [5%] with penicillin *v* 0/31 [0%] people with roxithromycin).[9] The RCTs comparing different antibiotics in a variety of skin infections gave no discrete information about adverse effects in people with cellulitis.[10–15]

Comment: **Oral versus intravenous antibiotics:** One small quasi-randomised trial (73 people with erysipelas in hospital with a body temperature > 38.5 °C but excluding patients with clinical signs of septicaemia; alternate allocation design) comparing oral with intravenous penicillin found no significant difference in clinical efficacy, which was assessed by indirect measures such as temperature fall, length of hospital stay, and absence from work.[16] No results were provided on relapse rates.

OPTION TREATMENT OF PREDISPOSING FACTORS TO PREVENT RECURRENCE

We found no RCTs or observational studies on the effects of treatment of predisposing factors for recurrence of cellulitis or erysipelas.

Benefits: We found no systematic review, RCTs, or observational studies.

Harms: We found no systematic review, RCTs, or observational studies.

Comment: Although there is a consensus that successful treatment of predisposing factors, such as lymphoedema, leg ulcer, toe web intertrigo and traumatic wounds, reduces the risk of developing cellulitis/erysipelas (see aetiology, p 2134), we found no RCTs or observational studies to support or refute this.

Chronic plaque psoriasis

Search date January 2003

Luigi Naldi and Berthold Rzany

QUESTIONS

INTERVENTIONS

Beneficial

Likely to be beneficial

Trade off between benefits and harms

Unknown effectiveness

*Based on consensus. We found insufficient evidence from RCTs.

See glossary, p 2161

Key Messages

- **Ingram regimen** One large RCT has found that the Ingram regimen is of similar effectiveness to psoralen plus ultraviolet A in clearing moderate to severe psoriasis.
- **Psoralen plus ultraviolet A** We found no systematic review or RCTs that compared psoralen plus ultraviolet A versus no psoralen plus ultraviolet A. One systematic review has found that 40 mg of 8-methoxypsoralen improves psoriasis clearance compared with 10 mg. One RCT found that psoralen plus ultraviolet A was slightly more effective in clearing psoriasis than dithranol. Long term adverse effects include photoaging and skin cancer (mainly squamous cell carcinoma).

- **Vitamin D derivatives** Systematic reviews have found that vitamin D derivatives improve plaque psoriasis compared with placebo, are at least as effective as topical steroids, and may be more effective than coal tars and dithranol. One review has found that calcipotriol monotherapy causes more irritation than "potent" topical steroids.
- **Dithranol** One systematic review of small RCTs has found that dithranol improves chronic plaque psoriasis after 4–8 weeks compared with placebo. The best evidence relates to its use in the Ingram regimen. One systematic review found that dithranol (short contact therapy) to be less effective than vitamin D derivatives and to cause more adverse effects.
- **Topical retinoids (tazarotene)** RCTs have found that tazarotene improves chronic plaque psoriasis in the short term compared with placebo or calcipotriol.
- **Ultraviolet B** There is a consensus that ultraviolet B is effective. However, we found insufficient RCT evidence on the effects of ultraviolet B compared with placebo, no treatment or other treatments, or on the effects of narrow band compared with broad band ultraviolet B for either clearance or maintenance treatment. One RCT found limited evidence that ultraviolet B given three times weekly clears psoriasis faster than twice weekly treatment.
- **Alefacept** Two RCTs found limited evidence that alefacept improved psoriasis compared with placebo, but increased adverse effects, including chills, nausea, cough, dizziness, and accidents.
- **Cyclosporin** One systematic review found that cyclosporin improved clearance compared with placebo. Optimal clearance rates occurred with a cyclosporin dose of 5.0 mg/kg daily. Any advantage of doses greater than 5.0 mg/kg daily may be offset by an increase in dose related adverse effects, particularly increased renal toxicity. The review found that a cyclosporin dose of 3.0 mg/kg daily was more effective than lower doses or placebo for maintenance.
- **Fumaric acid derivatives** One systematic review of four small RCTs found limited evidence that oral fumaric acid esters improved chronic plaque psoriasis after 16 weeks compared with placebo. However, acute adverse effects are common and include flushing and gastrointestinal symptoms. We found no evidence on the effects of fumaric acid derivatives as maintenance treatment.
- **Oral retinoids (etretinate, acitretin, liarozole)** We found limited evidence that oral retinoids improved clearance compared with placebo in people with plaque psoriasis. We found little reliable evidence on the effects of oral retinoids as maintenance treatment. Adverse effects led to discontinuation of treatment in 10–20% of people. Teratogenicity renders oral retinoids less acceptable.
- **Tacrolimus** One RCT found limited evidence that tacrolimus may improve psoriasis compared with placebo. Adverse effects are reported to be similar to those of cyclosporin.
- **Topical steroids** One systematic review and 12 additional RCTs have found that topical steroids, especially potent and very potent ones, improve psoriasis in the short term. Another systematic review found no difference in effectiveness between potent topical steroids and vitamin D derivatives, but found that vitamin D derivatives caused more irritation. Topical steroids may cause striae and atrophy, which increase with potency and use of occlusive dressings. Continuous use may lead to adrenocortical suppression, and case reports suggest that severe flares of the disease may occur on withdrawal.

Chronic plaque psoriasis

- **Emollients, keratolytics, capsaicin, and aloe vera** We found insufficient evidence on the effects of emollients, keratolytics, capsaicin, and herbal extracts of aloe vera.
- **Etanercept** We found insufficient evidence about effects of cytokine blocking agents (etanercept and infliximab) in people with plaque psoriasis.
- **Goeckerman treatment** We found no good evidence on the effects of the Goeckerman treatment.
- **Infliximab** We found insufficient evidence about effects of cytokine blocking agents (etanercept and infliximab) in people with plaque psoriasis.
- **Methotrexate** We found insufficient evidence about effects of methotrexate in people with chronic plaque psoriasis. Methotrexate can induce acute myelosuppression. Long term methotrexate carries the risk of hepatic fibrosis and cirrhosis, which is related to the dose regimen employed.
- **Pimecrolimus** We found limited evidence from one small RCT that pimecrolimus may improve psoriasis compared with placebo.
- **Tars** One systematic review found insufficient evidence from one small RCT for tar compared with placebo. Small RCTs found conflicting results on the effects of tars in combination with ultraviolet B exposure. One systematic review has found that coal tar, alone or in combination with allantoin and hydrocortisone, is less effective than vitamin D derivatives (calcipotriol).
- **Acupuncture; anti-CD4 monoclonal antibody; antistreptococcal treatments; balneotherapy; fish oil; heliotherapy; lifestyle changes; oral vitamin D; psychotherapy; sunbeds** We found insufficient evidence on the effects of these interventions.

DEFINITION Chronic plaque psoriasis is a chronic inflammatory skin disease that is characterised by well demarcated erythematous scaly patches on the extensor surfaces of the body and scalp. The lesions may itch, sting, and occasionally bleed. Dystrophic nail changes are found in more than a third of people with chronic plaque psoriasis, and psoriatic arthropathy occurs in 1–3%. The condition waxes and wanes, with wide variations in course and severity among individuals. Other varieties of psoriasis include guttate, inverse, pustular, and erythrodermic psoriasis. This review deals with treatments for chronic plaque psoriasis.

INCIDENCE/ PREVALENCE Psoriasis affects 1–2% of the general population. It is believed to be less frequent in people from Africa and Asia, but we found no reliable epidemiological data.[1]

AETIOLOGY/ RISK FACTORS About a third of people with psoriasis have a family history of psoriasis, but physical trauma, acute infection, and some medications (e.g. lithium salts and β blockers) are believed to trigger the condition. A few observational studies have linked the onset or relapse of psoriasis with stressful life events and personal habits, including cigarette smoking and, less consistently, alcohol consumption. Others have found an association of psoriasis with body mass index (see glossary, p 2161) and an inverse association with intake of fruit and vegetables.

PROGNOSIS We found no long term prognostic studies. With the exceptions of erythrodermic and acute generalised pustular psoriasis (severe conditions that affect < 1% of people with psoriasis and that require

intensive hospital care), psoriasis is not known to affect mortality. Psoriasis may substantially affect quality of life.[2] At present there is no cure for psoriasis.

AIMS OF INTERVENTION To achieve short term suppression of symptoms and long term modulation of disease severity; to improve quality of life, with minimal adverse effects of treatment.

OUTCOMES State of lesions over time; use of routine treatments; duration of remission; patient satisfaction and autonomy; disease related quality of life; adverse effects of treatment. We found no documented evidence that clinical activity scores, such as the Psoriasis Area and Severity Index (PASI; see glossary, p 2161) score, are reliable proxies for these outcomes. Many clinical studies provide no explicit criteria for severity.[3]

METHODS *Clinical Evidence* search and appraisal January 2003. The authors additionally hand searched several dermatological and medical journals for the years 1976–1996 as a project of the European Dermatoepidemiology Network. These were the *Journal of Investigative Dermatology*, *British Journal of Dermatology*, *Dermatology*, *Acta Dermo-Venereologica*, *Archives of Dermatology*, *Journal of the American Academy of Dermatology*, *Annales de Dermatologie et de Vénéréologie*, *Giornale Italiano di Dermatologia e Venereologia*, *Hautarzt*, *British Medical Journal*, *Lancet*, *Journal of the American Medical Association*, and *New England Journal of Medicine*.

QUESTION What are the effects of non-drug treatments?

OPTION NON-DRUG TREATMENTS

We found insufficient evidence on the effects of non-drug treatments.

Benefits: **Heliotherapy:** We found one crossover RCT (95 people), which compared 4 weeks of supervised heliotherapy versus no intervention.[4] Pre-crossover results found that heliotherapy significantly improved psoriasis compared with no intervention at 1 year (Psoriasis Area and Severity Index [PASI; see glossary, p 2161] score taking into consideration scaling, infiltration, and area: 4.2 with heliotherapy *v* 6.2 with no intervention). **Sunbeds:** We found one small RCT (38 people with chronic stable plaque psoriasis) comparing ultraviolet A (UVA) light versus placebo (visible light).[5] In each person, one side of the body was exposed to UVA light and the other to placebo. The trial found a small improvement in the modified PASI score (mean PASI score 3.9 with UVA *v* 4.2 with placebo; CI not reported; P = 0.04). **Fish oil supplementation:** We found six RCTs, which reported conflicting results (see table 1, p 2165).[6–11] **Oral vitamin D:** One RCT (50 people) found no significant difference in disease activity (measured by change in PASI score) between oral colecalciferol (cholecalciferol) and placebo after 12 weeks.[12] **Psychotherapy:** We found one small RCT (51 people), which compared individual psychotherapy (7 sessions) versus control.[13] It found that psychotherapy significantly improved disease activity compared with control at 12 weeks (AR for any improvement in PASI score: 74% with psychotherapy *v* 43% with control; difference reported as significant). **Lifestyle change:** We found no RCTs

of smoking cessation or dietary change in people with psoriasis. **Antistreptococcal treatments:** We found one systematic review (search date 1999, 1 RCT, 20 people) of antistreptococcal interventions for guttate and chronic plaque psoriasis.[14] The review found no evidence that tonsillectomy (or antibiotics) is beneficial compared with placebo or no treatment (no data reported in the review). **Balneotherapy:** We found one systematic review (search date 1999)[15] and two additional RCTs of salt water baths.[16,17] The systematic review identified five small RCTs comparing phototherapy plus salt water versus tap water baths. The included RCTs found conflicting results and the review did not report any summary effect estimate. The first additional RCT (71 people) found no significant difference between saline spa water plus phototherapy and phototherapy alone at 21 days, although phototherapy with or without spa water significantly improved symptoms compared with spa water alone (improvement in PASI score: 64% with combination treatment *v* 55% with phototherapy alone *v* 29% with spa water alone; $P < 0.001$ for combination or phototherapy *v* spa water alone).[16] The second, and weaker, additional RCT (50 people) found clinical improvement in more people with a thermal bath (bicarbonate, calcium, and magnesium rich water) than with a tap water bath (64% with thermal bath *v* 11% with tap water bath).[17] **Acupuncture:** We found one RCT (56 people) comparing classic acupuncture versus sham (placebo) acupuncture.[18] After 3 months, it found no significant difference in the reduction of mean PASI score between the two groups (mean reduction in PASI score 1.3 with classic acupuncture *v* 2.3 with sham acupuncture, $P > 0.05$).[18]

Harms: We found no good evidence on harms.

Comment: Because several trigger and perpetuating factors for psoriasis have been recognised, including physical trauma, acute infections, smoking, diet, and stress, disease severity might be modulated by non-drug treatments. However, we found no good evidence on the effects of non-drug treatments.

QUESTION What are the effects of topical drug treatments?

OPTION EMOLLIENTS, KERATOLYTICS, CAPSAICIN, AND ALOE VERA

We found insufficient evidence on the effects of emollients, keratolytics, capsaicin, and herbal extracts of aloe vera.

Benefits: **Emollients:** We found one small RCT (43 people).[19] It found that emollients temporarily improved psoriasis when they were combined with ultraviolet B radiation.[19] **Keratolytics:** We found one systematic review (search date 1999), which identified one small RCT comparing salicylic acid with placebo.[20] The RCT found no significant difference between treatments after 3 weeks (SMD −0.80, 95% CI −1.71 to +0.11). **Capsaicin:** We found one systematic review (search date 1994, 4 RCTs, 245 people).[21] It found that capsaicin significantly improved pain relief compared with placebo (OR for pain relief 2.80, 95% CI 1.69 to 4.62).

However, there was significant unexplained heterogeneity in the results from individual trials. **Aloe vera:** We found one systematic review (search date 1998, 10 RCTs), which evaluated aloe vera for a large variety of conditions including psoriasis. It found no clear evidence of effectiveness, but did not exclude the possibility of a clinically important effect (no data reported).[22]

Harms: Local irritation and contact dermatitis have been reported with emollients, keratolytics, capsaicin, and aloe vera.

Comment: Emollients and keratolytics are usually used as adjuncts to other treatments. Capsaicin and aloe vera are not widely accepted treatments for psoriasis management.

OPTION TARS

One systematic review found insufficient evidence from one small RCT for coal tar compared with placebo. Small RCTs found conflicting results on the effects of tars in combination with ultraviolet B exposure. One systematic review has found that coal tar, alone or in combination with allantoin and hydrocortisone, is less effective than vitamin D derivatives (calcipotriol).

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 1 RCT, 18 people).[20] The RCT found no significant difference between coal tar and placebo after 4 weeks (SMD –0.48, 95% CI –1.14 to +0.19).[20] **Coal tar plus fatty acids versus coal tar alone:** We found one small RCT (20 people; one treatment applied to the right side of the body and the other treatment to the left, the sides determined randomly).[23] After 8 weeks, it found no significant difference in a summed score for erythema, desquamation, and infiltration, between coal tar plus esterified essential fatty acids and coal tar alone (mean improvement in the score 53.9% with combination treatment *v* 56.1% with coal tar alone; P = 0.52). **Plus ultraviolet B plus dithranol:** We found four small RCTs which found conflicting results about the effects of coal tar when combined with ultraviolet B exposure and dithranol (see benefits of combination regimens, p 2153). **Versus vitamin D derivatives:** See vitamin D derivatives, p 2147.

Harms: Smell, staining, and burning are the main adverse effects of coal tar.

Comment: These RCTs were probably too small to detect a clinically important difference.

OPTION DITHRANOL

One systematic review of small RCTs has found that dithranol improves chronic plaque psoriasis after 4–8 weeks compared with placebo. The best evidence relates to its use in the Ingram regimen (see benefits of combination regimens, p 2153). One systematic review found that dithranol to be less effective than vitamin D derivatives and to cause more adverse effects.

Benefits: **Versus placebo:** We found one systematic review of topical preparations for the treatment of psoriasis (search date 1999, 3 small RCTs).[20] It found that dithranol significantly improved psoriasis at

4–8 weeks compared with placebo (SMD –1.04, 95% CI –1.65 to –0.42). **Conventional versus short contact treatment:** One systematic review of published studies (search date 1989, 22 small RCTs) compared conventional dithranol treatment versus dithranol short contact treatment (shorter contact time at higher concentrations).[24] It found no significant differences, but the trials were too small to rule out clinically important differences (data not reported in the review). **Versus vitamin D derivatives:** See vitamin D derivatives, p 2147.

Harms: Smell, staining, and burning are the main adverse effects of dithranol.

Comment: Few trials examined participant satisfaction, so it remains unclear whether short contact treatment is easier and more convenient for people at home compared with conventional dithranol treatment. The review performed the meta-analysis using data for the Total Severity Score, the Psoriasis Area and Severity Index score, and the Investigator Assessment of Global Improvement from the included RCTs.[20]

OPTION TOPICAL STEROIDS

One systematic review and 12 additional RCTs have found that topical steroids, especially potent and very potent ones, improve psoriasis in the short term. Another systematic review found no difference in effectiveness between potent topical steroids and vitamin D derivatives, but found that vitamin D derivatives caused more irritation. Topical steroids may cause striae and atrophy, which increase with potency and use of occlusive dressings. Continuous use may lead to adrenocortical suppression, and case reports suggest that severe flares of the disease may occur on withdrawal.

Benefits: We found one systematic review of topical steroid preparations for the treatment of psoriasis (search date 1999, 12 RCTs, 1686 people)[20] and 12 additional RCTs. **Clearance:** The review found that "potent" and "very potent" topical steroids significantly improved psoriasis compared with placebo (standardised mean difference: "potent" steroids –0.84, 95% CI –0.99 to –0.68; "very potent" steroids –1.51, 95% CI –1.76 to –1.25). The study duration was usually no longer than 4 weeks. **Maintenance:** One RCT (90 people with 1 target area cleared or nearly cleared of psoriasis by betamethasone dipropionate) found better control at 6 months with topical steroids applied once a week than with placebo (AR for maintenance of clearance in the target area 60% with steroids *v* 20% with placebo).[25] **Plus occlusive dressings:** Twelve small RCTs, mostly using people as their own controls, found that occlusive polyethylene or hydrocolloid dressings enhanced clinical activity of topical steroids. **Versus vitamin D derivatives:** See vitamin D derivatives, p 2147. **Versus topical retinoids:** See topical retinoids, p 2149.

Harms: Topical steroids can cause striae and atrophy, which increase with clinical potency and use of occlusive dressings. Continuous use may lead to adrenocortical suppression,[26] and case reports suggest that severe flares of the disease may occur on withdrawal. Diminishing clinical response with repeated use (tachyphylaxis) has been described, but we found no estimates of its frequency.

Comment: The review performed the meta-analysis using data for the Total Severity Score, the Psoriasis Area and Severity Index score, and the Investigator Assessment of Global Improvement.[20] **Maintenance:** The RCT assessed effects of treatment on lesions rather than on people.[25]

OPTION VITAMIN D DERIVATIVES

Systematic reviews have found that vitamin D derivatives improve plaque psoriasis compared with placebo, are at least as effective as topical steroids, and may be more effective than coal tars and dithranol. One review has found that calcipotriol monotherapy causes more irritation than "potent" topical steroids.

Benefits: We found one systematic review comparing calcipotriol with placebo (search date 1999, 37 RCTs, 6038 people),[27] one systematic review of combination regimens (search date 1999, 11 RCTs, 756 people),[28] one systematic review of topical preparations (search date 1999, 14 RCTs in 1537 people comparing vitamin D derivatives versus placebo and 34 RCTs comparing dithranol versus another treatment),[20] and 14 additional RCTs. **Versus placebo:** The first systematic review (search date 1999, 1 RCT) found that calcipotriol significantly improved mild to moderately severe plaque psoriasis compared with placebo (mean difference in the percentage change in severity index 44%, 95% CI 28% to 60%).[27] Long term uncontrolled studies found that treatment gains were maintained in about 70% of people for as long as the treatment was continued.[29] The third systematic review found that both calcipotriol and tacalcitol were significantly more effective than placebo at 3–8 weeks (calcipotriol, 10 RCTs, standardised WMD –0.74, 95% CI–0.55 to –0.93; tacalcitol, 4 RCTs, standardised WMD –0.89, 95% CI –0.59 to –1.18).[20] However, the clinical importance of these results is unclear. **Versus each other:** We found six RCTs comparing calcipotriol versus other vitamin D derivatives. One of these RCTs (287 people) found that after 8 weeks, calcipotriol twice daily was more effective than tacalcitol once daily in reducing severity of pruritus, erythema, infiltration, and scaling (mean reduction in a severity score assessing pruritus, erythema, infiltration, and scaling, on a scale from 0 [least severe] to 16 [most severe]: 4.03 with tacalcitol *v* 5.05 with calcipotriol; $P = 0.0003$).[30] A second RCT (144 people) found that maxacalcitol once daily compared favourably with calcipotriol once daily (people reporting large improvement on summed score for erythema, scaling, and induration or clearance after 8 weeks' treatment; 55% with maxacalcitol *v* 46% with calcipotriol).[31] **Versus topical steroids:** The third systematic review (search date 1999) found no significant difference between vitamin D derivatives and "potent" topical corticosteroids (9 RCTs, 1875 people; SMD +0.06, 95% CI –0.12

to +0.24).[20] The review found significant statistical heterogeneity among trials ($P < 0.01$).[20] The review found no significant difference between calcipotriol and clobetasol propionate (1 RCT; SMD –0.32, 95% CI –0.95 to +0.30). **Versus dithranol:** The third systematic review (4 RCTs of calcipotriol, 1 RCT of tacalcitol, total of 671 people) found that vitamin D derivatives significantly improved psoriasis compared with dithranol short contact therapy at 4–12 weeks (standardised WMD –0.44, 95% CI –0.72 to –0.16).[20] One additional RCT (171 people) not included in the systematic review found that, of people who initially improved on treatment, more stayed in remission with dithranol than with calcipotriol.[32] One subsequent RCT (88 people) found that calcipotriol ointment (80–100 g/week) plus scalp solution (30–50 mL/week) significantly improved psoriasis at 4 weeks compared with dithranol (change in PASI: –57.4% with calcipotriol *v* –36.1% with dithranol; $P = 0.004$).[33] **Versus coal tar:** The third systematic review found that calcipotriol significantly improved psoriasis compared with coal tar either alone or a combination of coal tar, allantoin, and hydrocortisone at 6–8 weeks (standardised WMD: coal tar alone, 2 RCTs –0.91, 95% CI–1.36 to –0.46; combination, 1 RCT –0.91, 95% CI –1.36 to –0.46).[20] **With other treatments:** Two systematic reviews[20,28] and three additional RCTs[34–36] compared combinations of calcipotriol with other therapies. One systematic review (search date 1999) found that calcipotriol plus "potent" topical steroids significantly improved psoriasis compared with calcipotriol alone (3 RCTs; SMD 0.42, 95% CI 0.12 to 0.72).[20] It found no significant difference between calcipotriol and calcipotriol plus "very potent" topical steroids (2 RCTs; SMD +0.37, 95% CI –0.08 to +0.81). The first additional RCT (1603 people) compared four treatments: calcipotriol plus steroid combination; calcipotriol alone; steroid alone; and placebo.[34] It found that the combination of calcipotriol plus steroid significantly improved psoriasis at 4 weeks compared with either calcipotriol or steroid alone (mean change in Psoriasis Area and Severity Index [PASI; see glossary, p 2161] score –71.3% with combination *v* – 57.2% with steroid alone *v* –46.1% with calcipotriol alone *v* –22.7% with placebo; difference for combination *v* steroid alone: –14.2%, 95% CI –17.6% to –10.8%).[34] The second additional RCT (46 people) found that the combination of calcipotriol plus short contact dithranol significantly improved psoriasis at 6 weeks compared with dithranol alone (PASI: 0 with combination *v* 1.21 with dithranol alone; $P = 0.0001$).[35] One systematic review (search date 1999, 11 RCTs, 756 people) found significant improvement in PASI score from adding calcipotriol to acitretin, cyclosporin, or psoralen plus ultraviolet A.[28] It found no significant difference in the rate of marked improvement (at 12 weeks for acitretin plus calcipotriol *v* acitretin RR 1.4, 95% CI 1.0 to 1.9; at 6 weeks for cyclosporin plus calcipotriol *v* cyclosporin RR 1.2, 95% CI 0.9 to 1.6; at 12 weeks for psoralen plus ultraviolet A plus calcipotriol *v* psoralen plus ultraviolet A RR 1.2, 95% CI 0.9 to 1.6; at 8 weeks for ultraviolet B plus calcipotriol *v* ultraviolet B RR 1.0, 95% CI 0.8 to 1.1), in cumulative exposure to phototherapy, or in use of

systemic treatment.[28] The third additional RCT (143 people) found that the combination of calcipotriol plus oral fumaric acid significantly improved psoriasis at 13 weeks compared fumaric acid alone (difference between treatments –24.2%, 95% CI –34.2% to –14.2%).[36]

Harms: **Versus steroids:** The first review (search date 1999) found that calcipotriol monotherapy caused more irritation than "potent" topical steroids (NNH 10, 95% CI 6 to 34).[27] Perilesional irritation from calcipotriol has been reported in as many as 25% of people, the face and skin folds being more susceptible. In the short term, the combination of a topical steroid may reduce the incidence of skin irritation.[37] Hypercalcaemia and hypercalciuria are dose related adverse effects. **Versus dithranol:** The third systematic review (4 RCTs, total of 671 people) found that vitamin D derivatives significantly reduced adverse effects compared with dithranol short contact therapy (change: –27%, 95% CI –36% to –17%).[20] One subsequent RCT (88 people) found no significant difference after 4 weeks between calcipotriol ointment (80–100 g/week) plus scalp solution (30–50 mL/week) and dithranol with respect to several parameters of calcium metabolism at 4 weeks.[33]

Comment: There is a consensus that the dosage of calcipotriol should be limited to 100 g a week.

OPTION TOPICAL RETINOIDS (TAZAROTENE)

RCTs have found that tazarotene improves chronic plaque psoriasis in the short term compared with placebo or calcipotriol.

Benefits: We found one systematic review of topical retinoid preparations for treating psoriasis (search date 1999, 1 RCT[34])[20] and nine additional RCTs (published in 8 papers) (see table 2, p 2166).[38–45] **Versus placebo:** Three RCTs (total of 1672 people) compared tazarotene versus placebo.[38–40] All found that tazarotene improved plaque psoriasis compared with placebo (see table 2, p 2166). **Versus steroids:** One RCT (275 people) found that once daily treatment with tazarotene (0.1% or 0.05%) was as effective in clearing psoriasis as treatment with the high potency topical steroid fluocinonide (0.05% twice daily).[44] **Plus steroids:** Three RCTs (total of 1198 people) found that adding topical mid- or high potency steroids to tazarotene treatment increased the response rate compared with tazarotene alone (see table 2, p 2166).[41,43,45] **Versus calcipotriol:** One RCT (120 people) found that once daily treatment with tazarotene 0.1% plus topical mometasone furoate 0.1% significantly improved psoriasis symptoms after 2 weeks compared with twice daily treatment with calcipotriol 0.005%. It found no significant difference between groups in the proportion of people attaining complete or almost complete clearance (see table 2, p 2166).[42]

Harms: The RCTs found that some perilesional irritation was reported in most people. Addition of steroids reduced the withdrawal rate and treatment related adverse effects.[43,45]

Comment: Tazarotene is contraindicated in women who are, or intend to become, pregnant because it is potentially teratogenic.

QUESTION What are the effects of treatments with ultraviolet light?

OPTION ULTRAVIOLET B

There is consensus that ultraviolet B is effective in people with plaque psoriasis. However, we found insufficient evidence on the effects of ultraviolet B compared with placebo, no treatment, or other treatments, or on the effects of narrow band compared with broad band ultraviolet B for either clearance or maintenance treatment. One RCT found limited evidence that ultraviolet B given three times weekly clears psoriasis faster than twice weekly treatment.

Benefits:

Versus placebo or no treatment: We found no RCTs. **Versus other treatments:** We found one systematic review (search date 1999, 2 small RCTs, 78 people).[46] One of the RCTs found that a significantly greater proportion of people achieved 80% clearance of lesions with ultraviolet B (UVB) plus acitretin compared with acitretin alone (89% with combined treatment *v* 22% with acitretin alone; ARR 67%, 95% CI 33% to 100%). The other RCT compared three treatments: narrow band UVB alone; narrow band UVB plus etretinate; and psoralen plus ultraviolet A (PUVA) plus etretinate. It was too small to draw reliable conclusions. It found no significant difference in response rates between PUVA plus etretinate and narrow band UVB plus etretinate (100% with PUVA plus etretinate *v* 93% with narrow band UVB plus etretinate; ARR +7%, 95% CI –6% to +20%). It found that significantly fewer people achieved a satisfactory response with narrow band UVB alone compared with PUVA plus etretinate (100% with PUVA plus etretinate *v* 80% with narrow band UVB plus etretinate; ARR 20%, 95% CI 0% to 40%). **Narrow band UVB versus broad band UVB on clearance:** We found one systematic review (search date 1999, 3 small crossover RCTs, 146 people) of narrow band UVB versus broad band UVB.[46] It was not possible to calculate response rates from the results reported by the RCTs. **Twice versus three times weekly narrow band UVB:** We found one RCT (113 people).[47] It found no significant difference between twice and three times weekly UVB in clearance rates but found that twice weekly treatment significantly increased the time to reach clearance compared with three times weekly treatment (clearance: 40/58 [69%] with twice weekly *v* 44/55 [80%] with three times weekly, $P = 0.21$; mean time to clearance: 88 days with twice weekly *v* 58 days with three times weekly, $P < 0.0001$).[47] **UVB versus PUVA:** We found no systematic review but found two RCTs.[48,49] The first RCT (183 people with moderate to severe psoriasis) found no significant difference in clearance rates between PUVA and UVB (clearance: 88% with PUVA *v* 80% with UVB; RR of non-clearance with PUVA *v* broad band UVB 0.62, 95% CI 0.29 to 1.22).[48] Subgroup analysis found that UVB radiation was significantly less effective in people with more than 50% body involvement. The second RCT (100 people) found that more people achieved clearance with PUVA compared with narrow band UVB (clearance: 84% with PUVA *v* 63% with UVB).[49] **Maintenance:** We found no systematic review but found one

RCT.[50] The RCT (104 people with initial clearance of symptoms) found significantly more people were still clear of symptoms after 181 days with weekly UVB compared with no maintenance treatment (> 50% with UVB *v* 28% with no UVB; RR relapse 0.67, 95% CI 0.41 to 0.92).[50]

Harms: UVB radiation may increase photoaging and risk of skin cancer. One systematic review (search date 1996) estimated that the excess annual risk of non-melanoma skin cancer associated with UVB radiation was likely to be less than 2%.[51]

Comment: We found insufficient evidence from RCTs on the effects of UVB. However, consensus regards the treatment as effective.

OPTION PSORALEN PLUS ULTRAVIOLET A

We found no systematic review or RCTs that compared psoralen plus ultraviolet A versus no psoralen plus ultraviolet A. One systematic review has found that 40 mg of 8-methoxypsoralen improves psoriasis clearance compared with 10 mg. One RCT found that psoralen plus ultraviolet A was slightly more effective in clearing psoriasis than dithranol. Long term adverse effects include photoaging and skin cancer (mainly squamous cell carcinoma).

Benefits: We found one systematic review of phototherapy and photochemotherapy (search date 1999, 51 RCTs).[46] Results could not be pooled because of trial heterogeneity. **Psoralen plus ultraviolet A (PUVA) versus no PUVA:** The systematic review found no RCTs.[46] **Comparison of different doses of psoralen:** The systematic review (2 RCTs, 167 people) found that higher dose psoralen significantly increased success (major improvement in or full remission) compared with lower dose psoralen (ARR 72%, 95% CI 54% to 90%; NNT 2).[46] The first RCT included in the systematic review compared 40 mg with 10 mg of 8-methoxypsoralen. The second RCT included in the systematic review compared 1.2 mg/kg 5-methoxypsoralen with 0.6 mg/kg. Both RCTs also found a lower mean cumulative ultraviolet A (UVA) dose to achieve success (54 J/cm^2 with 40 mg 8-methoxypsoralen *v* 77 J/cm^2 with 10 mg 8-methoxypsoralen; 53 J/cm^2 with 1.2 mg/kg 5-methoxypsoralen *v* 132 J/cm^2 with 0.6 mg/kg methoxypsoralen). **Comparison of different oral psoralens:** The systematic review included two RCTs that compared different oral psoralens.[52] One RCT (169 people) found no significant difference between 5-methoxypsoralen 1.2 mg/kg and 8-methoxypsoralen 0.6 mg/kg in the mean cumulative UVA dose needed for clearance (53 J/cm^2 with 5-methoxypsoralen *v* 45 J/cm^2 with 8-methoxypsoralen). The other RCT (38 people) found that people treated with 8-methoxypsoralen 0.6 mg/kg required a lower mean cumulative UVA dose to achieve success (155 J/cm^2 with 8-methoxypsoralen *v* 187 J/cm^2 with 1.2 mg/kg 5-methoxypsoralen; CI not reported; $P < 0.05$). **Comparison of different topical psoralens:** The systematic review included one RCT (38 people), which found no significant difference between 5-methoxypsoralen and 8-methoxypsoralen in the mean total dose of UVA required for clearance (56.8 J/cm^2 with 5-methoxypsoralen *v* 59.1 J/cm^2 with 8-methoxypsoralen).[46]

Comparison of different oral psoralen formulations: The systematic review included one RCT (47 people), which found no significant difference between liquid and crystalline forms of oral 8-methoxypsoralen in the proportion of people with marked improvement or clearance of psoriasis (liquid *v* crystalline: ARI +25%, 95% CI −1% to +51%; mean UVA dose to achieve clearance 68.7 J/cm^2 with liquid psoralen *v* 80.8 J/cm^2 with crystalline psoralen).[46] **Comparison of oral versus bath psoralen formulations:** The systematic review found two RCTs (137 people), which found no significant difference in the success rate (major improvement or clearance), but found significantly greater mean cumulative UVA dose for clearance with oral compared with topical psoralens (in the first RCT: 14.5 J/cm^2 with bath 8-methoxypsoralen *v* 60.1 J/cm^2 with oral 8-methoxypsoralen; in the other RCT: 23.5 J/cm^2 with bath 8-methoxypsoralen *v* 131.1 J/cm^2 with oral 8-methoxypsoralen).[46] **Comparison of dose setting strategies:** The systematic review included two RCTs (157 people) that compared the routine use of the minimal phototoxic dose of UVA at each treatment versus a strategy of setting the UVA dose according to skin type (see glossary, p 2161).[46] Neither study found any significant difference for success rate (clearance). One RCT found that the minimal phototoxic dose strategy (see glossary, p 2161) had a significantly higher median cumulative UVA dose for clearance (62.9 J/cm^2 with the minimal phototoxic dose *v* 39.5 J/cm^2 with the dose set on the basis of skin type). The second RCT found similar differences, but they were not significant. **Comparison of PUVA with other phototherapies:** The systematic review included five RCTs (285 people).[46] The largest RCT (100 people) found no significant difference between PUVA twice weekly and psoralen plus narrow band UVB twice weekly (ARR for clearance +12%, 95% CI −4% to +28%). **PUVA versus ultraviolet B:** See ultraviolet B, p 2150. **Comparison of PUVA and other treatments:** The systematic review included 25 RCTs (1268 people) that compared different combinations of ultraviolet radiation with systemic or topical treatments, including dithranol, tar, vitamin D_3 analogues, steroids, and fish oil.[46] The RCTs were mostly small and underpowered to detect clinically important differences. The largest of the RCTs (224 people) found that PUVA cleared psoriasis slightly more often than did dithranol (ARR 9%, 95% CI 0% to 18%). **Maintenance:** One large RCT (1005 people whose psoriasis had been cleared by PUVA) found that maintenance treatment with PUVA versus no maintenance treatment reduced relapse at 18 months compared with no maintenance (AR of flares 27% with treatment once a week *v* 34% with treatment once every 3 weeks *v* 62% with no treatment; RR for relapse with once weekly treatment *v* no treatment 0.44, 95% CI 0.32 to 0.56).[53]

Harms:

The best evidence on chronic toxicity comes from an ongoing study of more than 1300 people who first received PUVA treatment in 1975.[54] The study found a dose dependent increased risk of squamous cell carcinoma, basal cell carcinoma, and possibly malignant melanoma compared with the risk in the general population. A systematic review (search date 1998) of eight additional studies has confirmed the findings concerning non-melanoma skin cancer.[52] Premature photoaging is another expected adverse

effect. After less than 15 years, about a quarter of people exposed to 300 or more treatments of PUVA had at least one squamous cell carcinoma of the skin, with particularly high risk in people with skin types I and II. In people who wear UVA opaque glasses for 24 hours after psoralen ingestion, the risk of cataract development seems negligible. A combined analysis of two cohort studies (944 people treated with bath PUVA) excluded a threefold excess risk of squamous cell carcinoma after a mean follow up of 14.7 years, suggesting that bath PUVA is possibly safer than conventional PUVA.[55]

Comment: People receiving PUVA need close monitoring for acute toxicity and long term cutaneous carcinogenic effects.

OPTION COMBINATION REGIMENS

One large RCT has found that the Ingram regimen was of similar effectiveness to psoralen plus ultraviolet A in clearing moderate to severe psoriasis. We found no good evidence on effectiveness of the Goeckerman treatment.

Benefits: We found one systematic review (search date 1999) of calcipotriol plus phototherapy (see benefits of vitamin D derivatives, p 2147),[28] and one systematic review (search date 1999) examining treatment for severe psoriasis,[46] which compared different combinations of ultraviolet radiation compared with systemic or topical treatments, including dithranol, tar, vitamin D derivatives, steroids, and fish oil (see benefits of psoralen plus ultraviolet A, p 2151). **Ingram regimen:** One RCT (224 people) compared an inpatient Ingram regimen (see glossary, p 2161) (dithranol concentration 0.01–1.0%) with psoralen plus ultraviolet A (PUVA).[56] It found that PUVA significantly increased clearance rates compared with the Ingram regimen (clearance rate: 91% with PUVA *v* 82% with Ingram regimen; ARI for clearance 9%, 95% CI 1% to 17%). Five small RCTs (largest involving 53 people)[46] found conflicting results on the added efficacy of dithranol when combined with ultraviolet B (UVB) exposure. However, the trials were too small to rule out a clinically important difference. **Goeckerman treatment:** See glossary, p 2161. We found no good evidence on the effects of combining coal tar and UVB radiation. **Other combinations:** We found one systematic review (search date 1999; see benefits of vitamin D derivatives, p 2147)[28] and an additional RCT[57] of calcipotriol plus UVB or PUVA. The RCT (164 people) found that fewer UVB treatments were required to achieve clearance with calcipotriol plus UVB compared with UVB alone (median number of UVB treatments: 22 with calcipotriol plus UVB *v* 25 with UVB alone; no statistical analysis reported).[57]

Harms: Adverse effects vary with the treatments being combined. Local irritation often occurs.

Comment: None.

QUESTION What are the effects of systemic drug treatments?

OPTION ORAL RETINOIDS (ETRETINATE, ACITRETIN, LIAROZOLE)

We found limited evidence that oral retinoids improved clearance compared with placebo in people with plaque psoriasis. We found little reliable evidence on the effects of oral retinoids as maintenance treatment. Adverse effects lead to discontinuation of treatment in 10–20% of people. Teratogenicity renders oral retinoids less acceptable.

Benefits: We found one systematic review of people with severe psoriasis (search date 1999, 32 RCTs; 13 of etretinate, 11 of acitretin, 8 of acitretin *v* etretinate),[46] one systematic review (search date 2000) of people with psoriatic arthropathy,[58] and one (search date 1999) on the combination of acitretin with calcipotriol.[28] The main outcome was treatment success, as indicated by a specific decrease in Psoriasis Area and Severity Index (PASI; see glossary, p 2161) score or the extent of body surface area involved, or by a global improvement. Heterogeneity among trials often prevented pooling of data. **Retinoids versus placebo:** The review[46] found 11 RCTs (455 people) and we found one additional RCT.[59] Three RCTs allowed concomitant topical steroids. Heterogeneity prevented pooling. Overall, the review found limited evidence that retinoids improved symptoms (marked improvement or complete remission) compared with placebo. Three RCTs found that etretinate 1 mg/kg significantly increased response rate compared with placebo (the largest of these RCTs found almost or complete clearance in 35% with etretinate *v* 5% with placebo; ARR 30%, 95% CI 7% to 53%). However, one RCT found no significant difference in clearance rates between etretinate 50 mg and placebo (complete remission: 17% with etretinate *v* 6% with placebo; ARR +11%, 95% CI −2% to +24%). Results were extractable for only two of the RCTs comparing acitretin with placebo. One RCT (38 people) was underpowered and detected no differences between acitretin and placebo. The other RCT (80 people) found no significant difference in achieving 75% or greater decrease in PASI or a PASI score of less than 8 between acitretin 10 mg and placebo (40% of people with acitretin *v* 25% with placebo; ARR +15%, 95% CI −14% to +44%). Compared with placebo, higher doses of acitretin increased the proportion of people who achieved 75% or greater decrease in PASI or a PASI score of less than 8 (60% with 25 mg acitretin *v* 25% with placebo, ARR 35%, 95% CI 6% to 64%; 70% with 50 mg acitretin *v* 25% with placebo, ARR 45%, 95% CI 17% to 73%). The additional RCT (139 people) compared three doses of liarozole (50, 75, and 150 mg) versus placebo.[59] A total of 116 people completed the 12 week study period. Only 150 mg liarozole significantly increased the proportion of people in the "marked improvement or better" categories compared with placebo (38% with liarozole 150 mg daily *v* 6% with placebo; ARR 32%; CI not reported; $P < 0.001$). **Acitretin versus etretinate:** The review identified six RCTs (598 people), which found no significant difference between acitretin and etretinate in the proportion of people achieving a marked improvement (≥ 75% decrease in PASI or Psoriasis Severity Index [a modified PASI], or a marked or total clearance for the largest study, 74% of

people achieved clearance with 40 mg acitretin *v* 76% with 40 mg etretinate; ARR +2%, 95% CI −17% to +13%).[46] **Etretinate versus cyclosporin:** The review found two RCTs (286 people).[46] Results could not be pooled. The RCT using the higher dose of etretinate (0.7 mg/kg) found that significantly fewer people treated with etretinate than with cyclosporin 5 mg/kg achieved a marked response (≥ 75% decrease in PASI, 97% of people with cyclosporin *v* 73% with etretinate; ARR 24%, 95% CI 9% to 39%). **Retinoid plus psoralen plus ultraviolet A (PUVA) versus PUVA alone:** The review identified six RCTs (305 people).[46] Results could not be pooled. One RCT (30 people) found that retinoid plus PUVA significantly increased clearance rates compared with PUVA alone (93% with etretinate 0.75 mg/kg plus PUVA *v* 60% with PUVA plus placebo; ARR 33%, 95% CI 5% to 61%). The remaining studies did not report a significant difference between groups. **Retinoid plus PUVA versus retinoid alone:** We found no RCTs. **Retinoid plus ultraviolet B (UVB) (broad band or narrow band) versus UVB alone or retinoid alone:** The review included four RCTs (245 people).[46] Results could not be pooled. In each RCT, the combined treatment was superior to UVB alone. The largest RCT (82 people) found that acitretin 3 mg daily plus UVB significantly improved psoriasis compared with UVB alone (≥ 75% decrease in PASI: 57% of people with combination *v* 23% people with UVB alone; ARR 34%, 95% CI 14% to 54%). One small RCT (18 people) found that acitretin plus UVB significantly improved clearance rates compared with acitretin alone (achieved ≥ 80% clearance: 89% with combination *v* 22% with acitretin alone; ARR 67%, 95% CI 33% to 100%). **Retinoid combination with other treatments:** The systematic review included four RCTs (511 people), which found that a retinoid plus topical steroid was superior to the single treatments in improving subjective end points.[46] Another systematic review (search date 1999) found insufficient evidence on the combination of acitretin with calcipotriol (see benefits of vitamin D derivatives, p 2147).[28] **Maintenance:** One systematic review included two RCTs.[46] One of the RCTs (36 people achieving clearance with PUVA plus etretinate) found that low dose etretinate (half of the maximum dose tolerated) significantly reduced relapse rates over 1 year compared with placebo (44% with etretinate *v* 85% with placebo; ARR 41%, 95% CI 12% to 70%). The second RCT found no significant difference between three dosages of acitretin (10 *v* 25 *v* 50 mg daily) and placebo for 6 months.

Harms: Most people experience mucocutaneous adverse effects, such as dry skin, cheilitis, and conjunctivitis. Mucocutaneous effects were generally mild. Increased serum cholesterol and triglyceride concentrations occurred in about half of the people. Low grade hepatotoxicity was observed in about 1% of people treated with etretinate.[60] Two people treated with liarozole were withdrawn because of liver enzyme abnormalities. Occasionally, acute hepatitis occurred as a purported idiosyncratic hypersensitivity reaction. Radiographic evidence of extraspinal tendon and ligament calcifications has been

documented. In one cohort study, a quarter of 956 people treated with etretinate attributed a joint problem or its worsening to the drug.[60] Etretinate is a known teratogen and may be detected in the plasma for 2–3 years after treatment stops. Acitretin can undergo esterification to etretinate.

Comment: Women of childbearing age are given effective contraception for 1 month before starting etretinate and acitretin, throughout treatment, and after stopping treatment for at least 3 years because it is potentially teratogenic. Etretinate is no longer available in many countries.

OPTION METHOTREXATE

We found insufficient evidence about effects of methotrexate in people with chronic plaque psoriasis. Methotrexate can induce acute myelosuppression. Long term methotrexate carries the risk of hepatic fibrosis and cirrhosis, which is related to the dose regimen employed.

Benefits: We found one systematic review (search date 2000).[58] **Oral methotrexate; clearance:** The systematic review identified one small RCT (37 people with psoriatic arthritis), which found that methotrexate significantly reduced the surface area of psoriasis after 12 weeks compared with placebo (CI not reported; $P = 0.04$).[61] **Oral methotrexate; maintenance:** We found no RCTs.

Harms: In one uncontrolled case series, treatment was stopped in 33/113 (29%) people because of adverse effects.[54] The most serious acute reaction, particularly in elderly people, is dose related myelosuppression. In the long term, major adverse events included liver fibrosis and pulmonary toxicity. One systematic review (search date not reported) found that about 28% (95% CI 24% to 32%) of people taking long term methotrexate for psoriasis and rheumatoid arthritis developed liver fibrosis of histological grade I or higher on liver biopsy, whereas 5% developed advanced liver disease (histological grade IIIB or IV).[62] The risk was dose related and was higher with increased alcohol consumption. A limitation of the systematic review was the lack of untreated control groups. Pulmonary disease associated with methotrexate has been described as an acute or chronic interstitial pneumonitis.[63] Adverse pulmonary effects of treatment are considered much rarer in psoriasis than in rheumatoid arthritis, but we found no published evidence to support this claim. Several drug interactions that increase methotrexate toxicity have been described (e.g. with sulphonamides). Methotrexate seems to double the risk of developing squamous cell carcinoma in people exposed to psoralen plus ultraviolet A and may be an independent risk factor for this cancer in people with psoriatic arthritis.[54] A higher risk of lymphoproliferative diseases in long term users has been suggested by a few case reports. On the basis of data from a large case series (248 people), the cumulative incidence of lymphoma is not expected to be much higher than 1%.[64]

Comment: People using methotrexate are closely monitored for liver toxicity[46] and are advised to limit their consumption of alcohol. The most reliable test of liver damage remains needle biopsy of the liver. It is

rare for life threatening liver disease to develop with the first 1.0–1.5 g of methotrexate. In one uncontrolled case series (113 people with severe psoriasis), maintenance treatment with low dose methotrexate (weekly dose not exceeding 15 mg) provided satisfactory control of skin lesions in 81% of people (mean treatment duration 8 years).[65] When treatment was stopped, 45% of people experienced a full relapse within 6 months.

OPTION CYCLOSPORIN

One systematic review found that cyclosporin improved clearance compared with placebo. Optimal clearance rates occurred with a cyclosporin dose of 5.0 mg/kg daily. Any advantage of doses greater than 5.0 mg/kg daily may be offset by an increase in dose related adverse effects, particularly increased renal toxicity. The review found that a cyclosporin dose of 3.0 mg/kg daily was more effective than lower doses or than placebo for maintenance.

Benefits: We found one systematic review (search date 1999, 18 RCTs; 13 on induction of remission, 5 on maintenance of remission).[46] Success was defined mostly as reduction in Psoriasis Area and Severity Index (PASI; see glossary, p 2161) score or clinical criteria such as "clearance". Dosages of cyclosporin ranged from 1.25–14 mg/kg daily. Duration of treatment ranged from 4–12 weeks. Data could not be pooled. **Cyclosporin versus placebo for clearance:** The review included six RCTs (289 people).[46] Results for the proportions of people responding to each treatment were not extractable from each RCT (the largest study reported an ARR for a ≥ 75% reduction of PASI at 10 weeks of 22%, 95% CI 7% to 37% in favour of cyclosporin). **Cyclosporin versus etretinate for clearance:** The review included two RCTs (286 people).[46] The review found that cyclosporin 2.5 mg/kg daily significantly increased rates of achieving greater than 70% decrease in PASI compared with etretinate 0.5 mg/kg daily (62% with cyclosporin *v* 16% with etretinate; ARR 46%, CI 34% to 58%). Cyclosporin 5 mg/kg daily was more effective than 0.75 mg/kg daily etretinate (97% with cyclosporin *v* 73% with etretinate; ARR 24%, CI 9% to 39%). **Comparison of different cyclosporin doses:** Two non-blinded RCTs compared different dosages of cyclosporin (468 people), both finding that cyclosporin 5 mg/kg daily increased the proportion of people achieving a 75% decrease in PASI compared with cyclosporin 2.5 mg/kg daily (89% with 5 mg/kg daily *v* 48% with 2.5 mg/kg daily; ARR 41%, 95% CI 31% to 51%). **Cyclosporin plus calcipotriol versus cyclosporin:** We found one RCT (69 people), but the proportion of people responding to each treatment were not extractable. **Comparison of cyclosporin formulations:** Two RCTs (345 people, 12 weeks, 1 with a crossover design) found no significant difference in the proportion of people achieving a marked response (≥ 75% decrease in PASI) between conventional oil based cyclosporin formulation and the microemulsion preconcentrate formulation (the larger, parallel group RCT results: 78% of people treated with oil based formulation *v* 80% with microemulsion; ARI +2%, 95% CI −7% to +11%). **Maintenance:** The review included five RCTs of treatment to maintain remission.[46] Two RCTs compared two doses of cyclosporin (1.5 mg/kg or 3.0 mg/kg daily) versus

placebo.[66,67] Both RCTs found that 3.0 mg/kg daily cyclosporin was better than placebo for maintaining remission (first RCT: AR for "good response" after 24 weeks [defined as < 50% of baseline body surface area affected]; 58% with cyclosporin 3 mg/kg daily *v* 0% with cyclosporin 1.5 mg/kg daily *v* 16% with placebo; no further data reported in review;[66] second RCT: AR for "positive response" after 16 weeks [defined as increase of no more than 2 points on a 7 point severity scale where 1 = complete clearance and 7 = most severe]; 57% with cyclosporin 3 mg/kg daily *v* 21% with cyclosporin 1.5 mg/kg daily *v* 5% with placebo; no further data reported in review[67]). The third RCT compared two different cyclosporin formulations and found no significant difference in response after 24 weeks between an oil based and microemulsion preconcentrate formulation.[68] The fourth RCT (400 people) found that tapering off the cyclosporin dose increased time to relapse compared with abrupt stopping of cyclosporin (time to relapse 113 days with tapered cyclosporin *v* 109 days with abrupt stopping; P = 0.038).[69] The final RCT (37 people) found that, over the 36 months of treatment, continuous cyclosporin was more effective for maintaining remission than intermittent cyclosporin (remission maintained for 69% of the treatment period with continuous cyclosporin *v* 32% with intermittent treatment; P value not reported).[70]

Harms: Cyclosporin is associated with dose related hypertension (diastolic blood pressure > 90 mm Hg over 12 weeks: 4/36 [11%] with 1.25 mg/kg daily *v* 25/121 [21%] with 2.5 mg/kg daily *v* 16/60 [26%] with 5 mg/kg daily) and renal impairment (creatinine ≥ 130% of baseline value: 1% with 1.25 mg/kg daily *v* 5% with 2.5 mg/kg daily *v* 13% with 5 mg/kg daily).[46] The incidence of these adverse events increases over time. In a case series follow up study of 122 consecutive people treated continuously with cyclosporin for 3–76 months at a dose not exceeding 5 mg/kg daily, 104 people discontinued treatment.[71] The mean percentage of people who discontinued treatment because of adverse effects (mostly renal dysfunction and hypertension) rose from 14% at 12 months to 41% at 48 months. One RCT (400 people) found that intermittent treatment with a microemulsion formulation for 1 year (with maximum treatment periods of 12 weeks as 1–4 courses) was well tolerated and produced no clinically significant change in blood pressure or creatinine concentration.[46] With this regimen only 10 (2.5%) people withdrew because of adverse events. Long term follow up studies are needed to confirm this finding.

Comment: None.

OPTION IMMUNOSUPPRESSIVE DRUGS OTHER THAN CYCLOSPORIN

One RCT found limited evidence that tacrolimus may improve psoriasis compared with placebo. Adverse effects of tacrolimus are reported to be similar to those of cyclosporin. We found insufficient evidence about effects of pimecrolimus or anti-CD4 monoclonal antibodies. Two RCTs found limited evidence that alefacept improved psoriasis compared with placebo, but increased adverse effects, including chills, nausea, cough, dizziness, and accidents.

Benefits: We found no systematic review. **Tacrolimus:** We found two RCTs.[72,73] The first RCT (50 people), found that tacrolimus significantly increased response rates at 9 weeks compared with placebo (≥ 70% reduction in Psoriasis Area and Severity Index (PASI; see glossary, p 2161) score after treatment: 63% with tacrolimus *v* 25% with placebo; RR 0.62; CI not reported).[72] The second RCT (70 people) comparing topical tacrolimus with placebo in the treatment of a single plaque found no significant difference between treatments (local Psoriasis Severity Index score reduced by 33% with tacrolimus *v* 43% with placebo; P = 0.77; CI not reported).[73] **Pimecrolimus:** We found one small RCT (50 people) comparing five different doses of pimecrolimus (from 5 mg to 60 mg twice daily).[74] It found limited evidence that 20 or 30 mg oral pimecrolimus twice daily reduced psoriasis area and severity at 28 days compared with placebo (change in PASI from baseline: –60% with 20 mg *v* –75% with 30 mg *v* 0% with placebo; P values not reported).[74] However, we were unable to draw reliable conclusions from this small study. **Humanised anti-CD4 monoclonal antibody:** We found one RCT (28 people with moderate to severe psoriasis), which compared an anti-CD4 monoclonal antibody (OKTcdr4a) at low dose (250 mg) versus high dose (750 mg) versus placebo.[75] It found no significant difference between treatments (mean decrease in the PASI score at 15 days: 4% with low dose OKTcdr4a *v* 17% with high dose OKTcdr4a *v* 11% with placebo). **Alefacept:** We found two RCTs.[76,77] The first RCT (229 people) compared intravenous alefacept 0.025, 0.075, or 0.150 mg/kg versus placebo, weekly for 12 weeks with follow up for 12 additional weeks.[76] It found that alefacept significantly increased the proportion of people with 75% or greater decrease in baseline PASI score compared with placebo at 12 weeks (33% with alefacept 0.025 mg/kg *v* 11% with placebo; ARR 22%; P = 0.02; CI not reported).[76] The second RCT (553 people) found that once weekly 7.5 mg intravenous alefacept significantly increased response rates compared with placebo at 12 weeks (≥ 75% reduction of PASI: 28% with alefacept *v* 8% with placebo; P < 0.001; CI not reported).[77]

Harms: **Tacrolimus:** Most of the evidence concerning the safety of tacrolimus comes from studies in people with transplant. Despite major differences in their chemical structure, tacrolimus and cyclosporin seem to have a notably similar profile of adverse effects.[78] **Pimecrolimus:** We found no reliable data on the safety of oral pimecrolimus in people with psoriasis. **Alefacept:** The first RCT found an increased frequency of adverse effects with alefacept (dizziness, accidents, nausea, chills, and cough) compared with placebo.[76] The second RCT found that alefacept increased chills compared with placebo (10% with alefacept *v* 1% with placebo).[77]

Comment: The benefit and risk profile of these drugs in psoriasis is still poorly defined. Most evidence was found for alefacept. Alefacept is a recombinant protein that binds to CD2 receptor on memory effector T lymphocytes.

OPTION CYTOKINE BLOCKING AGENTS

We found insufficient evidence about effects of cytokine blocking agents (etanercept and infliximab) in people with plaque psoriasis.

Chronic plaque psoriasis

Benefits: We found no systematic review. **Etanercept:** We found one RCT (60 people mainly with psoriatic arthropathy, 19 with skin lesions).[79] A subgroup analysis for the 19 people with skin lesions found that etanercept significantly increased the proportion of people with 75% or greater improvement in Psoriasis Area and Severity Index score (see glossary, p 2161) compared with placebo (26% with etanercept *v* 0% with placebo; P = 0.015; CI not reported). The results of that subgroup analysis are too weak to allow any generalisable conclusion. **Infliximab:** We found one RCT (33 people with severe psoriasis), which compared weekly intravenous infliximab 5 mg/kg with infliximab 10 mg/kg and with placebo.[80] It found that both doses of infliximab significantly increased response rates at 10 weeks compared with placebo (good, excellent, or clear rating on Physician's Global Assessment: 91% with infliximab 10 mg/kg *v* 82% with infliximab 5 mg/kg *v* 18% with placebo; ARR for 10 mg/kg 73%, 95% CI 30% to 94%; ARR for 5 mg/kg 64%, 95% CI 20% to 89%).

Harms: Most of the evidence on the safety of etanercept and infliximab is from studies in people with rheumatoid arthritis or Crohn's disease. Cutaneous reactions to etanercept have been reported with a frequency of up to 5%, including reactions at the injection site and urticarial manifestations.[81] Upper respiratory tract infections have been reported. A few cases of lupus-like syndrome and severe infections have been reported with infliximab treatment.[82]

Comment: We found insufficient evidence to draw conclusions on the effects of cytokine blocking agents in people with plaque psoriasis.

OPTION FUMARIC ACID DERIVATIVES

One systematic review of four small RCTs found limited evidence that oral fumaric acid esters improved chronic plaque psoriasis after 16 weeks compared with placebo. However, acute adverse effects are common and include flushing and gastrointestinal symptoms. We found no evidence on the effects of fumaric acid derivatives as maintenance treatment.

Benefits: We found one systematic review (search date 1999, 4 placebo controlled RCTs, 203 people).[46] Two RCTs (123 people) compared a mixture of dimethylfumaric and monoethylfumaric acid esters versus placebo. Pooled analysis found that this mixture of fumaric acid derivatives significantly reduced severity compared with placebo at 16 weeks (pooled ARR for ≥ 70% reduction in Psoriasis Area and Severity Index [see glossary, p 2161] score 0.47, 95% CI 0.33 to 0.61).[46] The remaining RCTs in the review were reported in a single article[83] and compared either monoethylfumaric acid ester or dimethylfumaric acid ester versus placebo. The first of these RCTs found that dimethylfumaric acid ester alone significantly improved severity compared with placebo at 16 weeks (AR for ≥ 50% reduction in Psoriasis Area and Severity Index score 27% with dimethylfumaric acid alone *v* 0% placebo; ARR 27%, 95% CI 6% to 45%).[83] However, the other RCT found no significant difference in severity between monoethylfumaric acid ester and placebo at 16 weeks (ARR ≥ 50% improvement in PASI score –5%, 95% CI –22% to +12%).[83]

Harms: All large RCTs on fumaric acid esters found large withdrawal rates; 39% in the drug group of one RCT terminated the treatment prematurely, mostly because of gastrointestinal adverse effects.[46] Acute adverse effects, including flushing and gastrointestinal symptoms, were reported in up to 75% of people. In one RCT (50 people) of fumaric acid esters versus placebo for 16 weeks, diarrhoea was reported 27 times, stomach ache or stomach cramps 35 times, flush 21 times, and skin burning twice.[46] Another open study (101 people) reported adverse effects in 69% of people (mainly gastrointestinal [56%] and flushing [31%]).[46] Eosinophilia was often reported. There have been case reports of renal failure, but one recent systematic review found no evidence of significant renal impairment.[46]

Comment: None.

GLOSSARY

Body mass index A measure of obesity, defined as the weight (in kg) divided by the square of the height (in metres).

Goeckerman treatment A daily application of coal tar followed by ultraviolet B irradiation.

Ingram regimen A daily coal tar bath, ultraviolet B irradiation, and dithranol.

Psoriasis Area and Severity Index (PASI) score Composite score grading severity of psoriasis in four body regions according to erythema, scaling, thickness, and the total area of skin affected. Severity of each of erythema, scaling, and thickness, is graded from 0 to 4, and extension in each body region is graded from 1 to 6). The final composite score ranges from 0 to 72.

Skin types A clinical classification of an individual's burning and tanning tendencies. Usually ranges from skin phototype I (which always burns and never tans) to skin phototype VI (marked constitutive pigmentation).

Skin type regimen and minimal phototoxic dose regimen The four parameters of psoralen plus ultraviolet A are the dose of psoralen, the frequency of treatment, the initial dose of ultraviolet A (UVA), and the incremental UVA dose. The initial and incremental UVA doses are described by at least two regimens. In the minimal phototoxic dose regimen, the initial UVA dose is a fraction of the minimal phototoxic dose. Weekly increments in dose occur until the maximum dose is reached. In the skin type regimen, the initial dose is based on skin phototype. Weekly dose increments are decreased if erythema develops.

Substantive changes

Emollients, keratolytics, capsaicin, and aloe vera One systematic review added;[20] conclusions unchanged.

Tars One systematic review added;[20] conclusions unchanged.

Dithranol One systematic review added;[20] conclusions unchanged.

Topical steroids One systematic review added;[20] conclusions unchanged.

Vitamin D derivatives One systematic review and four RCTs added;[20,33–36] conclusions unchanged.

Topical retinoids (tazarotene) One systematic review added;[20] conclusions unchanged.

Ultraviolet light One RCT added;[47] conclusions unchanged.

Immunosuppressive drugs other than cyclosporin Two RCTs added;[74,77] conclusions unchanged.

Fumaric acid derivatives Evidence reassessed; intervention recategorised from Unknown effectiveness to Trade off between benefits and harms.

TABLE 1 **RCTs of fish oil supplementation (see text, p 2143).**

Ref	Intervention	Control regimen	Number of people	Outcome measure	Duration	Results (intervention *v* control)
6	Infusion of omega-3 fatty acid	Placebo (conventional omega-6)	83	Decrease in PASI by at least 50% over baseline	14 days	16/43 (37%) *v* 9/40 (23%) OR 0.4 (95% CI 0.1 to 1.2)
7	Evening primrose oil + fish oil capsule	Placebo (empty capsule)	38	Skin and joint disease activity	12 months	No difference in disease activity
8	Fish oil capsule	Placebo (corn oil)	145	PASI and total subjective score	4 months	No difference in disease activity
9	Fish oil capsule + topical steroid	Placebo (olive oil) + topical steroid	25	Rate of relapse on withdrawal of topical steroids	9 weeks	No difference in relapse
10	Fish oil capsule + UVB	Placebo (olive oil) + UVB	18	Total body surface area of psoriasis	19 weeks	Significantly greater improvement on fish oil
11	Fish oil	Olive oil	41	Clinical activity	8 weeks	No difference in disease activity

PASI, Psoriasis Area and Severity Index; Ref, reference; UVB, ultraviolet B.

TABLE 2 RCTs of tazarotene alone or in combination (see text, p 2149).

Ref	Study design	Intervention and control regimens	Number of people	Outcome measure	Duration	Results (intervention control)
38	Parallel group	Tazarotene 0.05% or 0.1% once daily v placebo	1303	Global response, reduction in plaque elevation and scaling	12 weeks	Significantly more effective than vehicle
39 (study A)	Within-participant control: 2 bilateral target plaques	Tazarotene 0.05% or 0.1% twice daily v placebo	45	Treatment success (defined as > 75% improvement from baseline); plaque Elevation, scaling, and erythema	6 weeks	Treatment success: 45% with 0.05% tazarotene gel v 13% with placebo after 6 weeks ($P < 0.05$)
39 (study B)	Within-participant control: 2 bilateral target plaques	Tazarotene 0.05% or 0.1% once or twice daily	108	Treatment success (defined as < 75% improvement from baseline); plaque Elevation, scaling, and erythema	8 weeks	ARs ranged from 48% to 63% depending on the various tazarotene treatment regimens after 8 weeks of treatment. Between group differences not reported
40	Parallel group	Tazarotene 0.05% or 0.1% v placebo	324 (318 evaluable)	Plaque elevation, scaling, and erythema; percentage treatment success (> 50% improvement) time to initial success	12 weeks	Clinical response was judged to be good, excellent, or completely cleared in 60% of those on tazarotene (0.1%) v 30% of those on placebo (RRR for tazarotene 0.1% v placebo 43%, 95% CI 30% to 60%).
41	Parallel group	Tazarotene 0.1% + high or mid-potency steroid v tazarotene alone	200	Global improvement	12 weeks	Better improvement with tazarotene + mid-potency steroid. No further data reported

TABLE 2 continued

Ref	Study design	Intervention and control regimens	Number of people	Outcome measure	Duration	Results (intervention control)
42	Parallel group	Tazarotene 0.1% + mometasone furoate once daily v calcipotriol twice daily	120 (106 evaluable)	Marked improvement (> 75% global improvement) or clearance (> 90%)	8 weeks	45% marked improvement on tazarotene v 26% on calcipotriol ($P < 0.05$). No significant difference for clearance
43 (study 1)	Within-participant control: 2 bilateral target plaques	Tazarotene + high-potency steroid v tazarotene + mid-potency steroid v tazarotene + placebo	300	Plaque improvement	12 weeks	91% and 95% of plaques improved on the combination regimen v 80% on tazarotene alone; $P < 0.05$
43 (study 2)	Within-participant control: 2 bilateral target plaques	Tazarotene + high-potency steroid each day v tazarotene alternating with a mid-potency corticosteroid or placebo	398	Plaque improvement	12 weeks	75% with tazarotene + high-potency steroid v 55% tazarotene alternating with a mid-potency corticosteroid v 54% with placebo ($P < 0.05$)
44	Parallel group	Tazarotene 0.1% with placebo, or with a low, mid-, or high potency steroid	300	Scaling, erythema and overall lesional severity	12 weeks	Higher response rates with combination regimens compared with tazarotene alone
45	Parallel group	Once daily tazarotene 0.05% or 0.1% v twice daily fluocinonide	348 (275 evaluable)	Scaling, erythema, elevation	12 weeks	No significant difference at 12 weeks

QUESTIONS

INTERVENTIONS

See glossary, p 2173

Key Messages

- **Insecticide based pharmaceutical products** Two RCTs identified by a systematic review found that permethrin and malathion both increased lice eradication rates compared with placebo. Limited evidence from an earlier systematic review suggested that permethrin increased eradication rates compared with lindane. We found inconclusive evidence from three RCTs about the comparative efficacy of insecticides and combing. One RCT found no significant difference between a herbal product and insecticide.
- **Herbal and essential oils** We found no RCTs that compared herbal treatment with placebo. One RCT found no significant difference in eradication rates between a herbal product (mixture of coconut, anise, and ylang ylang) and insecticide (permethrin, malathion, and piperonyl butoxide). However, results may not generalise to different concentrations of these components or to different herbal preparations.
- **Mechanical removal of lice or viable eggs by combing** We found inconclusive evidence from three RCTs about effects of combing instead of or in addition to insecticides.
- **Repellents** We found insufficient evidence on the effects of these interventions.

DEFINITION Head lice are obligate ectoparasites of socially active humans. They infest the scalp and attach their eggs to the hair shafts. Itching, resulting from multiple bites, is not diagnostic but may increase the index of suspicion. Eggs glued to hairs, whether hatched (nits) or unhatched, are not proof of active infection, because eggs may retain a viable appearance for weeks after death. A conclusive diagnosis can only be made by finding live lice.

INCIDENCE/ PREVALENCE We found no studies on incidence and no recent published prevalence results from any developed country. Anecdotal reports suggest that prevalence has increased in the past few years in most communities in the UK and USA.

AETIOLOGY/ RISK FACTORS Observational studies indicate that infections occur most frequently in school children, although there is no proof of a link with school attendance.[1,2] We found no evidence that lice prefer clean hair to dirty hair.

PROGNOSIS The infection is almost harmless. Sensitisation reactions to louse saliva and faeces may result in localised irritation and erythema. Secondary infection of scratches may occur. Lice have been identified as primary mechanical vectors of scalp pyoderma (see glossary, p 2173) caused by streptococci and staphylococci usually found on the skin.[3]

AIMS OF INTERVENTION To eliminate infestation by killing or removing all head lice and their eggs.

OUTCOMES Treatment success is given as the percentage of people completely cleared of head lice. There are no standard criteria for judging treatment success. Trials used different methods and, in many cases, the method was not stated. Few studies were pragmatic (see glossary, p 2172).

METHODS *Clinical Evidence* search and appraisal October 2003. The initial search was performed by the Cochrane Infectious Diseases Group at the Liverpool School of Tropical Medicine for a systematic review compiled in July 1998.[4]

QUESTION What are the effects of treatment for head lice?

OPTION INSECTICIDE BASED PHARMACEUTICAL PRODUCTS

Two RCTs identified by a systematic review found that permethrin and malathion both increased lice eradication rates compared with placebo. Limited evidence from an earlier systematic review suggested that permethrin increased eradication rates compared with lindane. We found inconclusive evidence from three RCTs about the comparative efficacy of insecticides and combing. One RCT found no significant difference between a herbal product and insecticide.

Benefits: We found two systematic reviews.[4,5] The first systematic review (search date 1995, 7 RCTs, 1808 people) assessed 11 insecticide products, including lindane, carbaryl, malathion, permethrin, and other pyrethroids in various vehicles.[5] A more recent systematic review (search date 2001, 2 RCTs, 345 children and adults) set stricter criteria for RCTs,[4] and excluded studies on which the earlier

review was based.[5] **Versus placebo:** The second systematic review identified one RCT (63 people) comparing permethrin with placebo.[4] It found that permethrin (1% cream rinse) significantly increased eradication rates compared with placebo after 7 and 14 days (7 days: 29/29 [100%] with permethrin *v* 3/34 [9%] with placebo; OR 36, 95% CI 14 to 97; 14 days: 28/29 [97%] with permethrin *v* 2/24 [8%] with placebo; OR 36, 95% CI 13 to 96). The second systematic review also identified one RCT (115 people) comparing malathion (0.5% alcoholic lotion) with placebo.[4] It found that malathion significantly increased eradication rates after 1 week compared with placebo (62/65 [95%] with malathion *v* 21/47 [45%] with placebo; RR 2.1, 95% CI 1.5 to 2.9; NNT 2, 95% CI 1 to 3). **Versus each other:** The first systematic review (7 RCTs, 726 people, search date 1995) found that permethrin (1% cream rinse) significantly increased eradication rates compared with lindane after 14 days (1% shampoo) (lindane *v* permethrin; 2 RCTs; OR for not clearing head lice 15.2, 95% CI 8.0 to 28.8).[5] **Versus mechanical removal of lice:** See mechanical removal of lice or viable eggs by combing, p 2171. **Versus herbal oils:** See herbal and essential oils, p 2172.

Harms: Only minor adverse effects have been reported for most insecticides. The exception is lindane, where there are extensive reports of CNS effects related to overdosing (treatment of scabies) and absorption (treatment of head lice). Transdermal passage of lindane occurs during treatment of head lice,[6] but we found no reports of adverse effects in this setting.

Comment: A number of studies were rejected by reviewers as they followed up participants for only 6 days, which is inadequate as the eggs take 7 days to hatch. Most investigators agree that a final examination after 14 days is necessary to determine cure. Three trials included in the more recent systematic review were conducted in developing countries where insecticide treatments were not regularly available.[4] This may have resulted in greater efficacy, because the insects may have had no previous exposure to the therapeutic agent. Studies *in vitro* suggest that other components of products (e.g. terpenoids and solvents) may be more effective pediculicides (see glossary, p 2172) than the insecticide itself.[7] Resistance to one or more insecticides is now common.[8–10] One RCT (193 people) investigating resistance compared malathion (0.5% lotion with terpenoids) with phenothrin (0.3% lotion) in a community where lice were identified *in vitro* as being tolerant of phenothrin.[11] After 1 day, malathion increased lice eradication rates compared with phenothrin (louse free: 87/95 [92%] with malathion *v* 39/98 [40%] with phenothrin; RR 2.3, 95% CI 1.7 to 2.9) and this difference had increased by day 7 (90/95 [95%] with malathion *v* 38/98 [39%] with phenothrin; RR 2.4, 95% CI 1.8 to 3.2). However, some children not free from lice on day 1 had become louse free by day 7 in both groups, suggesting that some parental intervention had influenced the results. This study suggests that resistance to pyrethroid insecticide may have influenced about 60% of the treatments.

OPTION MECHANICAL REMOVAL OF LICE OR VIABLE EGGS BY COMBING

We found inconclusive evidence from three RCTs about effects of combing instead of or in addition to insecticides.

Benefits: We found no systematic review. **Combing versus insecticide:** We found two RCTs that compared combing with an insecticide treatment.[12,13] The first RCT (72 people) compared "bug busting" (wet combing with conditioner) versus two applications of 0.5% malathion 7 days apart.[12] It found that malathion significantly improved lice eradication rates compared with "bug busting" after 14 days (12/32 [38%] with "bug busting" *v* 31/40 [78%] with malathion; RR for "bug busting" *v* malathion 0.48, 95% CI 0.30 to 0.78; NNT 3, 95% CI 2 to 5).[12] The second RCT (30 people) compared "bug busting" versus two weekly applications of phenothrin lotion (concentration not specified) plus combing. It found that "bug busting" significantly increased eradication of head lice after 14 days compared with phenothrin (eradication rates: 8/15 [53%] with "bug busting" *v* 2/15 [13%] with phenothrin group; RR 4.0, 95% CI 1.0 to 15.8; NNT 3, 95% CI 2 to 17).[13] **Combing plus insecticide:** We found one RCT (95 adults and children), which compared combing with a metal louse/nit comb plus 1% permethrin cream rinse with permethrin cream rinse alone.[14] In both groups permethrin was applied by a community practitioner and if lice were found after 7 days a further application of permethrin, or permethrin plus combing, was given. It found no significant difference in eradication rates with adjuvant combing compared with permethrin alone at 2, 8, and 15 days (louse free rates, at day 2: 49/59 [83%] with no combing *v* 24/33 [73%] with combing; RR 1.14, 95% CI 0.90 to 1.50; at day 8 before repeat treatment: 27/59 [46%] with no combing *v* 11/33 [33%] with combing; RR 0.92, 95% CI 0.60 to 1.40; at day 15: 47/60 [78%] with no combing *v* 24/33 [73%] with combing; RR 1.08, 95% CI 0.80 to 1.40). We found three RCTs comparing different pediculicides in combination with nit combing, but none included a non-combing or non-insecticide control group.[15–17]

Harms: Apart from discomfort, we found no evidence of harms from combing. Wet combing with conditioner may cause adverse reactions, which have been observed during normal cosmetic use.[18–22]

Comment: The first RCT looking at "bug busting" was designed be a pragmatic RCT (see glossary, p 2172) with results that are applicable to normal practice.[12] In the second RCT interventions were applied by trained nurses. "Bug busting" involved the use of different graded combs and specific hair conditioner, while people in the phenothrin group used a single head lice comb and unspecified hair conditioners. The follow up strategy for the combing group differed from that offered to the lotion group.[13] This difference may introduce bias and confounding. One observational study compared two groups of children with louse eggs but no lice at initial assessment.[23] These children were followed to see if they developed active infestation over a period of 14 days. More children with five or more eggs within 6 mm of the scalp developed infestations compared with those with

fewer than five eggs (infestation rates: 7/22 [32%] with ≥ 5 eggs *v* 2/28 [7%] with < 5 eggs; RR 4.45, 95% CI 1.02 to 19.30). The authors concluded that adequate follow up examinations are more likely to be productive than nit removal to prevent reinfestation.

OPTION HERBAL AND ESSENTIAL OILS

We found no RCTs that compared herbal products with placebo. One RCT found no significant difference in eradication rates between a herbal product (coconut, anise, and ylang ylang) and insecticide (permethrin and malathion, synergised with piperonyl butoxide). However, results may not generalise to different concentrations of these components or to different herbal preparations.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs that compared herbal products with placebo. We found one RCT (143 children) that compared a spray based on herbal oils (coconut, anise, and ylang ylang; concentrations unspecified) versus an insecticide spray (0.5% permethrin and 0.25% malathion, synergised with 2% piperonyl butoxide).[24] The herbal spray was used three times at 5 day intervals and the insecticide twice with 10 days between applications. It found no significant difference in eradication rates between the herbal product and insecticide (60/70 [86%] with herbal product *v* 59/73 [81%] with insecticide).

Harms: The RCT found no clinically detectable adverse effects with either herbal oils (a mixture of coconut, anise, and ylang ylang) or insecticide spray (permethrin and malathion, synergised with piperonyl butoxide).[24] A potential for toxic effects has been recognised for several essential oils.[25]

Comment: Results may not generalise to different concentrations of these herbal ingredients or to other herbal products.

OPTION REPELLENTS

We found no systematic review, RCTs, or cohort studies on the effects of chemicals (such as piperonal) used as repellents.

Benefits: We found no systematic review, RCTs, or cohort studies evaluating repellents.

Harms: We found no evidence of harms.

Comment: None.

GLOSSARY

Pediculicide Any compound or material (possibly a pesticide) that kills lice. This term is used specifically in place of "insecticide" as not all pediculicides are recognised pesticides. A pediculicide is distinct from an "ovicide", which kills louse eggs, although one substance may fulfil both functions.

Pragmatic RCT An RCT designed to provide results that are directly applicable to normal practice (compared with explanatory trials that are intended to clarify efficacy under ideal conditions). Pragmatic RCTs recruit a population that is representative of those who are normally treated, allow normal compliance with instructions (by avoiding incentives and by using oral instructions with advice to

follow manufacturers' instructions), and analyse results by "intention to treat" rather than by "on treatment" methods.

Scalp pyoderma Scalp pyoderma involves impetigo-like bacterial infections that result from scratching. In most cases they are due to streptococci with some staphylococcal involvement. Scalp pyoderma of this type is closely associated with long term louse infestation.

QUESTIONS

INTERVENTIONS

Key Messages

Prevention

- **Oral antiviral agents** Six RCTs provided limited evidence suggesting that prophylactic oral antiviral agents may reduce the frequency and severity of attacks compared with placebo, but the optimal timing and duration of treatment is uncertain.
- **Sunscreen** Two small crossover RCTs provided limited evidence that ultraviolet sunscreen may reduce herpes recurrence compared with placebo.
- **Topical antiviral agents** We found no RCTs on the effects of topical antiviral agents used as prophylaxis.

Treatment for first attack

- **Oral antiviral agents (aciclovir)** One small RCT in children found that oral aciclovir reduced the mean duration of pain compared with placebo. Another small RCT in children found that oral aciclovir reduced the median time to healing compared with placebo.
- **Topical antiviral agents** We found no RCTs on the effects of topical antiviral agents.

Treatment for recurrent attack

- **Oral antiviral agents** Four RCTs found that oral aciclovir and valaciclovir (if taken early in the attack) marginally reduced the duration of symptoms and pain compared with placebo. Two large RCTs found no significant difference between a 1 day and a two course regimen of valaciclovir and found that a higher proportion of people experienced headaches with valaciclovir compared with placebo.

- **Topical antiviral agents** Twelve RCTs provided limited evidence that topical penciclovir or aciclovir reduced the duration of pain and symptoms compared with placebo, but stronger evidence that healing time is reduced.
- **Topical anaesthetic agents** One small RCT provided limited evidence that topical tetracaine reduced the mean time to scab loss compared with placebo. However, the clinical importance of this result is unclear.
- **Zinc oxide cream** One small RCT provided limited evidence that zinc oxide cream reduced time to healing compared with placebo, but found that it increased the risk of skin irritation.

DEFINITION Herpes labialis is a mild self limiting infection with herpes simplex virus type 1. It causes pain and blistering on the lips and perioral area (cold sores); fever and constitutional symptoms are rare. Most people have no warning of an attack, but some experience a recognisable prodrome.

INCIDENCE/ PREVALENCE Herpes labialis accounts for about 1% of primary care consultations in the UK each year; 20–40% of people have experienced cold sores at some time.[1]

AETIOLOGY/ RISK FACTORS Herpes labialis is caused by herpes simplex virus type 1. After the primary infection, which usually occurs in childhood, the virus is thought to remain latent in the trigeminal ganglion.[2] A variety of factors, including exposure to bright sunlight, fatigue, or psychological stress, can precipitate a recurrence.

PROGNOSIS In most people, herpes labialis is a mild, self limiting illness. Recurrences are usually shorter and less severe than the initial attack. Healing is usually complete in 7–10 days without scarring.[3] Rates of reactivation are unknown. Herpes labialis can cause serious illness in immunocompromised people.

AIMS OF INTERVENTION To reduce the frequency and severity of recurrent attacks; to speed healing of lesions; to reduce pain, with minimal adverse effects.

OUTCOMES Severity of symptoms, duration of symptoms, time to crusting of lesions, time to healing, rate of recurrence, and adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION What are the effects of interventions aimed at preventing attacks?

OPTION ORAL/TOPICAL ANTIVIRAL AGENTS

Six RCTs provided limited evidence suggesting that prophylactic oral antiviral agents may reduce the frequency and severity of attacks compared with placebo, but the optimal timing and duration of treatment is uncertain. We found no RCTs on the effects of topical antiviral agents used as prophylaxis.

Benefits: We found no systematic review. **Topical antiviral agents:** We found no good quality RCTs. **Oral antiviral agents:** We found four RCTs[4–7] and one pooled analysis of two further RCTs.[8] The first RCT (147 American skiers with a history of herpes labialis precipitated by ultraviolet light) found that prophylactic oral aciclovir (400 mg twice

daily, beginning 12 hours before ultraviolet exposure) reduced frequency of attacks and duration of symptoms compared with placebo ($P < 0.05$).[4] The second RCT (239 Canadian skiers with a history of recurrent herpes labialis) found no significant difference in lesion occurrence between those who took aciclovir (800 mg twice daily, starting on the day before exposure to ultraviolet light for a minimum of 3 days to a maximum of 7 days) and those who took placebo (21/93 with aciclovir *v* 21/102 with placebo; $P = 0.92$).[5] The third RCT (20 people with recurrent herpes labialis) found that aciclovir (400 mg twice daily for 4 months) led to 53% fewer clinical recurrences than placebo ($P = 0.05$).[6] The fourth RCT (248 adults with a history of sun-induced recurrent herpes labialis) compared three different dosages of famciclovir (125 mg, 250 mg, and 500 mg) versus placebo.[7] Treatment was given three times daily for 5 days, beginning 48 hours after exposure to artificial ultraviolet light. The study found no significant difference in the number of lesions in the four groups, but increasing the dose of famciclovir significantly reduced the mean size ($P = 0.04$) and duration of lesions, in a dose–response relation. Compared with placebo, the 500 mg dose reduced the mean time to healing by 2 days ($P < 0.01$, absolute healing times not reported). The pooled analysis of two further RCTs (98 adults with a history of four or more attacks in the previous year) found that oral valaciclovir 500 mg daily significantly increased the chance of remaining recurrence free at 4 months, and significantly increased the time to recurrence compared with placebo (no recurrence within 4 months: 62% with oral valaciclovir *v* 40% with placebo; $P = 0.041$; mean time to recurrence: 13.1 weeks with oral valaciclovir *v* 9.6 weeks with placebo; $P = 0.016$).[8]

Harms: See harms under the effects of antiviral treatment for the first attack, p 2177.

Comment: All participants in the second RCT were allowed to use paracetamol (acetaminophen) and encouraged to use sunscreen.[5]

OPTION SUNSCREEN

Two small crossover RCTs provided limited evidence that ultraviolet sunscreen may reduce herpes recurrence compared with placebo.

Benefits: We found no systematic review. We found two small, crossover RCTs.[9,10] The first RCT (38 people with a history of recurrent herpes) found that sunscreen significantly reduced recurrence compared with placebo at 6 days (recurrence 0/35 [0%] with sunscreen *v* 27/38 [71%] with placebo; $P < 0.001$).[9] The second RCT (19 people exposed to a pre-established dose of ultraviolet light in a laboratory) found that sunscreen significantly reduced recurrence compared with placebo at 6 days (11/19 [58%] with placebo *v* 1/19 [5%] with sunscreen; $P < 0.01$; see comment below).[10]

Harms: None reported.

Comment: The conclusions from the RCTs should be considered with care.[9,10] Crossover studies have important limitations, and the second RCT was conducted under artificial conditions.[10]

QUESTION **What are the effects of antiviral treatment for the first attack of herpes labialis?**

OPTION **ORAL/TOPICAL ANTIVIRAL AGENTS**

We found no RCTs on the effects of topical antiviral agents. One small RCT in children found that oral aciclovir reduced the mean duration of pain compared with placebo. Another small RCT in children found that oral aciclovir reduced the median time to healing compared with placebo.

Benefits: We found no systematic review. **Topical antiviral agents:** We found no RCTs. **Oral antiviral agents:** We found two small RCTs in children.[11,12] One double blind RCT (20 children having their first attack) found that oral aciclovir (200 mg five times daily) significantly reduced mean duration of pain (duration of pain: 4.3 days with aciclovir *v* 5.0 days with placebo).[11] The second RCT (72 children aged 1–6 years with herpes simplex gingivostomatitis of less than 3 days' duration) found that oral aciclovir (15 mg/kg five times daily for 7 days) significantly reduced the median time to healing compared with placebo (4 days with aciclovir *v* 10 days with placebo; median difference 6 days, 95% CI 4 days to 8 days).[12] We found no RCTs in adults.

Harms: Trials have found that topical aciclovir is associated with rash, pruritus, and irritation in some people, but no more frequently than placebo.[13–15] Oral aciclovir is excreted in breast milk. Aciclovir has been used to treat pregnant women with genital herpes, and one systematic review (search date 1996, three studies) found no evidence of adverse effects in women or newborn children (see antiviral treatment for genital herpes during pregnancy, p 2073).[15] Evidence is limited, however, and clinically important adverse effects cannot be ruled out.

Comment: Research in this area is difficult because people do not usually consult clinicians until they have had several attacks of herpes labialis.

QUESTION **Do treatments taken at the beginning of or during a recurrent attack reduce the duration or severity of symptoms?**

OPTION **ORAL/TOPICAL ANTIVIRAL AGENTS**

Twelve RCTs provided limited evidence that topical penciclovir or aciclovir reduced the duration of pain and symptoms compared with placebo, but stronger evidence that penciclovir and aciclovir reduce healing time. Four RCTs found that oral aciclovir and valaciclovir (if taken early in the attack) marginally reduced the duration of symptoms and pain compared with placebo. Two large RCTs found no significant difference between a 1 day and a two course regimen of valaciclovir, and found that a higher proportion of people experienced headaches with valaciclovir compared with placebo.

Herpes labialis

Benefits: We found no systematic review. **Topical antiviral agents:** We found 12 RCTs (published in 11 papers), which found that topical penciclovir and aciclovir reduce healing time compared with placebo. They provided limited evidence that they reduce the duration of pain (see table 1, p 2181). **Oral antiviral agents:** We found four RCTs (published in three papers).[25–27] The first RCT (174 adults with recurrent herpes labialis) found that oral aciclovir (400 mg five times daily for 5 days) taken early in the attack (when the person first experienced tingling) reduced the duration of symptoms compared with placebo (8.1 days with oral aciclovir *v* 12.5 days with placebo; P = 0.02).[25] The second RCT (149 people) compared oral aciclovir taken within 12 hours of the onset of the first episode with placebo.[26] It found no significant difference in healing time or duration of pain between oral aciclovir and placebo (mean healing time: 7.23 days with aciclovir *v* 8.21 days with placebo; P value not reported; mean duration of pain: 1.12 days with aciclovir *v* 1.14 days with placebo; P value not reported). The third and fourth RCTs (presented in one paper) compared oral valaciclovir for 1 day (2 g twice daily); oral valaciclovir for 2 days (2 g twice daily for the first day followed by 1 g twice daily for the second day), and placebo in people aged at least 12 years with recurrent herpes labialis.[27] The third RCT (902 people) found that both oral valaciclovir regimens significantly reduced the median duration of attack compared with placebo (4.0 days with short course valaciclovir *v* 4.5 days with longer course valaciclovir *v* 5.0 days with placebo; $P < 0.001$ for short course valaciclovir *v* placebo; $P = 0.008$ for longer course valaciclovir *v* placebo). The fourth RCT (954 people) found that both oral valaciclovir regimens significantly reduced the median duration of episode compared with placebo (5.0 days with short course valaciclovir *v* 5.0 days with longer course valaciclovir *v* 5.5 days with placebo; $P < 0.001$ for 1 day valaciclovir *v* placebo; $P < 0.001$ with 2 day valaciclovir *v* placebo). Neither RCT found any significant difference between short course valaciclovir and longer course valaciclovir (P values not reported).

Harms: **Oral antivral agents:** The large third and fourth RCTs found similar numbers of adverse events for the 1 and 2 day valaciclovir regimens and placebo.[27] However, headache was more common with valaciclovir than with placebo (third RCT: 9% with short course valaciclovir *v* 9% with longer course valaciclovir *v* 4% with placebo; P values not reported; fourth RCT: 10% with short course valaciclovir *v* 9% with longer course valaciclovir *v* 5% with placebo; P values not reported).[27] The other most common adverse events reported were nausea (third RCT: 4% with 1 day valaciclovir *v* 5% with 2 day valaciclovir *v* 4% with placebo; P values not reported; fourth RCT: 4% with 1 day valaciclovir *v* 4% with 2 day valaciclovir *v* 5% with placebo; P values not reported) and diarrhoea (third RCT: 4% with 1 day valaciclovir *v* 3% with 2 day valaciclovir *v* 3% with placebo; P values not reported; fourth RCT: 2% with 1 day valaciclovir *v* 1% with 2 day valaciclovir *v* 3% with placebo; P values not reported). A small number of cases of dyspepsia, dry mouth, and flatulence were reported in all three treatment groups. See harms under the effects of antiviral treatment for the first attack, p 0.

Comment: We found no RCTs comparing early versus delayed intervention, so no firm conclusions about timing of treatment can be drawn. **Topical antiviral agents:** Fifteen people in the second RCT later took part in a crossover study in which they received the two forms of aciclovir (in random order) separated by a washout period of at least 1 month.[24] The study found that aciclovir in liposomes significantly reduced the time to crusting of lesions compared with aciclovir cream (1.8 *v* 3.5 days; $P < 0.05$). Too few people in that study experienced pain to analyse statistically the impact of the preparations on discomfort. One RCT was conducted under artificial conditions.[22] A number of the smaller trials that compared topical antiviral agents versus placebo found no significant effect of treatment. However, these studies may have lacked power to detect clinically important differences.

OPTION TOPICAL ANAESTHETIC AGENTS

One small RCT provided limited evidence that topical tetracaine reduced the mean time to scab loss compared with placebo. However, the clinical importance of this result is unclear.

Benefits: We found no systematic review. One double blind RCT (72 people) found that 1.8% tetracaine (amethocaine) cream, applied six times daily until scab loss occurred, significantly reduced mean time to scab loss compared with placebo (5.1 days with tetracaine *v* 7.2 days with placebo; $P = 0.002$).[28] It also found that tetracaine cream significantly increased a subjective treatment benefit index (participants rated the benefits of their treatment daily; 1 = no benefit at all; 10 = very effective treatment) compared with placebo (7.3 with tetracaine *v* 5.9 with placebo; $P = 0.036$). However, the clinical importance of these results is unclear.

Harms: None reported.

Comment: None.

OPTION ZINC OXIDE CREAM

One small RCT provided limited evidence that zinc oxide cream reduced time to healing compared with placebo but found that it increased the risk of skin irritation.

Benefits: One double blind RCT (46 people) found that zinc oxide/glycine (applied twice hourly during waking hours as soon as possible after the onset of an attack) significantly reduced time to healing compared with placebo (5.0 days with cream *v* 6.5 days with placebo; $P = 0.018$).[29]

Harms: The RCT reported adverse effects consisting of transient mild to moderate sensations of burning (7 [22%] people with zinc *v* 2 [7%] with placebo), itching (3 [9%] people with zinc *v* 1 [4%] with placebo), stinging (1 [3%] person with zinc *v* 1 [4%] with placebo), and tingling (1 [3%] person with zinc *v* 0 [0%] with placebo).[29] The RCT reported that all adverse effects resolved spontaneously. One person discontinued the active medication because of burning. One person discontinued the placebo because of lack of improvement.

Comment: See comment under antiviral agents for recurrent attacks, p 2179.

Substantive changes

Oral antiviral agents for prevention One pooled analysis of two RCTs added;[8] categorisation unchanged.

Oral antiviral agents for recurrent attacks Two RCTs added;[27] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Unknown effectiveness

Unlikely to be beneficial

To be covered in future updates

Sentinel lymph node excision
Treatment of metastatic malignant melanoma

See glossary, p 2190

Key Messages

- **High dose adjuvant alfa interferon** One RCT has found that high dose alfa interferon extends the time to relapse at median follow up of 6.9 years compared with no adjuvant treatment, and may improve overall survival. However, another RCT found no significant difference in relapse rates or overall survival between high dose interferon and no adjuvant treatment. Toxicity (myelosuppression, hepatotoxicity, and neurotoxicity) and withdrawal rates were high.
- **Adjuvant vaccines in people with malignant melanoma** Four RCTs found no significant difference in survival between adjuvant vaccines and surgery alone or surgery plus placebo vaccine in people with malignant melanoma, but they may have been underpowered to detect a clinically important difference.
- **Low dose adjuvant alfa interferon** RCTs found inconsistent evidence on the effects of low dose alfa interferon compared with no adjuvant treatment on relapse free and overall survival. Toxicity occurred in 10% of people.
- **Sunscreens in prevention** We found no RCTs on the preventive effects of sunscreens. One systematic review of case control studies found inconclusive evidence about the effects of sunscreen for preventing malignant melanoma. However, consensus suggests that the appropriate use of sunscreen (to reduce excessive exposure to sunlight rather than to prolong the time spent in the sun) may reduce the risk of developing melanoma.
- **Surveillance to prevent recurrence** We found no RCTs of surveillance to prevent recurrence of malignant melanoma.

- **Prophylactic lymph node dissection** One systematic review found no significant difference in survival at 5 years between elective lymph node dissection and delayed or no lymph node dissection in people with malignant melanoma without clinically detectable lymph node metastases.
- **Wide primary excision (no better than narrower excision)** RCTs found no significant difference in local recurrence rates or overall survival over 4–10 years between more radical local surgery (4–5 cm excision margins) and less radical surgery (1–2 cm excision margins). One RCT found that wide compared with narrow excision increased the need for skin grafting and the duration of hospital stay.

DEFINITION Cutaneous malignant melanoma is a tumour derived from melanocytes in the basal layer of the epidermis. After undergoing malignant transformation, the tumour becomes invasive by penetrating into and beyond the dermis.

INCIDENCE/PREVALENCE Incidence in developed countries has increased by 50% in the past 20 years. Incidence varies in different populations (see table 1, p 2192) and is about 10-fold higher in white than in non-white populations. Despite the rise in incidence, death rates have flattened and even fallen in some populations (e.g. in women and young men in Australia).[1,2] During the same period there has been a sixfold increase in the incidence of melanoma *in situ*, suggesting earlier detection.

AETIOLOGY/RISK FACTORS The number of common, atypical, and dysplastic naevi on a person's body correlates closely with the risk of developing malignant melanoma. A genetic predisposition probably accounts for 5–10% of all cases. Although the risk of developing malignant melanoma is higher in fair skinned populations living close to the equator, the relation between sun exposure, sunscreen use, and skin type and risk is not clear. Exposure to excessive sunlight and severe sunburn in childhood are associated with an increased risk of developing malignant melanoma in adult life. However, people do not necessarily develop tumours at sites of maximum exposure to the sun.

PROGNOSIS The prognosis of early malignant melanoma (stages I–III) (see table 2, p 2192) relates to the depth of invasion of the primary lesion, the presence of ulceration, and involvement of the regional lymph nodes, with the prognosis worsening with the number of nodes involved.[3] A person with a thin lesion (Breslow thickness [see glossary, p 2190] < 0.75 mm) and without lymph node involvement has a 3% risk of developing metastases and a 95% chance of surviving 5 years.[4] If regional lymph nodes are macroscopically involved then there is a 20–50% chance of surviving 5 years. Most studies have shown a better prognosis in women and in people with lesions on the extremities than in those with lesions on the trunk.

AIMS OF INTERVENTION To prevent melanoma; to detect melanoma earlier; to minimise extent of surgical treatment while still achieving cure of local disease; to optimise quality of life; and to eradicate occult micrometastatic disease, with minimum adverse effects.

Malignant melanoma (non-metastatic)

OUTCOMES **Prevention:** Incidence of malignant melanoma; mortality from malignant melanoma; rates and severity of sunburn (proxy measure). **Primary excision:** Local recurrence; overall survival; requirement for skin grafting. **Lymph node dissection and adjuvant treatment:** Overall survival; disease free survival; quality of life; morbidity of disease treatment.

METHODS *Clinical Evidence* search and appraisal February 2003, and hand searches of reference lists of all review articles found and of the main oncological and dermatological textbooks performed by the authors in 1998.

QUESTION What are the effects of interventions to prevent malignant melanoma?

OPTION SUNSCREENS

We found no RCTs on the preventive effects of sunscreens. Systematic reviews of case control studies found inconclusive evidence about the effects of sunscreen use in preventing malignant melanoma. However, consensus suggests that the appropriate use of sunscreen (to reduce excessive exposure to sunlight rather than to prolong the time spent in the sun) may reduce the risk of developing melanoma.

Benefits: We found no RCTs assessing the effects of sunscreens in preventing malignant melanoma (see comment below). One RCT (588 people) found that a sunscreen significantly reduced the incidence or progression of solar keratosis compared with placebo.[5] Another RCT (87 people) found that people who used a sunscreen with a high sun protection factor (SPF 30) spent more hours in the sun than people who used sunscreen with a lower sun protection factor (SPF 10).[6]

Harms: We found no RCTs (see comment below).

Comment: We found two systematic reviews of retrospective cohort studies.[7,8] The first review (search date not stated, 8 case control studies) found conflicting results.[7] Two case control studies (522 people with malignant melanoma, 1039 controls) identified by the review found that people who "regularly" used sunscreen were less likely to develop melanoma than were people who "never" used sunscreen, but three case control studies (831 people with melanoma, 1550 controls) that adjusted for confounding factors (such as fair skin pigmentation, tendency to sunburn, and participation in water sports) found no association between sunscreen use and the development of melanoma. Three case control studies (1389 people with melanoma, 1991 controls) identified by the review found that regular use of sunscreen may be associated with an increased risk of developing melanoma compared with no use.[7] Another three case control studies found no significant difference between sunscreen use and no use in the risk of developing melanoma.[7] The second review (search date 1999, 11 case control studies, including 8 studies identified by the first review and 2 excluded from the first review because of methodological problems, 3681 cases, 5386 controls) found no significant difference in the

risk of developing melanoma between people who "regularly", "often", or "always" used sunscreen and people who "never" used sunscreen (RR 1.11, 95% CI 0.37 to 3.32).[8] However, the review suggested that the results should be treated with caution because there was significant heterogeneity among the case control studies, and 8 of the 11 studies found that sunscreen use significantly increased the risk of melanoma compared with no sunscreen use.[8] Case control studies all have potential biases and confounding factors.[5] Although we found no prospective evidence, it would seem reasonable to take sensible precautions to avoid excessive exposure to sunlight, particularly in children and fair skinned individuals. A possible mechanism for the observed association between regular use of sunscreen and increased risk of developing melanoma may be that, because some sunscreens protect predominantly against ultraviolet B (which induces sunburn), people may spend more time exposed to higher doses of ultraviolet A.[6] Consensus suggests that sunscreens may have a role if used appropriately (SPF ≥ 15 and a star rating for ultraviolet A protection of 3–4), rather than being used to prolong the time spent in direct sunlight.

QUESTION **Is there an optimal margin for primary excision of melanoma of different Breslow thicknesses?**

OPTION **OPTIMAL EXCISION MARGIN**

One systematic review found no significant difference in overall survival over 4–10 years between more radical local surgery (4–5 cm excision margins) and less radical surgery (1–2 cm excision margins). Three RCTs found no significant difference in local recurrence rates between wider and narrower excision margins. One RCT found that wider versus narrower excision increased the need for skin grafting and the duration of hospital stay

Benefits: **Radical local surgery versus less radical surgery:** We found one systematic review (search date 2001, 4 RCTs, 2406 people with stage 1 and II melanoma [see comment below]).[9] It found no significant difference in overall survival at 5 years between narrower (1–2 cm) and wider (4–5 cm) excision margins (4 RCTs: 732/867 [84%] with narrower *v* 796/911 [87%] with wider; OR 0.79, 95% CI 0.61 to 1.04). The review[9] identified four RCTs[10–13] that assessed local recurrence, but it could not perform a meta-analysis for this outcome because of different durations of follow up among the trials (see table 3, p 2193).

Harms: One of the RCTs (612 people) found that narrow (1 cm) margin excision was associated with three local recurrences compared with wide margin excision, all in people with tumours 1–2 mm thick.[10] Local cure was achieved in two people with further surgery. Although not measured in the RCTs, there is potential for psychological and physical morbidity associated with further surgery after local recurrence.

Comment: Three of the RCTs identified by the review were in people with primary tumours of less than 2 mm Breslow thickness (see glossary, p 2190). We found one further RCT published only in abstract form

that suggests that reducing the excision margin (from 3 cm to 1 cm) in people with >2 mm primary melanoma may be associated with increased risk of relapse and mortality (Savage P, personal communication, 2003). For current recommended excision margins see table 4, p 2194.[14,15]

QUESTION **What are the effects of elective lymph node dissection in people with clinically uninvolved lymph nodes?**

OPTION **ELECTIVE LYMPH NODE DISSECTION IN PEOPLE WITH CLINICALLY UNINVOLVED LYMPH NODES**

One systematic review found no significant difference in survival at 5 years between elective lymph node dissection and delayed or no lymph node dissection in people with malignant melanoma without clinically detectable lymph node metastases, although an effect within particular subgroups cannot be ruled out.

Benefits: We found one systematic review (4 RCTs, 1704 people with stage I and II melanoma with no clinical evidence of lymph node metastases [see comment below]) comparing elective lymph node dissection versus surgery deferred until the time of clinical recurrence.[16] It found no significant difference in mortality at 5 years between elective lymph node dissection and delayed or no lymph node dissection (3 RCTs: 197/768 [26%] with elective dissection *v* 219/765 [29%] with delayed or no dissection; OR 0.86, 95% CI 0.68 to 1.09; see comment below). Retrospective subgroup analyses in the RCTs found non-significant trends in favour of elective lymph node dissection in certain groups of people (those with intermediate thickness tumours, especially those < 60 years of age), but such analyses are subject to bias.[17–20]

Harms: The systematic review gave no information on harms.[16] One retrospective case series found that lymph node dissection was associated with temporary seroma (17%), wound infection (9%), wound necrosis (3%), and lymphoedema (20%).[21]

Comment: In about 20% of people who do not have clinically apparent lymph node involvement, the lymph nodes will contain occult micrometastases. None of the RCTs gave data on morbidity and quality of life in people undergoing lymph node dissection. Sentinel lymph node excision is an alternative to elective lymph node dissection. It involves using a dye or radioactive tracer to identify which nodes are draining the primary lesion. Excision biopsy is then used to determine whether the node is involved with metastatic disease, prior to considering a full lymph node dissection. Sentinel lymph node excision is currently being evaluated in clinical trials (Crosby T, personal communication, 2001).

QUESTION **What are the effects of adjuvant treatment?**

OPTION **ALFA INTERFERON**

One RCT has found that adjuvant treatment with high dose alfa interferon extends the time to relapse at median follow up of 6.9 years compared with no adjuvant treatment, and may improve overall survival. However,

another RCT found no significant difference in relapse free or overall survival between high dose interferon and no adjuvant treatment. One RCT found that high dose alfa interferon improved both relapse free and overall survival compared with ganglioside GM2 vaccine. RCTs found inconsistent evidence on the effects of low dose interferon compared with no adjuvant treatment on relapse free and overall survival. Toxicity (myelosuppression, hepatotoxicity, and neurotoxicity) and withdrawal rates were high.

Benefits: We found one systematic review[22] (search date 2001, 8 RCTs,[23–30] 3178 people) and one additional RCT[31] comparing high or low dose interferon alfa versus no adjuvant treatment, and one RCT comparing high dose interferon versus ganglioside GM2 vaccine.[32] The review could not perform a meta-analysis because of heterogeneity among the trials in dose and duration of interferon and stage of disease of participants.[22] **High dose versus no adjuvant treatment (observation):** The systematic review[22] identified two RCTs.[23,25] The first RCT (280 people with resectable stage IIB [primary lesions > 4 mm] or stage III melanoma) identified by the review compared high dose alfa interferon (20 MU/m^2/day iv for 1 month, followed by 10 MU/m^2 sc 3 times/week for 11 months) versus observation.[23] At a median follow up of 6.9 years, it found that alfa interferon significantly improved disease free survival (median 1.7 *v* 1.0 years; P = 0.023) and overall survival (median 3.8 *v* 2.8 years; P = 0.0237) compared with observation.[23] Retrospective subgroup analysis found prolonged quality of life adjusted survival in people receiving alfa interferon.[33] The clinical importance of this gain varied with the values assigned by people in the trial for the impact of treatment related toxicity and the impact of time with relapsed disease. The second RCT (262 people with completely resected stage I and II melanoma, primary tumours > 0.7 mm, lymph node negative) identified by the review compared high dose interferon (20 MU/m^2 im 3 times/week for 12 weeks) versus observation and found no significant difference in disease free survival (mean 2.4 years with alfa interferon *v* 2.2 years with observation; P = 0.19) or overall survival (median 6.6 years with alfa interferon *v* 5.0 years with observation; P = 0.40).[25] **High dose versus ganglioside GM2 vaccine:** We found one RCT (880 people with resected stage IIB and III melanoma) comparing high dose interferon (20 MU/m^2 iv 5 times/week for 4 weeks plus 10 MU/m^2 sc 3 times/week for 48 weeks) versus ganglioside GM2 vaccine.[32] It found that, compared with ganglioside vaccine, alfa interferon significantly improved both relapse free survival (98/385 [25%] with alfa interferon *v* 151/389 [39%] with ganglioside; HR 1.47, 95% CI 1.14 to 1.90) and overall survival (52/385 [14%] *v* 81/389 [21%]; HR 1.52, 95% CI 1.07 to 2.15) over a median follow up of 16 months. **Low dose versus no adjuvant treatment:** The review identified five RCTs,[26–30] and we found one additional RCT.[31] Three of the RCTs identified by the review were in people with stage II melanoma (primary tumours > 1.5 mm and lymph node negative).[26,27,29] The first RCT (489 people with stage II melanoma) identified by the review comparing low dose alfa interferon (3 MU sc 3 times/week for 18 months) versus no adjuvant treatment found that alfa interferon significantly increased relapse free survival over a median 5 years (HR 0.75, 95% CI 0.57 to 0.98; P = 0.035).[26] It

found that overall survival rates after a median 5 years were higher with alfa interferon than with no adjuvant treatment, but the difference did not quite reach significance (HR 0.72, 95% CI 0.51 to 1.00; P = 0.059). The second RCT (311 people with stage II melanoma) identified by the review compared low dose alfa interferon (3 MU/day sc for 3 weeks and 3 times/week for 12 months) versus no adjuvant treatment after excision of the primary tumour.[27] At 41 months' follow up it found that alfa interferon significantly prolonged relapse free survival compared with no adjuvant treatment (P = 0.02). It found no significant difference in overall survival over 41 months between alfa interferon and no adjuvant treatment, but it may have been too small to exclude a clinically important difference (17/154 [11%] with alfa interferon *v* 21/157 [13%] with no adjuvant treatment; RR 0.82, 95% CI 0.45 to 1.50). The third RCT (654 people with stage II melanoma) identified by the review, published only in abstract form, found no significant difference in relapse free survival (P = 0.2) or overall survival (P = 1.0) at 4 years between low dose interferon (3 MU 3 times/week for 2 years or until recurrence) and observation.[29] The fourth RCT (96 people with stage II or III melanoma, primary tumours ≥ 3 mm Breslow thickness (see glossary, p 2190), or evidence of regional node involvement) identified by the review found no significant difference in relapse free survival or overall survival at a median follow up of 6 years between interferon (3 MU sc 3 times/week for 6 months) and observation, but it may have lacked power to exclude a clinically important difference.[30] The fifth RCT (424 people with stage III melanoma, lymph node metastases) compared low dose interferon (3 MU sc 3 times/week for 3 years) versus no adjuvant treatment.[28] It found no significant difference between low dose interferon and no adjuvant treatment in relapse free survival (28.4% with interferon *v* 27.5% with no adjuvant treatment; P = 0.50) or overall survival at 5 years (37% with interferon *v* 37% with no adjuvant treatment; P = 0.72). The additional RCT (830 people with stage II or III melanoma, primary tumours > 3 mm or lymph node involvement), published only as an abstract, compared low dose gamma or alfa interferon versus no adjuvant treatment for 12 months and found no significant difference in disease free survival (RR alfa interferon *v* no treatment 0.9, 95% CI 0.75 to 1.18; absolute numbers not provided) or overall survival at 6 years (reported as non-significant; no further data provided).[31] **High or low dose versus no adjuvant treatment:** One RCT (642 people with stage II or III primary or recurrent nodal involvement) identified by the review compared three interventions: high dose alfa interferon (20 MU/m^2/day iv 5 days/week for 1 month, followed by 10 MU/m^2 sc 3 times/week for 11 months); low dose alfa interferon (3 MU/m^2/day sc 3 times/week for 2 years); or observation.[24] It found that high dose interferon marginally but significantly improved relapse free survival over 5 years compared with observation (HR 1.28, 95% CI 1.00 to 1.65), but found no significant difference in overall survival (HR 1.0, 95% CI 0.75 to 1.33). It found no significant difference between low dose interferon and observation in relapse free survival (HR 1.19, 95% CI 0.93 to 1.53) or overall survival (HR 1.04, 95% CI 0.78 to 1.38) over 5 years.[24]

Harms: Interferons commonly cause malaise, fevers, and flu-like symptoms. **High dose versus no adjuvant treatment (observation):** In the first RCT identified by the review, high dose alfa interferon also caused significant (> grade 3) myelosuppression in 24% of people, hepatotoxicity in 15% (including 2 deaths), and neurotoxicity in 28%. At 11 months, only 25% of participants were receiving more than 80% of the planned dose.[23] **Low dose versus no adjuvant treatment:** In the first RCT identified by the review, 10% of people taking low dose interferon suffered significant toxicity.[26] The fifth RCT identified by the review found that 162/225 (72%) taking low dose alfa interferon developed World Health Organization (WHO) grade 1 toxicity,[34] 54/225 (24%) WHO grade 2 toxicity, and 9/225 (4%) no toxicity.[28]

Comment: RCTs investigating the effects of sustained release pegylated alfa interferon are underway (Savage P, personal communication, 2003).

OPTION VACCINES

Four RCTs found no significant difference in survival between adjuvant vaccines and surgery alone or surgery plus placebo vaccine in people with malignant melanoma, but they may have been underpowered to detect a clinically important difference.

Benefits: Four RCTs found no significant difference in survival between adjuvant vaccines and surgery alone or surgery plus placebo vaccine, but may have been underpowered to detect a clinically important difference.[35–38] The first RCT (700 people with stage IIB or III primary or recurrent nodal involvement) compared adjuvant vaccine (prepared from vaccinia melanoma cell lysates) versus surgery alone.[35] It found no significant difference between adjuvant vaccine and surgery alone in relapse free survival (51% with adjuvant treatment *v* 47% with no treatment) or overall survival (60% with adjuvant treatment *v* 55% with no treatment; reported as non-significant, CI not stated) at 5 years or 10 years. The second RCT (689 people with completely resected stage II melanoma, primary tumour 1.5–4 mm Breslow thickness [see glossary, p 2190]) found no significant difference in relapse free survival at 5 years between adjuvant vaccine (allogeneic melanoma cell lysate) and surgery alone (66% with vaccine *v* 62% with no vaccine; P = 0.17).[36] The third RCT (217 people with resected stage III melanoma) compared adjuvant vaccinia melanoma oncosylate versus placebo vaccine (vaccinia virus).[37] Over 5 years, it found no significant difference between adjuvant melanoma vaccine and placebo vaccine in disease free survival (P = 0.61) or overall survival (P = 0.79, absolute results presented graphically). The fourth RCT (38 people with resected stage III melanoma) compared polyvalent melanoma vaccine versus placebo vaccine (human albumin).[38] It found that melanoma vaccine significantly increased time to recurrence compared with placebo vaccine (1.6 years with vaccine *v* 0.6 years with placebo vaccine; P = 0.03), but found no significant difference in overall survival at 3 years (53% with vaccine *v* 33% with placebo vaccine; reported as non-significant, CI not stated).

Malignant melanoma (non-metastatic)

Harms: The first RCT found that melanoma vaccine was associated with erythema and ulceration at the injection site (47% of people), malaise (35%), and fever (20%).[35] The second RCT found that most people receiving melanoma vaccine had mild to moderate adverse effects and that 26 (9%) of people had severe adverse effects, including malaise, fatigue, visual complaints, fever, diarrhoea, thrombocytopenia, or skin rash.[36] The third RCT found that both melanoma vaccine and placebo vaccine were associated with erythema, swelling and tenderness at the injection site, headache, nausea, and fever.[37] The fourth RCT found that both vaccine and placebo vaccine were associated with skin reactions but found no other adverse effects.[38]

Comment: A different vaccine preparation was used in each RCT, making the results difficult to generalise.[35–38] More RCTs of vaccines and other active specific immunostimulants are needed.

OPTION SURVEILLANCE

We found no RCTs of surveillance to prevent recurrence of malignant melanoma.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: We found no RCTs.

Comment: Retrospective studies found that people presented with symptomatic recurrent malignant melanoma regardless of whether they were taking part in an intensive follow up programme.[39] Thinner lesions (< 0.75 mm) may require longer surveillance because recurrence peaks at 5–10 years.[40]

GLOSSARY

Breslow thickness The vertical depth (in mm) to which the tumour has penetrated.

QUESTIONS

INTERVENTIONS

Key Messages

- **Permethrin** One systematic review has found that permethrin increases clinical and parasitic cure after 28 days compared with crotamiton. The systematic review found conflicting results with permethrin versus lindane. One subsequent RCT found limited evidence that permethrin increased clinical cure at 14 days compared with ivermectin.
- **Crotamiton** One systematic review found that crotamiton was less successful in terms of clinical and parasitic cure after 28 days compared with permethrin. One systematic review identified one RCT that found no significant difference between crotamiton and lindane in clinical cure rates at 28 days.
- **Oral ivermectin** One systematic review identified one RCT that found that ivermectin increased clinical cure rates after 7 days compared with placebo. Another small RCT identified by the review found no significant difference between ivermectin and benzyl benzoate in clinical cure rates at 30 days. One subsequent RCT found that, compared with benzyl benzoate, ivermectin increased clinical cure rates at 30 days. One systematic review identified one small RCT that found no significant difference between ivermectin and lindane in cure rates at 15 days. One subsequent RCT found no significant difference between ivermectin and lindane in failed clinical cure rates at 2 weeks, but it found that ivermectin decreased failed clinical cure rates at 4 weeks. One RCT found limited evidence that ivermectin reduced clinical cure rates at 14 days compared with permethrin. Experience suggests oral ivermectin is safe in younger adults being treated for onchocerciasis, but no such experience exists for children, and there have been reports of increased risk of death in elderly people.
- **Lindane** One systematic review identified one RCT that found no significant difference between lindane and crotamiton in clinical cure rates at 28 days. The systematic review found conflicting results between lindane and permethrin after 28 days. Another small RCT identified by the review found no significant difference between lindane and ivermectin in cure rates at 15 days. One subsequent RCT found no significant difference between lindane and

ivermectin in failed clinical cure rates at 2 weeks, but it found a higher proportion of people with failed clinical cure with lindane compared with ivermectin at 4 weeks. We found reports of rare, serious adverse effects such as convulsions.

- **Benzyl benzoate** One systematic review identified one small RCT that found no significant difference between benzyl benzoate and ivermectin in clinical cure rates at 30 days. One subsequent RCT found that benzyl benzoate reduced clinical cure at 30 days compared with ivermectin. One systematic review identified one RCT that found no significant difference between benzyl benzoate and sulphur ointment in clinical cure at 8 or 14 days.
- **Malathion** One systematic review found no RCTs on the effects of malathion. Case series have reported cure rates in scabies of over 80%.
- **Sulphur compounds** One systematic review identified one RCT that found no significant difference between sulphur ointment and benzyl benzoate in clinical cure at 8 or 14 days.

DEFINITION Scabies is an infestation of the skin by the mite *Sarcoptes scabiei*.[1] Typical sites of infestation are skin folds and flexor surfaces. In adults, the most common sites are between the fingers and on the wrists, although infection may manifest in elderly people as a diffuse truncal eruption. In infants and children, the face, scalp, palms, and soles are also often affected.

INCIDENCE/ PREVALENCE Scabies is a common public health problem with an estimated prevalence of 300 million cases worldwide, mostly affecting people in developing countries, where prevalence can exceed 50%.[2] In industrialised countries it is most common in institutionalised communities. Case studies suggest that epidemic cycles occur every 7–15 years and that these partly reflect the population's immune status.

AETIOLOGY/ RISK FACTORS Scabies is particularly common where there is social disruption, overcrowding with close body contact, and limited access to water.[3] Young children, immobilised elderly people, people with HIV/AIDS, and other medically and immunologically compromised people are predisposed to infestation and have particularly high mite counts.[4]

PROGNOSIS Scabies is not life threatening, but the severe, persistent itch and secondary infections may be debilitating. Occasionally, crusted scabies develops. This form of the disease is resistant to routine treatment and can be a source of continued reinfestation and spread to others. A search conducted by the author found no reports of spontaneous remission.

AIMS OF INTERVENTION To eliminate the scabies mites and ova from the skin; to cure pruritus (itching); to prevent reinfestation; to prevent spread to other people.

OUTCOMES **Clinical cure:** Number of visible burrows and papular and vesicular eruptions; pruritus. **Parasitic cure:** Presence of mites, ova, or faecal pellets in skin scrapings under a magnifying lens or microscope. Outcomes should be assessed 28–30 days after the start of treatment, which is the time it takes for lesions to heal and for any eggs and mites to reach maturity if treatment fails.

METHODS *Clinical Evidence* search and appraisal January 2003.

QUESTION What are the effects of topical treatments?

OPTION PERMETHRIN

One systematic review has found that permethrin increases clinical and parasitic cure after 28 days compared with crotamiton. The systematic review found conflicting results between permethrin and lindane. One subsequent RCT found limited evidence that permethrin increased clinical cure at 14 days compared with ivermectin.

Benefits: We found no RCTs that compared permethrin versus placebo. We found one systematic review (search date 1999, 6 RCTs)[5] and one subsequent RCT[6] comparing permethrin versus other topical and oral agents. **Versus crotamiton:** The review (2 RCTs, 194 people) found that permethrin compared with crotamiton significantly increased clinical cure rates after 28 days (2 RCTs; OR for failed clinical cure with permethrin *v* crotamiton 0.21, 95% CI 0.10 to 0.47) and significantly increased parasitic cure after 28 days (1 RCT; 94 people; OR for failed parasitic cure with permethrin *v* crotamiton 0.21, 95% CI 0.08 to 0.53).[5] It found no significant difference between permethrin and crotamiton in self reported pruritus (1 RCT: OR for itch persistence with permethrin *v* with crotamiton 0.38, 95% CI 0.12 to 1.19). **Versus lindane:** The systematic review identified four RCTs that compared permethrin with lindane.[5] Overall, the review found that permethrin appeared to be more effective than lindane in clinical cure after 28 days. However, it found significant trial heterogeneity ($P < 0.005$). Two RCTs (100 people; 52 people) included in the review found that permethrin compared with lindane significantly reduced clinical failure (OR for failed clinical cure of permethrin *v* lindane 0.14, 95% CI 0.05 to 0.43; and 0.19, 95% CI 0.05 to 0.70) whereas two RCTs (99 people; 467 people), including the largest RCT, found no significant difference between permethrin and lindane (OR for failed clinical cure of permethrin *v* lindane 0.8, 95% CI 0.21 to 3.14; and 0.93, 95% CI 0.60 to 1.42).[5] **Versus oral ivermectin:** We found one subsequent RCT that compared topical permethrin versus oral ivermectin.[6] The RCT (85 people attending an outpatient clinic in India) assessed clinical cure at 14 days, and if not assessed as completely cured at that time the same treatment was repeated. It found that permethrin significantly decreased failed clinical cure rate at 14 days compared with ivermectin (OR for failed clinical cure of permethrin *v* ivermectin 0.12, 95% CI 0.04 to 0.39).

Harms: One RCT identified by the review reported five people with adverse effects: two in the permethrin group (rash and possible diarrhoea) and three in the lindane group (pruritic rash, papules, and diarrhoea).[7] During 1990–1995, six adverse events were reported per 100 000 units distributed in the USA (1 central nervous system adverse effect reported per 500 000 units of permethrin distributed).[8] Resistance to permethrin seems to be rare[8] (see harms of lindane, p 2198).

Comment: None.

OPTION LINDANE

One systematic review identified one RCT that found no significant difference between lindane and crotamiton in clinical cure rates at 28 days. The systematic review found conflicting results with lindane compared with permethrin after 28 days. Another small RCT identified by the review found no significant difference between lindane and ivermectin in cure rates at 15 days. One subsequent RCT found no significant difference between lindane and ivermectin in failed clinical cure rates at 2 weeks, but found a higher proportion of people with failed clinical cure with lindane than with ivermectin at 4 weeks. We found reports of rare, serious adverse effects such as convulsions.

Benefits: We found no RCTs comparing lindane versus placebo. We found one systematic review (search date 1999, 6 RCTs)[5] comparing lindane versus other topical and oral agents, and one subsequent RCT comparing lindane versus ivermectin.[9] **Versus crotamiton:** One RCT (100 adults and children) identified by the review found no significant difference in clinical cure rates at 28 days (OR for failed clinical cure with crotamiton *v* lindane 0.41, 95% CI 0.15 to 1.10).[5] However, confidence intervals are broad and a clinically important difference cannot be ruled out. **Versus permethrin:** See benefits of permethrin, p 2197. **Versus oral ivermectin:** One RCT[10] (53 adults referred to hospital with scabies) identified by the review found no significant difference between lindane and ivermectin in clinical cure rates at 15 days (failed clinical cure 14/27 [52%] with lindane *v* 12/26 [46%] with oral ivermectin; RR 0.89, 95% CI 0.51 to 1.55).[5] One subsequent RCT compared topical lindane versus ivermectin.[9] It found no significant difference in failed clinical cure rates between lindane and ivermectin at 2 weeks (failed clinical cure rate 70/100 [70%] with ivermectin *v* 81/100 [81%] with lindane; RR 0.86, 95% CI 0.74 to 1.01) but it found that ivermectin significantly increased clinical cure rates at 4 weeks compared with lindane (failed clinical cure rate 43/100 [43%] with ivermectin *v* 64/100 [64%] with lindane; RR 0.67, 95% CI 0.51 to 0.88).

Harms: One RCT identified by the review reported five people with adverse effects: two in the permethrin group (rash and possible diarrhoea) and three in the lindane group (pruritic rash, papules, and diarrhoea).[7] One RCT identified by the review reported that six people taking lindane had headaches, and one person each had headache, hypotension, abdominal pain, and vomiting in the ivermectin group.[10] Case reports have reported rare severe adverse effects (e.g. convulsions, other long term neurological complications, and aplastic anaemia) particularly when lindane was applied to people with extensive skin diseases and to children.[11–13] Figures from the World Health Organization Collaborating Centre for International Drug Monitoring covering summary reports from 47 countries suggest that lindane is more toxic than other preparations (see comment below).[14] Five convulsions were reported in people on benzyl benzoate, two in people on crotamiton, 48 in people on lindane, two in people on malathion, and 19 in people on permethrin. Deaths reported on benzyl benzoate were none, crotamiton one, lindane four, malathion none, and permethrin five.[14] Resistance to lindane has been reported in many countries.[15]

Comment: Lindane was withdrawn from the market in the UK in 1995 because of concern about possible adverse effects. The evidence linking lindane with convulsions is suggestive but not conclusive.[11–14] It is difficult to draw firm conclusions on the relative occurrence of severe adverse effects of different preparations reported to the World Health Organization Collaborating Centre for International Drug Monitoring because of incomplete information on incidence in relation to use; however, lindane and permethrin appear possibly to be more likely to be related to rare severe adverse effects. Safety results from trials and observational studies need to be summarised, particularly regarding additional risks in infants and pregnant women.

OPTION CROTAMITON

One systematic review found that crotamiton was less successful in terms of clinical and parasitic cure after 28 days compared with permethrin. One systematic review identified one RCT that found no significant difference between crotamiton and lindane in clinical cure rates at 28 days.

Benefits: We found no RCTs comparing crotamiton versus placebo. We found one systematic review (search date 1999, 3 RCTs) comparing crotamiton versus other topical agents.[5] **Crotamiton versus permethrin:** See benefits of permethrin, p 2197. **Crotamiton versus lindane:** See benefits of lindane, p 2198.

Harms: The RCTs reported no serious adverse effects[5] (see harms of lindane, p 2198).

Comment: None.

OPTION MALATHION

One systematic review found no RCTs on the effects of malathion. Case series have reported cure rates in scabies of over 80%.

Benefits: We found one systematic review (search date 1999) that identified no RCTs.[5]

Harms: We found no RCTs (see harms of lindane, p 2198).

Comment: Case series suggest that malathion is effective in curing infestation with scabies, with a cure rate of over 80% of people at 4 weeks.[16–18] The safety results from trials and observational studies need to be systematically reviewed, particularly with regard to additional risks in infants and pregnant women.

OPTION BENZYL BENZOATE

One systematic review identified one small RCT that found no significant difference between benzyl benzoate and ivermectin in clinical cure rates at 30 days. One subsequent RCT found that benzyl benzoate reduced clinical cure at 30 days compared with ivermectin. One systematic review identified one RCT that found no significant difference between benzyl benzoate and sulphur ointment in clinical cure at 8 or 14 days.

Scabies

Benefits: We found no RCTs comparing benzyl benzoate versus placebo. We found one systematic review (search date 1999, 2 RCTs, 202 people) comparing benzyl benzoate versus other agents[5] and one subsequent RCT comparing ivermectin and benzyl benzoate.[19] **Versus oral ivermectin:** The systematic review identified one RCT[20] and we found one subsequent RCT[19] (see benefits of oral ivermectin, p 2201). **Versus sulphur ointment:** One RCT identified by the review compared benzyl benzoate versus sulphur ointment (158 adults and children identified in a house to house survey of a semi-urban area of India).[21] It found no significant difference in the number of people with apparently cured lesions by 8 days (AR 68/89 [76%] with benzyl benzoate *v* 45/69 [65%] with sulphur ointment; RR 1.17, 95% CI 0.95 to 1.33) or by 14 days (AR 81/89 [91%] with benzyl benzoate *v* 67/69 [97%] with sulphur ointment; RR 0.94, 95% CI 0.86 to 1.01).

Harms: Both RCTs comparing benzyl benzoate versus oral ivermectin found that about a quarter of people treated with benzyl benzoate reported a transient increase in pruritus and dermatitis.[19,20] See harms of lindane, p 2198.

Comment: Non-randomised trials suggest benzyl benzoate has variable effectiveness (as low as 50%).[22,23] The low cure rate may be related to the concentration of the preparation and resistance of the mite to benzyl benzoate.

OPTION SULPHUR COMPOUNDS

One systematic review identified one RCT that found no significant difference between sulphur ointment and benzyl benzoate in clinical cure at 8 or 14 days.

Benefits: We found no RCTs comparing sulphur compounds versus placebo. **Versus benzyl benzoate:** We found one RCT (see benefits of benzyl benzoate, p 2200).[21]

Harms: Use of sulphur has been associated with increased local irritation in about a quarter of cases.[13]

Comment: None.

QUESTION What are the effects of systemic treatments?

OPTION ORAL IVERMECTIN

One systematic review identified one RCT that found that ivermectin increased clinical cure rates after 7 days compared with placebo. Another small RCT identified by the review found no significant difference between ivermectin and benzyl benzoate in clinical cure rates at 30 days. One subsequent RCT found that ivermectin increased clinical cure rates at 30 days compared with benzyl benzoate. One systematic review identified one small RCT that found no significant difference between ivermectin and lindane in cure rates at 15 days. One subsequent RCT found no significant difference between ivermectin and lindane in failed clinical cure rates at 2 weeks, but found that ivermectin increased clinical cure rates at 4 weeks. One RCT found limited evidence that ivermectin reduced clinical cure at 14 days compared with permethrin.

Experience suggests that oral ivermectin is safe in younger adults being treated for onchocerciasis, but no such experience exists for children and there have been reports of increased risk of death in elderly people.

Benefits: We found one systematic review (search date 1999, 3 RCTs)[5] and three subsequent RCTs[6,9,19] comparing oral ivermectin versus placebo or other agents. **Versus placebo:** One RCT (55 young adults and children aged > 5 years) identified by the review found that oral ivermectin significantly increased clinical cure rates after 7 days compared with placebo (23/29 [79%] with oral ivermectin *v* 4/26 [15%] with placebo; RR 5.2, 95% CI 2.1 to 12.9; NNT 2, 95% CI 1 to 3).[5] **Versus benzyl benzoate:** One small RCT (44 adults and children) identified by the review found no significant difference in clinical cure rates at 30 days (16/23 [70%] with oral ivermectin *v* 10/21 [48%] with benzyl benzoate; RR 1.5, 95% CI 0.9 to 2.5).[20] One subsequent small RCT (58 adults and children) found that oral ivermectin significantly increased clinical cure rates at 30 days compared with benzyl benzoate (27/29 [93%] with oral ivermectin *v* 14/29 [48%] with benzyl benzoate; RR 1.9, 95% CI 1.3 to 2.8).[19] **Versus lindane:** See benefits of lindane, p 2198. **Versus permethrin:** See benefits of permethrin, p 2197.

Harms: One RCT identified by the review reported that six people had headaches in the lindane group (out of 27 people), and one person each had headache, hypotension, abdominal pain, and vomiting in the ivermectin group (out of 26 people).[10] One RCT reported no adverse effects for oral ivermectin, whereas 7/29 (24%) people taking benzyl benzoate had a mild to moderate increase in skin irritation by day 2 of treatment.[19] One RCT comparing ivermectin versus lindane reported one headache in the ivermectin group.[9] Oral ivermectin has been used widely in adults with onchocerciasis, and even with repeated doses serious adverse effects have been rare.[24,25] Summary reports to the World Health Organization Collaborating Centre for International Drug Monitoring from five countries indicate that it is associated with rare severe side effects, including three convulsions and eight deaths.[26] We found no good evidence about its safety in children. An increased risk of death has been reported among elderly people taking oral ivermectin for scabies in a long term care facility.[27] It is not clear whether this was caused by oral ivermectin, interactions with other scabicides (including lindane and permethrin), or other treatments such as psychoactive drugs. Other studies reported no such complications from its use in elderly people.[28]

Comment: Case series suggest that oral ivermectin may be effective when included in the treatment of hyperkeratotic crusted scabies (also known as Norwegian scabies)[29–31] and in people with concomitant HIV disease.[4] The RCT comparing oral ivermectin versus placebo assessed outcomes 7 days after the intervention was administered, which may be an insufficient time in which to achieve cure.[5]

QUESTIONS

INTERVENTIONS

PREVENTION

Likely to be beneficial

TREATMENT

Unknown effectiveness

See glossary, p 2207

Key Messages

Prevention

- **Sunscreens in prevention (daily *v* discretionary use)** One RCT in adults in a subtropical community in Queensland, Australia found that daily compared with discretionary use of sunscreen on the head, neck, arms, and hands reduced the incidence of squamous cell carcinoma after 4.5 years.
- **Sunscreens to prevent development of new solar keratoses (*v* placebo)** One RCT in people aged over 40 years living in Victoria, Australia who had previous solar keratoses (a risk factor for squamous cell carcinoma) found that daily sunscreen reduced the incidence of new solar keratoses after 7 months compared with placebo.

Treatment

- **Micrographically controlled surgery (compared with standard surgical excision)** We found no RCTs or observational studies of sufficient quality comparing the effects of micrographically controlled surgery versus standard primary surgical excision on local recurrence rates.
- **Optimal primary excision margin** We found no RCTs or observational studies of sufficient quality relating size of primary excision margin to local recurrence rate.
- **Radiotherapy after surgery (compared with surgery alone)** We found no RCTs or observational studies of sufficient quality comparing the effects of radiotherapy after surgery versus surgery alone on local recurrence rates.

Squamous cell carcinoma of the skin (non-metastatic)

DEFINITION Cutaneous squamous cell carcinoma is a malignant tumour of keratinocytes arising in the epidermis, showing histological evidence of dermal invasion.

INCIDENCE/ PREVALENCE Incidence rates are often derived from surveys because few cancer registries routinely collect notifications of squamous cell carcinoma of the skin. Incidence rates on exposed skin vary markedly around the world according to skin colour and latitude, and range from negligible rates in black populations and white populations living at high latitudes to rates of about 1000/100 000 in white residents of tropical Australia.[1]

AETIOLOGY/ RISK FACTORS People with fair skin colour who sunburn easily without tanning, people with xeroderma pigmentosum (see glossary, p 2207),[2–4] and those who are immunosuppressed[5] are susceptible to squamous cell carcinoma. The strongest environmental risk factor for squamous cell carcinoma is chronic sun exposure. Cohort and case control studies have found that the risk of squamous cell carcinoma is three times greater in people with fair skin colour, a propensity to burn on initial exposure to sunlight, or a history of multiple sunburns. Clinical signs of chronic skin damage, especially solar keratoses, are also risk factors for cutaneous squamous cell carcinoma.[3,4] In people with multiple solar keratoses (> 15), the risk of squamous cell carcinoma is 10–15 times greater than in people with no solar keratoses.[3,4]

PROGNOSIS Prognosis is related to the location and size of tumour, histological pattern, depth of invasion, perineural involvement, and immunosuppression.[6,7] A worldwide review of 95 case series, each comprising at least 20 people, found that the overall metastasis rate for squamous cell carcinoma on the ear was 11% and on the lip 14%, compared with an average for all sites of 5%.[7] A review of 71 case series found that lesions less than 2 cm in diameter compared with lesions greater than 2 cm have less than half the local recurrence rate (7% *v* 15%), and less than a third of the rate of metastasis (9% *v* 30%).[7]

AIMS OF INTERVENTION To prevent the occurrence of squamous cell carcinoma; to achieve cure by eradicating local disease including microinvasive disease; to reduce mortality.

OUTCOMES **Prevention:** Incidence of cutaneous squamous cell carcinoma; mortality from squamous cell carcinoma. **Primary excision:** Local recurrence; survival; cosmetic outcome. **Radiotherapy after surgery:** Local recurrence; regional recurrence; survival.

METHODS *Clinical Evidence* search and appraisal May 2003, including a search for observational studies. The authors performed a supplementary search in December 2002 of reference lists of all identified review articles and relevant sections of dermatology textbooks.

QUESTION **Does the use of sunscreen help to prevent cutaneous squamous cell carcinoma?**

Adèle Green

OPTION SUNSCREEN

One RCT in people aged over 40 years living in Australia who had previous solar keratoses (a risk factor for squamous cell carcinoma) found that daily sunscreen for 7 months reduced the incidence of new solar keratoses compared with placebo. One RCT in adults in a subtropical community in Queensland, Australia found that daily compared with discretionary use of sunscreen on the head, neck, arms, and hands reduced the incidence of squamous cell carcinoma after 4.5 years.

Benefits: We found no systematic review. **Versus placebo:** One RCT (588 people with previous solar keratoses, aged > 40 years, living in Victoria, Australia) found that, compared with placebo, daily use of sunscreen significantly reduced the risk of new solar keratoses over 7 months (mean number of new lesions per person: 1.6 with sunscreen *v* 2.3 with placebo; RR 0.62, 95% CI 0.54 to 0.71), and significantly increased lesion remission (OR 1.5, 95% CI 1.3 to 1.8).[8] **Daily versus discretionary use:** One RCT (1621 adults in a subtropical community in Queensland, Australia) compared daily sunscreen (sun protection factor 15+) versus sunscreen at their usual discretionary rate.[9] People allocated to daily sunscreen were told to apply it to the head, neck, arms, and hands every morning and to reapply it after heavy sweating, bathing, or long sun exposure. They were reminded of this advice every 3 months by research staff when sunscreen supplies were replenished. The RCT found that daily sunscreen significantly reduced the incidence of squamous cell carcinoma tumours after 4.5 years compared with discretionary sunscreen (22 people with 28 new squamous cell carcinomas with daily sunscreen *v* 25 people with 46 new squamous cell carcinomas with discretionary sunscreen use; RR 0.61, 95% CI 0.46 to 0.81). Subgroup analysis found no significant difference between people with a history of skin cancer and those without.[9] However, confidence intervals were wide, suggesting that the subgroup analysis may have lacked sufficient power to rule out a clinically important difference.

Harms: Daily sunscreen caused contact allergy in a small proportion of users (< 10%)[8,10] and skin irritation in a variable proportion of users (2–15%).[8,9,10] In the placebo controlled RCT, no people tested were allergic to the active ingredients of sunscreen, but irritant reactions both to active sunscreen and the control base cream were observed.[8,10] The RCT of regular versus discretionary use found that daily sunscreen use was not associated with greater sun exposure, including recreational exposure.[9] However, another RCT assessing sun exposure times among young adults who used sunscreen while intentionally exposing themselves to the sun ("sunbathing") found that a sun protection factor 30 sunscreen compared with a sun protection factor 10 sunscreen was associated with significantly longer exposure times.[11]

Comment: In a long term prevention trial with skin cancer as the outcome, placebo sunscreen may be regarded as unethical. It would also be difficult to mask treatment allocation.

QUESTION **What is the optimal margin for primary excision of cutaneous squamous cell carcinoma?**

Robin Marks

OPTION **OPTIMAL PRIMARY EXCISION MARGIN**

We found no RCTs or observational studies of sufficient quality relating size of primary excision margin to local recurrence rate.

Benefits: We found no systematic review or RCTs assessing different excision margins at any sites measuring local recurrence (see comment below).

Harms: We found no RCTs. As with all kinds of surgery, there is a potential for tissue destruction and scarring — particularly of vital structures such as eyelids, lip margins, and motor and sensory nerves.

Comment: One prospective case series using micrographically controlled surgery (see glossary, p 2207) assessed excision margins in relation to histological extension of the tumour and found a 95% clearance rate of squamous cell carcinomas less than 2 cm in diameter with a margin of 4 mm of normal skin, and a 96% clearance rate of tumours greater than 2 cm with a margin of 6 mm.[12] The sites of scalp, ears, eyelid, nose, and lip were found to have more deeply invasive tumours. Numerous case series suggest that primary excision of cutaneous squamous cell carcinoma has a likelihood of local recurrence varying from 5–20% depending on tumour size, site, histopathological differentiation, perineural involvement, and depth of invasion.[7,13–18]

QUESTION **Does micrographically controlled surgery result in lower rates of local recurrence than standard primary excision?**

OPTION **MICROGRAPHICALLY CONTROLLED SURGERY VERSUS PRIMARY EXCISION**

We found no RCTs or observational studies of sufficient quality comparing the effects of micrographically controlled (Mohs') surgery versus standard primary surgical excision on local recurrence rates.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: Although we found no RCTs, it is thought that with all kinds of surgery there is potential for tissue destruction and scarring particularly of vital structures such as eyelids, lip margins, and motor and sensory nerves. However, Mohs' microscopic surgery (see glossary, p 2207) is considered more tissue sparing because of its specificity in determining the amount of normal surrounding tissue removed.

Comment: A review of case series since 1940 suggested a local recurrence rate of 3% after Mohs' surgery compared with 8% after primary excision of cutaneous squamous cell carcinoma. However, the evidence must be treated with caution because of differing study quality, the long time period covered, and potential differences between people treated with Mohs' surgery and those treated with non-Mohs' surgery.[7] A site specific comparison found lower 5 year local recurrence rates after Mohs' surgery than after primary excision for squamous cell carcinoma of the lip (2% with Mohs' *v* 16% with primary excision) and of the ear (5% with Mohs' *v* 19% with primary excision).[7]

QUESTION Does radiotherapy after surgery effect local recurrence of cutaneous squamous cell carcinoma?

Adèle Green

OPTION RADIOTHERAPY AFTER SURGERY

We found no RCTs or observational studies of sufficient quality comparing the effects of radiotherapy after surgery versus surgery alone on local recurrence rates.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: Although not measured, there is the potential for long term scar deterioration with postradiation depigmentation and gradual development of chronic radiodermatitis, including telangiectasiae, thinning of the skin, and hyperkeratosis (see glossary, p 2207).

Comment: In rare instances, squamous cell carcinomas cannot be excised completely and these have recurrence rates of over 50%.[19,20] Case series of inadequately excised squamous cell carcinomas, especially those with microscopic perineural invasion (see glossary, p 2207) found at the time of curative surgery, have reported recurrence rates of 20–25% after 5 years when surgery was followed by radiotherapy.[21,22] Ability to detect advanced perineural invasion can be enhanced by computerised tomography or magnetic resonance imaging.[23]

GLOSSARY

Hyperkeratosis Increased scaling on the surface of the skin.

Micrographically controlled surgery Does not use standard excision margins as the basis for achieving tumour clearance. The visible tumour and a thin margin of apparently normal skin are removed, mapped, and examined microscopically using a specialised sectioning technique at the time of surgery, and the surgery continues until there is microscopic confirmation of complete tumour clearance, at which stage the wound is closed.[24]

Perineural invasion Tumour invasion along (not in) a nerve.

Radiodermatitis Chronic non-malignant changes in the skin due to excessive radiation.

Telangiectasiae Permanently dilated small blood vessels in the skin.

Xeroderma pigmentosum An inherited disorder with defective repair of DNA damage caused by ultraviolet radiation, resulting in sun related skin cancers of all types at an early age.

Squamous cell carcinoma of the skin (non-metastatic)

Michael Bigby, Sam Gibbs, Ian Harvey, and Jane Sterling

QUESTIONS

INTERVENTIONS

See glossary, p 2222

Key Messages

Treatments

- **Topical treatments containing salicylic acid** One systematic review has found that simple topical treatments containing salicylic acid increase complete wart clearance, successful treatment, or loss of one or more warts after 6–12 weeks compared with placebo. The review identified two RCTs comparing salicylic acid versus cryotherapy. These found no significant difference in the proportion of people with wart clearance at 3–6 months.
- **Cryotherapy** One systematic review of two small RCTs found no significant difference between cryotherapy and placebo or no treatment in the proportion of people with wart clearance after 2–4 months. However, the RCTs may have been too small to detect a clinically important difference. The review identified two RCTs that found no significant difference between cryotherapy and salicylic acid in the proportion of people with wart clearance at 3–6 months. The review found that aggressive cryotherapy increased the proportion of people with wart clearance after 1–3 months compared with gentle cryotherapy.
- **Contact immunotherapy (dinitrochlorobenzene)** One systematic review found that contact immunotherapy using dinitrochlorobenzene increased wart clearance compared with placebo.
- **Carbon dioxide laser** One systematic review identified no RCTs on the effects of carbon dioxide laser.

Warts

- **Cimetidine** Three small RCTs provided insufficient evidence to compare cimetidine versus placebo, and one small RCT provided insufficient evidence to compare cimetidine versus local treatments. One small RCT found that cimetidine plus levamisole increased wart clearance at 12 weeks compared with cimetidine alone.
- **Distant healing** One RCT provided insufficient evidence to compare distant healing versus no treatment.
- **Hypnotic suggestion** We found no RCTs on the effects of hypnotic suggestion in the clearance of warts.
- **Inosine pranobex** One RCT provided insufficient evidence about the effects of inosine pranobex on wart clearance.
- **Intralesional bleomycin** RCTs found conflicting evidence on the effects of intralesional bleomycin. Two RCTs found that intralesional bleomycin increased the number of warts cured after 6 weeks compared with placebo. One RCT found no significant difference between bleomycin and placebo in the proportion of people with wart clearance after 30 days, and another RCT found weak evidence that bleomycin cured fewer warts than placebo after 3 months. A fifth RCT found no significant difference between different concentrations of bleomycin in the proportion of warts cured after 3 months.
- **Levamisole** Two RCTs and one CCT provided insufficient evidence on the effects of levamisole compared with placebo on the clearance of warts. One RCT found that levamisole plus cimetidine increased wart clearance at 12 weeks compared with cimetidine alone.
- **Photodynamic treatment** RCTs provided insufficient evidence on the effects of photodynamic treatment on wart clearance.
- **Pulsed dye laser** One RCT provided insufficient evidence on the effects of pulsed dye laser.
- **Surgical procedures** One systematic review identified no RCTs on the effects of surgical procedures on wart clearance.
- **Systemic interferon α** We found no RCTs of sufficient quality on the effects of systemic interferon α.
- **Homeopathy** Two RCTs found no significant difference between homeopathy and placebo in the proportion of people with wart clearance after 8–18 weeks.

DEFINITION Non-genital warts (verrucas) are an extremely common, benign, and usually self limiting skin disease. Infection of epidermal cells with the human papillomavirus results in cell proliferation and a thickened, warty papule on the skin. Any area of skin can be infected, but the most common sites involved are the hands and feet. Genital warts are not covered in this review (see chapter on genital warts, p 2089).

INCIDENCE/ PREVALENCE There are few reliable, population based data on the incidence and prevalence of non-genital warts. Prevalence probably varies widely between different age groups, populations, and periods of time. Two large population based studies found prevalence rates of 0.84% in the USA[1] and 12.9% in Russia.[2] Prevalence is highest in children and young adults, and two studies in school populations have shown prevalence rates of 12% in 4–6 year olds in the UK[3] and 24% in 16–18 year olds in Australia.[4]

AETIOLOGY/ RISK FACTORS Warts are caused by human papillomavirus, of which there are over 70 different types. They are most common at sites of trauma, such as the hands and feet, and probably result from inoculation of virus into minimally damaged areas of epithelium. Warts on the feet can be acquired from walking barefoot in communal areas where other people walk barefoot. One observational study (146 adolescents) found that the prevalence of warts on the feet was 27% in those that used a communal shower room compared with 1.3% in those that used the locker room.[5] Warts on the hand are also an occupational risk for butchers and meat handlers. One cross-sectional survey (1086 people) found that the prevalence of warts on the hand was 33% in abattoir workers, 34% in retail butchers, 20% in engineering fitters, and 15% in office workers.[6] Immunosuppression is another important risk factor. One observational study in immunosuppressed renal transplant recipients found that at 5 years or longer after transplantation 90% had warts.[7]

PROGNOSIS Non-genital warts in immunocompetent people are harmless and usually resolve spontaneously as a result of natural immunity within months or years. The rate of resolution is highly variable and probably depends on several factors, including host immunity, age, human papillomavirus type, and site of infection. One cohort study (1000 children in long stay accommodation) found that two thirds of warts resolved without treatment within a 2 year period.[8] One systematic review (search date 2000, 17 RCTs) comparing local treatments versus placebo found that about 30% of people using placebo (range 0–73%) had no warts after about 10 weeks (range 4–24 weeks).[9]

AIMS OF INTERVENTION To eliminate warts, with minimal adverse effects.

OUTCOMES Wart clearance (generally accepted as complete eradication of warts from the treated area); adverse effects of treatment; recurrence.

METHODS *Clinical Evidence* search and appraisal September 2003 and hand searches by the contributors. We have reported wart clearance where possible. However, some RCTs reported outcomes such as number of warts cured or loss of single warts. Where RCTs have reported outcomes other than wart clearance this has been highlighted in the text.

QUESTION What are the effects of treatments?

OPTION INTRALESIONAL BLEOMYCIN

Sam Gibbs, Ian Harvey, and Jane Sterling

RCTs found conflicting evidence on the effects of intralesional bleomycin. Two RCTs found that intralesional bleomycin increased the number of warts cured after 6 weeks compared with placebo. One RCT found no significant difference between bleomycin and placebo in the proportion of people with wart clearance after 30 days, and another RCT found weak

evidence that bleomycin cured fewer warts than placebo after 3 months. A fifth RCT found no significant difference between different concentrations of bleomycin in the proportion of warts cured after 3 months.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 159 people).[9] The review did not perform a meta-analysis because of trial heterogeneity. **Versus placebo:** Four RCTs (133 people) identified by the review compared intralesional bleomycin versus placebo.[10–13] The first RCT (24 adults with warts unsuccessfully treated for > 3 months) compared bleomycin 0.1% versus saline placebo.[10] Matched pairs of warts on the left and right side of the body were injected with bleomycin or saline. It found that bleomycin significantly increased the proportion of people with a more favourable response (not defined) after 6 weeks compared with placebo (21/24 [88%] with bleomycin *v* 3/24 [13%] with placebo; $P < 0.001$) and increased the number of warts cured after 6 weeks (34/59 [58%] with bleomycin *v* 6/59 [10%] with placebo; $P < 0.001$).[10] The second small RCT (16 people) found that bleomycin 0.1% significantly increased the number of warts cured at 6 weeks compared with placebo (31/38 [82%] with bleomycin *v* 16/46 [34%] with placebo; $P < 0.001$; see comment below).[11] The third RCT (62 adults) compared four groups: bleomycin 0.1% in saline, bleomycin 0.1% in oil, saline placebo, and sesame oil placebo.[12] It found no significant difference between individual groups (P value not reported) but combined results for bleomycin compared with combined results for placebo found significantly fewer warts cured with bleomycin after 3 months (4/22 [18%] with bleomycin in saline *v* 5/22 [23%] with bleomycin in oil *v* 8/19 [42%] with saline placebo *v* 5/11 [46%] with sesame oil placebo; $P = 0.018$; see comment below). The fourth RCT (31 people), which compared 0.1% bleomycin versus placebo, found no significant difference in the proportion of people with wart clearance after 30 days (15/16 [94%] with bleomycin *v* 11/15 [73%] with placebo; RR 1.28, 95% CI 0.92 to 1.78).[13] **Different concentrations of bleomycin:** The fifth RCT (26 adults) found no significant difference between bleomycin 0.25, 0.5, and 1.0% in the proportion of warts cured after 3 months (11/15 [73%] with 0.25% *v* 26/30 [86%] with 0.5% *v* 25/34 [74%] with 1.0%; $P > 0.05$; see comment below).[14]

Harms: **Versus placebo:** In the first RCT, one person withdrew because of pain during injection and one withdrew because of pain after injection.[10] The third RCT reported dullness, pain, swelling, or bleeding in 19/62 (31%) of all participants but did not specify which treatment they received.[12] The other RCTs found that pain was experienced by most people (no further data reported).[11,14] In two of the RCTs, local anaesthetic was used routinely before the injection of bleomycin.[11,13] **Different concentrations of bleomycin:** The RCT comparing different concentrations of bleomycin reported pain at the injection site in most people, irrespective of dose (no further data reported).[14]

Comment: The results of two of the RCTs should be interpreted with caution as they randomised people but analysed number of warts cured rather than proportion of people cured.[11,12] In the RCT comparing different

concentrations of bleomycin, the disparity in the number of warts assessed in each group could be explained by the exclusion of warts that spontaneously regressed from the analysis, and by a high withdrawal rate in people receiving bleomycin 0.25%.[14]

OPTION CARBON DIOXIDE LASER

Sam Gibbs, Ian Harvey, and Jane Sterling

One systematic review identified no RCTs on the effects of carbon dioxide laser.

Benefits: One systematic review (search date 2000) identified no RCTs.[9]

Harms: We found no RCTs.

Comment: None.

OPTION CIMETIDINE

Michael Bigby

Three small RCTs provided insufficient evidence to compare cimetidine versus placebo, and one small RCT provided insufficient evidence to compare cimetidine versus local treatments. One small RCT found that cimetidine plus levamisole increased wart clearance at 12 weeks compared with cimetidine alone.

Benefits: We found no systematic review. **Versus placebo:** We found three small RCTs.[15–17] The first RCT (39 people aged > 15 years), which compared cimetidine 2400 mg daily versus placebo, found no significant difference in the proportion of people with wart clearance after 12 weeks (5/19 [26%] with cimetidine *v* 1/20 [5%] with placebo; RR 3.14, 95% CI 0.75 to 5.66).[15] The second RCT (54 people), which compared cimetidine (400 mg 3 times daily) versus placebo, found no significant difference in the proportion of people with wart clearance after 12 weeks (10/36 [27%] with cimetidine *v* 4/18 [22%] with placebo; RR 1.3, 95% CI 0.5 to 3.4).[16] The third RCT (70 women and children), which compared cimetidine 25–40 mg/kg versus placebo, found no significant difference in the proportion of people with wart clearance after 3 months (9/35 [26%] with cimetidine *v* 8/35 [23%] with placebo; RR 1.1, 95% CI 0.5 to 2.6).[17] **Versus local treatments:** One small RCT (13 people) compared cimetidine 30–40 mg/kg versus topical treatment (cryotherapy [see glossary, p 2222], salicylic acid, and other [not specified]).[18] It found no significant difference between cimetidine and topical treatments in the proportion of people with wart clearance after 8 weeks (2/6 [33%] with cimetidine *v* 3/7 [42%] with topical treatments; RR 0.78, 95% CI 0.19 to 3.21). **Cimetidine plus levamisole:** See benefits of levamisole, p 2219.

Harms: **Versus placebo:** Two of the RCTs, which compared cimetidine versus placebo, found no adverse effects associated with cimetidine.[16,17] The third RCT found no significant difference between cimetidine and placebo in the proportion of people with gastrointestinal symptoms, fatigue, dyspnoea, or hair thinning (5/19 [26%] with cimetidine *v* 5/21 [24%] with placebo).[15] **Versus local**

treatments: In the RCT comparing cimetidine with local treatments, 1/6 [17%] people taking cimetidine developed watery, green diarrhoea, and 1/6 [17%] had a rash and abdominal pain.[18] **Cimetidine plus levamisole:** See harms of levamisole, p 2219.

Comment: The RCTs may have been too small to exclude a clinically important difference between treatments.[15–18]

OPTION CRYOTHERAPY

Sam Gibbs, Ian Harvey, and Jane Sterling

One systematic review of two small RCTs found no significant difference between cryotherapy and placebo or no treatment in the proportion of people with wart clearance after 2–4 months. However, the RCTs may have been too small to detect a clinically important difference. The review identified two RCTs that found no significant difference between cryotherapy and salicylic acid in the proportion of people with wart clearance at 3–6 months. The review found that aggressive cryotherapy increased the proportion of people with wart clearance after 1–3 months compared with gentle cryotherapy.

Benefits: We found one systematic review (search date 2000, 13 RCTs, 1389 people).[9] **Versus placebo or no treatment:** The review found no significant difference between cryotherapy (see glossary, p 2222) and topical placebo cream or no treatment in the proportion of people with wart clearance at 2–4 months (2 RCTs, 69 people: 11/31 [35%] with cryotherapy *v* 13/38 [34%] with placebo or no treatment; RR 0.95, 95% CI 0.49 to 1.84).[9] **Versus photodynamic treatment:** One RCT identified by the review (28 adults receiving topical salicylic acid) compared cryotherapy versus four different types of photodynamic treatment (see glossary, p 2222) (3 episodes of white light photodynamic treatment, 1 episode of white light photodynamic treatment, 3 episodes of red light photodynamic treatment, and 3 episodes of blue light photodynamic treatment).[19] It found that cryotherapy reduced the number of warts significantly less than white light or red light photodynamic treatment after 4–6 weeks (20% with cryotherapy *v* 73% with white photodynamic treatment 3 times [$P < 0.01$] *v* 71% with white photodynamic treatment once [P value not reported] *v* 42% with red light photodynamic treatment 3 times [$P = 0.03$]). **Versus salicylic acid:** The review found no significant difference between cryotherapy and salicylic acid in the proportion of people with wart clearance at 3–6 months (2 RCTs, 320 people: 107/165 [65%] with cryotherapy *v* 96/155 [62%] with salicylic acid; RR 1.04, 95% CI 0.88 to 1.22).[9] **Aggressive versus gentle cryotherapy (defined by length of freeze):** Four RCTs (592 adults) identified by the review found that aggressive compared with gentle cryotherapy significantly increased the proportion of people with wart clearance after 1–3 months (159/304 [52%] with aggressive cryotherapy *v* 89/288 [31%] with gentle cryotherapy; RR 1.68, 95% CI 1.37 to 2.06; NNT 5, 95% CI 4 to 7).[9] Definitions of aggressive and gentle differed and some RCTs included warts that were resistant to treatment and others did not. **Interval between freezes:** Three RCTs (313 people) identified by the review found no significant difference between cryotherapy at 2, 3, or 4 weekly

intervals in wart clearance at the end of the trial (not specified).[9] **Number of freezes:** One RCT (115 people not cured after 3 months of 3 weekly cryotherapy) identified by the review found no significant difference between no further treatment and prolonging cryotherapy for a further 3 months in the proportion of people with wart clearance (after a total of 6 months: 43% with no further treatment *v* 38% with prolonged cryotherapy; no further data reported to calculate RR).[9]

Harms: **Versus placebo or no treatment:** The review did not report on harms. **Versus photodynamic treatment:** In the RCT comparing cryotherapy versus photodynamic treatment, one person receiving cryotherapy withdrew because of pain.[19] Photodynamic treatment was associated with burning and itching during the first few minutes of treatment and mild discomfort throughout treatment in all people receiving it. **Versus salicylic acid:** The review did not report on harms. **Aggressive versus gentle cryotherapy:** One RCT identified by the review found that aggressive compared with gentle cryotherapy significantly increased pain or blistering (64/100 [64%] with aggressive cryotherapy *v* 44/100 [44%] with gentle cryotherapy; RR 1.44, 95% CI 1.14 to 1.75; NNH 5, 95% CI 3 to 16).[20] Five people withdrew from the aggressive group and one from the gentle group because of pain and blistering. **Interval between freezes:** One RCT identified by the review found that cryotherapy at 1 weekly intervals was associated with pain, blistering, or both in 29% of people; at 2 weekly intervals in 7%; and at 3 weekly intervals in 0% (no further data reported).[21] **Number of freezes:** The review did not report on harms.

Comment: The evidence from available RCTs about cryotherapy is both limited and contradictory. Heterogeneity of study design, methodology, and the populations included make it extremely difficult to draw firm conclusions.[9] For instance, some RCTs identified by the review included all types of warts on the hands and feet in all age groups, whereas others were more selective and simply looked at hand warts, or excluded certain groups such as mosaic plantar warts or warts that were resistant to treatment. Of particular note is the likelihood that wart clinic populations used for these studies might have had different characteristics in different periods of time. For instance, hospital based studies carried out in the 1970s in the UK would have included a higher proportion of people with warts that had never been treated before, which have a greater chance of cure, spontaneous resolution, or both. In the 1980s and 1990s more people with warts were being treated in primary care; consequently, the people included in hospital based RCTs were more likely to have warts that were resistant to treatment, with correspondingly lower cure rates.

OPTION DISTANT HEALING

Michael Bigby

One RCT provided insufficient evidence to compare distant healing versus no treatment.

Warts

Benefits: We found no systematic review. One double blind RCT (84 people) compared distant healing (see glossary, p 2222) (see comment below) versus no treatment.[22] Wart clearance was not reported. It found no significant difference between distant healing and no treatment in proportion of warts at 6 weeks (increase of 0.2 warts with distant healing *v* decrease of 1.1 warts with no treatment; P = 0.25) or in mean change in size of three representative warts.

Harms: The RCT gave no information on adverse effects.[22]

Comment: In the RCT 10 experienced healers located within 150 miles of the area in which participants lived performed distant healing for 6 weeks.[22]

OPTION HOMEOPATHY

Michael Bigby

Two RCTs found no significant difference between homeopathy and placebo in the proportion of people with wart clearance after 8–18 weeks.

Benefits: We found no systematic review but found two RCTs comparing homeopathy versus placebo.[23,24] The first RCT (174 people), which compared homeopathy (Thuya 30CH, antimony crudum 7CH, nitricium acidum 7CH for 6 weeks) versus placebo found no significant difference between groups in the proportion of people with wart clearance after 18 weeks (16/80 [20%] with homeopathy *v* 20/82 [24%] with placebo; ARR +4%, 95% CI –8% to +17%).[23] The second RCT (67 people) found no significant difference between homeopathy (individually selected regimen) and placebo in the proportion of people with wart clearance after 8 weeks (5/34 [15%] with homeopathy *v* 1/33 [3%] with placebo; RR 4.85, 95% CI 0.60 to 39.35).[24]

Harms: The first RCT found no significant difference between homeopathy and placebo in the proportion of people with stomach ache, loose stools, fatigue, and acne (2/86 [2%] with homeopathy *v* 4/88 [5%] with placebo; RR 0.51, 95% CI 0.10 to 2.72).[23] The second RCT gave no information on adverse effects.[24]

Comment: Performing RCTs of homeopathic treatment is difficult because a major principle of homeopathy is to individualise treatment to the overall condition of the person. One RCT overcame this difficulty by allowing practitioners to evaluate all people before randomisation and select homeopathic regimens appropriate to each of their overall conditions.[24] People were then randomised to their individually selected regimen (10 different regimens were used) or to placebo.

OPTION HYPNOTIC SUGGESTION

Michael Bigby

We found no RCTs on the effects of hypnotic suggestion in the clearance of warts.

Benefits: We found no systematic review or RCTs that assessed the effects of hypnotic suggestion on complete wart clearance. We found three RCTs that assessed the effects of hypnotic suggestion on the loss of one single wart (see comment below).[25,26]

Harms: The RCTs of loss of one wart gave no information on adverse effects.[25,26]

Comment: **Versus topical salicylic acid, topical placebo, or no treatment:** Three RCTs, two of which were reported in the same article, assessed the effects of hypnotic suggestion on the loss of one wart.[25,26] The first RCT (40 people) compared four treatments: hypnotic suggestion, topical salicylic acid, topical placebo, and no treatment.[25] People were given a 10 minute hypnotic induction procedure involving inter related suggestions for sleep, drowsiness, and entering hypnosis, followed by a 2 minute suggestion of wart regression imagery repeated again after 30 seconds. People were then awakened and instructed to practice their wart regression imagery twice daily for 6 weeks.[25] It found that hypnotic suggestion significantly increased the proportion of people with loss of one wart at 6 weeks compared with salicylic acid, topical placebo, or no treatment (6/10 [60%] with hypnosis *v* 0/10 [0%] with salicylic acid *v* 1/10 [10%] with topical placebo *v* 3/10 [30%] with no treatment; $P < 0.05$). **Versus sham laser or no treatment:** The second RCT (64 people) compared three treatments: hypnotic suggestion, sham laser, and no treatment.[26] It used the same procedure for hypnotic suggestion as the first RCT, except people were given a 5 minute hypnotic induction.[26] The cold laser placebo group in the RCT received two 4 minute treatments with a simulated laser and were told to count their warts daily and assess whether they experienced any sensations in their warts. It found that hypnosis significantly increased the proportion of people with loss of one wart after 6 weeks compared with no treatment (11/22 [50%] with hypnosis *v* 2/17 [12%] with no treatment; $P < 0.01$). It found that a higher proportion of people treated with hypnosis compared with sham treatment lost at least one wart but the difference was not significant (11/22 [50%] with hypnosis *v* 6/24 [25%] with sham treatment; $P = 0.06$). People who lost warts had significantly more warts at baseline than those who did not lose warts ($P < 0.01$).[26] **Versus hypnotic suggestion plus relaxation or no treatment:** The third RCT (76 people) compared four groups: hypnotic suggestion, hypnotic suggestion plus relaxation, suggestion alone, and no treatment.[26] It used the same hypnotic suggestion as the second RCT. The hypnotic suggestion plus relaxation group received a 5 minute relaxation procedure involving interrelated suggestions for relaxation and comfort instead of the induction procedure, and the suggestion alone group received suggestions for wart regression without the hypnotic induction procedure.[26] It found that hypnotic suggestion significantly increased the proportion of people who lost warts after 6 weeks compared with no treatment (4/19 [21%] with hypnotic suggestion *v* 0/19 [0%] with no treatment; $P < 0.05$). However, it found no significant difference between hypnotic suggestion plus relaxation and no treatment (2/19 [11%] with hypnotic suggestion plus relaxation *v* 0/19 [0%] with no treatment; no further data reported).

OPTION CONTACT IMMUNOTHERAPY

Sam Gibbs, Ian Harvey, and Jane Sterling

One systematic review found that contact immunotherapy (see glossary, p 2222) using dinitrochlorobenzene increased wart clearance compared with placebo.

Benefits: We found one systematic review (search date 2000, 2 RCTs, 80 people).[9] It found that dinitrochlorobenzene 2% solution followed by 1% solution significantly increased the proportion of people with wart clearance at the end of the trial compared with placebo (32/40 [80%] with dinitrochlorobenzene *v* 15/40 [38%] with placebo; RR 1.88, 95% CI 1.27 to 2.79). The end of trial was 4 months in one RCT and unspecified in the other.[9]

Harms: The systematic review gave no information on adverse effects.[9] One of the RCTs identified by the review found that 6/20 (30%) of people developed an inflammatory reaction to dinitrochlorobenzene 2% solution only after the second application, but that all of these people subsequently experienced significant local irritation with or without blistering when they were treated with dinitrochlorobenzene 1% solution.[27] No-one withdrew from the study.

Comment: None.

OPTION INOSINE PRANOBEX

Michael Bigby

One RCT provided insufficient evidence about the effects of inosine pranobex on wart clearance.

Benefits: We found no systematic review. We found one RCT (50 people aged > 12 years receiving topical salicylic acid and cryotherapy [see glossary, p 2222]), which compared inosine pranobex (1 g 3 times daily for 1 month) versus placebo.[28] It found no significant difference in the proportion of people with wart clearance at 6 months (9/24 [38%] with inosine pranobex *v* 9/26 [35%] with placebo; RR 1.08, 95% 0.52 to 2.27).[28]

Harms: One person taking inosine pranobex developed a sore throat.[28]

Comment: The RCT could have been too small to exclude a clinically important difference between treatments.

OPTION SYSTEMIC INTERFERON α

Michael Bigby

We found no RCTs of sufficient quality on the effects of systemic interferon α.

Benefits: We found no systematic review and no RCTs of sufficient quality.

Harms: We found no RCTs.

Comment: None.

OPTION LEVAMISOLE

Michael Bigby

Two RCTs and one CCT provided insufficient evidence on the effects of levamisole compared with placebo on clearance of warts. One RCT found that levamisole plus cimetidine increased wart clearance at 12 weeks compared with cimetidine alone.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs[29,30] and one CCT.[31] The first RCT (60 people), which compared levamisole (150 mg 3 times weekly for 10 weeks) versus placebo, found no significant difference between groups in the proportion of people with wart clearance after 3 months (5/29 [17%] with levamisole *v* 6/31 [19%] with placebo; RR 0.89, 95% CI 0.30 to 2.61).[29] The second RCT (32 people), which compared levamisole (2.5 mg/kg twice weekly) versus placebo, found no significant difference between groups in wart clearance after 8 weeks (7/14 [50%] with levamisole *v* 10/18 [55%] with placebo; RR 0.90, 95% CI 0.46 to 1.75).[30] **Levamisole plus cimetidine:** One RCT (48 people) found that levamisole (150 mg twice weekly) plus cimetidine (30 mg/kg daily divided into 3 doses) versus cimetidine alone 30 mg/kg daily significantly increased the proportion of people with wart clearance at 12 weeks (15/24 [62%] with cimetidine plus levamisole *v* 8/24 [33%] with cimetidine alone; RR 1.78, 95% CI 1.01 to 2.49).[32]

Harms: **Versus placebo:** The RCTs and CCT comparing levamisole versus placebo gave no information on adverse effects.[29–31] **Levamisole plus cimetidine:** In the RCT that compared levamisole plus cimetidine versus cimetidine alone, two people taking levamisole plus cimetidine withdrew because of severe nausea.[32] One person taking levamisole plus cimetidine and one person taking cimetidine alone experienced change in taste and constitutional symptoms (fatigue, weakness, and myalgia).[32]

Comment: The RCTs may have been too small to detect a clinically important difference between treatments.[29,30] One CCT (40 people), which compared levamisole (5 mg/kg for 3 days every 2 weeks) versus placebo, found that levamisole significantly increased the proportion of people with wart clearance after 5 months (12/20 [60%] with levamisole *v* 1/20 [5%] with placebo; RR 12.0, 95% CI 1.7 to 83.8).[31] The lack of randomisation in the CCT means that the results should be interpreted with caution.[31]

OPTION PHOTODYNAMIC TREATMENT

Sam Gibbs, Ian Harvey, and Jane Sterling

RCTs provided insufficient evidence on the effects of photodynamic treatment on wart clearance.

Benefits: We found one systematic review (search date 2000, 4 RCTs, 240 people)[9] and one subsequent RCT.[33] **Versus placebo:** The review could not perform a meta-analysis because of trial heterogeneity; one of the RCTs assessed complete wart clearance, the others assessed proportion of warts cured.[9] The first RCT (52 people) in

the review compared proflavine photodynamic treatment (see glossary, p 2222) or neutral red photodynamic treatment versus placebo in a left/right hand design.[34] Matched pairs of warts on the left and right hands were treated with photodynamic treatment or placebo. It found no significant difference between proflavine photodynamic treatment and neutral red photodynamic treatment in the proportion of people with wart clearance after 8 weeks (10/27 [37%] with proflavine photodynamic treatment *v* 10/23 [43%] with neutral red photodynamic treatment; RR 0.85, 95% CI 0.43 to 1.68). In all those who responded to treatment, the warts on the placebo treated side also resolved.[34] The second RCT in the review (45 adults with warts unsuccessfully treated for > 3 months), which compared aminolaevulinic acid photodynamic treatment versus placebo photodynamic treatment, found that aminolaevulinic acid photodynamic treatment significantly increased the proportion of warts cured after 18 weeks (64/114 [56%] with aminolaevulinic acid photodynamic treatment *v* 47/113 [42%] with placebo photodynamic treatment; $P < 0.05$).[35] One subsequent RCT (67 people with warts unsuccessfully treated for > 12 months who had received keratolytic ointment under an occlusive dressing for 7 days) compared aminolaevulinic acid photodynamic treatment three times versus placebo photodynamic treatment.[33] It found that aminolaevulinic acid photodynamic treatment compared with placebo significantly increased the number of warts cured after 4 months (48/64 [75%] with aminolaevulinic acid photodynamic treatment *v* 13/57 [23%] with placebo; $P < 0.01$). **Versus cryotherapy:** See glossary, p 2222. The review identified one RCT (see benefits of cryotherapy, p 2214). **Versus salicylic acid plus creosote:** One RCT (120 people) identified by the review found no significant difference between methylthioninium chloride (methylene blue)/dimethyl sulfoxide (dimethyl sulphoxide) photodynamic treatment and salicylic acid plus creosote in the proportion of people with wart clearance after 8 weeks (5/65 [8%] with methylthioninium chloride/dimethyl sulfoxide *v* 8/55 [15%] with salicylic acid; RR 0.54, 95% CI 0.19 to 1.55).[36]

Harms: **Versus placebo:** One of the RCTs identified by the review found that aminolaevulinic acid photodynamic treatment significantly increased the risk of painful warts (light–unbearable pain) immediately after treatment compared with placebo.[35] Burning and itching continued for up to 48 hours in some people and 3/30 (10%) withdrew because of pain during treatment. The subsequent RCT found that people receiving aminolaevulinic acid photodynamic treatment experienced a burning sensation or slight pain during treatment, and moderate swelling and mild erythema of the treated area 24 hours after treatment.[33] **Versus cryotherapy:** See harms of cryotherapy, p 2215. **Versus salicylic acid plus creosote:** The RCT did not report on harms.

Comment: Unpublished data from the subsequent RCT showed cure rates at 22 months of 45/64 (71%) with photodynamic treatment compared with 13/57 (23%) with placebo and, using patients as the unit of analysis, 26/34 (76%) with photodynamic treatment versus 13/33 (42%) with placebo. Differences in trial methodology makes it difficult to draw conclusions.[9]

OPTION PULSED DYE LASER

Sam Gibbs, Ian Harvey, and Jane Sterling

One RCT provided insufficient evidence on the effects of pulsed dye laser.

Benefits: We found one systematic review (search date 2000, 1 RCT).[9] The RCT (40 people using daily topical salicylic acid, 194 warts) in the review compared pulsed dye laser versus cryotherapy (see glossary, p 2222) or cantharidin.[37] All treatments were used at monthly intervals up to a maximum of four times. It found no difference between pulsed dye laser and cryotherapy or cantharidin in complete wart clearance at the end of the study (66% with pulsed dye laser *v* 70% with either cryotherapy or cantharidin). Fifteen of the 35 participants were contacted by telephone at an average of 11 months after treatment. It found no significant difference between pulsed dye laser and cryotherapy or cantharidin in the proportion of these people who had recurrence of at least one wart (3/10 [30%] with pulsed dye laser *v* 2/5 [40%] with either cryotherapy or cantharidin; RR 0.75, 95% CI 0.18 to 3.14).[37]

Harms: The RCT found that no significant adverse events occurred in either treatment group.[37]

Comment: None.

OPTION TOPICAL TREATMENTS CONTAINING SALICYLIC ACID

Sam Gibbs, Ian Harvey, and Jane Sterling

One systematic review has found that simple topical treatments containing salicylic acid increase complete wart clearance, successful treatment, or loss of one or more warts after 6–12 weeks compared with placebo. The review identified two RCTs comparing salicylic acid versus cryotherapy. These found no significant difference in the proportion of people with wart clearance at 3–6 months.

Benefits: We found one systematic review (search date 2000, 9 RCTs, 816 people) of topical salicylic acid.[9] **Versus placebo or no treatment:** The review (6 RCTs, 376 people) found that salicylic acid compared with placebo significantly increased the proportion of people with either complete wart clearance, successful treatment (not defined), or loss of one or more warts after 6–12 weeks (144/191 [75%] with salicylic acid *v* 89/185 [48%] with placebo; RR 1.55, 95% CI 1.32 to 1.82; NNT 4, 95% CI 3 to 6) (see comment below). **Versus cryotherapy:** See glossary, p 2222. The review identified two RCTs (see benefits of cryotherapy, p 2214). **Salicylic acid plus creosote versus photodynamic treatment:** See glossary, p 2222. The review identified one RCT (see benefits of photodynamic treatment salicylic acid plus creosote, p 2219).

Harms: Some of the RCTs identified by the review found that salicylic acid was associated with minor skin irritation.[9]

Comment: Trial heterogeneity and poor quality of the RCTs included in the review mean that the pooled results should be treated with caution.[9] However, sensitivity analysis found that removal of the two RCTs that did not use complete wart clearance did not significantly alter the results.

Warts

OPTION **SURGICAL PROCEDURES**

Sam Gibbs, Ian Harvey, and Jane Sterling

One systematic review identified no RCTs on the effects of surgical procedures on wart clearance.

Benefits: We found one systematic review (search date 2000), which identified no RCTs.[9]

Harms: We found no evidence.

Comment: None.

GLOSSARY

Contact immunotherapy Contact sensitisers such as dinitrochlorobenzene, diphencyprone, and squaric acid dibutyl ester result in allergic dermatitis, which stimulates an immune reaction in close proximity to the wart.

Cryotherapy A destructive treatment based on the targeted freezing of tissue using liquid nitrogen, dimethyl ether propane, or carbon dioxide snow. Liquid nitrogen achieves the lowest temperatures and is now the most commonly used agent.

Distant healing A flow/channelling/projection of energy between healer and participant at a distance.

Photodynamic treatment Combines the application of a photosensitising substance (usually aminolaevulinic acid) to the wart and subsequent irradiation with wavelengths of light that are absorbed by the photosensitising substance and lead to destruction of the target tissue.

Wrinkles

Search date April 2003

Miny Samuel, Rebecca Brooke, and Christopher Griffiths

QUESTIONS

INTERVENTIONS

See glossary, p 2236

Key Messages

Prevention

- **Sunscreens; vitamins (vitamin C and vitamin E)** We found no RCTs on the effects of these interventions in preventing wrinkles.

Treatment

- **Tazarotene (0.1% strength more beneficial than lower strength or placebo)** Two RCTs in people with moderately photodamaged skin found that tazarotene cream improved fine wrinkling compared with placebo at 24 weeks. One RCT found no significant difference between tazarotene cream and tretinoin in fine wrinkling at 24 weeks.
- **Tretinoin (for fine wrinkles after 6 months)** RCTs in people with mild to moderate photodamage found that topical tretinoin applied for up to 48 weeks improved fine wrinkles compared with vehicle cream, but the effect on coarse wrinkles differed among studies. Three RCTs in people with moderate to severe photodamage found that topical tretinoin (0.01–0.02%) applied for 6 months improved fine and coarse wrinkles on the face compared with vehicle cream. Common short term adverse effects with tretinoin included itching, burning, and erythema. Skin peeling was the most common persistent adverse effect, which was most frequent and severe at 12–16 weeks.

- **Isotretinoin** In people with mild to severe photodamage, two RCTs found that isotretinoin cream improved fine and coarse wrinkles after 36 weeks compared with vehicle cream. Severe facial irritation occurred in 5–10% of people using isotretinoin.
- **Carbon dioxide laser** We found no RCTs comparing carbon dioxide laser versus placebo or no treatment. We found insufficient evidence from small RCTs about the effects of carbon dioxide laser compared with dermabrasion, chemical peel, or other laser treatments.
- **Dermabrasion** We found no RCTs comparing dermabrasion versus placebo or no treatment. Three small RCTs in women with perioral wrinkles found no significant difference between dermabrasion and carbon dioxide laser in improvement in wrinkles at 4–6 months. Adverse effects were commonly reported. Erythema was reported in all three RCTs, two of which found that erythema was more common with laser than with dermabrasion.
- **Facelift** We found no RCTs on the effects of facelifts.
- **Oral natural cartilage polysaccharides** One RCT found no significant difference between an oral preparation of cartilage polysaccharide and placebo in wrinkle appearance at 3 months. Smaller RCTs found that oral cartilage polysaccharide reduced fine, moderate, or severe wrinkles compared with placebo. However, these studies were small and of limited reliability. We found limited evidence that some preparations may be more effective than others.
- **Retinyl esters** We found no systematic review or RCTs of retinyl esters that evaluated clinical outcomes.
- **Topical antioxidants (ascorbic acid)** One poor quality RCT found limited evidence that an ascorbic acid formulation compared with a vehicle cream applied daily to the face for 3 months improved fine and coarse wrinkles. Stinging and erythema were common but were not analysed by treatment group. We were unable to draw reliable conclusions from this study.
- **Topical natural cartilage polysaccharides** One small RCT found that a topical commercial preparation of natural cartilage polysaccharide reduced the number of fine and coarse wrinkles at 120 days compared with placebo. However, we were unable to draw reliable conclusions from this study.

DEFINITION Wrinkles, also known as rhytides, are visible creases or folds in the skin. Wrinkles less than 1 mm in width and depth are defined as fine wrinkles and those greater than 1 mm are coarse wrinkles. Most RCTs have studied wrinkles on the face, forearms, and hands.

INCIDENCE/ PREVALENCE We found no information on the incidence of wrinkles alone, only on the incidence of skin photodamage (see glossary, p 2236), which includes a spectrum of features such as wrinkles, hyperpigmentation, tactile roughness, and telangiectasia. The incidence of ultraviolet light associated skin disorders increases with age and develops over several decades. One Australian study (1539 people aged 20–55 years living in Queensland) found moderate to severe photoageing in 72% of men and 47% of women under 30 years of age.[1] The severity of photoageing was significantly greater with increasing age, and was independently associated with solar keratoses ($P < 0.01$) and skin cancer ($P < 0.05$). Wrinkling was more common in people with white skin, especially skin phototypes I and II. One study reported that the incidence of photodamage in

Wrinkles

European and North American populations with Fitzpatrick skin types I, II, and III (see glossary, p 2236) is about 80–90%.[2] We found few reports of photodamage in black skin (phototypes V and VI).

AETIOLOGY/ RISK FACTORS Wrinkles may be caused by intrinsic factors (e.g. ageing, hormonal status, and intercurrent diseases) and by extrinsic factors (e.g. exposure to ultraviolet radiation and cigarette smoke). These factors contribute to epidermal thinning, loss of elasticity, skin fragility, and creases and lines in the skin. The severity of photodamage varies with skin type, which includes skin colour and the capacity to tan.[3] One review of five observational studies found that facial wrinkles in men and women were more common in smokers than in non-smokers.[4] It also found that the risk of moderate to severe wrinkles in lifelong smokers was more than twice that in current smokers (RR 2.57, 95% CI 1.83 to 3.06). Oestrogen deficiency may contribute to wrinkles in postmenopausal women.[5]

PROGNOSIS Although wrinkles cannot be considered a medical illness requiring intervention, concerns about ageing may commonly affect quality of life. Such concerns are likely to be influenced by geographical differences, culture, and personal values. In some cases concerns about physical appearance can lead to difficulties with interpersonal interactions, occupational functioning, and self esteem.[6] In societies in which the ageing population is growing and a high value is placed on the maintenance of a youthful appearance, there is a growing preference for interventions that ameliorate the visible signs of ageing.

AIMS OF INTERVENTION To prevent skin wrinkling; to improve fine and coarse wrinkling in adults; to minimise adverse effects of treatment; to improve quality of life.

OUTCOMES Physician and patient evaluation of wrinkles, and adverse effects of treatment. We excluded RCTs based solely on non-clinical outcomes, such as histological assessment, photography, or optical profilometry. Quality of life was not reported in any trial.

METHODS *Clinical Evidence* search and appraisal April 2003. Most RCTs recruited people with moderate to severe photodamage and wrinkles, rather than people with wrinkles alone.

QUESTION **What are the effects of interventions to prevent skin wrinkles?**

OPTION **SUNSCREENS**

We found no RCTs on the effects of sunscreens in preventing wrinkles.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: We found two non-systematic reviews that reported the effects of sunscreens on the incidence of photodamage and skin cancer but they did not assess the effect of sunscreens in preventing wrinkles.[7,8]

OPTION VITAMINS

We found no RCTs on the effects of vitamins C or E on wrinkles.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION What are the effects of treatments for skin wrinkles?

OPTION TOPICAL ANTIOXIDANTS

One poor quality RCT found limited evidence that an ascorbic acid formulation compared with a vehicle cream applied daily to the face for 3 months improved fine and coarse wrinkling. Stinging and erythema were common but were not quantified according to treatment. We were unable to draw reliable conclusions from this study.

Benefits: We found no systematic review. We found one small and brief crossover RCT (28 people, age 36–72 years, with mild to moderate photodamage [see glossary, p 2236]) comparing topical ascorbic acid (0.5 mL) in a vehicle cream versus the vehicle cream alone applied once daily for 12 weeks.[9] Only 19 people completed the trial. Participants were randomly assigned to treatments to the left and right sides of the face. Improvement was assessed by investigators with reference to pretreatment photographs, and graded as "much improved", "improved", "no change", or "worse". Analysis, not by intention to treat, found that significantly more people had improvement in fine and course wrinkles with ascorbic acid at 12 weeks (fine wrinkles 16/19 [84%] *v* 3/19 [15.8%]; P = 0.02; coarse wrinkles 13/19 [68%] *v* 6/19 [32%]; P = 0.01). The RCT also found that significantly more participants reported improvement in wrinkles with ascorbic acid than with vehicle cream (number of people reporting wrinkles as being "slightly improved", "improved", or "much improved": 16/19 [84%] *v* 3/19 [16%]; RR 5.33, 95% CI 1.85 to 15.34).

Harms: Adverse effects in the RCT, which were not quantified by treatment given, included stinging in 11 people (55%), erythema in five people (24%), and dry skin in one person (0.05%).[9] Symptoms responded to moisturisation and usually resolved within the first 2 months of treatment.

Comment: The RCT is limited by its small sample size and short duration, and by the high withdrawal rate (9/28 [32%]), which compromises the validity of the results.[9]

OPTION TRETINOIN

RCTs in people with mild to moderate photodamage found that topical tretinoin applied for up to 48 weeks improved fine wrinkles compared with vehicle cream but the effect on coarse wrinkles differed among studies. Three RCTs in people with moderate to severe photodamage found that topical tretinoin (0.01%–0.02%) applied for 6 months improved fine and

coarse wrinkles on the face compared with vehicle cream. Common short term adverse effects with tretinoin included itching, burning, and erythema. Skin peeling was the most common persistent adverse effect, which was most frequent and severe at 12–16 weeks.

Benefits: We found no systematic review. **Versus vehicle cream:** We found 12 double blind, vehicle controlled RCTs (see table A on web extra).[10–20] Seven of the RCTs included people with mild to moderate photodamage with Fitzpatrick skin types I–III (see glossary, p 2236). Three of the RCTs (in 2 published articles) included people with moderate to severe photodamage (see glossary, p 2236).[19,20] All three found that tretinoin cream improved fine and coarse facial wrinkles at 24 weeks. The remaining two RCTs did not clearly define the extent of photodamage. The RCTs compared tretinoin (0.1%, 0.05%, 0.02%, 0.01%, 0.025%, and 0.001%) once daily, three times weekly, or once weekly versus a vehicle cream for 12–48 weeks. All of the RCTs that examined higher strength creams (tretinoin 0.1%, 0.05%, and 0.02%) found that tretinoin significantly improved fine wrinkles compared with vehicle cream. Two of three RCTs examining lower strength creams (tretinoin 0.01% and 0.001%) found a significant reduction in fine wrinkles compared with vehicle cream.[15,18] One RCT found no significant difference between lower strength tretinoin cream and vehicle cream.[17] Assessment of improvement by the participants and investigators was consistent although the degree of improvement varied. The effect on coarse wrinkles was inconsistent.

Harms: Overall, the most common adverse effects reported after the application of tretinoin were dry skin/peeling, which were most frequent and severe after 12–16 weeks and tended to be persistent; and itching, burning/stinging, and erythema, which peaked during the first 2 weeks and decreased with time. One RCT found that erythema and scaling occurred in a significantly greater proportion people using tretinoin 0.1% than in those using tretinoin 0.025% (16/36 [44%] *v* 5/39 [13%]; RR 3.47, 95% CI 1.41 to 8.49).[19] Two RCTs, described in one report, found that more people reported skin irritation for tretinoin cream versus placebo, but that irritation was generally mild and well tolerated (skin irritation 20% with tretinoin *v* 7% with vehicle in 1 RCT, and 38% with tretinoin *v* 11% with vehicle in the other RCT).[20] Signs and symptoms of skin irritation (erythema, peeling, dryness, burning, or stinging) tended to peak during the first 4 weeks of the trial period. We found individual case reports of congenital defects associated with topical tretinoin used during the first trimester of pregnancy.[21,22] We found one observational study that identified 215 case histories of women who used tretinoin cream for acne during the first trimester of pregnancy and compared them with 430 age matched, non-exposed women who delivered infants at the same hospital.[23] It found no significant difference in the incidence of major congenital disorders (1.9% *v* 2.6%; RR 0.7, 95% CI 0.2 to 2.3).

Comment: The RCTs were limited by small sample sizes, short duration, and inconsistencies among investigator and participant assessments.[10–19]

OPTION RETINYL ESTERS

We found no RCTs of retinyl esters that evaluated clinical outcomes.

Benefits: We found no systematic review or RCTs that evaluated clinical outcomes.

Harms: We found no RCTs.

Comment: None.

OPTION ISOTRETINOIN

In people with mild to severe photodamage, two RCTs found that isotretinoin cream improved fine and coarse wrinkles after 36 weeks compared with vehicle cream. Severe facial irritation occurred in 5–10% of people using isotretinoin.

Benefits: We found no systematic review. We found two RCTs (see table B on web extra).[24,25] The first RCT (776 people in 17 US centres, aged 20–76 years, with mild to moderate facial photodamage [see glossary, p 2236]) compared isotretinoin 0.05% applied once daily for 12 weeks followed by 0.1% for another 24 weeks versus vehicle cream for 36 weeks.[24] Assessment of photodamage performed by a physician was graded on a 100 mm visual analogue scale (0 = no change from baseline; +50 mm = improvement; and –50 mm = worse). Photographs taken at baseline were compared with photographs taken after 12, 24, and 36 weeks. Only 613 people (79%) remained in the study at 36 weeks and analysis was not by intention to treat. Physician assessment at 36 weeks found that isotretinoin compared with vehicle cream significantly improved overall skin appearance and fine wrinkles (see table B on web extra). Participant assessment found no significant difference between treatments in overall skin appearance, but isotretinoin significantly improved fine wrinkles. Pretreatment and post-treatment photographs were also assessed by five dermatologists; all found that isotretinoin significantly improved fine wrinkles (see table B on web extra). The second RCT (800 people in 20 European centres, mean age 53.5 years, Fitzpatrick skin types I–IV [see glossary, p 2236] with moderate/severe facial photodamage, mild to severe photodamage of the forearms and hands) compared isotretinoin 0.1% versus vehicle cream for 36 weeks.[25] The methods employed in the trial were the same as those in the first RCT. Physician assessment at 36 weeks found that isotretinoin significantly improved overall appearance, fine and coarse wrinkles of the face, and fine wrinkles of the forearms and hands compared with vehicle cream (see table B on web extra). Participant and panel assessment found consistent results.

Harms: The first RCT reported that severe tolerability reactions, which were unspecified, occurred in "less than 5% of people" taking isotretinoin.[24] More people using isotretinoin withdrew from the study because of local irritation (5 *v* 1). The second RCT found that facial symptoms were more common in people using isotretinoin than in those using vehicle cream (erythema 65% *v* 26%, peeling 54% *v*

8%, burning 64% *v* 16%, and pruritus 45% *v* 13%).[25] Severe facial irritation occurred in 5–10% of people, causing 3.6% of people to discontinue treatment. Irritation usually occurred during the first few weeks of treatment and was alleviated by emollients or brief interruption of treatment.

Comment: None.

OPTION TAZAROTENE

One RCT in people with moderately photodamaged skin found that tazarotene cream (0.1%, 0.05%, 0.025%, and 0.01%) improved fine wrinkling compared with placebo at 24 weeks but found no significant difference between tazarotene cream and tretinoin. A second RCT found that tazarotene 0.1% improved both fine and coarse wrinkling at 24 weeks compared with placebo cream.

Benefits: We found no systematic review. We found two RCTs.[26,27] The first RCT (349 men and women aged ≥ 18 years with Fitzpatrick skin types I–IV [see glossary, p 2236]) compared tazarotene (0.1%, 0.05%, 0.025%, and 0.01%), placebo cream, and tretinoin (0.05%) applied once daily for 24 weeks.[26] **Versus tretinoin:** The RCT found no significant difference in fine wrinkling assessed monthly for 24 weeks between tretinoin and any concentration of tazarotene (percentage of people improved at least 1 grade on a 6 point scale for fine wrinkling at 24 weeks, results presented graphically: about 58% for tretinoin *v* about 40–55% for tazarotene; P value not reported).[26] **Versus vehicle cream:** The RCT found a significant improvement for all concentrations of tazarotene (0.1%, 0.05%, 0.025%, and 0.01%) in fine wrinkling at 24 weeks compared with placebo (percentage of people improved at least 1 grade on a 6 point scale for fine wrinkling, results presented graphically: about 40% for 0.025% tazarotene, about 45% for 0.01% tazarotene, and about 55% for 0.05% and 0.1% tazarotene *v* 18% for placebo; $P < 0.05$).[26] The second RCT (563 men and women aged 18 years or older with Fitzpatrick skin types I–IV) compared tazarotene 0.1% versus placebo cream applied once daily for 24 weeks.[27] Tazarotene was significantly more effective than placebo in improving both fine and coarse wrinkling after 24 weeks (percentage of people improved at least 1 grade on a 5 point scale for both fine and coarse wrinkling at 24 weeks, results presented graphically: fine wrinkling about 42% with tazarotene *v* about 18% with placebo, $P < 0.001$; coarse wrinkling about 15% with tazarotene 0.1% *v* about 8% with placebo, $P < 0.001$).

Harms: Adverse events were reported by most people in the first RCT (249/349 [71.3%]).[26] Most were considered to be treatment related. The most frequent adverse events were signs and symptoms of local skin irritation, such as mild to moderate desquamation, burning sensation, erythema, pruritus, and dry skin. "Severe" treatment related adverse events were reported by fewer than 3% of people in the 0.1%, 0.05%, and 0.01% tazarotene groups and by 5% in the tretinoin 0.05% group. In the second RCT adverse events were reported mainly during the first 2 weeks of therapy.[27] The main

adverse events were desquamation (105/283 [37.1%] with tazarotene *v* 8/280 [2.9%] with placebo), erythema (84/283 [29.7%] with tazarotene *v* 6/280 [2.1%] with placebo), and burning (82/283 [29%] with tazarotene *v* 1/280 [0.4%] with placebo).

Comment: None.

OPTION TOPICAL NATURAL CARTILAGE POLYSACCHARIDES

One small RCT found that a topical preparation of cartilage polysaccharide reduced fine and coarse wrinkles at 120 days compared with placebo. However, we were unable to draw reliable conclusions from this study.

Benefits: We found no systematic review. **Versus placebo:** We found one double blind RCT (30 women, aged 40–60 years, with moderate to severe facial wrinkles) comparing a topical 1% cartilage polysaccharide twice daily for 120 days on one side of the face versus placebo on the other.[28] It found that active treatment significantly increased the number of women with no shallow (< 1 mm), moderate (1 mm), or deep (> 1 mm) wrinkles after 120 days (treatment *v* placebo: no shallow wrinkles 30/30 *v* 0/30; no moderate wrinkles 27/30 *v* 0/30; no deep wrinkles 5/30 *v* 2/30; overall $P < 0.001$). The clinical importance of these results is unclear (see comment below).

Harms: No adverse effects were reported by any of the participants in the RCT.[28]

Comment: The RCT is limited by its small sample size and by potential difficulties with concealment of allocation.[28] Application of creams to each side of the face may result in contamination (one side receiving treatment intended for the other side).

OPTION ORAL NATURAL CARTILAGE POLYSACCHARIDES

One RCT found no significant difference between an oral preparation of cartilage polysaccharide and placebo in wrinkle appearance at 3 months. Smaller RCTs reported that oral cartilage polysaccharide reduced fine, moderate, or severe wrinkles compared with placebo. However, these studies were small and of limited reliability. We found limited evidence that some preparations may be more effective than others.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs.[29–31] The first, a double blind RCT (144 people, aged 35–50 years, with Fitzpatrick skin type II or III and mild to moderate photoageing [see glossary, p 2236]), compared a commercial preparation of a cartilage polysaccharide (Imedeen® 400 or 200 mg/day) versus placebo for 3 months.[29] It found no significant difference between either dose of active treatment and placebo in face or eye wrinkles, as assessed by investigator or subject analyses on a 10 cm visual analogue scale and by assessment of photographs by a dermatologist. The second RCT (30 women, aged 40–60 years, with moderate to severe wrinkles) compared a different commercial oral cartilage polysaccharide preparation (Vivida® 500 mg/day) versus placebo for 90 days.[30] Assessment of wrinkles

was measured by the investigator on a three point scale (0 = absent; 1 = moderate; 2 = severe). The RCT found that treatment significantly reduced the number of women with moderate or severe wrinkles at 45 days (overall $P < 0.01$) and at 90 days ($P < 0.001$) compared with placebo. The third RCT (30 women, aged 35–60 years, with Fitzpatrick skin types II or III and mild to moderate wrinkles) compared a preparation of 750 mg marine fish cartilage with antioxidant mix (*Ginkgo biloba*, flavonoids, *Centella asiatica*) daily versus placebo (soybean oil) for 8 weeks.[31] A trained investigator assessed clinical outcome on a 0–9 scale (0 = no signs; 9 = severe signs; based on assessment of dryness, pigmentation, skin tone, and fine superficial wrinkles). It was not clear whether results were directly compared between groups. However, the RCT reported that, at 8 weeks, treatment significantly improved superficial fine wrinkles from baseline whereas placebo did not (results presented graphically: wrinkle score 5.5 at baseline and 4.5 at 8 weeks with treatment; 5.4 at baseline and 5.1 at 8 weeks with placebo). **Versus each other:** One double blind RCT (30 women, aged 40–60 years, with moderate to severe wrinkles) compared two commercial preparations.[32] Participants were given Vivida® 500 mg daily or Imedeen® 380 mg daily for 90 days. At 90 days, the RCT found that Vivida® significantly increased the number of women with no wrinkles (10/15 [66%] *v* 3/15 [20%]) and reduced the number of women with severe wrinkles (0/15 [0%] *v* 7/15 [47%]; overall $P < 0.01$) compared with Imedeen®. It found no significant difference in the number of women with moderate wrinkles (5/15 [33%] *v* 5/15 [33%]; RR 1.0, 95% CI 0.4 to 2.7).

Harms: The first RCT found no significant difference between Imedeen® and placebo in adverse effects (23/96 [24%] *v* 10/48 [21%]; $P > 0.05$).[29] Acne and seborrhoea were the most common skin related events (24/38 [63%]) and oedema and weight increase were the most frequently reported non-skin related events (18/47 [38%]), but the proportions attributable to active treatment or placebo were not specified. The second RCT reported that "some" people taking Vivida® developed mild pimples during the first 3–4 weeks.[30] The third RCT reported that some people experienced epigastric discomfort (numbers or treatment arm not reported), but no other adverse effects were reported. [31] In the final RCT, 33% of people using Vivida® had mild facial pimples during the first 3–4 weeks compared with no adverse effects in the Imedeen® group.[32]

Comment: In the RCT of Vivida® versus placebo, the grading of wrinkling is unusual in that wrinkles were graded as severe, moderate, or absent, without a grading of "mild".[30] One might have expected that wrinkles would have reduced from moderate/severe to mild rather than to absent. The RCTs are small, and the possibility of publication bias cannot be excluded. It is not clear whether the RCT of marine fish cartilage with antioxidant was blinded.[31] The available evidence is inadequate to assess accurately the effects of oral cartilage preparations.

OPTION DERMABRASION

We found no RCTs comparing dermabrasion versus placebo or no treatment. Three small RCTs in women with perioral wrinkles found no significant difference between dermabrasion and carbon dioxide laser in improvement in wrinkles at 4–6 months. Adverse effects were commonly reported. Erythema was reported in all three RCTs, two of which found that erythema was more common with laser than with dermabrasion.

Benefits: **Versus placebo/control:** We found no RCTs. **Versus carbon dioxide (CO_2) laser:** We found three RCTs comparing dermabrasion versus a CO_2 laser.[33–35] The first RCT (20 women, 48–76 years old with moderate/severe wrinkles of the upper lip, Fitzpatrick skin types I–III [see glossary, p 2236]) compared dermabrasion with a coarse diamond fraize versus CO_2 laser to the left or right upper lip.[33] Upper lip wrinkles were graded as 0 (none) to 5 (severe) by an independent investigator before treatment and 6 months later. The average pretreatment wrinkle score was 4.3 for the laser side and 4.4 for the dermabrasion side. The RCT found no significant difference in wrinkle score between treatments at 6 months (areas retaining wrinkle score of 4/5: 1/19 [5%] with dermabrasion *v* 2/19 [11%] with laser; P = 0.22). The second RCT (15 women, 46–73 years old with perioral wrinkles, Fitzpatrick skin types I–III) compared dermabrasion versus a CO_2 laser to the left and right sides of the perioral area.[34] The mean pretreatment wrinkle score on both sides of the perioral area was 3.73 (1 = mild; 5 = severe). The RCT found no significant difference in mean post-treatment wrinkle score at 4 months, as assessed by the investigator (2.64 with laser *v* 2.79 with dermabrasion; P = 0.35). The third RCT (20 women, 44–74 years old with perioral wrinkles, moderate to severe photodamage [see glossary, p 2236], Fitzpatrick skin type not specified) compared dermabrasion versus a CO_2 laser to the left or right sides of the perioral area.[35] Photographs of participants assessed by plastic surgeons were graded in terms of improvement in wrinkles (0 = no improvement to 5 = best improvement) at 1 and 6 months after treatment. The RCT found that laser significantly improved the wrinkle score at 1 month (2.33 *v* 2.01; P = 0.002) but not at 6 months (2.55 *v* 2.22; P = 0.02) compared with dermabrasion. The RCT also found that significantly more women rated a greater improvement in wrinkles with laser than with dermabrasion at 6 months (13/20 [65%] *v* 3/20 [15%]; P = 0.001; 4 women reported no difference).

Harms: In the first RCT, 85% of women had erythema on the upper lip, which was similar on sides of the face treated with CO_2 laser and dermabrasion 1 month after treatment.[33] In 10% of people the erythema was worse on the laser treated side, and in 5% it was worse on the dermabraded side. The average duration of erythema was 2.5 months for both treatments. One woman developed a hypertrophic scar on the dermabraded side. Three people developed herpetic lesions several days after treatment, despite valaciclovir prophylaxis. Other complications such as pain, oedema, eczema, and whiteheads resolved either spontaneously or with minimal treatment. The second RCT found that erythema was

significantly increased on the laser side compared with the dermabrasion side at 1 month (P = 0.003) but not at 4 months (P = 0.15).[34] The third RCT found that laser significantly increased erythema at 1 month compared with dermabrasion (P < 0.001).[35] Also, significantly more people reported that "post-treatment drainage" was worse with laser than with dermabrasion (10/20 [50%] *v* 2/20 [10%]; P = 0.002).

Comment: The RCTs found inconsistent results, were small, and may not have been powered to detect a significant difference between treatments.[33–35] The RCTs varied in their grading of wrinkles, and in participant and investigator assessments. The available evidence is insufficient to define the effects of dermabrasion for wrinkles.

OPTION CARBON DIOXIDE LASER

We found no RCTs comparing carbon dioxide laser versus placebo or no treatment. We found insufficient evidence from small RCTs about the effects of carbon dioxide laser compared with dermabrasion, chemical peel, or other laser treatments.

Benefits: We found no systematic review. **Versus placebo/no treatment:** We found no RCTs. **Versus dermabrasion:** See benefits of dermabrasion, p 2233. **Versus chemical peel:** We found one double blind RCT (20 women, aged 51–71 years, with upper lip wrinkles, Fitzpatrick skin types I–III [see glossary, p 2236]) comparing a carbon dioxide (CO_2) laser versus a phenol chemical peel.[36] At the start of the RCT, photographs of each participant were graded by an independent investigator in terms of the severity of upper lip wrinkles (0 = none; 5 = severe). Participants were then randomly assigned to receive laser treatment on one side of the upper lip and chemical peel on the other. The RCT found that CO_2 laser was less effective than chemical peel at 6 months (wrinkle score reduced from 4.30 to 1.11 with laser *v* 4.20 to 0.47 with chemical peel; mean difference in post-treatment score 0.54; P < 0.03; see comment below). A second RCT (24 men and women, aged 43–73 years, with Fitzpatrick skin types I–III) compared CO_2 laser versus trichloroacetic acid chemical peel applied to opposite sides of the face.[37] It found that CO_2 laser was more effective than chemical peel for reducing severity of periorbital wrinkles after 6 months (severity assessed by independent blinded investigator on a 5 point scale [0 = none; 5 = severe]: score improved from 4.00 to 1.75 with laser treatment *v* from 4.13 to 3.29 with chemical peel; P < 0.001). **Versus erbium:YAG laser:** We found three RCTs.[38–40] The first RCT (21 women, aged 39–74 years, with upper lip wrinkles, Fitzpatrick skin types I–IV) compared variable pulse erbium:YAG laser (see glossary, p 2236) versus CO_2 laser to the left or right sides of the upper lip.[38] Photographs and digital images of participants were recorded preoperatively and at intervals up to 2 months after treatment. The RCT found that there was a greater overall improvement (which was not defined) in wrinkles with CO_2 laser than with erbium:YAG laser (improvement: 63% *v* 54%; P value not reported). The second RCT (13 people [12 were women] aged 30–80 years, with perioral or periorbital wrinkles, Fitzpatrick skin types I–III) compared treatment with one pass pulsed CO_2 laser

versus four passes erbium:YAG laser to periorbital or perioral sites or both.[39] Each participant received CO_2 laser on one side of the face and erbium:YAG laser on the other by random allocation. Wrinkles were graded from 0 (absent) to 8 (severe) based on photographs. The RCT found no significant difference between treatments for wrinkle improvement (time to outcome not stated; average improvement in wrinkle scores from baseline about 1–2 points in both groups; P value for difference not reported). However, the RCT might have been too small to exclude a clinically important difference. The third RCT (21 people [19 were women] aged 18–90 years, with perioral or periorbital wrinkles, Fitzpatrick skin types I–III) compared variable pulse erbium:YAG laser versus CO_2 laser to the left or right sides of the face by alternate allocation.[40] Photographs of participants were taken preoperatively and at 1 week, 2 weeks, 2 months, and 6 months. Investigators and participants were not blinded to treatment allocation, but a blinded panel of dermatologists also assessed outcomes. The RCT found that CO_2 laser improved wrinkles significantly more than erbium:YAG laser at 6 months (measured by aggregate of investigators', participants', and panel's assessments; $P < 0.03$; further data not reported; see comment below). **Versus CO_2 laser plus variable pulse erbium:YAG laser:** We found one double blind RCT.[41] The RCT (20 people, aged 42–72 years with upper lip wrinkles, Fitzpatrick skin types I–III) compared CO_2 laser versus CO_2 laser plus variable pulse erbium:YAG laser to right or left sides of the upper lip. Photographs recorded before treatment and at intervals after treatment for up to 4 months were graded by investigators, but no details of grading were provided. The RCT found no significant difference in improvement in perioral wrinkles at 4 months (67.5% with laser alone *v* 68.5% with combination; P value not reported).

Harms:

Versus chemical peel: The first RCT found that 55% of people had erythema and/or coagulum on the upper lip; in 35% of people this was more severe on the chemical peel side, and in 10% it was more severe on the laser treated side.[36] One person developed an 8 mm hypertrophic scar on the phenol treated side. Herpes simplex infection was reported in three people, which responded to valaciclovir (treatment side not reported). The second RCT found that the erythema lasted for a mean of 4.5 months after laser treatment and 2.5 months after chemical peel.[37] Scarring developed in 13/24 (52%) people with laser treatment and 3/24 (12.5%) with chemical peel. All scars improved or resolved after treatment with topical silicone paste or intralesional steroids. Contact dermatitis to bacitracin–polymyxin B ointment occurred in four participants. This resolved after switching topical therapy to petrolatum and a low potency topical steroid. Hypopigmentation developed in 6/24 (25%) participants in the CO_2 laser treated arm but resolved or improved by the end of the study (no other data given). Milia formation was also relatively common during the prolonged healing phase but resolved or improved with tretinoin or manual extraction (no data reported). **Versus erbium:YAG laser:** In the first RCT postoperative erythema occurred with both treatments, but there was no significant difference (P value not reported).[38] Only one person was reported to have mild hyperpigmentation at around 4 weeks after treatment with erbium:YAG laser, which had cleared

by 3 months. The second RCT found that postoperative erythema was significantly less frequent with CO_2 laser than with erbium:YAG laser at 2 weeks ($P < 0.04$) but rates were similar at 2 and 6 months.[39] The RCT found no significant difference between treatments for rates of hyperpigmentation. The third RCT found that both treatments were associated with erythema (at 2 weeks AR 67% with erbium:YAG laser *v* 95% with CO_2 laser; at 2 months AR 24% with erbium:YAG laser *v* 62% with CO_2 laser; at 6 months AR for mild erythema 0% with erbium:YAG laser *v* 10% with CO_2 laser).[40] Hypopigmentation (5% with erbium:YAG laser *v* 43% with CO_2 laser; $P < 0.05$) and hyperpigmentation (24% with erbium:YAG laser *v* 29% with CO_2 laser) were seen. Hyperpigmentation resolved spontaneously in all cases within 6 months. **Versus CO_2 laser plus variable pulse erbium:YAG laser:** One RCT reported no significant difference between treatments for erythema or pain.[41]

Comment: The effects of chemical peels and CO_2 lasers are likely to be dependent on the expertise of the dermatological surgeon, and therefore results may not generalise to different populations.[36] The difference in outcomes was not expressed dichotomously, and the clinical importance of the mean "0.54 units" difference in wrinkle score with CO_2 laser compared with chemical peel is difficult to interpret. The available evidence is too weak to define the effects of CO_2 laser on wrinkles.[36] The results of the third RCT comparing CO_2 versus erbium:YAG laser should be interpreted with caution because the participants and investigators were not blinded to treatment allocation.[40]

OPTION FACELIFT

We found no systematic review or RCTs on the effects of facelifts.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: The effectiveness and safety of facelift surgery is likely to depend on the expertise of the surgeon.

GLOSSARY

Erbium:YAG laser An yttrium aluminium garnet laser.
Fitzpatrick skin phototype classification I = always burns easily, never tans; II = always burns easily, tans minimally; III = burns moderately, tans gradually (light brown); IV = burns minimally, always tans well (brown); V = rarely burns, tans profusely (dark brown); VI = never burns, deeply pigmented (black).
Mild/moderate/severe photodamage A spectrum of features including wrinkles, hyperpigmentation, tactile roughness, and telangiectasia. Usually measured on a scale from 0–9 (0 = none; 1–3 = mild; 4–6 = moderate; and 7–9 = severe).

Drug treatments

See glossary, p 2242

Key Messages

Treatments in older people

- **Cognitive behavioural therapy** One systematic review identified one small RCT, which found that individual or group cognitive behavioural therapy improved sleep quality at 3 months compared with no treatment, although mean sleep quality scores were consistent with continuing insomnia both with and without treatment.
- **Exercise programmes** One systematic review identified one small RCT. It found that sleep quality improved after a 16 week programme of regular, moderate intensity exercise four times a week compared with no treatment. However, mean sleep quality score were consistent with persisting insomnia both with and without exercise.
- **Timed exposure to bright light** One systematic review found no RCTs comparing the effects of timed bright light exposure with other treatments or no treatment.

Insomnia

DEFINITION Insomnia is defined by the US National Institutes of Health as experience of poor quality sleep, with difficulty in initiating or maintaining sleep, waking too early in the morning, or failing to feel refreshed. Chronic insomnia is defined as insomnia occurring for at least three nights a week for 1 month or more.[1] Primary insomnia is defined as chronic insomnia without specific underlying medical or psychiatric disorders such as sleep apnoea, depression, or dementia. This topic only looks at primary insomnia.

INCIDENCE/ PREVALENCE Across all adult age groups, up to 40% of people have insomnia.[2] However, prevalence increases with age, with estimates ranging from 31–38% in people aged 18–64 years to 45% in people aged 65–79 years.[3]

AETIOLOGY/ RISK FACTORS The cause of insomnia is uncertain. The risk of primary insomnia increases with age and may be related to changes in circadian rhythms associated with age. Psychological factors and lifestyle changes may exacerbate perceived effects of changes in sleep patterns associated with age, leading to reduced satisfaction with sleep.[4] Other risk factors in all age groups include hyperarousal, chronic stress, and daytime napping.[1,5]

PROGNOSIS We found few reliable data on long term morbidity and mortality in people with primary insomnia. Primary insomnia is a chronic and relapsing condition.[6] Likely consequences include reduced quality of life and increased risk of accidents owing to daytime sleepiness. People with primary insomnia may be at greater risk of dependence on hypnotic medication, depression, dementia, and falls, and may be more likely to require residential care.[6,7]

AIMS OF INTERVENTION To improve satisfaction with sleep; to prevent sleepiness and improve functional ability during the daytime.

OUTCOMES Quality of life; self report of sleep satisfaction; sleep quality scales such as the Pittsburgh Sleep Quality Index (PSQI — see glossary, p 2242); performance on attentional task tests; daytime functioning scales such as the Stanford Sleepiness Scale and the Epworth Sleepiness Scale. We excluded measures that record only time or duration of sleep, or wakefulness in the comments, because each of these measures may not directly correlate with symptoms.

METHODS *Clinical Evidence* search and appraisal June 2003. Only studies examining the effects of treatments in people with chronic primary insomnia were included.

QUESTION What are the effects of non-drug treatments in older people?

OPTION COGNITIVE BEHAVIOURAL THERAPY

One systematic review identified one small RCT, which found that individual or group cognitive behavioural therapy improved sleep quality at 3 months compared with no treatment, although mean sleep quality scores were consistent with continuing insomnia at 3 months both with and without treatment.

Benefits: We found one systematic review (search date 2002, 6 RCTs, 282 people with primary insomnia, at least 80% of whom were ≥60 years old).[8] Only one of the included RCTs (36 people) reported on outcomes relevant to the present review. It found that group or individual cognitive behavioural therapy (see glossary, p 2242) (consisting of sleep hygiene, stimulus control, sleep restriction, muscle relaxation, and sleep education) significantly improved Pittsburgh Sleep Quality Index (see glossary, p 2242) scores compared with no treatment, both immediately after treatment and at 3 months (mean scores immediately after treatment: 7.8 with cognitive behavioural therapy *v* 10.6 with no treatment; WMD –2.80, 95% CI –5.44 to –0.16; mean scores at 3 months: 6.20 with cognitive behavioural therapy *v* 10.20 with no treatment; WMD –4.00, 95% CI –6.62 to –1.38).

Harms: The systematic review did not report on harms.[8]

Comment: In the RCT, Pittsburgh Sleep Quality Index was assessed by investigators who were blind to treatment allocation.[8] We found one subsequent RCT (75 adults), in which 45% of participants were older than 55 years.[9] It compared three treatments: cognitive behavioural therapy (sleep education, stimulus control, and restrictions on time spent in bed), relaxation therapy, and a placebo treatment that involved listening to descriptions of neutral activities before going to bed. The trial did not separate results for different age groups. Overall, it found no significant differences among treatments for symptoms (100 point insomnia symptom questionnaire).[9]

OPTION EXERCISE PROGRAMMES

One systematic review identified one small RCT, which found that sleep quality improved after a 16 week programme of regular, moderate intensity exercise four times a week compared with no treatment. However, mean sleep quality scores were consistent with persisting insomnia both with and without exercise.

Benefits: We found one systematic review (search date 2002, 1 RCT, 43 people with primary insomnia, at least 80% of whom were ≥60 years old).[10] The included RCT compared 16 weeks of regular moderate intensity exercise (30–40 minutes of walking or low impact aerobics 4 times a week) with no treatment. It found that, after completion, the exercise programme significantly improved Pittsburgh Sleep Quality Index (see glossary, p 2242) more than no treatment (mean scores after treatment: 5.4 with exercise therapy *v* 8.8 with no treatment; mean improvement in score for exercise programme *v* no treatment: 3.4, 95% CI 1.9 to 5.4).[10] We found no subsequent RCTs.

Harms: The systematic review did not report on harms.[10]

Comment: None.

OPTION TIMED EXPOSURE TO BRIGHT LIGHT

One systematic review found no RCTs comparing timed bright light exposure with other or no treatment.

Insomnia

Benefits: We found one systematic review that compared the effects of timed bright light exposure with other or no treatment in people aged 60 years and over (search date 2001).[11] It identified no RCTs. We found no RCTs published after the review.

Harms: The review did not report on harms.[11]

Comment: None.

GLOSSARY

Cognitive behavioural therapy The following cognitive behavioural therapies were considered in this review: stimulus control, sleep hygiene education, muscle relaxation, sleep restriction, and cognitive therapy. Stimulus control consists of measures to control the stimuli that affect sleep, such as establishing a standard wake up time, getting out of bed during long periods of wakefulness, and eliminating non-nocturnal sleep. Sleep hygiene education informs people about lifestyle modifications that may impair or enhance sleep, such as avoiding alcohol, heavy meals, and exercise before going to bed, and aims to alter expectations about normal sleep durations. Muscle relaxation involves sequential muscle tensing and relaxing. Sleep restriction reduces the time spent in bed to increase the proportion of time spent asleep while in bed. Cognitive therapy aims to identify and alter beliefs and expectations about sleep and sleep onset (e.g. beliefs about "necessary" sleep duration). Cognitive behavioural therapy may be undertaken on a one-to-one basis (individual therapy) or with a group of people (group therapy).
Pittsburgh Sleep Quality Index (PSQI) A validated 21 point scale (0 = best, 21 = worst) to measure subjective sleep quality. A score above 5 indicates insomnia.

Jet lag

Search date April 2003

Andrew Herxheimer

QUESTIONS

INTERVENTIONS

*The adverse effects of melatonin have not yet been adequately investigated

Key Messages

- **Melatonin** One systematic review found that melatonin reduced mean jet lag scores on eastward and westward flights compared with placebo. The review found case reports of possible adverse effects, and suggests that people with epilepsy or on warfarin (or other oral anticoagulants) should not use melatonin without medical supervision. It concluded that the pharmacology and toxicology of melatonin needs systematic study, and routine pharmaceutical quality control of melatonin products is necessary. One RCT found no significant difference between melatonin plus zolpidem and placebo in alleviating symptoms of jet lag.
- **Hypnotics** One RCT found no significant difference between zopiclone and placebo in subjective jet lag scores, but found that zopiclone increased sleep duration compared with placebo. One RCT found that zolpidem improved sleep quality compared with placebo. One RCT found that zolpidem was more effective in alleviating symptoms of jet lag compared with placebo, but found no significant difference between zolpidem plus melatonin and placebo. Adverse effects reported with hypnotics include headache, dizziness, nausea, confusion, and amnesia. Short term benefits of hypnotics have to be considered in light of potential adverse effects.
- **Lifestyle and environmental adaptations (eating, avoiding alcohol or caffeine, sleeping, daylight exposure, arousal)** We found no RCTs on the effects of eating, avoiding alcohol or caffeine, sleeping, daylight exposure, or arousal. Such RCTs are likely to be performed.

Jet lag

DEFINITION Jet lag is a syndrome associated with rapid long haul flights across several time zones, characterised by sleep disturbances, daytime fatigue, reduced performance, gastrointestinal problems, and generalised malaise.[1] As with most syndromes, not all the components have to be present in any one case. It is due to the "body clock" continuing to function in the day–night rhythm of the place of departure. The rhythm adapts gradually under the influence of light and dark, mediated by melatonin secreted by the pineal gland: darkness switches on melatonin secretion, exposure to strong light switches it off.

INCIDENCE/ PREVALENCE Jet lag affects most air travellers crossing five or more time zones. The incidence and severity of jet lag increases with the number of time zones crossed.

AETIOLOGY/ RISK FACTORS Someone who has previously experienced jet lag is liable to do so again. Jet lag is worse the more time zones are crossed in one flight, or series of flights, within a few days. Westward travel generally causes less disruption than eastward travel as it is easier to lengthen, rather than to shorten, the natural circadian cycle.[2]

PROGNOSIS Jet lag is worst immediately after travel and gradually resolves over 4–6 days as the person adjusts to the new local time.[2] The more time zones are crossed, the longer it takes to wear off.

AIMS OF INTERVENTION To prevent or minimise jet lag, with minimal adverse effects.

OUTCOMES Subjective jet lag score; sleep duration and quality; daytime alertness.

METHODS *Clinical Evidence* search and appraisal April 2003. The author added data from the update of his own Cochrane Review. This topic includes studies whose purpose was the prevention of jet lag, in which interventions may have been given before or after travelling. RCTs were included if the authors described the basis of their definition of jet lag, even if not all components of the syndrome were looked for or documented.

QUESTION **What are the effects of interventions to prevent or minimise jet lag?** New

OPTION MELATONIN

One systematic review found that melatonin reduced mean jet lag scores on eastward and westward flights compared with placebo. The review found case reports of possible adverse effects, and suggests that people with epilepsy or on warfarin (or other oral anticoagulants) should not use melatonin without medical supervision. It concluded that the pharmacology and toxicology of melatonin needs systematic study, and routine pharmaceutical quality control of melatonin products is necessary. One RCT found no significant difference between melatonin plus zolpidem and placebo in alleviating symptoms of jet lag.

Benefits: **Versus placebo:** We found one systematic review (search date 2003, 10 RCTs, 975 people) that compared melatonin versus placebo.[2] Nine RCTs included in the review were in air travellers, and

one was in international airline cabin staff (see comment below). In the RCTs, melatonin was given in a varying combination of either before the flight, on the day of the flight, and after the flight. The review's primary outcome measure was the subjective rating of jet lag. Four RCTs reported global jet lag scores that could be combined (single scale 0–100 where 0 = no jet lag and 100 = extreme jet lag). The review found that melatonin significantly reduced mean subjective jet lag scores on eastward and westward flights compared with placebo (eastward flights: 4 RCTs, 142 travellers, weighted mean jet lag score 30.9 with melatonin *v* 50.7 with placebo; WMD −19.5, 95% CI −28.1 to −10.9; westward flights: 2 RCTs, 90 travellers, weighted mean jet lag score 22.3 with melatonin *v* 40.6 with placebo; WMD −17.3, 95% CI −27.3 to −7.3).[2] The review reported that melatonin reduced the symptoms of jet lag in eight RCTs, whereas two RCTs found no effect on symptoms between melatonin and placebo (see comment below). **Timing of melatonin:** One RCT included in the review (52 international airline cabin crew completing a 9 day tour of duty) compared melatonin after arrival ("post"); melatonin before and after arrival ("pre and post"); versus placebo. The review reported that "overall recovery" after the flight was no better in the "pre and post" group compared with placebo, whereas the "post" group had significantly less jet lag ($P < 0.005$) and sleep disturbance ($P < 0.01$) compared with placebo.[2] However, the review noted that it was difficult to generalise from this finding because the airline staff had complex disordered circadian rhythms due to rapidly repeated flights.[2] **Melatonin plus zolpidem:** One RCT included in the review compared melatonin plus zolpidem versus placebo (see benefits of hypnotics, p 2246).

Harms:

The adverse effects of melatonin have not yet been adequately investigated (see comment below). The review noted that most RCTs did not look for adverse effects systematically, and many symptoms were difficult to distinguish from symptoms or manifestations of jet lag itself.[2] One RCT found no significant difference between melatonin and placebo in adverse effects; another found that a disorientating "rocking" feeling was significantly more frequent with melatonin ($P = 0.036$).[2] Hypnotic effects after melatonin occurred in five RCTs affecting about 10% of people (further details not reported).[2] Other effects included headache or heavy head (2 RCTs); disorientation (1 RCT); ear, nose, and throat problems; nausea; and gastrointestinal problems (absolute numbers not reported; P values not reported).[2] One person had difficulty in swallowing and breathing within 20 minutes of taking melatonin.[2] Symptoms subsided after 45 minutes. They recurred after a further dose of melatonin. The review reported that the adverse events in the trials occurred during treatment and appeared to have been short lived.[2] The review noted that the pharmacology and toxicology of melatonin had not been systematically studied. It found six published and 19 unpublished case reports of possible related adverse effects on the central nervous system (including, among other symptoms, confusion, ataxia, headache, and convulsant effects), blood clotting (prothrombin increased or decreased, suspected interaction with warfarin), cardiovascular system (including, among other symptoms, chest pain and dyspnoea), and skin (fixed drug eruption). Whilst noting the difficulty of interpreting such data,

it suggested particular concern regarding the use of melatonin in people with epilepsy and in people taking warfarin or other oral anticoagulants, and that people in these groups should not use melatonin without an informed (medical) discussion, concluding that further investigation was needed.[2] **Melatonin plus zolpidem:** See harms of hypnotics, p 2247.

Comment: The trials reviewed did not state whether travellers were frequent flyers or not. Two RCTs found no effect on symptoms with melatonin.[2] In the first of these RCTs, the review noted that there might have been insufficient time between inward and outward flights for participants to have fully adjusted to the new time zone. Hence, people may have suffered less jet lag on the return flight than might be expected, making it harder to detect effects. In the second RCT, the review noted that melatonin may have reduced jet lag after 3 days but the statistical analysis in the RCT did not test this. One RCT reported details of the source of melatonin; most did not state the pharmaceutical form used.[2] Some melatonin products have been found to contain unidentified impurities.[1] The review concluded that "the pharmacology and toxicology of melatonin needs systematic study, and routine pharmaceutical quality control of melatonin products must be established".[2]

OPTION HYPNOTICS

One RCT found no significant difference between zopiclone and placebo in subjective jet lag scores, but found that zopiclone increased sleep duration compared with placebo. One RCT found that zolpidem improved sleep quality compared with placebo. One RCT found that zolpidem was more effective in alleviating symptoms of jet lag compared with placebo, but found no significant difference between zolpidem plus melatonin and placebo. Adverse effects reported with hypnotics include headache, dizziness, nausea, confusion, and amnesia. Short term benefits of hypnotics have to be considered in light of potential adverse effects.

Benefits: We found no systematic review but found three RCTs.[3–5] **Versus placebo:** The first RCT (33 people, westward flight crossing 5 time zones; see comment below) compared zopiclone (taken 30 minutes before bedtime on the first 4 nights after the flight) versus placebo.[3] It found no significant difference between zopiclone and placebo in subjective jet lag scores on the first, second, fifth, and sixth days after the flight. The RCT found that zopiclone significantly increased sleep duration on nights two ($P < 0.05$) and three ($P < 0.01$) after the flight compared with placebo. The second RCT (133 people, 25–65 years of age who had travelled overseas at least twice during the past 24 months, eastward flights crossing 5–9 time zones) compared zolpidem (taken immediately before bedtime on the first 3 nights after the flight) versus placebo.[4] It examined sleep disturbance in jet lag. It found that zolpidem significantly reduced the mean number of awakenings on the first two nights after the flight compared with placebo ($P < 0.05$) and significantly improved sleep quality on the first three nights after the flight compared with placebo ($P < 0.05$). **Zolpidem plus melatonin:** The third RCT (137 people, eastward flight crossing 6–9 time zones; see comment below) compared zolpidem alone;

melatonin alone; zolpidem plus melatonin; and placebo.[5] Study medication was taken during the flight and at bedtime for four consecutive days after the flight. The RCT found that zolpidem alone was significantly more effective in alleviating symptoms of jet lag on the fourth day after the flight than placebo ($P < 0.05$), but found no significant difference between zolpidem plus melatonin and placebo. It found that zolpidem alone and zolpidem plus melatonin significantly improved overall self rated sleep quality during the flight compared with placebo ($P < 0.05$).

Harms: **Versus placebo:** The first RCT did not report on harms.[3] In the second RCT, adverse events included headache (12/68 [17.6%] of people with zolpidem *v* 6/65 [9.2%] with placebo), rhinitis (2/68 [2.9%] *v* 1/65 [1.5%]), diarrhoea (2/68 [2.9%] *v* 1/65 [1.5%]), abnormal dreaming (2/68 [2.9%] *v* 0/65 [0%]), and sinusitis (0/68 [0%] *v* 2/65 [3.1%]).[4] **Zolpidem plus melatonin:** In the third RCT, adverse events were most frequent with zolpidem plus melatonin (total adverse events reported: 19 with zolpidem alone *v* 21 with melatonin plus zolpidem *v* 6 with placebo; statistical analysis not reported).[5] The most common adverse events included nausea (4/34 [12%] of people with zolpidem alone *v* 4/29 [14%] with melatonin plus zolpidem *v* 1/39 [3%] with placebo), vomiting (2/34 [6%] *v* 2/29 [7%] *v* 0/39 [0%]), confusion (2/34 [6%] *v* 4/29 [14%] *v* 0/39 [0%]), dizziness (1/34 [3%] *v* 2/29 [7%] *v* 0/39 [0%]), headache (2/34 [6%] *v* 2/29 [7%] *v* 1/39 [3%]), amnesia (1/34 [3%] *v* 2/29 [7%] *v* 0/39 [0%]), palpitations (1/34 [3%] *v* 0/29 [0%] *v* 0/39 [0%]), sweating (0/34 [0%] *v* 1/29 [3%] *v* 1/39 [3%]) and dry mouth (1/34 [3%] *v* 1/29 [3%] *v* 0/39 [0%]). One person taking zolpidem plus melatonin was incapacitated by adverse events.

Comment: In the first RCT, subjective jet lag scores were assessed using a 100 mm visual analogue scale: jet lag symptoms were described as feeling tired at unusual times of the day, bad mood, feeling of ill-being, digestive problems, and absence of energy.[3] The third RCT used a 100 mm visual analogue scale to assess the severity of jet lag symptoms and effectiveness of medication.[5] Disruption of sleep is a major component of jet lag, and hypnotics have been used to try to reduce it. The short term benefit seems to be outweighed by the wide range of unpleasant effects, some of them common.

OPTION LIFESTYLE AND ENVIRONMENTAL ADAPTATIONS (EATING, AVOIDING ALCOHOL OR CAFFEINE, SLEEPING, DAYLIGHT EXPOSURE, AROUSAL)

We found no RCTs on the effects of eating, avoiding alcohol or caffeine, sleeping, daylight exposure, or arousal. Such RCTs are unlikely to be performed

Benefits: We found no systematic review or RCTs looking at the lifestyle and environmental adaptations of eating, avoiding alcohol or caffeine, sleeping, daylight exposure, or arousal: that is, doing interesting things such as sightseeing or visiting friends (see comment below). We found one RCT that used artificial light exposure (see comment below).

Harms: We found no evidence on harms.

Comment: RCTs on the effects of lifestyle and environmental adaptation are unlikely to be performed. There is much physiological and anecdotal evidence to support environmental adaptation. Light is the major external environmental cue that pushes the circadian phase towards the light–dark rhythm at the destination. Endogenous melatonin production by the pineal gland is switched on by darkness, normally at dusk, and inhibited by bright light.[2] It has been suggested that after a westward flight it may be worth staying awake while it is daylight at the destination and trying to sleep when it gets dark; and after an eastward flight, being awake but avoiding bright light in the morning, and being outdoors as much as possible in the afternoon.[1,6] Such behaviour may adjust the body clock and turn on the body's own melatonin secretion at the right time. Other cues may reinforce the effect of light, such as eating modestly at the times that correspond to usual meal times, and taking comfortable exercise.[1] We found one RCT (20 people, age 21–34 years old) that compared artificial bright white light via a head mounted light visor versus artificial dim red light for 3 hours on the first two evenings after a westward flight crossing six time zones.[7] Salivary melatonin was measured to detect the onset of evening secretion, and sleep quality and jet lag were rated subjectively. The RCT found that bright light produced a mean delay in salivary melatonin secretion of 1 hour compared with dim light (that is, put the body clock 1 hour forward). However, it found no significant difference between bright light and dim light in sleep quality or jet lag severity.[7]

Drug treatment; surgical procedures

See glossary, p 2259

Key Messages

- **Nasal continuous positive airway pressure in moderate to severe obstructive sleep apnoea-hypopnoea syndrome (OSAHS)** Systematic reviews and subsequent RCTs have found that nasal continuous positive airway pressure reduces daytime sleepiness, improves vigilance and cognitive functioning, and reduces depression in people with moderate to severe OSAHS after 3–9 months compared with placebo, oral appliances, or no treatment.
- **Nasal continuous positive airway pressure in mild OSAHS** One systematic review of four RCTs in people with mild OSAHS found no significant difference between nasal continuous positive airway pressure and conservative treatment or placebo tablets in daytime sleepiness, but found significant improvement in some measures of cognitive performance at about 4 weeks. One subsequent RCT found no significant difference between nasal continuous positive pressure plus conservative treatment and conservative treatment alone for daytime sleepiness or functional or cognitive outcomes, but found significant improvement in sleep apnoea-hypopnoea related symptoms at 3 and 6 months.
- **Oral appliance in mild OSAHS** One RCT found that oral appliances that produce mandibular advancement reduced apnoea and hypopnoea, but had no significant effect on daytime sleepiness or quality of life compared with uvulopalatopharyngoplasty in people with mild OSAHS.
- **Oral appliance in moderate to severe OSAHS** RCTs have found that oral appliances that produce anterior advancement of the mandible reduce daytime sleepiness and sleep disordered breathing at 1–4 weeks in people with moderate to severe OSAHS compared with no treatment or control oral appliances.
- **Weight loss in mild OSAHS** One systematic review found no RCTs on the effects of weight loss in people with mild OSAHS.

Sleep apnoea

- **Weight loss in moderate to severe OSAHS** One systematic review found no RCTs on the effects of weight loss in people with moderate to severe OSAHS.

DEFINITION Obstructive sleep apnoea-hypopnoea syndrome (OSAHS) is abnormal breathing during sleep that causes recurrent arousals, sleep fragmentation, and nocturnal hypoxaemia. It is associated with daytime sleepiness, impaired vigilance and cognitive functioning, and reduced quality of life.[1,2] Criteria for the diagnosis of significant sleep disordered breathing (see glossary, p 2260) have not been rigorously assessed, but have been set by consensus and convention.[3,4] Diagnostic criteria have variable sensitivity and specificity. For example, an apnoea/hypopnoea index (see glossary, p 2259) of 5–20 episodes an hour is often used to define borderline to mild OSAHS, 20–35 to define moderate OSAHS, and more than 35 to define severe OSAHS.[5] However, people with upper airway resistance syndrome (see glossary, p 2260) have an index below five episodes an hour,[6] and many healthy elderly people have an index greater than five episodes an hour.[7] In an effort to obtain an international consensus, new criteria have been proposed but have not been widely used.[8] The most pragmatic test for clinically significant OSAHS is to show clinical improvement in daytime symptoms after treatment for sleep disordered breathing. In this topic, the criteria for OSAHS include apnoeas and hypopnoeas (see glossary, p 2259) caused by upper airway obstruction. Central sleep apnoea and sleep associated hypoventilation syndromes are not covered here.

INCIDENCE/ PREVALENCE The Wisconsin Sleep Cohort Study of over 1000 people (mean age 47 years) in North America found a prevalence of apnoea/hypopnoea index greater than five episodes an hour in 24% of men and 9% of women, and of OSAHS with an index greater than five plus excessive sleepiness in 4% of men and 2% of women.[9] There are international differences in the occurrence of OSAHS, for which obesity is considered to be an important determinant.[10] Ethnic differences in prevalence have also been found after adjustment for other risk factors.[7,10] Little is known about the burden of illness in developing countries.

AETIOLOGY/ RISK FACTORS The site of the upper airway obstruction in the OSAHS is around the level of the tongue, soft palate, or epiglottis. Disorders that predispose to either narrowing of the upper airway or reduction in its stability (e.g. obesity, certain craniofacial abnormalities, vocal cord abnormalities, and enlarged tonsils) have been associated with an increased risk of OSAHS. It has been estimated that a 1 kg/m^2 increase in body mass index (3.2 kg for a person 1.8 m tall) leads to a 30% increase (95% CI 13% to 50%) in the relative risk of developing abnormal sleep disordered breathing (apnoea/hypopnoea index ≥ 5/hour) over a period of 4 years.[10] Other strong associations include increasing age and sex (male to female ratio is 2 : 1). Weaker associations include menopause, family history, smoking, and night time nasal congestion.[10]

PROGNOSIS The long term prognosis of people with untreated severe OSAHS is poor with respect to quality of life, likelihood of motor vehicle accidents, hypertension, and possibly cardiovascular disease and premature mortality.[11] Unfortunately, the prognosis of both treated

and untreated OSAHS is unclear.[7] The limitations in the evidence include bias in the selection of participants, short duration of follow up, and variation in the measurement of confounders (e.g. smoking, alcohol use, and other cardiovascular risk factors). Treatment is widespread, making it difficult to find evidence on prognosis for untreated OSAHS. Observational studies support a causal association between OSAHS and systemic hypertension, which increases with the severity of OSAHS (OR 1.21 for mild OSAHS to 3.07 for severe OSAHS).[11] OSAHS increases the risk of motor vehicle accidents three- to sevenfold.[11,12] It is associated with increased risk of premature mortality, cardiovascular disease, and impaired neurocognitive functioning.[11]

AIMS OF INTERVENTION

To minimise or eliminate symptoms of daytime sleepiness; to improve vigilance and quality of life; to reduce or abolish the increased risk of motor vehicle accidents and cardiovascular events; to enhance compliance with treatment; to minimise adverse effects of treatment.

OUTCOMES

Daytime sleepiness: Subjective and objective measures such as Epworth Sleepiness Scale, Multiple Sleep Latency Test, and Maintenance of Wakefulness Test. **Quality of life:** General measures such as the Medical Outcomes Study 36-item Short Form Health Survey and the General Health Questionnaire; measures of mood such as the Hospital Anxiety and Depression Scale, the Beck Depression Inventory, and the Profile of Mood States; measures of energy and vitality such as the 36-item Short Form SF-36 energy scale, the UWIST Mood Adjective Checklist, and the energy and vitality scale of the Nottingham Health Profile. Disease specific quality of life measures include the Functional Outcomes of Sleep Questionnaire. **Cognitive performance measures:** Steer Clear, Trailmaking Test B, Digit Symbol Substitution, and Paced Auditory Serial Addition-2 Second Timing. **Mortality and morbidity:** For example, road traffic accidents, hypertension, stroke, cardiac failure, and ischaemic heart disease. **Intermediate outcomes:** Measures of the degree of disturbed breathing during sleep, such as the number of apnoeas and hypopnoeas an hour (apnoea/hypopnoea index), the frequency of arousals, and the degree of sleep fragmentation. Details of validated outcome measures for daytime sleepiness, quality of life and cognitive performance are listed in table 1, p 2263.[13–25]

METHODS

Clinical Evidence search and appraisal December 2002 and ongoing additional hand searches by the author. Different RCTs have used slightly different definitions of OSAHS. An attempt has been made to provide some details of the definitions used. Further clarification will be attempted in future *Clinical Evidence* updates.

QUESTION What are the effects of treatment of moderate to severe obstructive sleep apnoea-hypopnoea syndrome?

OPTION NASAL CONTINUOUS POSITIVE AIRWAY PRESSURE IN MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

Systematic reviews and subsequent RCTs have found that nasal continuous positive airway pressure reduces daytime sleepiness, improves vigilance and cognitive functioning, and reduces depression compared with placebo, oral appliances, or no treatment in people with moderate to severe obstructive sleep apnoea-hypopnoea syndrome.

Benefits:

Versus no treatment: We found one systematic review (search date 1999, 1 RCT) comparing nasal continuous positive airway pressure (CPAP — see glossary, p 2259) versus control for 3 months.[5] The included RCT (105 people with severe obstructive sleep apnoea-hypopnoea syndrome [OSAHS], mean apnoea/hypopnoea index [see glossary, p 2259] 56/hour, and mean Epworth Sleepiness Scale 12) did not compare effects of nasal CPAP versus control directly. However, it found that nasal CPAP significantly reduced daytime sleepiness from baseline, whereas the control treatment did not (mean Epworth Sleepiness Scale was reduced from 12.1 to 5.6 with nasal CPAP, $P < 0.01$, CI not reported; and was reduced from 11.4 to 10.6 with control, NS).[26]

Versus sham/subtherapeutic nasal CPAP: We found one systematic review (search date 1999, 1 RCT),[5] one report of 6 month follow up from the RCT identified by the review,[27] and three subsequent RCTs,[28–30] which compared nasal CPAP versus sham/subtherapeutic nasal CPAP (see glossary, p 2260). The RCT identified by the systematic review (107 people with moderate to severe OSAHS) found that nasal CPAP significantly reduced daytime sleepiness at 1 month compared with sham/subtherapeutic nasal CPAP (mean improvement in Epworth Sleepiness Scale with CPAP *v* control 7.0, $P < 0.0001$, CI not reported; mean improvement in Maintenance of Wakefulness Test with CPAP *v* control 6.75 min, $P = 0.005$).[31] The first subsequent RCT (55 people with moderate to severe sleep disordered breathing [see glossary, p 2260], all with an apnoea/hypopnoea index > 30/hour [average > 50/hour], but with no or very little complaint of excessive daytime sleepiness [average Epworth Sleepiness Scale was 7/24, normal is < 10/24]) found no significant difference in daytime sleepiness after 6 weeks between nasal CPAP and sham nasal CPAP (change in Epworth Sleepiness Scale: 1, 95% CI 0 to 2 with nasal CPAP *v* 1, 95% CI 0 to 2 with sham nasal CPAP).[28] It also found no significant difference in a range of measures of cognitive functioning or in 24 hour blood pressure readings. The second subsequent RCT (59 men with an Epworth Sleepiness Scale > 10 and moderate to severe OSAHS; 48 people included in this RCT were also included in the RCT[31] described above) compared the effects of nasal CPAP versus sham nasal CPAP on simulated driving performance for 1 month.[29] It found that nasal CPAP significantly reduced daytime sleepiness compared with sham nasal CPAP (subjective measures: $P = 0.0006$; objective measures: $P = 0.003$; CI not reported). The third subsequent RCT (45 people with moderate to severe OSAHS)

found that nasal CPAP significantly reduced daytime sleepiness and functional outcomes compared with sham nasal CPAP after 6 weeks (mean change in Epworth Sleepiness Scale –9.48 with nasal CPAP *v* –2.27 with sham nasal CPAP, $P < 0.001$; mean change in sleep apnoea-hypopnoea syndrome related symptoms score –18.48 with nasal CPAP *v* –4.45 with sham nasal CPAP, $P < 0.001$; mean change in Functional Outcomes of Sleep Questionnaire [general productivity domain] 3.99 with nasal CPAP *v* 0.50 with sham nasal CPAP, $P < 0.05$; and mean change in Functional Outcomes of Sleep Questionnaire [vigilance domain] 8.52 with nasal CPAP *v* 3.44 with sham nasal CPAP, $P < 0.01$).[30] **Versus oral placebo tablets:** We found one systematic review[32] and one subsequent RCT[33] comparing nasal CPAP versus oral placebo tablets. The systematic review (search date 2001, 3 crossover RCTs, 82 people) compared nasal CPAP versus oral placebo tablets in people with moderate OSAHS.[32] The RCTs in the systematic review were found to have some methodological shortcomings. The review found no significant difference in sleep latency between nasal CPAP and oral placebo tablets (Multiple Sleep Latency Test: WMD +0.90 minutes, 95% CI –0.84 minutes to +2.62 minutes) or cognitive functioning (Steer Clear: WMD –5.04, 95% CI –20.1 to +10.0).[32] The subsequent RCT (68 people with moderate to severe OSAHS, apnoea/hypopnoea index range 15–129/hour, Epworth Sleepiness Scale range 6–24) compared nasal CPAP versus oral placebo tablets over 4 weeks.[33] It found that nasal CPAP significantly reduced daytime sleepiness over 4 weeks compared with oral placebo tablets (Epworth Sleepiness Scale 10.1 with nasal CPAP *v* 12.5 with placebo tablets; $P = 0.001$) and quality of life (Functional Outcomes of Sleep Questionnaire total score 12.4 with nasal CPAP *v* 11.6 with placebo tablets; $P = 0.01$).[33] **Versus oral appliances:** We found one systematic review (search date 2001,[32] 60 people, 3 RCTs[34–36]) and one subsequent RCT, which compared nasal CPAP with oral appliances (see glossary, p 2259) (removable mandibular advancement devices).[37] The systematic review found that nasal CPAP significantly improved apnoea/hypopnoea index compared with oral appliance (WMD –7.3/hour, –10.0/hour to –4.7/hour).[32] One RCT included in the review found no significant difference in sleepiness between nasal CPAP and oral appliances.[36] Overall, the review found that people preferred an oral appliance over nasal CPAP (OR 9.5, 95% CI 4.3 to 21.1). However, the trial results were significantly heterogeneous.[32] The subsequent RCT (48 people with a mean apnoea/hypopnoea index of 31 ± 26/hour and Epworth Sleepiness Scale of 14 ± 4; crossover design) found that CPAP significantly improved apnoea/hypopnoea index, symptoms, functional outcomes and aspects of quality of life after 8 weeks compared with mandibular repositioning splint (apnoea/hypopnoea index: 8 with CPAP *v* 15 with splint; Epworth Sleepiness Scale: 8 *v* 12; symptoms: 17 *v* 11; effectiveness rating: 5 *v* 7; Functional Outcomes of Sleep Questionnaire: 13 *v* 14; SF–36 mental component: 48 *v* 52; health transition scores: 2.9 *v* 2.4; P for all these outcomes < 0.01). However, objective sleepiness, cognitive performance, and preference for treatments were not significantly different between treatments.[37]

Sleep apnoea

Harms: Neither of the systematic reviews summarised any harmful effects found in the RCTs that were reviewed.[5,32] One systematic review (search date 1999) reported a high prevalence of minor adverse effects from nasal CPAP treatment, the most common being dry mouth, nose, and throat (40%).[5] We found one case series (52 consecutive people with severe OSAHS, mean oxygen desaturation index 43/hour), in which the occurrence of nasopharyngeal symptoms was studied systematically before and after nasal CPAP.[38] It found that nasopharyngeal symptoms were common before nasal CPAP in OSAHS (nasal dryness 74%, sneezing 51%, blocked nose 43%, and rhinorrhoea 37%) and increased during nasal CPAP (sneezing 75% and rhinorrhoea 57%), with greater discomfort in winter. Other adverse effects of nasal CPAP include local effects of the mask on the nasal bridge, mask discomfort, nasal congestion, rhinitis, sore eyes, headache, chest discomfort, and noise disturbance.

Comment: The RCTs have problems with their methods and with applicability of results. First, severity of sleep disordered breathing (using apnoea/hypopnoea index, etc.) is not a good guide to severity of daytime sleepiness, which is a major symptom.[28] Second, it is not clear whether the sham or subtherapeutic CPAP used in some "placebo" groups are truly inactive treatments. Third, RCT evidence reports short term symptomatic outcomes only, rather than longer term complications, such as mortality, motor vehicle accident rate, hypertension, stroke, and ischaemic heart disease.

OPTION WEIGHT LOSS IN MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

We found no RCTs on the effect of weight loss in people with moderate to severe obstructive sleep apnoea-hypopnoea syndrome.

Benefits: We found one systematic review (search date 2000), which identified no RCTs on the effect of weight loss in people with obstructive sleep apnoea-hypopnoea syndrome (OSAHS); see comment below.[39]

Harms: We found no RCTs on the effects of weight loss in people with OSAHS.

Comment: One review of the effect of body weight in OSAHS found no RCTs but included case series in which weight loss, especially that achieved by surgery, was associated with improvement, mainly in people with severe OSAHS.[40] Large relative improvements in apnoea/hypopnoea index (see glossary, p 2259) (–72% to –98%) were found after a weight loss of 30–70% of initial weight.[40] It seems that weight loss has the potential to benefit obese persons with OSAHS. There is consensus that advice about weight reduction is an important component of management. However, weight loss is difficult and advice may need to be combined with nasal continuous positive airway pressure (see glossary, p 2259) in people with moderate and severe OSAHS.

OPTION ORAL APPLIANCES IN MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

RCTs have found that oral appliances that produce anterior advancement of the mandible reduce daytime sleepiness and sleep disordered breathing at 1–4 weeks in people with moderate to severe obstructive sleep apnoea-hypopnoea syndrome compared with no treatment or control oral appliances.

Benefits:

Versus no treatment: We found no systematic review but found one RCT.[41] The RCT (crossover, 24 people with moderate obstructive sleep apnoea-hypopnoea syndrome [OSAHS]; mean apnoea/hypopnoea index [see glossary, p 2259] 26.7 and significant daytime sleepiness [Epworth Sleepiness Scale 11.9]) compared two different oral appliances (see glossary, p 2259) that produced mandibular advancement versus no treatment for 1 week each. It found that, after 1 week, both oral appliances significantly reduced daytime sleepiness and sleep disordered breathing (see glossary, p 2260) compared with no treatment (daytime sleepiness: Epworth Sleepiness Scale 9.0, 95% CI 6.5 to 11.0 with first oral appliance; 9.0, 95% CI 6.5 to 10.0 with second oral appliance; and 13.5, 95% CI 9.5 to 16.0 with no oral appliance; $P < 0.01$ for each oral appliance *v* no oral appliance; apnoea/hypopnoea index: 8.7, 95% CI 5.8 to 11.6 with first oral appliance; 7.9, 95% CI 4.8 to 11.0 with second oral appliance; 22.6, 95% CI 16.5 to 28.7 with no oral appliance; $P < 0.05$ for each oral appliance *v* no oral appliance). It also found that oral appliance versus no treatment significantly reduced interference with daily tasks, snoring frequency and loudness, and improved performance ability and energy level compared with no treatment. **Versus control oral appliances:** We found three RCTs comparing an oral appliance that produced anterior advancement of the mandible (removable mandibular advancement device) versus an oral appliance that did not (control intervention).[42–44] The first RCT (24 adults with loud snoring and severe OSAHS) found that mandibular advancement device significantly reduced daytime sleepiness compared with control after 2 weeks (Epworth Sleepiness Scale –3.8 with mandibular advancement device *v* –0.5 with control oral appliance; $P < 0.005$).[42] There was a significant withdrawal rate, with only 10 people in the mandibular advancement group and eight people in the control group providing outcome data after 2 weeks of treatment. The second RCT (crossover study, 28 people with moderate to severe OSAHS [average apnoea/hypopnoea index 27/hour]) compared a mandibular advancement splint versus control (oral appliance that did not advance the mandible) for 1 week each.[43] It found that mandibular advancement splint significantly reduced daytime sleepiness and apnoea/hypopnoea index compared with control oral appliance (Epworth Sleepiness Scale 3.9 with mandibular advancement splint *v* 10.1 with control oral appliance, $P < 0.01$, CI not reported; apnoea/hypopnoea index: 14/hour with mandibular advancement splint *v* 30/hour with control oral appliance, $P < 0.0001$, CI not reported). The third RCT[44] (85 patients, 14 women with mean Epworth Sleepiness Scale of 11, crossover design) found that an active mandibular advancement splint significantly increased sleep latency and improved sleepiness compared

with an inactive mandibular advancement splint at 4 weeks (decrease in sleep latency for active *v* inactive treatment: 1.2 minutes, 95% CI 0.3 minutes to 2.1 minutes; improvement in Epworth Sleepiness Scale for active *v* inactive treatment: 2 points, 95% CI 1 point to 3 points; proportion of people with normal Epworth Sleepiness score: 82% with active *v* 62% with inactive, $P < 0.01$). **Versus nasal continuous positive airway pressure:** See glossary, p 2259. See benefits of nasal continuous positive airway pressure in moderate to severe OSAHS, p 2252.

Harms: **Versus no treatment:** The RCT did not report on adverse effects.[41] One small series (22 people involved in the RCT) investigated adverse effects over 12–30 months.[45] It found that adverse effects were common (mucosal dryness [86%], tooth discomfort [59%], and hypersalivation [55%]) but did not require discontinuation of treatment. **Versus control oral appliances:** The first RCT did not report on adverse effects.[42] The second RCT reported the following adverse effects: excessive salivation (50%), gum irritation (20%), mouth dryness (46%), jaw discomfort (12.5%), and tooth grinding (12.5%).[43] Those adverse effects were described as mild to moderate, lasting less than 3 weeks, and not preventing the use of the mandibular advancement splint.

Comment: Oral appliances are commonly used for snoring. We found one systematic review (search date 1994, 304 people with mean apnoea/hypopnoea index in the severe range, 21 publications, 19 case series), which found that about 70% of people had a 50% or greater reduction in apnoea/hypopnoea index.[46] There is insufficient evidence about long term effectiveness and adverse effects. One RCT (24 people, crossover design), which compared an oral appliance with a small bite opening (4 mm) versus one with a larger opening (14 mm) found no significant difference in sleep disordered breathing or Epworth Sleepiness Scale.[47]

QUESTION What are the effects of treatment for mild obstructive sleep apnoea-hypopnoea syndrome?

OPTION NASAL CONTINUOUS POSITIVE AIRWAY PRESSURE IN MILD OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

One systematic review of four RCTs in people with mild obstructive sleep apnoea-hypopnoea syndrome found no significant difference between nasal continuous positive airway pressure and conservative treatment or placebo tablets in daytime sleepiness, but found significant improvement in some measures of cognitive performance at about 4 weeks. One subsequent RCT found no significant difference between nasal continuous positive pressure plus conservative treatment and conservative treatment alone for daytime sleepiness or functional or cognitive outcomes, but found significant improvement in sleep apnoea-hypopnoea related symptoms at 3 and 6 months.

Benefits: **Versus no treatment:** We found no RCTs. **Versus conservative treatment or oral placebo tablets:** We found one systematic review[5] and one subsequent RCT.[48] The systematic review (search

date 1999, 4 RCTs, 208 people with mild obstructive sleep apnoea-hypopnoea syndrome [OSAHS]) compared nasal continuous positive airway pressure (CPAP — see glossary, p 2259) versus conservative treatment (sleep hygiene and advice about weight reduction) or oral placebo tablets for at least 4 weeks.[5] It found no significant difference between nasal CPAP and conservative treatment or oral placebo tablets in daytime sleepiness (1 RCT:[49] mean reduction in Epworth Sleepiness Scale –0.57, 95% CI –1.39 to +0.25; 3 RCTs:[50–52] Multiple Sleep Latency Test, graphical representation; mean effect about 0 with 95% CI of about ± 0.7). It found no significant difference between nasal CPAP and conservative treatment or oral placebo tablets in two measures of cognitive performance, but found significant improvement in two other measures of cognitive performance (no significant difference in Steer Clear, 2 RCTs;[49,50] or Digit Symbol Substitution, 2 RCTs;[49,51] significant improvement in Trailmaking Test B, 3 RCTs:[49–51] $P = 0.003$; 2 RCTs, Paced Auditory Serial Addition-2 Second Timing:[49,50] $P < 0.0001$; CI not reported). The review found no significant difference between nasal CPAP and oral placebo tablets for quality of life and anxiety measures, but found significant improvement for depression and for energy and vitality (quality of life: 2 RCTs, 36-item Short Form general perception);[49,51] anxiety measures (2 RCTs, Hospital Anxiety and Depression Scale);[49,50] depression (2 RCTs, Hospital Anxiety and Depression Scale;[49,50] 1 RCT, Beck Depression Inventory;[51] combined $P = 0.0004$); energy and vitality (2 RCTs, 36-item Short Form vitality;[49,51] 1 RCT, UWIST Mood Adjective Checklist Energetic Arousal Score;[50] combined $P = 0.013$; 1 RCT, energy/fatigue subscore of MOD;[52] $P < 0.05$). The three RCTs that reported a symptom score (in-house questionnaires using an analogue scale) showed a significant benefit of appliance over placebo (combined $P = 0.006$).[49–51] We found one subsequent RCT (142 people with mild OSAHS) comparing nasal CPAP plus conservative treatment (sleep hygiene and weight loss) versus conservative treatment alone.[48] It found that nasal CPAP plus conservative treatment significantly reduced symptoms at 3 and 6 months compared with conservative treatment alone (sleep apnoea-hypopnoea syndrome related symptom score 14 with nasal CPAP plus conservative treatment *v* 19 with conservative treatment alone; $P < 0.001$). However, it found no significant difference between nasal CPAP plus conservative treatment in daytime sleepiness or functional outcomes at 3 and 6 months compared with conservative treatment alone (results not by intention to treat, 17 people excluded; Epworth Sleepiness Scale 10.5 with nasal CPAP plus conservative treatment *v* 12.0 with conservative treatment alone; $P = 0.67$ at 3 months; 9.6 with nasal CPAP plus conservative treatment *v* 11.8 with conservative treatment alone; $P = 0.11$ at 6 months; Multiple Sleep Latency Test not reported at 3 months; 10 minutes with nasal CPAP plus conservative treatment *v* 11 minutes with conservative treatment alone, $P = 0.87$; Functional Outcomes of Sleep Questionnaire score 106 with nasal CPAP plus conservative treatment *v* 102 with conservative treatment alone at 3 and at 6 months, $P = 0.29$ at 3 months and $P = 0.06$ at 6

months). The RCT also found no significant difference between treatments in several measures of cognitive function at 3 or 6 months (e.g. Steer Clear score 10% in both groups at 3 months, P = 0.65; 8% in both groups at 6 months, P = 0.88). **Versus oral appliances:** We found no reliable RCTs.

Harms: The systematic review grouped mild and moderate to severe OSAHS for reporting of adverse effects (see harms of nasal continuous positive airway pressure in moderate to severe OSAHS, p 2254).[5] The subsequent RCT did not report on harms.[48]

Comment: People with mild OSAHS find nasal CPAP less acceptable. People with an apnoea/hypopnoea index (see glossary, p 2259) below 15/hour have been found to have half the long term use of nasal CPAP compared with people with an apnoea/hypopnoea index greater than 15/hour.[53] In the RCT published after the review, adherence by people with mild OSAHS was moderately high (4.8 hours/day).[48] Treatment acceptance was also good (62% of people who finished the trial chose to continue CPAP).

OPTION WEIGHT LOSS IN MILD OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

One systematic review found no RCTs on the effect of weight loss in people with mild obstructive sleep apnoea-hypopnoea syndrome.

Benefits: We found one systematic review (search date 2000), which found no RCTs on the effect of weight loss in people with obstructive sleep apnoea-hypopnoea syndrome (see comment below).[39]

Harms: We found no RCTs on the effect of weight loss in people with mild obstructive sleep apnoea-hypopnoea syndrome.

Comment: We found one large population based cohort study (690 people with sleep disordered breathing [see glossary, p 2260], including those who did not qualify for diagnosis of obstructive sleep apnoea-hypopnoea syndrome) that evaluated sleep disordered breathing at 4 year intervals over 10 years.[54] It found an association between changes in weight and apnoea/hypopnoea index (see glossary, p 2259) (weight gain of 10% was associated with an increase in apnoea/hypopnoea index of 32% [95% CI 20% to 45%]; weight loss of 10% was associated with a decrease in apnoea/hypopnoea index of 26% [95% CI 18% to 34%]).

OPTION ORAL APPLIANCES IN MILD OBSTRUCTIVE SLEEP APNOEA-HYPOPNOEA SYNDROME

One RCT found that oral appliances that produce mandibular advancement reduced apnoea and hypopnoea, but had no significant effect on daytime sleepiness or quality of life compared with uvulopalatopharyngoplasty in people with mild obstructive sleep apnoea-hypopnoea syndrome.

Benefits: **Versus surgical treatment (uvulopalatopharyngoplasty):** We found three reports comparing an oral appliance (see glossary, p 2259) (producing anterior advancement of the mandible) versus uvulopalatopharyngoplasty.[55–57] However, they were all related to

the same RCT of 95 people with mild obstructive sleep apnoea-hypopnoea syndrome (mean apnoea/hypopnoea index (see glossary, p 2259) 18.2/hour, 95% CI 15.7/hour to 20.8/hour in oral appliance group; 20.4/hour, 95% CI 17.4/hour to 23.3/hour in the uvulopalatopharyngoplasty group). Successful treatment was defined as a reduction in apnoea/hypopnoea index to less than 10/hour. The RCT found that the oral appliance significantly improved the apnoea/hypopnoea index compared with uvulopalatopharyngoplasty at 12 months (78% improved with oral appliance *v* 51% with uvulopalatopharyngoplasty; $P < 0.05$; CI not reported). It found no significant difference between oral appliance and uvulopalatopharyngoplasty in daytime sleepiness (as measured using 5 questions, with a 5 point scale for each),[55] quality of life (Minor Symptoms Evaluation Profile), or vitality, contentment, and sleep.[57] The uvulopalatopharyngoplasty group had a better contentment score.

Harms: The RCTs on oral appliances have generally been too brief to evaluate clinically important adverse effects. See harms of oral appliances in moderate to severe obstructive sleep apnoea-hypopnoea syndrome, p 2256.

Comment: Oral appliances are used commonly for people with snoring with or without mild sleep apnoea (see glossary, p 2259). Although the number and duration of trials are not ideal, there is consensus that oral appliances are effective.[58]

GLOSSARY

Apnoea Absence of airflow at the nose and mouth for at least 10 seconds. Sometimes defined indirectly in terms of oxygen desaturation index (impact on pulse oximetry saturation is measured as the number of occasions an hour when oxygen saturation falls by ≥ 4%). Apnoeas may be "central", in which there is cessation of inspiratory effort, or "obstructive", in which inspiratory efforts continue but are ineffective because of upper airway obstruction.

Apnoea/hypopnoea index The sum of apnoeas and hypopnoeas per hour of sleep. Although the generally accepted cut off point for "normal" is an index of five per hour, there are several definitions of normal, of which at least four are applicable to the situation of sleep disordered breathing: levels that are inside the range found in a "normal" (i.e. healthy) population; levels that are well removed from those found in a target disorder such as obstructive sleep apnoea-hypopnoea syndrome; levels that are not associated with a significant risk of disease and disability; and levels for which there is evidence of a significant benefit of treatment.[4]

Continuous positive airway pressure (CPAP) Involves applying positive pressure from a blower motor to the upper airway through tubing and a soft nasal mask or a facemask. It provides a "pneumatic splint" to the upper airway. Because nasal delivery is the most common in the published literature, we refer to "nasal CPAP".

Hypopnoea A major reduction (> 50%) in airflow at the nose and mouth for at least 10 seconds. A smaller reduction in airflow may be accepted as hypopnoea if it is associated with either an arousal or a reduction in oxygen saturation of 4% or more.

Oral appliance The term "oral appliance" is generic for devices that are placed in the mouth in order to change the position of the mandible, tongue, and other structures in the upper airway to reduce snoring or the upper airway obstruction of

obstructive sleep apnoea-hypopnoea syndrome. Specific types are referred to as mandibular advancement devices or splints.

Sham/subtherapeutic nasal continuous positive airway pressure This involves the use of the nasal mask and continuous positive airway pressure machine, but with inadequate pressure generated to overcome upper airway obstruction during sleep.

Sleep disordered breathing Can be described as apnoeas (no airflow for 10 s or more) or hypopnoeas (markedly reduced airflow for 10 s or more). The choice of 10 seconds is by convention. The usual measure of the degree of sleep disordered breathing is the apnoea/hypopnoea index. Features of sleep disordered breathing include snoring, witnessed episodes of absent breathing (apnoeas), abnormal breathing during sleep, nocturnal hypoxaemia, and abnormal sleep architecture.

Upper airway resistance syndrome Measurement of inspiratory effort by oesophageal pressure shows recurrent episodes of increased inspiratory effort that maintain stable ventilation but are associated with arousals and sleep fragmentation. These episodes are also referred to as respiratory effort related arousal events.[8] More recent techniques of measuring nasal air flow can show changes consistent with upper airway resistance syndrome without the need for an oesophageal pressure catheter.[59]

TABLE 1 **Validated outcome measures (see text, p 2251).**

Outcome measure (abbreviation)	Description	Scoring
Epworth sleepiness scale (ESS)[13]	Questionnaire developed to measure the general level of sleepiness by the likelihood of falling asleep in eight common situations	The score for each question ranges from 0 (no likelihood of falling asleep) to 3 highly likely to fall asleep). A lower score indicates less daytime sleepiness in the last week. Maximum score 24 Normal < 10 Severe > 16–24
Multiple Sleep Latency test (MSLT)[14]	A daytime sleep laboratory based test in which the patient is asked to try and fall asleep when placed in a quiet dark room for 20 minutes at 2-hourly intervals. Monitoring is by electroencephalography. The time between lights out and sleep onset (sleep latency) is measured in minutes. The mean value of 4–5 test sleeps in the day is calculated. The mean sleep latency is considered an "objective" sleep measure of daytime sleepiness. A reduced score indicates an increase in daytime sleepiness.	Mean adult sleep latency of < 5 minutes is indicative of pathological sleepiness Mild 5–7 minutes Borderline 8–9 minutes Normal ≥ 10 minutes
Maintence of Wakefulness Test (MWT)[15]	Similar to the MSLT, but the patient is asked to stay awake during the 20 minutes in a dark room	Sleep latencies of < 20 minutes are indicative of pathological sleepiness
Quality of life		
Medical Outcomes Survey Short form 36 (SF–36)[16]	A short form health survey that measures generic health related quality of life. The instrument is used widely to evaluate Health Related Quality of Life across various populations It is a 36 item questionnaire comprising eight health concepts : physical functioning; role limitations due to physical health problems; bodily pain; social functioning; general mental health; role limitations due to emotional problems; vitality, energy or fatigue; general health perceptions	Most of the 36 items are scored on a 3–6 point Likert scale. Scaling for different questions includes ranges from excellent to poor; limited a lot to not limited at all; not at all to extremely; and otheres. A higher score reflects a better health related quality of life

TABLE 1 continued

Outcome measure (abbreviation)	Description	Scoring
General Health Questionnaire – 28 (GHQ–28)[17]	A self administered screening test, designed to identify short term changes in mental health. The most popular of the GHQ, it has 28 questions, seven in each sub–scale of depression, anxiety, social dysfunction and somatic symptoms	Four subscores as well as a total score are obtained. The higher the score the more severe the condition. A 4 point scoring system ranges from a "better/healthier than normal" option, through a "same as usual" and a "worse/more than usual" to a "much worse/more than usual" option
Hospital Anxiety and Depression scale (HADS)[18]	A 14 item questionnaire designed to identify clinical depression and anxiety. Seven items conceptually assess depression and seven items were derived from psychic manifestations of anxiety neurosis	Overall level of severity of each mood on a 4 point scale (0–3). A score of 8 is clinically significant, a score of 11 or more is highly clinically significant
Beck Depression Inventory (BDI)[19]	A measurement of clinical depression with 21 statements regarding a symptom associated with depression (e.g. appetite, mood, sense of failure)	Scores range from 0, indicating the absence of the particular symptom, to 3 for most severe
Profile of Mood States (POMS)[20]	A self report designed to measure six dimensions of mood, which include: tension–anxiety; depression–dejection; anger–hostility; vigour–activity; fatigue–inertia; and confusion– bewilderment. It consists of 65 short phrases describing feeling and mood, with respondents asked to indicate mood readtions for the "past week including today" or for shorter periods such as "right now"	A five point Likert type scale ranging from 0 for no mood reaction to 5, indicating extreme mood reaction
University of Wales Institute of Science and Technology (UWIST) Mood adaptive checklist (UMACL)[21]	A measurement of mood with four subscales: hedonic tone, anger, tense arousal, and energetic arousal. Except for anger, which only has positively loaded items, each one is made up of a combination of positively loaded and negatively loaded items	The final score is the result of adding the positively loaded answers and subtracting the negatively loaded answers

TABLE 1 continued

Outcome measure (abbreviation)	Description	Scoring
Nottingham Health Profile (NHP) [22]	Generic health related quality of life measure made up of 38 items that can be used to produce scores for six domains of health, including: physical mobility (8 items), pain (8 items), social isolation (5 items), emotional reactions (9 items), energy (3 items) and sleep (5 items)	Yes/No answers and domain scores ranging from 0 to 100. Mean score is calculated across all items within each domain. Overall score is the mean across all items. The higher the score the greater the health problem
Functional Outcomes of Sleep Questionnaire (FOSQ) [23]	A sleep specific functional measure designed to evaluate the impact of sleep disorders and excessive sleepiness. Thirty five items represent five subscales: activity level, vigilance, intimacy and sexual relationships, general productivity, and social outcome	Individual scores of each subscale are obtained and summated to produce a global score. The lower the score the greater the dysfunction as a result of sleepiness. Four levels of response: no difficulty, a little, moderate, or extreme plus non–participation. Scored on a 5 point Likert scale
Cognitive performance measures		
SteerClear (SC)[24]	A computer program designed to simulate a long, mundane highway drive and to characterise the decrements in driving ability. The patient is required to avoid obstacles that randomly appear on a two lane highway by pressing a single computer key. Performance on this 30 minute task is reflected by the number of obstacles passed and the number hit	Reducing the number of obstacles hit reflects improved vigilance
Trailmaking B tests (TTB)[25]	A test for broad cognitive performance that uses the connect a dot concept requiring the patient to draw lines from circle to circle to consecutively link numbers and letters in the quickest time possible	Better cognitive performance is indicated by a reduction in score, which reflects the time taken to complete the task
Digit Symbol Substitution (DSS)[25]	Cognitive speed is tested by matching individually presented symbols to their numbers using a reference key	Improved speed of performance is reflected by an increased score
Paced Auditory Serial Addition Task – 2 second timing (PASAT–2)[25]	A test of auditory attention and concentration by evaluating the time taken to add up numbers presented every 2 seconds	An increase in the score indicates improved ability to maintain concentration under distraction

Breast cancer (metastatic)

Search date September 2003

QUESTIONS

INTERVENTIONS

See glossary, p 2292

Key Messages

First line hormonal treatment

- **Tamoxifen in oestrogen receptor positive women** RCTs have found that antioestrogens (primarily tamoxifen) increase response rates in women with metastatic breast cancer, particularly women with oestrogen receptor positive disease. RCTs have found no significant difference in response rates or overall survival between tamoxifen and progestins or ovarian ablation, but tamoxifen is associated with fewer adverse effects. One RCT has found that tamoxifen was less effective than medroxyprogesterone in improving bone pain. Two RCTs in women with metastatic postmenopausal breast cancer have found that tamoxifen and the aromatase inhibitor anastrozole are similarly effective in reducing time to disease progression. One RCT found that tamoxifen was less effective than the aromatase inhibitor letrozole in reducing time to disease progression.

Breast cancer (metastatic)

- **First line hormonal treatment with antioestrogens (tamoxifen) or progestins (no significant difference in survival compared with non-taxane combination chemotherapy so may be preferable in women with oestrogen receptor positive disease)** One systematic review found no significant difference in survival at 12 or 24 months between first line hormonal treatment with progestins or tamoxifen and non-taxane combination chemotherapy. The review suggested that hormonal treatment may be preferable to chemotherapy as first line treatment in women with oestrogen receptor positive disease unless disease is rapidly progressing. It found that response rates were lower with hormonal treatment than with chemotherapy but it was associated with less nausea, vomiting, and alopecia.
- **Selective aromatase inhibitors in postmenopausal women (as effective as tamoxifen in reducing time to disease progression)** Two RCTs have found that the aromatase inhibitor anastrozole as first line treatment in metastatic postmenopausal breast cancer is at least as effective as tamoxifen in reducing time to disease progression and may cause less thromboembolic adverse events and vaginal bleeding. One RCT found that the aromatase inhibitor letrozole was superior to tamoxifen in reducing time to disease progression.
- **Combined gonadorelin analogues plus tamoxifen in premenopausal women** RCTs in premenopausal women with oestrogen receptor positive metastatic breast cancer have found that first line treatment with gonadorelin analogues plus tamoxifen improves response rates, overall survival, and progression free survival compared with gonadorelin analogues alone.
- **Ovarian ablation in premenopausal women (no significant difference in response rates or survival compared with tamoxifen but associated with substantial adverse effects)** One systematic review and one subsequent RCT in premenopausal women found no significant difference in response rate, duration of response, or survival between ovarian ablation (surgery or irradiation) and tamoxifen as first line treatment. Ovarian ablation is associated with substantial adverse effects such as hot flushes and "tumour flare".
- **Progestins (beneficial in women with bone pain or anorexia compared with tamoxifen)** RCTs found no significant difference in response rates, remission rates, or survival between medroxyprogesterone and tamoxifen as first line treatment. However, they found that medroxyprogesterone increased nausea, vaginal bleeding, and exacerbations of hypertension. One RCT has found that medroxyprogesterone improved bone pain compared with tamoxifen. Observational evidence suggests that progestins may increase appetite, weight gain, and wellbeing.

Second line hormonal treatment

- **Selective aromatase inhibitors in postmenopausal women (prolong survival compared with progestins, as effective in delaying progression as antioestrogens)** RCTs have found that, in postmenopausal women with metastatic breast cancer who have relapsed on adjuvant tamoxifen or progressed during first line treatment with tamoxifen, the selective aromatase inhibitors anastrozole, letrozole, and exemestane prolong survival compared with progestins (megestrol) or non-selective aromatase inhibitors (aminoglutethimide), with fewer adverse effects. Two RCTs found that anastrozole was as effective as fulvestrant for delaying progression. The evidence suggests that selective aromatase inhibitors are better tolerated than previous standard second line treatment with a progestin or aminoglutethimide, and are most effective in oestrogen receptor positive women.

- **Progestins (less effective than selective aromatase inhibitors and have more adverse effects)** RCTs have found that, in postmenopausal women with metastatic breast cancer who have relapsed on adjuvant tamoxifen or progressed during first line treatment with tamoxifen, progestins are less effective in second line treatment than selective aromatase inhibitors and have more adverse effects.

First line chemotherapy

- **Anthracycline based non-taxane combination chemotherapy regimens (CAF) containing doxorubicin (increase response rates and survival compared with other regimens)** RCTs have found that combination chemotherapy regimens containing an anthracycline, such as doxorubicin (CAF) as first line treatment increase response rates, time to progression, and survival compared with other regimens.
- **Classical non-taxane combination chemotherapy (CMF) (increases response rates and survival compared with modified CMF)** One systematic review has found that classical CMF as first line treatment increases response rate and survival compared with modified CMF regimens.
- **Taxane based combination chemotherapy (may increase response rates compared with non-taxane combination chemotherapy)** One systematic review found that taxane based combination chemotherapy as first or second line treatment increased overall survival, time to progression, and overall response compared with non-taxane combination chemotherapy. It found no significant difference in overall survival if the analysis was restricted to RCTs of first line chemotherapy.
- **High dose chemotherapy (no significant difference in overall survival compared with standard chemotherapy and increased adverse effects)** One systematic review found no significant difference in overall survival over 1–5 years between high dose chemotherapy (requiring haematopoietic transplant) and standard dose chemotherapy. It found that high dose chemotherapy increased treatment related morbidity and mortality compared with standard chemotherapy.

First line chemotherapy plus monoclonal antibodies

- **Chemotherapy plus monoclonal antibody (trastuzumab) in women with overexpressed HER2/neu oncogene** One RCT has found that, in women whose tumours overexpress HER2/neu oncogene, standard chemotherapy plus the monoclonal antibody trastuzumab as first line treatment increased the time to disease progression, objective response, and overall survival compared with standard chemotherapy alone. The most serious adverse effect observed was cardiac dysfunction in women who received an anthracycline plus trastuzumab.

Second line chemotherapy

- **Taxane based combination chemotherapy (increases response rates in women with anthracycline resistant disease compared with non-taxane combination chemotherapy)** One systematic review has found that taxane based combination chemotherapy as first or second line treatment increased overall survival, time to progression, and overall response compared with non-taxane combination chemotherapy. The difference remained significant if the analysis was limited to women who had previously received anthracyclines. RCTs found no significant difference in progression or overall survival between docetaxel and 5-fluorouracil plus vinorelbine or between paclitaxel and capecitabine given as second line chemotherapy.

Breast cancer (metastatic)

- **Capecitabine for anthracycline resistant disease** One RCT found similar response rates and time to disease progression between capacitabine and paclitaxel after anthracycline failure.
- **Semisynthetic vinca alkaloids for anthracycline resistant disease** One RCT found no significant difference in progression or overall survival between 5-fluorouracil plus vinorelbine and docetaxel given as second line chemotherapy. Another RCT has found that second line vinorelbine improved survival and reduced progression compared with melphalan. A third RCT found no significant difference in survival or quality of life between vinorelbine plus doxorubicin and vinorelbine alone.

Treatments for bone, cerebral, spinal cord, or choroidal metastases

- **Radiotherapy for spinal cord compression** We found no RCTs. Spinal cord compression is an emergency. Retrospective analyses found that early radiotherapy improved outcomes. However, fewer than 10% of people walked again if severe deterioration of motor function occurred before radiotherapy.
- **Radiotherapy plus appropriate analgesia for bone metastases** We found no RCTs. We found limited evidence from non-randomised studies that persistent and localised bone pain can be treated successfully in over 80% of women with radiotherapy plus concomitant appropriate analgesia (from non-steroidal anti-inflammatory drugs to morphine and its derivatives) and that cranial nerve compession can be treated successfully with radiotherapy in 50–80% of people. RCTs found no evidence that short courses are less effective for pain relief than long courses of radiotherapy. One RCT found that different fractionation schedules can be used to treat neuropathic bone pain effectively.
- **Radiotherapy plus high dose steroids in spinal cord compression** One small RCT in women with spinal cord compression suggested that adding high dose steroids to radiotherapy improved the chance of walking 6 months after treatment compared with radiotherapy alone.
- **Bisphosphonates for bone metastases** RCTs in women receiving standard chemotherapy or hormonal treatment for bone metastases secondary to metastatic breast cancer found that bisphosphonates reduced and delayed skeletal complications compared with placebo. None of the RCTs found an impact on overall survival.
- **Radiotherapy for cerebral metastases** We found no RCTs. Retrospective studies suggest that whole brain radiation improves neurological function in some women with brain metastases secondary to breast cancer.
- **Radiotherapy for choroidal metastases** We found no RCTs. Retrospective studies suggest that radiotherapy benefits some women with choroidal metastases.
- **Intrathecal chemotherapy for cerebral metastases; radiation sensitisers for cerebral metastases surgical resection for cerebral metastases** We found insufficient evidence to assess these interventions in women with cerebral metastases.

DEFINITION Metastatic or advanced breast cancer is the presence of disease at distant sites such as the bone, liver, or lung. It is not treatable by primary surgery and is currently considered incurable. However, young people with good performance status may survive for 15–20 years.[1] Symptoms may include pain from bone metastases, breathlessness from spread to the lung, and nausea or abdominal discomfort from liver involvement.

INCIDENCE/ PREVALENCE Breast cancer is the second most frequent cancer in the world (1.05 million people) and is by far the most common malignant disease in women (22% of all new cancer cases). Worldwide, the ratio of mortality to incidence is about 36%. It ranks fifth as a cause of death from cancer overall (although it is the leading cause of cancer mortality in women — the 370 000 annual deaths represent 13.9% of cancer deaths in women). In the USA, metastatic breast cancer causes 46 000 deaths, and in the UK causes 15 000 deaths.[2] It is the most prevalent cancer in the world today and there are an estimated 3.9 million women alive who have had breast cancer diagnosed in the past 5 years (compared, for example, with lung cancer, where there are 1.4 million alive). The true prevalence of metastatic disease is high because some women live with the disease for many years. Since 1990, there has been an overall increase in incidence rates of about 1.5% annually.[3]

AETIOLOGY/ RISK FACTORS The risk of metastatic disease relates to known prognostic factors in the original primary tumour. These factors include oestrogen receptor negative disease, primary tumours 3 cm or more in diameter, and axillary node involvement — recurrence occurred within 10 years of adjuvant chemotherapy (see glossary, p 2293) for early breast cancer (see glossary, p 2293) in 60–70% of node positive women and 25–30% of node negative women in one large systematic review.[4]

PROGNOSIS Prognosis depends on age, extent of disease, and oestrogen receptor status. There is also evidence that overexpression of the product of the HER2/neu oncogene, which occurs in about a third of women with metastatic breast cancer, is associated with a worse prognosis.[5] A short disease free interval (see glossary, p 2293) (e.g. < 1 year) between surgery for early breast cancer and developing metastases suggests that the recurrent disease is likely to be resistant to adjuvant treatment (see glossary, p 2292).[6] In women who receive no treatment for metastatic disease, the median survival from diagnosis of metastases is 12 months.[7] The choice of first line treatment (see glossary, p 2293) (hormonal or chemotherapy) is based on a variety of clinical factors (see table 1, p 2299).[8–11] In many countries, such as the USA, Canada, and some countries in Europe, there is evidence of a decrease in death rates in recent years. This probably reflects improvements in treatment (and therefore improved survival) as well as earlier diagnosis.[2,12]

AIMS OF INTERVENTION To relieve symptoms, prolong life, and improve quality of life, with minimal adverse effects.

OUTCOMES Symptoms; progression free survival; overall objective response rate; complete response; partial response (see glossary, p 2294); duration of response; disease stabilisation; time to progression of disease (progression defined as > 25% increase in lesion size or the appearance of new lesions); quality of life;[13] improvement in performance status (according to validated scales of daily functioning/activity);[14] adverse effects and toxicity of treatment;[15] and overall survival. Preservation of function, pain, incidence of fractures, requirement for radiotherapy or surgery in people with

bone, spinal, cerebral, or choroidal metastases. Response to treatment is a surrogate outcome measure for assessing the effects of treatment on survival or quality of life. The link between clinical and proxy outcomes has not been clearly validated. Women who respond to treatment are more likely to experience improved symptomatic relief, performance status, and survival.[16–18] One recent prospective study (300 women with metastatic breast cancer) found a significant relationship between improvement and objective response for three symptoms, in particular cancer pain, shortness of breath, and abnormal mood. Symptom improvement was greatest in those women who had a complete or partial response.[19]

METHODS *Clinical Evidence* search and appraisal September 2003. The authors looked for good quality systematic reviews that used the outcome measures listed above. Where they found no good systematic reviews, they included relevant randomised phase III trials using these outcomes. Studies presented only in abstract form were discarded. Response to treatment is often assessed in an unblinded fashion, introducing the possibility of bias. We found few trials of good quality that reported on symptoms or quality of life.

QUESTION What are the effects of first line hormonal treatment?

OPTION ANTIOESTROGENS (TAMOXIFEN)

RCTs have found that antioestrogens (primarily tamoxifen) increase response rates in women with oestrogen receptor positive metastatic breast cancer. RCTs have found no significant difference in response rates or overall survival between tamoxifen and progestins or ovarian ablation, but tamoxifen is associated with fewer adverse effects. One RCT found that tamoxifen was less effective than medroxyprogesterone in improving bone pain. Two RCTs in women with metastatic postmenopausal breast cancer have found that tamoxifen and the aromatase inhibitor anastrozole are similarly effective in reducing time to disease progression but that tamoxifen may cause more thromboembolic adverse effects and vaginal bleeding. One RCT found that tamoxifen was less effective than the aromatase inhibitor letrozole in reducing time to disease progression. One systematic review found no significant difference in survival at 12 or 24 months between first line hormonal treatment (with tamoxifen or progestins) and non-taxane combination chemotherapy. The review suggested that hormonal treatment may be preferable to chemotherapy as first line treatment in women with oestrogen receptor positive disease unless disease is rapidly progressing. It found that response rates were lower with hormonal treatment than with chemotherapy but it was associated with less nausea, vomiting, and alopecia.

Benefits: We found no systematic review. Non-systematic reviews identified 86 RCTs in 5353 women with metastatic breast cancer unselected for oestrogen receptor status. The overall objective response rate to tamoxifen (see glossary, p 2294) was 34%. Disease stabilisation was achieved in a further 20%, and overall the median duration of response was 12–18 months.[8,9] The likelihood of responding to tamoxifen was highest (60–70%) in postmenopausal women with

oestrogen receptor positive disease (see comment below).[10,11] **Versus progestins:** See benefits of progestins as first line hormonal treatment, p 2274. **Versus ovarian ablation in premenopausal women:** See ovarian ablation in premenopausal women, p 2274. **Versus anastrozole in postmenopausal women:** See benefits of selective aromatase inhibitors as first line hormonal treatment in postmenopausal women, p 2276. **Versus letrozole in postmenopausal women:** See benefits of selective aromatase inhibitors as first line hormonal treatment in postmenopausal women, p 2276. **Versus non-taxane combination chemotherapy:** See glossary, p 2293. See benefits of non-taxane combination chemotherapy as first line treatment, p 2280.

Harms: **Minor adverse effects:** Tamoxifen is well tolerated in women with metastatic breast cancer; fewer than 3% of women discontinued tamoxifen as a result of toxicity.[20] Reported adverse effects included minor gastrointestinal upset (8%), hot flushes (27%), and menstrual disturbance in premenopausal women (13%).[21] **Tumour flare:** During the first few weeks of treatment, tumour flare occurred in fewer than 5% of women. For those with bone metastases, this may have resulted in increased pain or symptomatic hypercalcaemia. **Relapse:** Most women who initially respond to tamoxifen eventually progress and develop acquired resistance to tamoxifen, although they may still respond to further hormonal interventions.[22]

Comment: **Antioestrogens:** An emerging problem is that many women have already received adjuvant tamoxifen for early breast cancer (see glossary, p 2293) or have developed metastatic disease while still taking tamoxifen, and are thus considered resistant to it. Effective second line treatment (see glossary, p 2294) hormonal drugs, such as selective aromatase inhibitors (see glossary, p 2293), are now used after tamoxifen failure (see selective aromatase inhibitors in postmenopausal women, p 2277), and RCTs have compared selective aromatase inhibitors with tamoxifen as first line treatment (see glossary, p 2293) (see selective aromatase inhibitors as first line treatment in postmenopausal women, p 2276). New non-steroidal antioestrogens (toremifene, idoxifene, raloxifene) and steroidal antioestrogens (fulvestrant) are more selective than tamoxifen and may have fewer long term adverse effects. RCTs comparing some of these drugs with tamoxifen as first line hormonal treatment (see glossary, p 2293) in metastatic breast cancer are in progress. So far, one RCT in 658 women has found no evidence of clear clinical superiority of toremifene over tamoxifen.[23]

OPTION PROGESTINS

RCTs found no significant difference in response rates, remission rates, or survival between medroxyprogesterone and tamoxifen as first line treatment. However, they found that medroxyprogesterone increased nausea, vaginal bleeding, and exacerbations of hypertension. One RCT found that medroxyprogesterone improved bone pain compared with tamoxifen. Observational evidence suggests that progestins may increase appetite, weight gain, and wellbeing. One systematic review found no significant difference in survival at 12 or 24 months between first line hormonal treatment (with progestins or tamoxifen) and non-taxane

combination chemotherapy. The review suggested that hormonal treatment may be preferable to chemotherapy as first line treatment in women with oestrogen receptor positive disease unless disease is rapidly progressing. It found that response rates were lower with hormonal treatment than with chemotherapy but it was associated with less nausea, vomiting, and alopecia.

Benefits: **Versus tamoxifen:** We found one systematic review (search date 1991, 7 RCTs, 801 women with metastatic breast cancer)[24] and one subsequent RCT[25]comparing medroxyprogesterone versus tamoxifen (see glossary, p 2294). The review found no significant difference in response rates (35–54%), remission rates, or survival between the two groups. Benefits of progestins (see glossary, p 2294) included an analgesic effect (assessed using questionnaires), especially on painful bone metastases,[26] increased appetite, weight gain, and a feeling of wellbeing. The subsequent RCT (166 women) found that medroxyprogesterone increased the rate of response of bone metastases compared with tamoxifen (33% with medroxyprogesterone *v* 13% with tamoxifen; $P = 0.01$). It found no significant difference in survival.[25] It also found that medroxyprogesterone significantly increased weight gain compared with tamoxifen (mean 17 lb [7.6 kg] with medroxyprogesterone *v* mean 5 lb [2.2 kg] with tamoxifen; $P < 0.001$). **Versus non-taxane combination chemotherapy:** See glossary, p 2293. See benefits of non-taxane based combination chemotherapy as first line treatment, p 2280.

Harms: **Versus tamoxifen:** The systematic review gave no information on adverse effects.[24] The subsequent RCT) found that tamoxifen significantly increased nausea and vomiting compared with medroxyprogesterone ($P < 0.001$).[25] Six women taking medroxyprogesterone withdrew because of adverse effects compared with none taking tamoxifen. One non-systematic review found that adverse effects associated with medroxyprogesterone were common at higher doses and included nausea (14%), vaginal bleeding (10%), and exacerbation of hypertension. In women with lymphangitis carcinomatosis, progestins may exacerbate symptoms of breathlessness.[27]

Comment: In view of the lack of evidence of greater benefit, and the evidence of greater harm, progestins are generally reserved for second or third line hormonal treatment (see glossary, p 2293) in women with advanced breast cancer who have not responded to tamoxifen.

OPTION OVARIAN ABLATION IN PREMENOPAUSAL WOMEN

One systematic review and one subsequent RCT in premenopausal women found no significant difference in response rate, duration of response, or survival between ovarian ablation (surgery or irradiation) and tamoxifen as first line treatment. Ovarian ablation is associated with substantial adverse effects such as hot flushes and "tumour flare".

Benefits: **Versus tamoxifen:** We found one systematic review (search date not stated, 4 RCTs, 220 premenopausal women)[28] and one subsequent RCT[29] comparing ovarian ablation (carried out by either surgery or irradiation) versus tamoxifen (see glossary, p 2294). The

review found no significant difference between treatments in response rate, response duration, or survival.[28] The subsequent RCT (39 premenopausal women) comparing initial treatment ovarian ablation versus tamoxifen found similar results (OR for progressive disease (see glossary, p 2294) 0.71, 95% CI 0.37 to 1.38; median survival 2.46 years with ovarian ablation *v* 2.35 years with tamoxifen; P = 0.98; OR for mortality 1.07, 95% CI 0.55 to 2.06).[29] **Different methods of ovarian ablation:** We found two RCTs comparing gonadorelin analogues (see glossary, p 2293) versus surgical ovariectomy or irradiation. They found no significant difference in survival between treatments.[30,31]

Harms: **Different methods of ovarian ablation:** Adverse effects include hot flushes (75% with gonadorelin analogues *v* 46% with surgical ovariectomy) and "tumour flare" (16% with gonadorelin analogues).[30] In addition, the risks of surgical ovariectomy include those associated with general anaesthesia.

Comment: None.

OPTION COMBINED GONADORELIN ANALOGUES PLUS TAMOXIFEN IN PREMENOPAUSAL WOMEN

RCTs in premenopausal women with oestrogen receptor positive metastatic breast cancer have found that first line treatment with gonadorelin analogues plus tamoxifen improves response rates, overall survival, and progression free survival compared with gonadorelin analogues alone.

Benefits: **Versus gonadorelin analogues alone:** We found one non-systematic review (4 RCTs, 506 premenopausal women, primarily with oestrogen receptor positive metastatic breast cancer).[32] It found combined endocrine treatment with gonadorelin analogues plus tamoxifen significantly improved both progression free survival (see glossary, p 2294) (HR 0.70, 95% CI 0.58 to 0.85; P = 0.0003) and overall survival (HR 0.78, 95% CI 0.63 to 0.96; P = 0.02) compared with a gonadorelin analogue alone.[32] The overall response rate was also significantly higher for combined treatment (OR 0.67, 95% CI 0.46 to 0.96; P = 0.03).

Harms: **Versus gonadorelin analogues alone:** Although the meta-analysis did not analyse differences in tolerability, the largest of the individual trials found there was no significant difference in expected hormonal adverse effects (hot flushes, vaginal discharge) between the combined treatment and gonadorelin analogues alone.

Comment: We found that combined endocrine treatment in metastatic breast cancer was more beneficial than single agent treatment. Research is now aiming to establish whether there is any additional benefit from complete oestrogen deprivation in premenopausal women using ovarian ablation with gonadorelin analogues combined with aromatase inhibitors (see glossary, p 2293).

OPTION SELECTIVE AROMATASE INHIBITORS AS FIRST LINE HORMONAL TREATMENT IN POSTMENOPAUSAL WOMEN

Two RCTs have found that the aromatase inhibitor anastrozole as first line treatment in metastatic postmenopausal breast cancer is at least as effective as tamoxifen in reducing time to disease progression and may cause less thromboembolic adverse events and vaginal bleeding. One RCT found that the aromatase inhibitor letrozole was superior to tamoxifen in reducing time to disease progression.

Benefits:

Anastrozole versus antioestrogens (tamoxifen): We found two RCTs comparing anastrozole versus tamoxifen (see glossary, p 2294).[33,34] The first RCT (668 women) found no significant difference in time to disease progression (see glossary, p 2294) (HR 0.99, 95% CI 0.86 to 1.12) or response rate (32.9% with anastrozole *v* 32.6% with tamoxifen).[33] The second RCT (353 women) found that anastrozole significantly prolonged time to progression (HR for progression, tamoxifen *v* anastrozole 1.44, 95% CI 1.16 to 1.82).[34] Neither trial reported on the effect on survival because of insufficient data, but a survival analysis of data from both RCTs at 2 years found no significant effect on survival.[35]

Letrozole versus antioestrogens (tamoxifen): We found one RCT (907 women) comparing letrozole versus tamoxifen.[36] It found that letrozole significantly increased the time to progression (9.4 months with letrozole *v* 6.0 months with tamoxifen; $P < 0.0001$), time to treatment failure (9.0 months with letrozole *v* 5.7 months with tamoxifen; $P < 0.0001$), and response rates (32% with letrozole *v* 21% with tamoxifen; $P = 0.0002$).[36] It found no significant difference in overall survival (34 months with letrozole *v* 30 months with tamoxifen; reported as non-significant, CI not reported).[36] Subgroup analysis of 562 women with normal HER2/neu oncogene expression included in the RCT[36] found that letrozole significantly increased objective response rates and time to progression compared with tamoxifen but subgroup analysis of 398 women with elevated HER2/neu oncogene expression found no significant difference in objective response rates between letrozole and tamoxifen.[37]

Harms:

Anastrozole versus antioestrogens (tamoxifen): In both trials, anastrozole was associated with reduced thromboembolism and vaginal bleeding compared with tamoxifen (thromboembolic events: 4.8% with anastrozole *v* 7.3% with tamoxifen;[33] vaginal bleeding: 4.1% with anastrozole *v* 8.2% with tamoxifen;[34] CIs not reported).

Letrozole versus tamoxifen: The RCT found that the frequency of adverse events was similar with letrozole and tamoxifen.[36]

Comment:

These RCTs[33,34,38] have confirmed that the selective third generation aromatase inhibitors (see glossary, p 2293) are more efficacious than tamoxifen, with a similar if not better safety profile. These treatments may, therefore, replace tamoxifen as the first line (see glossary, p 2293) endocrine treatment of choice for postmenopausal women with oestrogen receptor positive metastatic breast cancer. Results from the letrozole trials suggest an early survival advantage for women treated with letrozole rather than tamoxifen, which was not seen on further follow up owing to the prospective crossover of a large number of patients at progression.[39]

QUESTION **What are the effects of second line hormonal treatment in women who have not responded to tamoxifen?**

OPTION PROGESTINS

RCTs have found that, in postmenopausal women with metastatic breast cancer who have relapsed on adjuvant tamoxifen or progressed during first line treatment with tamoxifen, progestins are less effective in second line treatment than selective aromatase inhibitors and have more adverse effects.

Benefits: **Versus selective aromatase inhibitors:** See glossary, p 2293. See benefits of selective aromatase inhibitors in postmenopausal women, p 2277.

Harms: **Versus selective aromatase inhibitors:** See harms of selective aromatase inhibitors in postmenopausal women, p 2278.

Comment: In women who are not responding to tamoxifen, progestins (see glossary, p 2294) may have a role in increasing feelings of wellbeing and relieving anorexia.

OPTION SELECTIVE AROMATASE INHIBITORS IN POSTMENOPAUSAL WOMEN

RCTs have found that, in postmenopausal women with metastatic breast cancer who have relapsed on adjuvant tamoxifen or progressed during first line treatment with tamoxifen, the selective aromatase inhibitors anastrozole, letrozole, and exemestane prolong survival compared with progestins (megestrol) or non-selective aromatase inhibitors (aminoglutethimide), with fewer adverse effects. Two RCTs found that anastrozole was as effective as fulvestrant for delaying progression. The evidence suggests that selective aromatase inhibitors are better tolerated than previous standard second line treatment with a progestin or aminoglutethimide, and are most effective in oestrogen receptor positive women.

Benefits: **Anastrozole versus progestins (megestrol):** A meta-analysis of the two randomised phase III trials comparing anastrozole versus megestrol (764 postmenopausal women with metastatic breast cancer unresponsive to tamoxifen [see glossary, p 2294], median age 65 years, 70% oestrogen receptor positive, 30% oestrogen receptor status unknown) found no significant difference in objective response rates (10.3% with anastrozole *v* 7.9% with megestrol), or in the proportion of women whose disease was stabilised for 6 months (25.1% with anastrozole *v* 26.1% with megestrol).[40] A subsequent analysis after a median of 31 months' follow up found a significant improvement in overall survival with anastrozole (HR for death 0.78; P = 0.02), with an absolute improvement in 2 year survival from 46% to 56%; P = 0.02) and an improvement in median survival of 4 months (from 22.5 months to 26.7 months).[41]
Anastrozole versus antioestrogens (fulvestrant): We found two RCTs comparing anastrozole versus fulvestrant.[42,43] The first RCT (400 postmenopausal women with locally advanced or metastatic breast cancer who had progressed on endocrine treatment) found

that fulvestrant increased time to progression (see glossary, p 2294) compared with anastrozole, although the difference was not significant (median time to progression: 5.4 months with fulvestrant *v* 3.4 months with anastrozole; proportion of people who had disease progression over a median 16.8 months: 83.5% with fulvestrant with *v* 86.1% with anasrazole; HR 0.92, 95% CI 0.74 to 1.14).[42] Among 70 women who responded to treatment, fulvestrant increased duration of response compared with anastrozole (19.0 months with fulvestrant *v* 10.8 months with anastrozole; P = 0.01). The second RCT (451 postmenopausal women with locally advanced or metastatic breast cancer who had progressed on endocrine treatment) found no significant difference between fulvestrant and anastrozole in time to progression (median time to progression: 5.5 months with fulvestrant *v* 5.1 months with anastrozole; HR 0.98, 95% CI 0.80 to 1.21).[43] **Exemestane versus progestins (megestrol):** One RCT (769 women) found that exemestane significantly improved median survival time, median duration of treatment success, and time to progression compared with megestrol (median survival time: not reached with exemestane *v* 123 weeks with megestrol; P = 0.039; median duration of overall success [complete response/partial response—see glossary, p 2294—or stable disease ≥ 24 weeks]: 60.1 with exemestane *v* 49.1 weeks with megestrol; P = 0.025; time to tumour progression: 20.3 with exemestane *v* 16.6 weeks with megestrol; P = 0.037).[45] Compared with megestrol, there were similar or greater improvements in pain control, tumour related signs and symptoms, and quality of life with exemestane.[45] **Letrozole versus progestins (megestrol) or non-selective aromatase inhibitors (aminoglutethimide):** We found two large RCTs comparing letrozole 0.5 or 2.5 mg versus megestrol (551 women)[46] and versus aminoglutethimide (555 women).[47] Both RCTs were in postmenopausal women with metastatic breast cancer unresponsive to tamoxifen (median age 64–65 years, 55% oestrogen receptor positive, 45% oestrogen receptor status unknown). The first RCT found that letrozole 2.5 mg significantly increased the response rate, duration of response, and time to treatment failure compared with megestrol (P < 0.05 for all outcomes).[46] The second RCT found letrozole improved overall survival and progression rates compared with aminoglutethimide (overall survival: HR 0.64, 95% CI 0.49 to 0.85; progression: HR 0.72, 95% CI 0.57 to 0.92).[47]

Harms: The selective aromatase inhibitors (see glossary, p 2293) were generally well tolerated and associated with fewer adverse events than aminoglutethimide or progestins (see glossary, p 2294). **Anastrozole:** In the RCTs, anastrozole 1 mg increased minor gastrointestinal disturbance (nausea or change in bowel habit) compared with megestrol (29% with anastrozole *v* 21% with megestrol; P = 0.005). However, it reduced weight gain (AR for ≥ 5% weight gain: 13% with anastrozole *v* 34% with megestrol; P < 0.0001).[40] The RCTs comparing anastrozole versus fulvestrant found that both treatments were well tolerated.[42,43] The first RCT found that the proportion of women who had hot flushes was similar in both groups (23.5% with fulvestrant *v* 24.9% with anastrozole; CI not reported).[42] The second RCT reported that 1.3% of people stopped anastrozole because of adverse effects compared with 3.2% taking

fulvestrant (CI not reported).[43] The incidence of weight gain (1.5% with fulvestrant *v* 1.6% with anastrozole), vaginitis (3.4% with fulvestrant *v* 2.6% with anastrozole), and thromboembolic disease (3.4% with fulvestrant *v* 6.7% with anastrozole) was low in both groups (CI not reported for any outcome).[43] Joint disorders (including arthritis, arthralgia, and arthrosis) were reported by 9.3% of people taking fulvestrant and 13.5% of people taking anastrozole (CI not reported). **Exemestane:** In the RCTs, progestin increased adverse events compared with exemestane (45.8% with progestin *v* 39.1% with exemestane). The most frequently reported adverse events with exemestane were low grade hot flushes (12.6%), nausea (9.2%), and fatigue (7.5%). In the RCT comparing exemestane versus megestrol, both drugs were well tolerated, although grade 3 or 4 weight changes (> 10% weight gain) were more common with megestrol (17.1% with megestrol *v* 7.6% with exemestane; P = 0.001).[45] **Letrozole:** The first RCT found that, compared with megestrol, letrozole 2.5 mg significantly reduced the proportion of women who had serious cardiovascular adverse events (10% with letrozole *v* 29% with megestrol; ARR 19%, 95% CI 11% to 27%). It found no significant difference in weight gain although fewer women taking letrozole had weight gain (≥ 10% weight gain: 6% with letrozole *v* 11% with megestrol; reported as non-significant, CI not reported).[46] The second RCT found that fewer women taking letrozole 2.5 mg had skin rash and serious drug related adverse events compared with women taking aminoglutethimide (skin rash: 3% with letrozole *v* 11% with aminoglutethimide; serious drug related adverse events: 0% with letrozole *v* 3% with aminoglutethimide; CI not reported).[47]

Comment: The evidence indicates greater efficacy and tolerability of anastrozole and letrozole over megestrol acetate or aminoglutethimide. There is a consensus that they are agents of choice as second line hormonal treatment (see glossary, p 2293) in postmenopausal women no longer responding to tamoxifen. Exemestane is currently being evaluated in phase III trials.[44] A phase II trial conducted in 2000 has evaluated the activity of exemestane in metastatic breast cancer after failure of other non-steroidal aromatase inhibitors.[48] A total of 241 people were enrolled; 56% had received aminoglutethimide, 19% anastrozole, and 17% letrozole. Exemestane produced objective responses in 7% of treated women, including 8% of women after failure of treatment with aminoglutethimide and 5% after failure of other non-steroidal aromatase inhibitors (anastrozole, letrozole, and vorozole), and an overall success rate (complete response plus partial response plus no change for ≥ 24 weeks) of 24%. Women who do not respond to anastrozole or letrozole may respond to exemestane.

QUESTION What are the effects of first line chemotherapy?

OPTION NON-TAXANE COMBINATION CHEMOTHERAPY

We found no RCTs comparing non-taxane combination chemotherapy versus no chemotherapy in women with metastatic breast cancer. Trials comparing one type of chemotherapy versus another found that first line

chemotherapy was associated with an objective tumour response in 40–60% of women, with a median response duration of 6–12 months irrespective of menopausal or oestrogen receptor status. A small proportion of women achieve complete remission, which may persist for an extended length of time (see high dose versus standard dose chemotherapy, p 2284). One systematic review has found that classical non-taxane combination chemotherapy as first line treatment increases response rate and survival compared with modified CMF regimens. RCTs have found that combination chemotherapy regimens containing an anthracycline, such as doxorubicin (CAF) as first line treatment increase response rates, time to progression, and survival compared with other regimens. One systematic review found no significant difference in survival at 12 or 24 months between first line non-taxane combination chemotherapy and hormonal treatment with tamoxifen or progestins. The review suggested that hormonal treatment may be preferable to chemotherapy as first line treatment in women with oestrogen receptor positive disease unless disease is rapidly progressing. It found that chemotherapy increased response rates but also increased nausea, vomiting, and alopecia. One systematic review found that non-taxane combination chemotherapy as first or second line treatment was less effective than taxane based combination chemotherapy in increasing overall survival, time to progression, and overall response. It found no significant difference in overall survival if the analysis was restricted to RCTs of first line chemotherapy.

Benefits:

Versus best supportive care: We found no systematic review and no RCTs comparing first line chemotherapy (see glossary, p 2293) versus palliative (best supportive) care in women with metastatic breast cancer. **Different non-taxane chemotherapy regimens:** We found two systematic reviews (search date 1997,[20] 189 RCTs, 31 510 women; search date not reported,[51] 5 RCTs, 1088 people) and two subsequent RCTs[56,57] evaluating different chemotherapy regimens. **"Classical" versus modified CMF:** In the largest RCT identified by the first review[20] (254 postmenopausal women with metastatic breast cancer who had received no prior chemotherapy) the classical CMF (see glossary, p 2293) regimen significantly improved survival and response rate compared with a modified version, in which all three drugs were given intravenously every 3 weeks (response rate: 48% with classical CMF *v* 29% with modified; P = 0.03; median survival: 17 months with classical CMF *v* 12 months with modified; P = 0.016).[49] Another RCT identified by the review[20] (133 women who had received no prior chemotherapy) found that standard dose CMF significantly improved both response rate (30% with standard dose *v* 11% with low dose; P = 0.03) and symptom control compared with low dose CMF.[50] **CAF versus CMF:** The second review (5 RCTs, 1088 people) found that CAF (see glossary, p 2293) regimens increased response rate (HR 0.56, 95% CI 0.43 to 0.73), time to progression (see glossary, p 2294) (HR 0.69, 95% CI 0.59 to 0.81), and survival (HR 0.78, 95% CI 0.67 to 0.90) compared with non-anthracycline based regimens.[51] However, two of the included RCTs found no evidence of improved survival.[52,53] **Standard versus modified CAF regimens:** Two large multicentre trials identified by the first review[20] comparing CAF (containing doxorubicin) versus FEC (see glossary, p 2293), a modified anthracycline based regimen containing epirubicin, found

no significant difference in response rates (263 women, response rate 52% with CAF *v* 50% with FEC;[54] 497 women, response rate 56% with CAF *v* 54% with FEC[55]). One subsequent RCT (249 women) comparing standard CAF (containing doxorubicin) versus a modified, better tolerated, anthracycline based regimen containing mitoxantrone (mitozantrone) found that the regimen containing doxorubicin significantly prolonged the time to progression (3.2 months with regimen containing mitoxantrone *v* 5.3 months with regimen containing doxorubicin; P = 0.03) and increased median survival (10.9 months with regimen containing mitoxantrone *v* 15.2 months with regimen containing doxorubicin; P = 0.003).[56] **CAF or modified CAF versus mitoxantrone and vinorelbine (MV):** One subsequent RCT (281 women) comparing MV versus either CAF or FEC found no significant difference in response rates among treatments (35% with MV *v* 33% with CAF or FEC).[57] Subgroup analysis in women who had received prior adjuvant treatment (see glossary, p 2292) found that MV significantly improved response rate and progression free survival compared with other treatments (response rate: 33% with MV *v* 13% with CAF or FEC; P = 0.025; progression free survival: 9 months with MV *v* 6 months with CAF or FEC; P = 0.014).[57] **Versus hormonal treatment (antioestrogens or progestins):** We found one systematic review (search date 2002, 10 RCTs, total number of women not reported) comparing chemotherapy alone versus hormonal treatment (see glossary, p 2293) alone.[58] It found no significant difference in survival at 12 or 24 months (6 RCTs, 112/349 [32%] with chemotherapy *v* 104/330 [31%] with hormonal treatment; HR 1.03, 95% CI 0.74 to 1.43; see comment below).[58] It found that chemotherapy significantly increased response rates compared with hormonal treatment (7 RCTs, 767 women, 131/374 [35%] with chemotherapy *v* 110/393 [28%] with hormonal treatment; RR 1.25, 95% CI 1.01 to 1.54; see comment below). **Versus taxane based combination chemotherapy:** See benefits of taxane based combination chemotherapy as first line treatment, p 2283.

Harms: **Versus best supportive care:** We found no RCTs. **Different chemotherapy regimens:** The toxicity profiles of different combination chemotherapy regimens vary. In RCTs, anthracycline based regimens (CAF) and non-anthracycline based regimens (CMF) are equally associated with haematological toxicity,[53] but CAF is more likely to be associated with alopecia (34% with CAF *v* 22% with CMF) and severe nausea and vomiting (17% with CAF *v* 7% with CMF; P = 0.05). Other studies reported the incidence of greater than grade 3 alopecia (complete hair loss) to be 55–61% with CAF, which was significantly higher than with either mitoxantrone or epirubicin (FEC [see glossary, p 2293]).[55,56] In one of the trials comparing CAF versus FEC, FEC was associated with fewer episodes of grade 2 or greater neutropenia (10% with FEC *v* 13.1% with CAF), and significantly lower rates of nausea and vomiting (7.8% with FEC *v* 13.3% with CAF; P < 0.01), and no cardiotoxicity (8 women taking CAF discontinued treatment because of cardiac dysfunction compared with none taking FEC).[54] MV was associated with less nausea and vomiting and alopecia than CAF or FEC, although myelosuppression was greater (P = 0.001). **Versus hormonal treatment (antioestrogens or progestins):** The

review reported little information on adverse effects.[58] Six RCTs included in the review found that more people receiving chemotherapy had nausea, vomiting, and alopecia than people taking hormonal treatment (CI not reported). **Versus taxane based combination chemotherapy:** See harms of taxane based combination chemotherapy as first line treatment, p 2283.

Comment: **Versus hormonal treatment (antioestrogens or progestins):** The choice of first line treatment (hormonal or chemotherapy) is based on a variety of clinical factors (see table 1, p 2299).[8–11] The systematic review found significant heterogeneity among the trials analysed for response rates (P = 0.0009).[58] The review suggested that, in women with oestrogen receptor positive disease, hormonal treatment may be recommended except in women with rapidly progressing disease.[58] In one RCT (231 women having first line treatment, 60% oestrogen receptor positive, 40% oestrogen receptor status unknown), women were randomised to receive either chemotherapy (CAF) or chemotherapy plus hormonal treatment (CAF plus tamoxifen [see glossary, p 2294] and fluoxymesterone). Response rates and time to treatment failure were similar for women who received chemo–hormonal treatment compared with chemotherapy alone (time to treatment failure 13.4 months with chemo–hormonal *v* 10.3 months with chemotherapy; P = 0.087).[59] The effect on time to treatment failure was just significant for women who were oestrogen receptor positive compared with those who were negative (17.4 months for oestrogen receptor positive *v* 10.3 months for oestrogen receptor negative; P = 0.048). Oestrogen receptor status had no effect on overall survival. The choice of a specific drug or regimen is based on which drugs have already been given as adjuvant treatment, together with the likelihood of benefit balanced against a given drug's adverse effects and tolerability profile. Retrospective series in sequential decades (from 1950–1980) have assessed the effect of chemotherapy on the survival of women from the time of diagnosis with metastatic breast cancer. They suggest that the introduction of chemotherapy has improved median survival by about 9 months (from 12 months without treatment to 21 months with treatment).[7,60] This median survival conceals a bimodal distribution of benefit, with the 40–60% of women who respond to treatment achieving survival of 1 year or greater, and the non-responders experiencing little or no survival benefit. With the increasing use of adjuvant chemotherapy,[61] more women who develop metastatic disease will have received combination chemotherapy. In the treatment of metastatic breast cancer, better quality of life scores predict better outcome (this is not the case in adjuvant treatment).[62] In one RCT (283 women with metastatic breast cancer) evaluating quality of life as a primary end point, no significant differences were found between women randomised to receive either docetaxel or sequential methotrexate and fluorouracil. This suggests that choice of treatment should be based on expected clinical effect.[63] This may influence the likelihood of response to further treatment.[63,64] The prevention of nausea and vomiting caused by chemotherapy has been studied in one RCT (619 women).[65] It compared placebo versus dexamethasone versus dexamethasone plus ondansetron after chemotherapy. In people

who did not have acute nausea and vomiting with chemotherapy, dexamethasone alone was found to provide adequate protection against delayed nausea and vomiting.[65] **Duration of chemotherapy:** The optimal duration of chemotherapy for metastatic breast cancer is unknown, although a more recent systematic review (search date not stated; 65 publications reporting 97 treatment comparisons) has found that more, rather than fewer, cycles of chemotherapy given at appropriate doses improved survival (ratio of median survivals 1.23, 95% CI 1.01 to 1.49; P = 0.01).[66]

OPTION TAXANE BASED COMBINATION CHEMOTHERAPY

One systematic review found that taxane based combination chemotherapy as first or second line treatment increased overall survival, time to progression, and overall response compared with non-taxane combination chemotherapy. It found no significant difference in overall survival if the analysis was restricted to RCTs of first line chemotherapy.

Benefits:

Versus non-taxane combination chemotherapy: See glossary, p 2293. We found one systematic review (search date 2003, 20 RCTs), which compared taxane based versus non-taxane based combination chemotherapy for first or second line (see glossary, p 2294) treatment.[67] Twelve RCTs assessed progression free and overall survival. The review found that taxane containing combination chemotherapy as first or second line treatment significantly increased overall survival compared with non-taxane based chemotherapy (proportion of women who died: 1397/1947 [72%] with taxane based *v* 1262/1696 [75%] with non-taxane based; HR 0.90, 95% CI 0.84 to 0.97).[67] It found that, compared with non-taxane based combination chemotherapy, taxanes as first or second line treatment significantly increased time to progression (see glossary, p 2294) (HR 0.87, 95% CI 0.81 to 0.93) and response rates (OR 1.29, 95% CI 1.13 to 1.47). The review found no significant difference in overall survival if the analysis was restricted to RCTs of first line chemotherapy (6 RCTs; HR 0.92, 95% CI 0.84 to 1.02).

Harms:

The review found that taxane based combination chemotherapy (see glossary, p 2294) was associated with more neurotoxicity and alopecia than non-taxane based regimens.[67]

Comment:

The review found no significant heterogeneity among the trials included in the analysis of overall survival.[67] However, it found significant heterogeneity among the trials included in the analysis of time to progression and response rates (P < 0.00001), probably reflecting the varying efficacy of the comparator regimens used in the trials. When all trials are considered, taxane containing regimens seem to improve overall survival, time to progression, and overall response in women with metastatic breast cancer. The degree of heterogeneity encountered indicates that taxane containing regimens are more effective than some, but not all non-taxane containing regimens.

OPTION HIGH DOSE VERSUS STANDARD DOSE CHEMOTHERAPY

One systematic review found no significant difference in overall survival over 1–5 years between high dose chemotherapy (requiring haematopoietic transplant) and standard dose chemotherapy. It found that high dose chemotherapy increased treatment related morbidity and mortality compared with standard chemotherapy.

Benefits: We found one systematic review (search date 2002; 5 RCTs of first line high dose chemotherapy (see glossary, p 2293) plus bone marrow or stem cell transplant; 740 women).[68] It found that high dose chemotherapy significantly increased progression free survival (see glossary, p 2294) at 1 and 2 years (at 2 years: RR 1.96, 95% CI 1.32 to 2.90). It found no significant difference in progression free survival at 3 or 5 years (at 5 years: RR 1.21, 95% CI 0.40 to 3.69). It found no significant difference between high and standard dose chemotherapy in overall survival at 1, 2, 3, or 5 years (at 5 years: RR 1.28, 95% CI 0.72 to 2.27).

Harms: The review found that high dose chemotherapy significantly increased treatment related death compared with standard dose chemotherapy (10/382 [2.6%] with high dose *v* 0/358 [0%] with standard dose; RR 5.70, 95% CI 1.30 to 25.00).[68] It found that high dose chemotherapy significantly increased leucopenia, diarrhoea, cardiotoxicity, thrombocytopenia, and anaemia (leucopenia: RR 1.97, 95% CI 1.58 to 2.45; diarrhoea: RR 22.00, 95% CI 3.05 to 159.00; cardiotoxicity RR 3.15, 95% CI 1.15 to 8.59; thrombocytopenia: RR 19.50, 95% CI 7.49 to 50.80; anaemia: RR 11.30, 95% CI 4.80 to 26.80).[68]

Comment: Fifteen years' follow up of women with metastatic breast cancer treated with standard dose FAC (see glossary, p 2293) found that 263/1581 (16.6%) women achieved a complete response (see glossary, p 2293) and that median time to progression was 2 years; 19% of these women remained free of disease at 5 years.[18] Any long term remissions associated with high dose chemotherapy in metastatic disease must be interpreted in the context of these figures. It remains to be seen if certain women, for example those with a complete response after standard dose chemotherapy, may benefit from subsequent high dose chemotherapy.[69,70]

QUESTION What are the effects of first line chemotherapy in combination with a monoclonal antibody?

OPTION STANDARD CHEMOTHERAPY PLUS TRASTUZUMAB

One RCT found that, in women whose tumours overexpress HER2/neu oncogene, standard chemotherapy plus the monoclonal antibody trastuzumab as first line treatment increased the time to disease progression, objective response, and overall survival compared with standard chemotherapy alone. The most serious adverse effect observed was cardiac dysfunction in women who received an anthracycline plus trastuzumab.

Benefits: **Versus chemotherapy alone:** One RCT (469 women with HER2/neu oncogene overexpression) compared standard chemotherapy (see glossary, p 2293) alone versus standard chemotherapy plus trastuzumab.[71] Women who had not previously received postoperative chemotherapy with an anthracycline were treated with doxorubicin (or epirubicin) and cyclophosphamide with or without trastuzumab. Women who had previously received postoperative anthracycline were treated with paclitaxel with or without trastuzumab. Adding trastuzumab to chemotherapy significantly prolonged the time to disease progression (7.4 months with trastuzumab plus chemotherapy *v* 4.6 months with chemotherapy; $P < 0.001$), increased objective response (50% with trastuzumab plus chemotherapy *v* 32% with chemotherapy; $P < 0.001$), and improved overall survival (25.1 months with trastuzumab plus chemotherapy *v* 20.3 months with chemotherapy; $P = 0.046$).[71] We found one subsequent report of this RCT comparing trastuzumab plus chemotherapy versus chemotherapy alone.[72] It reported on quality of life among 400 of the enrolled 469 women and found that trastuzumab plus chemotherapy significantly improved reported global quality of life scores compared with chemotherapy alone (rate of improvement of quality of life assessed with European Organisation for Research and Treatment Care Quality of Life Questionnaire: 51% with trastuzumab plus chemotherapy *v* 36% with chemotherapy; $P < 0.05$).

Harms: **Versus chemotherapy alone:** Cardiac dysfunction occurred in 27% of women given anthracycline plus cyclophosphamide plus trastuzumab compared with 8% given anthracycline plus cyclophosphamide alone, 13% given paclitaxel plus trastuzumab and 1% given paclitaxel alone.[71] Symptoms usually improved with standard medical management, although two women died from cardiac dysfunction. About 25% of women had chills, fever, or both during the initial infusion; no episodes of anaphylaxis occurred.

Comment: Trastuzumab based combination treatment was effective at reducing the relative risk of death by 20% at a median follow up of 30 months. Few studies have shown that adding a single agent improves survival to this degree. Cardiac toxicity seems only significant in people concurrently receiving an anthracycline. The most appropriate treatment duration in responders is unclear. We found one RCT comparing two different dosing regimens of trastuzumab as first line treatment (see glossary, p 2293) in 114 women with HER2/neu oncogene overexpressing metastatic breast cancer. It found no significant difference between the high dose regimen (8 mg/kg loading dose followed by 4 mg/kg weekly) and low dose regimen (4 mg/kg loading dose followed by 2 mg/kg weekly) for time to progression (see glossary, p 2294) or time to death (median time to progression: 3.5 months with high dose [95% CI 3.3 months to 5.5 months] *v* 3.8 months with low dose [95% CI 2.4 months to 5.5 months]; median survival: 22.9 months with high dose [95% CI 16.0 months to 37.1 months] *v* 25.8 months with low dose [95% CI 13.3 months to 34.7 months]).[73] Adverse effects included asthenia (23%), fever (22%), nausea (14%), and cardiac dysfunction (2%).

QUESTION What are the effects of second line chemotherapy?

OPTION TAXANE BASED COMBINATION CHEMOTHERAPY

One systematic review found that taxane based combination chemotherapy as first or second line treatment increased overall survival, time to progression, and overall response compared with non-taxane combination chemotherapy. The difference remained significant if the analysis was limited to women who had previously received anthracyclines. RCTs found no significant difference in progression or overall survival between docetaxel and 5-fluorouracil plus vinorelbine or between paclitaxel and capecitabine given as second line chemotherapy.

Benefits: **Versus non-taxane combination chemotherapy:** See glossary, p 2293. We found one systematic review (search date 2003, 20 RCTs), which compared taxane based versus non-taxane based combination chemotherapy for first or second line (see glossary, p 2294) treatment.[67] Twelve RCTs assessed progression free and overall survival. The review found that taxane containing combination chemotherapy as first or second line treatment significantly increased overall survival compared with non-taxane based chemotherapy (proportion of women who died: 1397/1947 [72%] with taxane based *v* 1262/1696 [75%] with non-taxane based; HR 0.90, 95% CI 0.84 to 0.97).[67] It found that this difference remained significant if the analysis was restricted to women who had previously received anthracyclines (5 RCTs, 403/568 [71%] with taxane based *v* 422/555 [76%] with non-taxane based; HR 0.87, 95% CI 0.76 to 0.99). **Versus semisynthetic vinca alkaloids:** One RCT (176 women after anthracycline treatment failure) identified by the review[67] compared docetaxel versus 5-fluorouracil plus vinorelbine.[74] It found no significant difference between treatments in time to progression (see glossary, p 2294) or overall survival (median time to progression: 5.1 months with docetaxel *v* 6.5 months with 5-fluorouracil plus vinorelbine; $P = 0.34$; median overall survival: 16.0 months with docetaxel *v* 15.0 months with 5-fluorouracil plus vinorelbine; P value not reported).[74] **Versus capecitabine:** See benefits of capecitabine, p 2288.

Harms: **Versus non-taxane combination chemotherapy:** The review found that taxane based chemotherapy was associated with more neurotoxicity and alopecia than non-taxane based regimens.[67] **Versus semisynthetic vinca alkaloids:** The RCT comparing docetaxel versus 5-fluorouracil plus vinorelbine found that 5-fluorouracil plus vinorelbine significantly increased severe thrombocytopenia and severe stomatitis compared with docetaxel (severe thrombocytopenia: 10% with 5-fluorouracil plus vinorelbine *v* 1% with docetaxel, $P = 0.02$; severe stomatitis: 40% with 5-fluorouracil plus vinorelbine *v* 5% with docetaxel, $P < 0.0001$). Docetaxel significantly increased grade 3/4 neutropenia compared with 5-fluorouracil and vinorelbine (82% with 5-fluorouracil plus vinorelbine *v* 67% with docetaxel, $P = 0.02$).[74] **Versus capecitabine:** See harms of capecitabine, p 2288.

Comment: The taxanes (see glossary, p 2294), paclitaxel and docetaxel, have an established role as second line treatment in metastatic breast cancer, especially in people with disease progression despite a previous anthracycline based regimen, with evidence in some RCTs for a survival advantage over other available options. Trials are in progress to determine the efficacy and tolerability of taxanes in combination with anthracyclines as first line treatment (see glossary, p 2293), although there are concerns about cardiac toxicity. At present, the indication for docetaxel remains as a single drug for second line treatment, especially in anthracycline resistant (see glossary, p 2292) disease, although definitive results on improvement in quality of life are awaited.

OPTION SEMISYNTHETIC VINCA ALKALOIDS

One RCT found no significant difference in progression or overall survival between 5-fluorouracil plus vinorelbine and docetaxel given as second line chemotherapy. Another RCT found that second line vinorelbine improved survival and reduced progression compared with melphalan. A third RCT found no significant difference in survival or quality of life between vinorelbine plus doxorubicin and vinorelbine alone.

Benefits: **Versus non-taxane combination chemotherapy:** See glossary, p 2293. One RCT (183 women with anthracycline resistant (see glossary, p 2292) disease) found increased time to progression (see glossary, p 2294) and survival with vinorelbine 30 mg/m^2 weekly compared with intravenous melphalan (median survival 35 weeks with vinorelbine *v* 31 weeks with melphalan; $P < 0.001$).[75] **Plus non-taxane combination chemotherapy versus non-taxane combination chemotherapy alone:** We found one RCT (303 women, first or second line (see glossary, p 2294) treatment, no previous vinca alkaloid or anthracycline treatment) comparing doxorubicin plus vinorelbine versus doxorubicin alone. The response rates, quality of life scores, and overall survival were not significantly improved with combined chemotherapy (see glossary, p 2293) in this setting.[76] **Versus taxane based combination chemotherapy:** See benefits of taxane based combination chemotherapy, p 2286.

Harms: One RCT comparing vinorelbine versus anthracycline based chemotherapy (FAC/first or second line treatment found that vinorelbine was associated with considerably lower rates of nausea (8% with vinorelbine *v* 16% with anthracycline based; $P = 0.03$) and grade 3 alopecia (7% with vinorelbine *v* 30% with anthracycline based; $P = 0.0001$), although haematological toxicity that delayed treatment was more frequent (27% with vinorelbine *v* 17% with anthracycline based).[77] **Versus taxane based combination chemotherapy:** See harms of taxane based combination chemotherapy, p 2286.

Comment: One uncontrolled study of vinorelbine found an objective response rate of 31%, with less than 5% grade 3 or 4 toxicities.[78] It seems to have a favourable toxicity profile, but results from phase III trials are

awaited. Vinorelbine plus protracted infusional fluorouracil is an active and well tolerated regimen (overall response rate: 61.4%, 95% CI 50.9% to 70.9%), and further trials are underway.[79] One uncontrolled study of vinorelbine plus gemcitabine twice weekly found an objective response rate of 54%.[80]

OPTION CAPECITABINE

One RCT found similar response rates and time to disease progression between capacitabine and paclitaxel after anthracycline failure.

Benefits: **Versus taxane based combination chemotherapy:** We found one systematic review (search date 2000) assessing the oral fluoropyrimidine capecitabine in metastatic breast cancer,[81] which identified one RCT (42 women) comparing capecitabine versus paclitaxel as second or third line treatment after anthracycline failure. It found similar response rates and time to disease progression between capacitabine and paclitaxel (response: 8/22 [36%] with capecitabine *v* 4/20 [20%] with paclitaxel; time to progression 92 days with capecitabine *v* 95 days with paclitaxel; CI not reported).

Harms: **Versus taxane based combination chemotherapy:** The most commonly reported grade 3/4 toxicities were hand–foot syndrome (13%), diarrhoea (12%), and stomatitis (4%).[81]

Comment: Promising activity has been seen with capecitabine in paclitaxel refractory, heavily pretreated women,[82] and the low toxicity profile, together with evidence of efficacy, all warrant further investigation of this drug as an alternative to more toxic second or third line chemotherapy (see glossary, p 2293) schedules. It has been suggested that the effectiveness of docetaxel may be increased by the addition of capecitabine,[83] and RCTs are underway.

QUESTION What are the effects of treatments for bone metastases?

OPTION BISPHOSPHONATES

RCTs in women receiving standard chemotherapy or hormonal treatment for bone metastases secondary to metastatic breast cancer found that bisphosphonates reduced and delayed skeletal complications compared with placebo. They found no significant difference in survival.

Benefits: We found one systematic review (search date not stated[84]) and one subsequent RCT.[85] The review (13 RCTs, 4395 women with metastatic breast cancer who had bone involvement) compared adding bisphosphonates (see glossary, p 2293) versus adding placebo to standard treatment (either chemotherapy or hormonal treatment [see glossary, p 2293]).[84] It found that, compared with placebo, bisphosphonates significantly reduced "skeletal events" (5 RCTs, 416/767 [54%] with bisphosphonates *v* 482/786 [61%] with no bisphosphonates; RR 0.88, 95% CI 0.81 to 0.96). It found no significant difference in survival (8 RCTs, 594/815 [73%] with bisphosphonates *v* 624/841 [74%] with no bisphosphonates; RR 0.99, 95% CI 0.93 to 1.04). "Skeletal events" were defined as:

new bone metastases, pathological fractures, spinal cord compression, irradiation of or surgery on bone, or the development or progression of bone pain.[84] Four RCTs identified by the review found that bisphosphonates delayed the time to a first "skeletal event" compared with placebo ($P < 0.05$ in all 4 RCTs). One subsequent RCT (466 women) found that, compared with placebo, ibandronate (2 or 6 mg once every 3–4 weeks) reduced new bone events (2.65 with ibandronate 6 mg *v* 4.24 with ibandronate 2 mg *v* 3.64 with placebo; $P = 0.032$ for ibandronate 6 mg *v* placebo) and decreased bone pain scores over 2 years' treatment (reported as significant, results presented graphically, CI not reported).[85] **Versus radiotherapy:** We found no RCTs.

Harms: RCTs identified by the review suggested that bisphosphonates were well tolerated with no serious adverse events in women treated for up to 2 years.[84] Fever and asymptomatic hypocalcaemia were the most commonly reported adverse effects in women receiving intravenous pamidronate. Mild gastrointestinal toxicity was the most frequently reported adverse effect of oral clodronate. In one RCT identified by the review, gastrointestinal toxicity (nausea and vomiting) was the cause of withdrawal in 25% of women taking oral pamidronate. The subsequent RCT found that three women taking ibandronate had serious adverse effects (asthenia, hydronephrosis, oedema, and bone pain) related to treatment.[85] **Versus radiotherapy:** We found no RCTs.

Comment: Large RCTs are in progress in the adjuvant setting to see whether these agents may delay or prevent the development of bone metastases. The American Society of Clinical Oncology released recent guidelines on the use of bisphosphonates, stating that this treatment reduces the rate of bone complications (although not mortality) in women with lytic bone disease who may or may not also be receiving systemic treatment (chemotherapy or endocrine treatment).[86] It remains unclear exactly when to start or stop treatment, which may affect the costs involved.[87] Although these effects are likely to improve quality of life, this outcome has not been formally evaluated. We found no evidence that bisphosphonates improve survival.

OPTION RADIOTHERAPY

We found no RCTs. We found limited evidence from non-randomised studies that persistent and localised bone pain can be treated successfully in over 80% of women with radiotherapy plus concomitant appropriate analgesia (from non-steroidal anti-inflammatory drugs to morphine and its derivatives) and that cranial nerve compession can be treated successfully with radiotherapy in 50–80% of people. RCTs found no evidence that short courses are less effective for pain relief than long courses of radiotherapy. One RCT found that different fractionation schedules can be used to treat neuropathic bone pain effectively.

Benefits: We found no systematic review and no RCTs comparing radiotherapy versus no treatment or bisphosphonates (see glossary, p 2293) (see comment below). **Pain control:** Questionnaire studies found that control of pain was successful in over 80% of women

who received radiotherapy for bone metastases, with concomitant use of appropriate analgesia according to the World Health Organization ladder (this moves upwards from non-steroidal anti-inflammatory drugs and paracetamol to mild opiates through to morphine and its derivatives).[88] **Cranial nerve compression:** In people with skull base metastases causing cranial nerve involvement, retrospective studies suggest that radiotherapy leads to improvement in 50–80% of women, which is usually maintained.[89] **Different radiotherapy regimens:** We found two RCTs comparing different radiotherapy regimens. These found no significant difference between short courses (8 Gy as a single fraction) and longer courses (e.g. 20 Gy/5 fractions or 30 Gy/10 fractions).[90,91] Studies of accelerated fractionation schedules (e.g. twice daily treatments for 5 days) have failed to show any benefit over conventional regimens in the control of disease secondary to metastatic breast cancer.[92] Published interim results from one RCT (270 women) have found that different fractionation regimens can be used to treat neuropathic bone pain effectively.[93] **Versus bisphosphonates:** We found no RCTs.

Harms: Adverse effects of radiotherapy for bone metastases include nausea and vomiting.[92] Higher dose fractions a day produce more toxic effects.

Comment: Randomised comparisons against no treatment or placebo would be considered unethical in palliative care, and even RCTs comparing one treatment versus another are difficult to undertake because it is reasonable to try many different options in order to make a woman comfortable. Rating of success of end of life care is difficult. Usual outcomes, such as response rates and survival duration, do not apply.[94]

QUESTION What are the effects of treatments for spinal cord metastases?

OPTION RADIOTHERAPY

We found no RCTs. Spinal cord compression is an emergency. Retrospective studies suggest that early radiotherapy improves outcomes. However, fewer than 10% of people walked again if severe deterioration of motor function occurred before radiotherapy. One small RCT in women with spinal cord compression suggested that adding high dose steroids to radiotherapy improved the chance of walking 6 months after treatment compared with radiotherapy alone.

Benefits: We found no systematic review or RCTs. Retrospective analyses found an improvement with early radiotherapy, but fewer than 10% of people walked again if severe deterioration of motor function occurred before radiotherapy.[95] **Addition of high dose steroids:** One blinded RCT (57 women) evaluated addition of high dose steroids to radiotherapy. It found that more women were walking 6 months after receiving dexamethasone (96 mg intravenous bolus followed by 96 mg orally for 3 days) compared with those who received no steroids (59% with steroids *v* 33% with no steroids).[96]

Harms: In the RCT of high dose steroids, significant adverse effects caused withdrawal from treatment in 11% of people.[96] Use of lower doses of glucocorticoids in the control of symptoms from cerebral metastases may result in short term agitation and the longer term development of Cushingoid facies.

Comment: See comment of radiotherapy for bone metastases, p 2290.

QUESTION What are the effects of treatments for cerebral metastases?

OPTION RADIOTHERAPY

We found no RCTs. Evidence from retrospective studies suggests that whole brain irradiation impairs neurological function in some women with brain metastases secondary to breast cancer.

Benefits: We found no systematic review or RCTs. Retrospective studies suggest that whole brain radiation produces general improvement in neurological function in 40–70% of women with brain metastases secondary to breast cancer.[97] **Different radiotherapy regimens:** One RCT (544 symptomatic people) that compared two whole brain radiotherapy schedules (30 Gy/10 fractions *v* 12 Gy/2 fractions) found no evidence that the response rate or duration of response in people with multiple brain metastases were improved with higher doses of radiation compared with the shorter regimen.[92]

Harms: Adverse effects of radiotherapy in the treatment of cerebral metastases include alopecia and somnolence.[92] Higher dose fractions a day produce more toxic effects.

Comment: See comment under radiotherapy for bone metastases, p 2290. There is a consensus that raised intracranial pressure associated with cerebral metastases is best managed by dexamethasone given immediately with anticonvulsants to control seizures if necessary.

OPTION SURGICAL RESECTION

We found insufficient evidence to assess surgical resection in people with cerebral metastases.

Benefits: One retrospective cohort study nested in one RCT (859 women) found that there may be some beneficial effect in a small subgroup of people (those with Karnofsky Performance Status 70–100, absent or controlled primary tumour, age < 60 years, and cerebral [not other] metastases).[98]

Harms: The cohort study gave no information on harms.[98]

Comment: None.

OPTION INTRATHECAL CHEMOTHERAPY OR RADIATION SENSITISERS

We found no RCTs or observational studies of intrathecal chemotherapy in people with cerebral metastases. One open label case control study found limited evidence that adding intravenous RSR13, a radiation sensitiser, during whole brain radiotherapy may prolong survival.

Breast cancer (metastatic)

Benefits: **Intrathecal chemotherapy:** We found no RCTs or observational studies of intrathecal chemotherapy (see glossary, p 2293). **Radiation sensitisers:** One open label case control study (57 women) assessed mortality in women receiving RSR13, a radiation sensitiser, during radiotherapy compared with mortality in a database of women receiving radiotherapy alone. It found that significantly more women receiving RSR13 survived over 2 years than women receiving radiotherapy alone ($P = 0.0267$).[99]

Harms: **Intrathecal chemotherapy:** We found no RCTs or observational studies of sufficient quality of intrathecal chemotherapy. **Radiation sensitisers:** RSR13 requires central line administration during the days when brain radiotherapy is given and seems to be associated with transient hypoxia in a subgroup.

Comment: None.

QUESTION **What are the effects of treatments for choroidal metastases?**

OPTION **RADIOTHERAPY**

We found no RCTs. Retrospective studies suggest that radiotherapy benefits some women with choroidal metastases.

Benefits: We found no systematic review and no RCTs. One prospective cohort study (56 people, 62% with breast cancer)[100] and one case series (32 women)[101] suggested that external beam radiotherapy at doses of about 40 Gy prevented functional loss and may increase visual acuity. Retrospective studies suggest that radiotherapy benefits 70% of people.[102]

Harms: People with choroidal metastases who are treated with radiotherapy may lose the sight in that eye. Optic atrophy and proliferative radiation retinopathy are possible late complications.

Comment: See comment of radiotherapy for bone metastases, p 2290. Generally, choroidal metastases occur later than metastases to other organs. Choroidal metastasis is considered a poor prognostic sign; most people die within 6 months of diagnosis. Systemic chemotherapy (see glossary, p 2293) can induce partial or complete remission of metastatic choroidal breast carcinoma.[103] Recent retrospective studies have shown that krypton red or argon green laser photocoagulation is feasible, easy, rapid, and effective for small choroidal breast carcinoma.[104] Women with deteriorating vision are likely to benefit from emergency assessment and treatment for choroidal metastases.

GLOSSARY

Adjuvant treatment This usually refers to systemic chemotherapy, hormonal treatment, or both, taken after removal of a primary tumour (in this case, surgery for early breast cancer), with the aim of killing any remaining micrometastatic tumour cells and thus preventing recurrence.

Anthracycline resistance This applies to people who have received at least one chemotherapeutic regimen with anthracyclines (doxorubicin or epirubicin) in either an adjuvant setting or for metastatic disease. Primary resistance to an anthracycline

is defined as progressive disease during or within 6 months after completion of adjuvant anthracycline. People without any documented tumour response to first line chemotherapy that included anthracyclines for metastatic disease are also classified as having primary resistance. Secondary resistance is defined as disease progression after a documented clinical response to first line chemotherapy with anthracyclines for metastatic disease. Secondary resistance can be divided further into three categories, as follows: (1) absolute resistance, or disease progression during treatment with regimens that contained anthracyclines after a period of response; (2) relative resistance, or disease progression within 6 months after completion of the chemotherapy; and (3) sensitive regrowth, or disease progression more than 6 months after completion of the chemotherapy.[105]

Aromatase inhibitors Drugs that block the conversion of androgens into oestrogens. Aminoglutethimide, anastrozole, and letrozole are non-steroidal aromatase inhibitors. Formestane and exemestane are steroidal aromatase inhibitors. Anastrozole, formestane, exemestane, and letrozole are selective inhibitors of oestrogen synthetase, which is a part of the aromatase enzyme system. Aminoglutethimide also inhibits adrenal steroid production. These drugs cause oestrogen suppression in postmenopausal women.

Bisphosphonates (pamidronate, clodronate) Bone specific palliative drugs that inhibit osteoclast induced bone resorption associated with breast cancer metastases.

Chemotherapy Treatment with cytotoxic drugs (see also non-taxane and taxane based combination chemotherapy regimens below).

Complete response Disappearance of all known lesions on two separate measurements at least 4 weeks apart.

Disease free interval Time between surgery for early breast cancer (see below) and metastatic breast cancer developing.

Early breast cancer Operable disease, restricted to the breast and sometimes to local lymph nodes.

First line treatment Initial treatment for a particular condition that has previously not been treated. For example, first line treatment for metastatic breast cancer may include chemotherapy, hormonal treatment, or both.

Gonadorelin analogues (Also called luteinising hormone releasing hormone [LHRH] agonists.) These are synthetic peptides that occupy the receptors for gonadorelin in the pituitary gland. Continuous administration of gonadorelin agonists may initially increase the release of luteinising hormone, but continuous administration blocks the physiological pulsatile luteinising hormone release and this causes a fall in oestrogen levels.

Hormonal treatment Includes treatment with antioestrogens such as tamoxifen, aromatase inhibitors, and progestins.

Non-taxane combination chemotherapy regimens Use of different combinations of cytotoxic drugs:

CAF Cyclophosphamide (500 mg/m^2 iv), doxorubicin (50 mg/m^2 iv), and fluorouracil (500 mg/m^2 iv) every 3 weeks for up to six cycles of treatment are given, depending on response.

Classical CMF Cyclophosphamide (100 mg/m^2 orally days 1–14), methotrexate (40 mg/m^2 iv days 1 and 8), and fluorouracil (600 mg/m^2 iv days 1 and 8) every 4 weeks for up to six cycles of treatment are given, depending on response.

FAC Fluorouracil, doxorubicin, and cyclophosphamide every 3 weeks for up to six cycles of treatment are given, depending on response.

FEC Fluorouracil, epirubicin, and cyclophosphamide every 3 weeks for up to six cycles of treatment are given, depending on response.

Overall objective response rate The proportion of treated people in whom a complete (see above) or partial response (see below) is observed.

Breast cancer (metastatic)

Partial response More than a 50% reduction in the size of lesions.
Progestins (medroxyprogesterone, megestrol) The antitumour effects of progestins may be mediated by a direct action on tumour cells, or an indirect effect on the pituitary–ovarian/adrenal axes.
Progression free survival (or time to progression) Interval between diagnosis of metastatic disease and diagnosis of progression.
Progressive disease More than a 25% increase in the size of lesions, or the appearance of new lesions.
Second line treatment Treatment given after relapse after first line treatment (see above).
Tamoxifen An oral, non-steroidal, competitive oestrogen receptor antagonist.
Taxane based combination chemotherapy regimens Chemotherapy regimens containing taxanes such as paclitaxel and docetaxel, which are derived from the Pacific yew tree *Taxus brevifolia*.

Substantive changes

Selective aromatase inhibitors as first line hormonal treatment in postmenopausal women One RCT found that the aromatase inhibitor letrozole was superior to tamoxifen in reducing time to disease progression;[36] categorisation unchanged.
Non-taxane combination chemotherapy One systematic review found no significant difference in survival at 12 or 24 months between first line non-taxane combination chemotherapy and hormonal treatment with tamoxifen or progestins. The review suggested that hormonal treatment may be preferable to chemotherapy as first line treatment in women with oestrogen receptor positive disease unless disease is rapidly progressing.[58] First line hormonal treatment categorised as Likely to be beneficial compared with non-taxane combination chemotherapy.
Taxane based combination chemotherapy as first line treatment One systematic review found that taxane based combination chemotherapy as first or second line treatment increased overall survival, time to progression, and overall response compared with non-taxane combination chemotherapy.[67] It found no significant difference in overall survival if the analysis was restricted to RCTs of first line chemotherapy. Categorised as Likely to be beneficial compared with non-taxane combination chemotherapy.
Taxane based combination chemotherapy as second line treatment One systematic review added;[67] categorisation unchanged.
Bisphosphonates One systematic review[84] and one subsequent RCT[85] added; categorisation unchanged.
Radiation sensitisers for cerebral metastases One open label case control study suggested that adding intravenous RSR13, a radiation sensitiser, during whole brain radiotherapy may prolong survival.[99] Categorised as Unknown effectiveness.
Radiotherapy for choroidal metastases One prospective cohort study added;[100] categorisation unchanged.

TABLE 1 **Clinical factors that predict response to hormonal treatment in metastatic breast cancer, based on results of RCTs (see text, p 2271).[8–11]**

Factors predictive of good response to hormonal treatment
Postmenopausal status
Disease limited to soft tissue sites (skin, nodes)
Oestrogen receptor positive tumour
Long disease free interval since primary treatment for early breast cancer (> 18–24 months)
Factors making initial hormonal treatment less appropriate
Symptomatic visceral metastases (e.g. lymphangitis carcinomatosis or progressive liver metastases)
Oestrogen receptor negative tumour
Short disease free interval (12–18 months)
Relapse on adjuvant tamoxifen (unless oestrogen receptor positive tumour and other features predictive of good response)

Breast cancer (non-metastatic)

Search date June 2003

J Michael Dixon, Alan Rodger, and Justin Stebbing

QUESTIONS

INTERVENTIONS

Key Messages

Ductal carcinoma *in situ*

- **Radiotherapy after breast conserving surgery (reduces recurrence)** Two RCTs have found that radiotherapy after breast conserving surgery for ductal carcinoma *in situ* reduces local recurrence and invasive carcinoma compared with no radiotherapy after 4 and 8 years. However, they found no evidence of an effect on survival. One RCT in women having local excision found no significant difference between tamoxifen plus radiotherapy and radiotherapy alone in total invasive or ductal carcinoma *in situ* events after median follow up of 1 year.
- **Tamoxifen plus radiotherapy after breast conserving surgery (reduces recurrence)** One RCT found that adjuvant tamoxifen reduced breast cancer events in women who have had wide excision and radiotherapy after median follow up of 6 years, although subgroup analysis suggested that benefit may be limited to people with oestrogen receptor positive tumours. It found no evidence of an effect on survival. One RCT in women having local excision found no significant difference between tamoxifen plus radiotherapy and radiotherapy alone in invasive or ductal carcinoma *in situ* events after median follow up of 1 year.

Primary operable breast cancer

- **Adjuvant chemotherapy** One systematic review has found that adjuvant chemotherapy reduces recurrence and improves survival at 10 years compared with no chemotherapy. The benefit seems to be independent of nodal or menopausal status, although the absolute improvements are greater in women with node positive disease, and probably greater in younger women.
- **Adjuvant tamoxifen** One systematic review has found that adjuvant tamoxifen taken for up to 5 years reduces the risk of recurrence and death in women with oestrogen receptor positive tumours irrespective of age, menopausal status, nodal involvement, or the addition of chemotherapy. Five years of treatment

seems better than shorter durations, but available evidence does not find benefit associated with prolongation beyond 5 years. Tamoxifen slightly increases the risk of endometrial cancer, but we found no evidence of an overall adverse effect on non-breast cancer mortality.

- **Anthracycline regimens as adjuvant chemotherapy** One systematic review has found that adjuvant regimens containing an anthracycline reduce recurrence, and improve survival compared with a standard multidrug chemotherapy (CMF) regimen at 5 years.
- **Breast conserving surgery (similar survival to more extensive surgery)** Systematic reviews and long term results of included RCTs have found that, providing all local disease is excised, more extensive surgery does not increase survival up to 20 years. More extensive local resection in breast conserving surgery gives worse cosmetic results.
- **Combined chemotherapy plus tamoxifen** One RCT found that adding chemotherapy (CMF) to tamoxifen improves survival at 5 years in women with lymph node negative, oestrogen receptor positive early breast cancer.
- **Ovarian ablation in premenopausal women** One systematic review has found that in women less than 50 years of age, ovarian ablation improves survival for at least 15 years compared with no ablation.
- **Radiotherapy after breast conserving surgery (reduces local recurrence; no evidence of effect on survival)** One systematic review has found that adding radiotherapy (see glossary, p 2328) to breast conserving surgery reduces the risk of isolated local recurrence and loss of a breast. However, it does not increase survival at 10 years. Rates of survival and local recurrence are similar with radiotherapy plus either breast conserving surgery or mastectomy. One RCT found that radiotherapy (with and without tamoxifen) reduced ipsilateral breast cancer recurrence compared with tamoxifen alone after median follow up of 87 months. It found no significant difference in survival.
- **Radiotherapy after mastectomy in women at high risk of local recurrence** One systematic review has found that radiotherapy to the chest wall after mastectomy reduces the risk of local recurrence by about two thirds and the risk of death from breast cancer at 10 years. It found no evidence of effect on overall 10 year survival. Radiotherapy may be associated with late adverse effects, which are rare, including pneumonitis, pericarditis, arm oedema, brachial plexopathy, and radionecrotic rib fracture.
- **Neoadjuvant chemotherapy (reduces mastectomy rates more effectively than adjuvant chemotherapy; no evidence of effect on survival)** RCTs have found that neoadjuvant chemotherapy reduces mastectomy rates compared with adjuvant chemotherapy. However, it found no significant difference in survival at 4–10 years.
- **Total nodal radiotherapy in high risk disease** RCTs have found that, in women with high risk disease, total nodal irradiation improves survival compared with no irradiation. An earlier systematic review found reduced locoregional recurrence, but no evidence of improved survival.
- **Axillary clearance (no evidence of survival benefit and increased morbidity compared with axillary sampling)** RCTs found no significant difference in survival at 5–10 years between axillary clearance and axillary sampling, axillary radiotherapy, or sampling plus radiotherapy combined. One systematic review of mainly poor quality evidence found that the risk of arm lymphoedema was highest with axillary clearance plus radiotherapy, lower with axillary sampling plus radiotherapy, and lowest with sampling alone.

- **Axillary radiotherapy** One systematic review has found that axillary radiotherapy reduces isolated local recurrence compared with axillary clearance. It found no significant difference in mortality or overall recurrence at 10 years. One systematic review of mainly poor quality evidence found that radiotherapy plus axillary surgery was associated with arm lymphoedema.
- **Radiotherapy after mastectomy in women not at high risk of local recurrence** One systematic review has found that radiotherapy to the chest wall after mastectomy reduces the risk of local recurrence by about two thirds and the risk of death from breast cancer at 10 years. However, it found no evidence of effect on overall 10 year survival. Radiotherapy may be associated with late adverse effects, which are rare, including pneumonitis, pericarditis, arm oedema, brachial plexopathy, and radionecrotic rib fracture. There is, therefore, a trade off between absolute benefits and harms in women not at high risk of local recurrence.
- **Radiotherapy to the internal mammary chain** One RCT found no significant difference in relapse or survival at 2–3 years between radiotherapy and no radiotherapy to the internal mammary chain. Treatment may increase radiation induced cardiac morbidity.
- **Radiotherapy to the ipsilateral supraclavicular fossa** We found insufficient evidence about the effects of irradiation of the ipsilateral supraclavicular fossa on survival. RCTs have found that radiotherapy reduces the risk of supraclavicular fossa nodal recurrence.
- **Enhanced dose regimens of adjuvant chemotherapy** RCTs found no significant improvement from enhanced dose regimens.
- **Prolonged chemotherapy (8–12 months *v* 4–6 months)** One systematic review found no additional benefit from prolonging adjuvant chemotherapy from 4–6 to 8–12 months.
- **Radical mastectomy (no greater survival than less extensive surgery)** Systematic reviews and long term follow up of one RCT found no significant difference between radical, total, supraradical, or simple mastectomy in survival up to 25 years. More extensive surgery results in greater mutilation.
- **High dose chemotherapy plus bone marrow or peripheral blood stem cell autograft** One systematic review found no significant difference between high dose chemotherapy plus autograft and conventional chemotherapy in 5 year survival for women with early, poor prognosis breast cancer. The review found that high dose chemotherapy increased treatment related and non-cancer related deaths compared with conventional chemotherapy.

Locally advanced breast cancer

- **Radiotherapy** For locally advanced breast cancer that is rendered operable, small RCTs found that radiotherapy or surgery as sole local treatments have similar effects on response rates, duration of response, and overall survival.
- **Radiotherapy after attempted curative surgery** One RCT found weak evidence that radiotherapy after attempted curative surgery may reduce local and regional recurrence compared with no further local treatment.
- **Surgery** For locally advanced breast cancer that is rendered operable, small RCTs found that surgery or radiotherapy as sole local treatments have similar effects on response rates, duration of response, and overall survival.
- **Tamoxifen plus radiotherapy (improves survival compared with radiotherapy)** One RCT found that hormone treatment plus radiotherapy improved locoregional recurrence at 6 years and improved median survival at 8 years compared with radiotherapy alone.

Breast cancer (non-metastatic)

- **Chemotherapy (cyclophosphamide/methotrexate/fluorouracil or anthracycline based regimens)** We found no evidence that the cytotoxic, multidrug chemotherapy regimen (CMF) improves survival, disease free survival, or long term locoregional control.

DEFINITION

Ductal carcinoma in situ is a non-invasive (see glossary, p 2328) tumour characterised by the presence of malignant cells in the breast ducts but with no evidence that they breach the basement membrane and invade into periductal connective tissues. **Invasive breast cancer** can be separated into three main groups: early (see glossary, p 2328) or operable breast cancer, locally advanced disease (see glossary, p 2327), and metastatic breast cancer (see metastatic breast cancer, p 2266). **Operable breast cancer** is apparently restricted to the breast and sometimes to local lymph nodes and can be removed surgically. Although these women do not have overt metastases at the time of staging (see glossary, p 2328), they remain at risk of local recurrence and of metastatic spread. They can be divided into those with tumours greater than 4 cm with multifocal cancers that can be treated by mastectomy, and those with tumours less than 4 cm with unifocal cancers that can be treated by breast conserving surgery (see glossary, p 2328). **Locally advanced breast cancer** is defined according to the TNM staging system (see glossary, p 2329) of the UICC TNM system (see glossary, p 2329)[1] as stage III B (includes T4 a–d; N2 disease, but absence of metastases). It is a disease presentation with evidence (clinical or histopathological) of skin, or chest wall involvement, or axillary nodes matted together by tumour extension, or a combination of these features. **Metastatic breast cancer** is presented in a separate topic (see metastatic breast cancer, p 2266).

INCIDENCE/ PREVALENCE

Breast cancer affects 1/10–1/11 women in the UK and causes about 21 000 deaths a year. Prevalence is about five times higher, with over 100 000 women living with breast cancer at any one time. Of the 15 000 new cases of breast cancer a year in the UK, most will present with primary operable disease.[2]

AETIOLOGY/ RISK FACTORS

The risk of breast cancer increases with age, doubling every 10 years up to the menopause. Risk factors include an early age at menarche, older age at menopause, older age at birth of first child, family history, atypical hyperplasia, excess alcohol intake, radiation exposure to developing breast tissue, oral contraceptive use, postmenopausal hormone replacement therapy, and obesity. Risk in different countries varies fivefold. The cause of breast cancer in most women is unknown. About 5% of breast cancers can be attributed to mutations in the genes *BRCA1* and *BRCA2*.[3]

PROGNOSIS

Primary carcinoma of the breast is potentially curable. The risk of relapse depends on various clinicopathological features, including axillary node involvement, oestrogen receptor status, and tumour size. Tumour size, axillary node status, histological grade, and oestrogen receptor status provide the most significant prognostic information. Of women with operable disease 70% are alive 5 years after diagnosis and treatment (adjuvant drug treatment is given to most women after surgery). Risk of recurrence is highest during the first 5 years, but the risk remains even 15–20 years after surgery. Those with node positive disease have a 50–60% chance of

recurrence within 5 years, compared with 30–35% for node negative disease. Recurrence at 10 years, according to one large systematic review,[4] is 60–70% compared with 25–30% of node negative women. The prognosis for a disease free survival (see glossary, p 2328) at 5 years is worse for stage III B (33%) than that for stage III A (71%). Five year overall survival is 44% for stage III B and 84% for stage III A.[5] Poor survival and high rates of local recurrence characterise locally advanced breast cancer.

AIMS OF INTERVENTION To improve survival; to prevent local or regional node recurrence; to obtain prognostic information on the type and extent of tumour and the status of the axillary lymph nodes; to optimise cosmetic results and minimise psychosocial impact; to minimise adverse effects of treatment; and to maximise quality of life.

OUTCOMES Survival; rates of local and regional recurrence; rates of mastectomy after breast conserving treatment; rates of development of metastases; cosmetic outcomes; quality of life; incidence of adverse effects of treatment, including upper limb lymphoedema.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION What are the effects of interventions after breast conserving surgery for ductal carcinoma *in situ*?

OPTION RADIOTHERAPY

J Michael Dixon and Alan Rodger

Two RCTs have found that radiotherapy after breast conserving surgery for ductal carcinoma *in situ* reduces local recurrence and invasive carcinoma compared with no radiotherapy after 4 and 8 years. However, they found no evidence of an effect on survival. One RCT in women having local excision found no significant difference between tamoxifen plus radiotherapy and radiotherapy alone in total invasive or ductal carcinoma *in situ* events after median follow up of 1 year.

Benefits: We found no systematic review but found two RCTs comparing radiotherapy (see glossary, p 2328) with no radiotherapy after surgery for ductal carcinoma *in situ* (DCIS).[6,7] **Versus no radiotherapy:** The first RCT (814 women) found no significant difference in survival at 8 years with radiotherapy compared with no radiotherapy. It found significant reductions in risk of local recurrence, recurrent DCIS, and invasive carcinoma with radiotherapy compared with no radiotherapy (survival 95% with radiotherapy *v* 94% with no radiotherapy; local recurrence 12.1% with radiotherapy *v* 26.8% with no radiotherapy; $P < 0.0005$; risk of recurrent DCIS 8.2% with radiotherapy *v* 13.4% with no radiotherapy; $P = 0.007$; risk of invasive carcinoma 3.9% with radiotherapy *v* 13.4% with no radiotherapy; $P < 0.0001$).[6] The second RCT (1002 women) found that radiotherapy significantly reduced local recurrence of DCIS in women at median follow up of 4.25 years.[7] At 4 years, local relapse free survival was more likely with surgery plus radiotherapy than with surgery alone (91% with surgery plus radiotherapy *v* 84% with surgery alone; $P = 0.005$; HR 0.62, 95% CI 0.44 to 0.87). More women were free of DCIS recurrence after 4 years with radiotherapy but the difference was not significant (95%

with surgery plus radiotherapy *v* 92% with surgery alone; HR 0.65, 95% CI 0.43 to 1.03). There was a significant reduction in invasive recurrence (96% with surgery plus radiotherapy *v* 92% with surgery alone; HR 0.60, 95% CI 0.37 to 0.97).[7] **Versus radiotherapy plus tamoxifen:** See tamoxifen plus radiotherapy, p 2306.

Harms: One RCT found an increase in contralateral breast cancer associated with radiotherapy at 4 years (3% with surgery plus radiotherapy *v* 1% with surgery alone; HR 2.57, 95% CI 1.24 to 5.33).[7]

Comment: Subset analyses may be required to identify subgroups of women who benefit most from radiotherapy after breast conserving surgery (see glossary, p 2328). We found one further large RCT (1694 people), which randomised 912 people to tamoxifen (see glossary, p 2329), radiotherapy, both, or none.[8] Of the remaining 782 people, 664 were given the choice between radiotherapy and no radiotherapy, and were further randomised to tamoxifen or no tamoxifen. Similarly, the remaining 118 people were given the choice between tamoxifen and no tamoxifen, and were further randomised to radiotherapy or no radiotherapy. However, the study did not present results comparing radiotherapy alone versus no treatment or versus tamoxifen alone. It found that radiotherapy (with or without tamoxifen) significantly reduced ipsilateral invasive disease (HR 0.45, 95% CI 0.24 to 0.85), ipsilateral DCIS recurrence (HR 0.36, 95% CI 0.19 to 0.66), and all ipsilateral events (HR 0.38, 95% CI 0.25 to 0.59) compared with no radiotherapy (with or without tamoxifen).

OPTION TAMOXIFEN PLUS RADIOTHERAPY

One RCT found that adjuvant tamoxifen reduced breast cancer events in women who have had wide excision and radiotherapy after median follow of 6 years, although subgroup analysis suggested that benefit may be limited to people with oestrogen receptor positive tumours. It found no evidence of an effect on survival. One RCT in women having local excision found no significant difference between tamoxifen plus radiotherapy and radiotherapy alone in total invasive or ductal carcinoma *in situ* events after median follow up of 1 year.

Benefits: We found no systematic review but we found two RCTs.[8,9] **Versus radiotherapy plus placebo:** The first RCT (1804 women with ductal carcinoma *in situ* [DCIS] treated with wide excision and radiotherapy [adjuvant tamoxifen (see glossary, p 2329) 20 mg daily versus placebo for 5 years.[8] At median follow up of 74 months, there were fewer breast cancer events with tamoxifen than with placebo and fewer invasive ipsilateral or contralateral breast cancers (breast cancer events: OR 0.63, 95% CI 0.47 to 0.83; invasive ipsilateral or contralateral breast cancers: OR 0.57, 95% CI 0.38 to 0.85). However, there was no significant difference in overall survival (RR 0.88, 95% CI 0.33 to 2.28). A subsequent subgroup analysis found that only people with oestrogen receptor positive DCIS derive a benefit from tamoxifen.[10] **Versus radiotherapy alone:** The second RCT (1694 women having local excision) compared four treatments in a factorial design: no adjuvant treatment (see glossary, p 2327), tamoxifen alone, radiotherapy alone, and

tamoxifen plus radiotherapy (see comment of radiotherapy).[8] It found no significant difference between tamoxifen plus radiotherapy and radiotherapy alone in ipsilateral invasive disease, ipsilateral DCIS, and invasive or DCIS events after median follow up of 1 year (523 women in comparison; ipsilateral invasive disease: HR 1.25, 95% CI 0.43 to 3.61; ipsilateral DCIS: HR 0.75, 95% CI 0.28 to 2.02; invasive or DCIS: 3% in both groups; HR 0.95, 95% CI 0.51 to 1.77).[8]

Harms: One RCT found a higher, but non-significant rate of endometrial cancers associated with tamoxifen (RR 3.4, 95% CI 0.6 to 33.4).[9] The RCT did not report results comparing harms of tamoxifen plus radiotherapy versus radiotherapy alone.[8]

Comment: None.

QUESTION What are the effects of neoadjuvant chemotherapy in the management of primary breast cancer?

Justin Stebbing

OPTION NEOADJUVANT CHEMOTHERAPY FOR MANAGEMENT OF PRIMARY BREAST CANCER

Five RCTs found no difference in survival with neoadjuvant chemotherapy compared with adjuvant chemotherapy in women with primary breast cancer.

Benefits: We found no systematic review. We found five RCTs comparing neoadjuvant chemotherapy with adjuvant chemotherapy (see glossary, p 2327).[11–15] The first RCT (272 women with tumours > 3 cm in whom mastectomy was indicated) compared preoperative (neoadjuvant) EVMTV (epirubicin, vincristine, mitomycin-C, thiotepa, vindesine) chemotherapy versus mastectomy followed by EVMTV regimen.[11] At an initial median follow up of 34 months, a significant survival difference was reported in favour of neoadjuvant chemotherapy (85% with preoperative EVMTV *v* 95% with mastectomy plus EVMTV; P = 0.04). However, the final analysis at 124 months showed that the survival improvement was no longer significant, with survival of about 55% in both groups.[16] The second RCT (414 women) compared four cycles of FAC (see glossary, p 2328) chemotherapy given either preoperatively or postoperatively.[12] At 54 months' follow up, the primary (neoadjuvant) chemotherapy group had a better overall survival (86% with preoperative *v* 68% with postoperative; P = 0.039); however, a subsequent analysis at 105 months did not show a long term survival benefit.[17] The third RCT (309 women) compared four cycles of MM (mitoxantrone [mitozantrone], methotrexate) chemotherapy, then surgery, then four cycles of MM with surgery, then eight cycles of MM.[13] At 48 months' follow up, there was no difference in survival between the neoadjuvant and adjuvant groups (84% with neoadjuvant *v* 82% with adjuvant; reported as not significant). The fourth, and largest RCT (NSABP-18), in which 1523 women were randomised to four cycles of adriamycin (doxorubicin) plus cyclophosphamide (AC) either preoperatively or postoperatively, found identical survival rates (67%) in the two groups at 60 months.[14] The fifth RCT (698

women) compared four cycles of fluorouracil, epirubicin, and cyclophosphamide given either preoperatively or postoperatively.[15] It found no significant difference between preoperative and postoperative chemotherapy in overall survival (82% with preoperative *v* 84% with postoperative; HR 1.16, 95% CI 0.83 to 1.63), progression free survival (65% with preoperative *v* 70% with postoperative; HR 1.15, 95% CI 0.89 to 1.48), or locoregional recurrence at 4 years (21.5% with preoperative *v* 17.8% with postoperative; HR 1.13, 95% CI 0.70 to 1.81).

Harms: We found no evidence that neoadjuvant chemotherapy has a negative impact on survival.

Comment: We found no evidence to support the use of neoadjuvant chemotherapy to improve the chances of survival for operable breast cancers outside the context of an RCT.

QUESTION What is the effect of neoadjuvant chemotherapy on mastectomy rates?

Justin Stebbing

OPTION NEOADJUVANT CHEMOTHERAPY TO REDUCE MASTECTOMY RATES

Three RCTs have found that neoadjuvant chemotherapy leads to a marked reduction in the mastectomy rate.

Benefits: **Neoadjuvant versus adjuvant chemotherapy:** We found no systematic review but found three RCTs, which found a lower rate of mastectomy in women who had received neoadjuvant chemotherapy (see glossary, p 2328) compared with women receiving adjuvant chemotherapy (see glossary, p 2327).[14,18,19] **MM regimen:** One RCT (309 women receiving MM [mitoxantrone, methotrexate] chemotherapy) found that neoadjuvant significantly reduced the mastectomy rate compared with adjuvant chemotherapy (13% with neoadjuvant *v* 28% with adjuvant; $P < 0.005$).[18] **AC (adriamycin [doxorubicin], cyclophosphamide) regimen:** One RCT (1523 women) found that breast conservation rates were lower in the adjuvant arm (60% with adjuvant *v* 67% with neoadjuvant), although this was not significant.[14] **FAC regimen:** See glossary, p 2328. One RCT assessed 272 women at diagnosis in terms of the recommended surgical procedure, and two of three women who were initially advised to have mastectomy were able to have breast conserving surgery (see glossary, p 2328) after neoadjuvant chemotherapy.[19]

Harms: None of the RCTs reported a significantly higher local recurrence rate with neoadjuvant chemotherapy compared with adjuvant chemotherapy.[14,18,19]

Comment: With an increased number of conservative operations being performed after downstaging by neoadjuvant chemotherapy for large primary tumours, there are theoretical concerns that this may result

in an increased rate of local recurrence. Neoadjuvant chemotherapy can lead to a reduction in the requirement for mastectomy and as such an increase in breast conserving surgery. In the three RCTs of women with operable breast cancer receiving breast conserving surgery, this has not been associated with a significant increase in the rate of local recurrence.[14,18,19]

QUESTION What are the effects of different regimens used in the neoadjuvant setting?

Justin Stebbing

OPTION DIFFERENT NEOADJUVANT CHEMOTHERAPY REGIMENS

We found insufficient evidence that any one of the common neoadjuvant chemotherapy regimens improves survival, recurrence, or quality of life.

Benefits: We found no systematic review. We found one non-systematic review[13] and five additional RCTs[14,20–23] comparing adjuvant versus neoadjuvant chemotherapy (see glossary, p 2328) using a variety of regimens. Most studies used anthracycline (see glossary, p 2327) based regimens, which are of proved benefit in the adjuvant setting.[20] **AC regimen:** In one RCT women were treated with AC (adriamycin [doxorubicin], cyclophosphamide) and found an objective response rate (complete or partial clinical response) of 79%.[14] **MM regimen:** One RCT found that MM (mitoxantrone, methotrexate) in the UK RCT gave an overall objective response rate (see glossary, p 2328) of 85%.[13] Three RCTs compared different neoadjuvant regimens. **FAC regimen versus paclitaxel:** An RCT (174 women in the USA) compared conventional FAC (see glossary, p 2328) versus single agent paclitaxel, and found similar response rates in both groups (79% with FAC *v* 80% with paclitaxel), with no significant difference in survival rates.[21] **Comparison between MPEMi, MPEpiE, and MPEpiV regimens:** A European RCT (101 women treated with three different combinations: MPEMi [methotrexate, cisplatin, etoposide, mitomycin-C], MPEpiE [methotrexate, cisplatin, epirubicin, etoposide], and MPEpiV [methotrexate, cisplatin, epirubicin, vincristine]) found the response to be 89%, with no significant differences between the groups.[22] **Sequencing of anthracycline based chemotherapy and docetaxel:** We found two RCTs.[24,25] The first RCT (104 women who had achieved complete or partial clinical response to four cycles of CVAP [cyclophosphamide, adriamycin [doxorubicin], vincristine, and prednisolone]) compared a further four cycles of CVAP versus four cycles of docetaxel.[24] It found that further treatment with docetaxel significantly improved clinical complete response rate compared with further CVAP (clinical complete response rate: 85% with docetaxel *v* 64% with CVAP; $P = 0.03$).[24] In the second RCT (2411 people), all people received four cycles of AC and were then randomly allocated to three regimens: surgery alone, four cycles of docetaxel followed by surgery, or surgery followed by four cycles of docetaxel.[25] Preliminary results of this RCT found that, at the time of surgery, preoperative docetaxel improved clinical complete response rate compared with no preoperative docetaxel (65% with docetaxel *v* 40% with no docetaxel; $P < 0.001$). Final results, which

will also examine effects of postoperative docetaxel, are awaited. **Navelbine based regimens:** We found no fully published RCTs (see comment below). **Comparison between routes of administration:** We found one Japanese study comparing routes of administration.[23] It compared no neoadjuvant treatment, neoadjuvant intravenous epirubicin, or intra-arterial epirubicin. Response rates were higher in women receiving intra-arterial epirubicin compared with intravenous epirubicin (68% with intra-arterial epirubicin *v* 36% with iv epirubicin; $P < 0.05$); however, this was not associated with a survival benefit.

Harms: **FAC versus paclitaxel:** In the RCT in the USA comparing FAC versus paclitaxel, rates of septic neutropenia (53% with paclitaxel *v* 21% with FAC) and granulocyte colony stimulating factor usage (56% with paclitaxel *v* 25% with FAC) were higher in women taking paclitaxel.[21]

Comment: More work is needed to determine the optimal regimen for neoadjuvant treatment. We found little evidence in the literature comparing different combinations, but anthracycline based combinations probably remain the treatment of choice. Ongoing RCTs are investigating the role of taxane sequencing after anthracycline based treatment (NSABP-27), and anthracycline in combination with fluorouracil infusion. **Navelbine based regimens:** We found one RCT (published as an abstract, 147 women), which compared AC, navelbine plus mitoxantrone (NM), and navelbine plus epirubicin (NE). Response rates were 65% with AC, 73% with NM, and 86% with NE. The time to outcome was not stated. The trial is ongoing although NM has been stopped because of haematological toxicity.[26]

QUESTION Is the extent of surgery related to outcome in early invasive breast cancer?

J Michael Dixon and Alan Rodger

OPTION EXTENSIVE VERSUS LESS EXTENSIVE SURGERY

Two systematic reviews and long term follow up of included RCTs have found that more extensive surgery does not improve outcomes in women with early invasive breast cancer (see glossary, p 2328), providing that all local disease is excised. Cosmetic appearance is worse with more extensive surgery.

Benefits: **Comparisons between supraradical, radical, and total mastectomy:** See glossary, p 2328. We found one systematic review (search date not reported, 5 RCTs, 2090 women with operable breast cancer) comparing supraradical mastectomy versus radical mastectomy, radical versus total mastectomy (see glossary, p 2329), and supraradical versus total mastectomy.[27] It found no significant difference in risk of death over 10 years (ARR of more extensive *v* less extensive surgery +0.02, 95% CI −0.04 to +0.08). **Comparisons between radical, total, and simple mastectomy:** The same review included four RCTs comparing either radical versus simple mastectomy (3 RCTs) or total versus

simple mastectomy (1 RCT) in 1296 women with operable breast cancer.[27] Meta-analysis found no significant difference in risk of death over 10 years (ARR for more extensive *v* less extensive surgery +2%, 95% CI −5% to +9%). One included RCT (1079 women) comparing radical mastectomy and total mastectomy with or without axillary radiotherapy (see glossary, p 2328) has now reported 25 year follow up results.[28] It found no significant difference in survival between total and radical mastectomy (in women with negative nodes: HR for total mastectomy plus radiotherapy [see glossary, p 2328] *v* radical mastectomy 1.08, 95% CI 0.91 to 1.28; HR for total mastectomy without radiotherapy *v* radical mastectomy 1.03, 95% CI 0.87 to 1.23; in women with positive nodes: HR for total mastectomy plus radiotherapy *v* radical mastectomy 1.06, 95% CI 0.89 to 1.27). **Mastectomy versus breast conservation:** We found two systematic reviews.[27,29] One review (search date 1995) analysed data on 10 year survival from six RCTs comparing breast conservation with mastectomy.[29] Meta-analysis of data from five of the RCTs (3006 women) found no significant difference in the risk of death at 10 years (OR breast conservation *v* mastectomy 0.91, 95% CI 0.78 to 1.05). The sixth RCT used different protocols. Where more than half of node positive women in both mastectomy and breast conservation groups received adjuvant nodal radiotherapy (see glossary, p 2327), both groups had similar survival rates. Where fewer than half of node positive women in both groups received adjuvant nodal radiotherapy, survival was better with breast conservation (OR *v* with mastectomy 0.69, 95% CI 0.49 to 0.97). In the second review (search date not reported, 9 RCTs, 4981 women potentially suitable for breast conserving surgery [see glossary, p 2328]) all women received postoperative radiotherapy.[27] Meta-analysis found no significant difference in risk of death over 10 years (RRR for breast conservation *v* mastectomy +2%, 95% CI −5% to +9%). It also found no significant difference in rates of local recurrence (6 RCTs, 3107 women; RRR mastectomy *v* breast conservation +4%, 95% CI −4% to +12%). Two RCTs included in the reviews have now reported 20 year follow up results.[30,31] The first RCT (701 women with breast cancer < 2 cm diameter) found no significant difference between radical mastectomy and quadrantectomy (see glossary, p 2328) for all cause mortality at 20 years (death rate about 42% in both groups; P = 1.0).[30] The second RCT (1851 women) compared lumpectomy (see glossary, p 2328) alone, lumpectomy plus breast irradiation, and total mastectomy.[31] It found no significant difference between lumpectomy and total mastectomy for mortality at 20 years (HR lumpectomy alone *v* mastectomy 1.05, 95% CI 0.90 to 1.23; HR lumpectomy plus irradiation *v* mastectomy 0.97, 95% CI 0.77 to 1.06). **Different extents of local excision in breast conservation:** We found no systematic review. We found one RCT (705 women) comparing lumpectomy versus quadrantectomy.[32] There were significantly more local recurrences with lumpectomy than with quadrantectomy (7% with lumpectomy *v* 2% with quadrantectomy), but a major factor associated with local recurrence in the lumpectomy group was incomplete excision (see comment below).[33] We found no RCTs comparing wide local excision (complete excision microscopically) with quadrantectomy.

Breast cancer (non-metastatic)

Harms: More extensive surgery results in greater mutilation. Between 60–90% of women having breast conservation have an excellent or good cosmetic result (median 83%, 95% CI 67% to 87%).[32,34–42] The single most important factor influencing cosmetic outcome is the volume of tissue excised; the larger the amount of tissue excised the worse the cosmetic result.[32] The RCT of different extents of local excision in breast conservation found that, in a subset of 148 women, there was a significantly higher rate of poor cosmetic outcome with quadrantectomy (RR quadrantectomy *v* lumpectomy 3.1, 95% CI 1.2 to 8.1).[32] Only isolated small studies have shown no correlation between extent of surgical excision and cosmesis.[40]

Comment: The link between completeness of excision and local recurrence after breast conservation has been evaluated in 16 centres.[33] In 13 of these, incomplete excision was associated with an increased relative risk of local recurrence compared with complete excision (estimated median RRI 3.4%, 95% CI 2.6% to 4.6%). The three centres not reporting increased rates of local recurrence after incomplete excision gave much higher doses of local radiotherapy (65–72 Gy) to people with involved margins. Two centres also used re-excision, and women with involved margins had only focal margin involvement.

QUESTION What are the effects of different radiotherapy regimens in operable breast cancer?

J Michael Dixon and Alan Rodger

OPTION RADIOTHERAPY AFTER BREAST CONSERVING SURGERY

One systematic review has found that radiotherapy reduces the risk of isolated local recurrence and loss of a breast. However, it does not increase 10 year survival compared with breast conserving surgery alone. Similar rates of survival and local recurrence are achieved with breast conserving surgery plus radiotherapy as with mastectomy. One RCT found that radiotherapy (with and without tamoxifen) reduced ipsilateral breast cancer recurrence compared with tamoxifen alone after median follow up of 87 months. It found no significant difference in survival.

Benefits: **Versus breast conserving surgery alone:** We found one systematic review (search date not reported, 4 RCTs, 382–1450 women), comparing breast conserving surgery plus radiotherapy (see glossary, p 2328) with breast conserving surgery alone. All four RCTs began before 1985 and used megavoltage x rays.[27] Pooled data from RCTs reporting sites of local recurrence (781 women) found that women with isolated local recurrence were less likely to have received radiotherapy (OR 0.25, 95% CI 0.16 to 0.34). Even an RCT limited to "good prognosis disease" (tumour ≤ 2 cm, node negative, 381 people) found a significantly lower local relapse rate with radiotherapy at 5 years (relapse rate 2.3%, 95% CI 1.0% to 4.3% with radiotherapy *v* 18.4%, 95% CI 12.5% to 24.2% with no radiotherapy).[43] Ten year data found that radiotherapy was associated with significantly lower local recurrence rates (relapse rate 8.5%, 95% CI 3.9% to 13.1% with radiotherapy *v* 24.0%, 95%

CI 17.6% to 30.4% with no radiotherapy). There was no significant difference in overall survival (77.5% with radiotherapy *v* 78% with no radiotherapy).[44] One subsequent RCT (585 people) also found that after 6 years the proportion of women free of locoregional disease and with breast conservation was higher with radiotherapy than with no radiotherapy (93.8% with radiotherapy *v* 81.3% with no radiotherapy).[45] Pooled data from all four RCTs found no significant difference in 10 year survival (80.1% with radiotherapy *v* 78.9% with no radiotherapy). **Versus mastectomy:** The systematic review identified nine RCTs (4891 women) comparing breast radiotherapy after breast conserving surgery versus simple or modified radical mastectomy (see glossary, p 2328) in women with invasive breast cancer.[27] It found no difference in survival rates at 10 years (22.9% with radiotherapy after breast conserving surgery *v* 22.9% with radical mastectomy; CI not reported) or in local recurrence (6.2% radiotherapy after breast conserving surgery *v* 5.9% radical mastectomy from pooled data from 6 RCTs, 3107 women).[27] **Versus tamoxifen:** We found one RCT (1009 women after lumpectomy [see glossary, p 2328] for node negative invasive breast cancer ≤ 1 cm) that compared three treatments: radiotherapy (started 2 weeks after surgery, 50 Gy over 5 weeks with or without external beam boost), radiotherapy plus tamoxifen (see glossary, p 2329), and tamoxifen alone.[46] It found that radiotherapy (with and without tamoxifen) significantly reduced ipsilateral breast cancer recurrence compared with tamoxifen alone after median follow up of 87 months (23/332 [7%] with radiotherapy alone *v* 9/334 [2.7%] with radiotherapy plus tamoxifen *v* 45/334 [13%] with tamoxifen alone; HR for radiotherapy alone *v* tamoxifen alone 0.51,95% CI 0.31 to 0.84; P = 0.008; HR for radiotherapy plus tamoxifen *v* tamoxifen alone 0.19, 95% CI 0.09 to 0.39; P < 0.001). It found no significant difference in survival or events (tumour recurrence, contralateral breast cancer, other second primary breast cancer, or death with no evidence of cancer) between all three treatments (survival: 312/332 [94.0%] with radiotherapy alone *v* 314/334 [94.0%] with tamoxifen alone *v* 312/334 [93.4%] with radiotherapy plus tamoxifen; P = 0.93; events: 61/332 [18.4%] with radiotherapy alone *v* 74/334 [22.2%] with tamoxifen alone *v* 52/334 [15.6%] with radiotherapy plus tamoxifen; P = 0.08).

Harms:

The RCTs and systematic review included in a consensus document published in 1998 (mainly of women having breast conserving surgery or mastectomy with variation in radiotherapy techniques, doses, and fractionation) reported two severe adverse effects of radiotherapy, namely acute pneumonitis (0.7–7.0%) and pericarditis (0–0.3%), and the following long term adverse effects: significant arm oedema (1% without axillary dissection), radionecrotic rib fracture (1.1–1.5%), and brachial plexopathy (0–1.8%).[47] The risk and severity of adverse effects increased with volume irradiated, total dose received, dose per fraction, previous surgery (e.g. axillary dissection), and radiotherapy techniques that caused overlap in irradiated tissues. The review found an increased risk of non-breast cancer death (OR 1.24, 95% CI 1.09 to 1.43).[27] One systematic review (search date not reported)[48] of 10 RCTs found that the excess of non-breast cancer deaths after chest wall radiotherapy

was caused by cardiac deaths resulting from the radiotherapy, but recent RCTs with data beyond 10 years did not find an excess of cardiac deaths.[49–51] A more recent systematic review (search date not reported, 40 RCTs in early breast cancer with meta-analysis of 10 and 20 year results) confirms a reduction in local recurrence of two thirds, a reduction in breast cancer mortality, but an increase in other, particularly vascular, mortality.[52] Overall, 20 year survival was 37.1% with radiotherapy compared with 35.9% for controls (two sided P value = 0.06). Studies assessing cosmetic results have mainly been retrospective using poorly validated outcomes. The effects of social, psychological, and financial disruptions from attending 5–6 weeks of radiotherapy have not been addressed clearly. There is an extremely low reported incidence of radiation induced malignancy, usually soft tissue sarcomas, in the irradiated breast. **Versus tamoxifen:** One RCT (1009 women after lumpectomy in node negative invasive breast cancer ≤ 1 cm) comparing radiotherapy, radiotherapy plus tamoxifen, and tamoxifen alone found no significant difference between treatments in endometrial cancer or other second primary cancers (endometrial cancer: 1/332 [0.3%] with radiotherapy alone *v* 1/334 [0.3%] with tamoxifen alone *v* 5/334 [1.5%] with radiotherapy plus tamoxifen; P = 0.12; other second primary cancer: 10/332 [3%] with radiotherapy alone *v* 14/334 [4.2%] with tamoxifen alone *v* 15/334 [4.5%] with radiotherapy plus tamoxifen; P = 0.65).[46]

Comment: The four RCTs comparing breast conserving surgery with and without radiotherapy, as well as retrospective case series, found that prognostic factors for local recurrence after breast conserving surgery include positive tumour margins, an extensive intraduct component, younger age, lymphovascular invasion, histological grade, and systemic treatment. The only consistent independent risk factor is avoiding radiotherapy. Although there is no published evidence of a difference in survival at 10 years, recent results from the Fifth Early Breast Cancer Trialists' Group meeting suggest a reduction in breast cancer death in women having breast surgery with radiotherapy compared with no radiotherapy (6100 women; 3.9% [SE 1.2%] increase in survival) (Dixon M, personal communication, 2001).

OPTION RADIOTHERAPY AFTER MASTECTOMY

RCTs from a systematic review have found that radiotherapy to the chest wall after mastectomy reduces the risk of local recurrence by about two thirds, and reduces the risk of death from breast cancer at 10 years compared with mastectomy alone. Radiotherapy may be associated with late adverse effects, which are rare, including pneumonitis, pericarditis, arm oedema, brachial plexopathy, and radionecrotic rib fracture.

Benefits: We found one systematic review (search date not reported, 32 RCTs) comparing mastectomy with mastectomy followed by radiotherapy (see glossary, p 2328) to the chest wall.[27] Five RCTs were of mastectomy alone (4541 women), four of mastectomy and axillary sampling (3286 women), and 23 of mastectomy and axillary clearance (see glossary, p 2328) (6378 women). The review found that radiotherapy reduced local recurrence by two thirds and slightly

reduced breast cancer mortality (mortality: OR 0.94, 95% CI 0.88 to 1.00). However, it found no significant difference in overall survival (overall survival: OR 0.98, 95% CI 0.93 to 1.03).[27] **Versus mastectomy plus adjuvant chemotherapy or tamoxifen alone:** Two subsequent RCTs in high risk women receiving adjuvant (see glossary, p 2327) chemotherapy (CMF [see glossary, p 2328]) after mastectomy compared irradiation to the chest wall and peripheral lymphatics versus no radiotherapy.[49,50] One RCT found radiotherapy reduced relative locoregional relapse rates by 56% (RR 0.44, 95% CI 0.26 to 0.77), and the other RCT by 76% (AR 58% with radiotherapy *v* 14% with no radiotherapy).[49,50] One RCT found that survival at 10 years was higher with radiotherapy (54%, 95% CI 51% to 58% with radiotherapy *v* 45%, 95% CI 42% to 48% with no radiotherapy).[50] The other, smaller RCT found a 29% relative reduction in mortality at 15 years with radiotherapy (RR 0.71, CI 0.51 to 0.99), although when these results were pooled with the results of the review no significant difference in overall mortality was detected (OR 0.96, 95% CI 0.91 to 1.01).[27,49,53,54] Another RCT in high risk postmenopausal women who had a mastectomy and received tamoxifen (see glossary, p 2329) 30 mg daily for 1 year compared irradiation of the chest wall and peripheral lymphatics versus no radiotherapy. It found that radiotherapy reduced local or regional recurrence (as first site of recurrence) from 35% to 8%. Overall survival at 10 years was higher with radiotherapy (45%, 95% CI 41% to 49% with radiotherapy *v* 36%, 95% CI 33% to 40% with no radiotherapy).[53] We found no evidence that reduction in relative risk of local recurrence was affected by age, nodal status, receptor status, tumour grade, or tumour size, or that the effect of radiotherapy on mortality varied significantly with extent of surgery, type of radiotherapy (megavoltage or orthovoltage), years the RCTs commenced or completed recruitment, or whether systemic treatment was given.[54]

Harms: See harms of radiotherapy after breast conserving surgery, p 2313. Three RCTs of total nodal irradiation (see glossary, p 2329) after mastectomy in high risk disease found no significant increase in cardiac mortality.[49–51,53]

Comment: The RCTs in the large systematic review were heterogeneous, in part because they began when RCT methods were less developed.[27] They varied in randomisation processes, areas irradiated, use of systemic treatment, radiotherapy doses, fractionation, and treatment schedules. We found little good evidence to identify which women should have postmastectomy radiotherapy to prevent local recurrence. One review of retrospective data found that extent of axillary node involvement, larger tumour size, higher histological grade, presence of lymphovascular invasion, and involvement of tumour margins reduced the absolute chance of successful treatment.[54–57]

OPTION RADIOTHERAPY TO THE INTERNAL MAMMARY CHAIN

One RCT found no significant difference in relapse or survival at 2–3 years between radiotherapy and no radiotherapy to the internal mammary chain. Treatment may increase radiation induced cardiac morbidity.

Breast cancer (non-metastatic)

Benefits: We found no systematic review. We found one RCT (270 women treated with breast conserving surgery and radiotherapy [see glossary, p 2328]), which compared internal mammary chain irradiation versus no internal mammary chain irradiation.[58] At median follow up of 2.7 years there was no significant difference in relapse or survival (numbers not reported).

Harms: See harms of radiotherapy after breast conserving surgery, p 2313. Radiotherapy to the internal mammary chain is more likely to affect the heart compared with other types of radiotherapy.

Comment: The risk of internal mammary chain node involvement is related to the location and size of the primary tumour and, most importantly, histopathological axillary nodal status. Up to 30% of women with axillary involvement will also exhibit internal mammary chain nodal metastases. Central or medial breast cancers are more likely to metastasise to the internal mammary chain, as are larger tumours.[59,60] The risk of internal mammary chain recurrence is low, and after modified radical mastectomy (see glossary, p 2328) alone is 2%.[61] Modern radiotherapy planning and delivery should involve an assessment of the position and depth of the internal mammary chain nodes to be treated (using computerised tomography or ultrasound), and computer assisted placement, arrangement, and determination of dose distribution; these technologies were unavailable at the time of most RCTs included in the reviews.[27,48] Recent indirect evidence from RCTs suggests improved survival from nodal irradiation (including radiation to the internal mammary chain) after modified radical mastectomy combined with systemic treatment.[49,50,53] Another RCT of internal mammary chain irradiation has started recently (sponsored by the European Organisation for Research and Treatment of Cancer [EORTC]).

OPTION RADIOTHERAPY TO THE IPSILATERAL SUPRACLAVICULAR FOSSA

We found insufficient evidence to assess the impact on survival of irradiation of the ipsilateral supraclavicular fossa. RCTs have found that radiotherapy is associated with reduced risk of supraclavicular fossa nodal recurrence. Morbidity associated with irradiation of the supraclavicular fossa is rare and, where it occurs, is mild and temporary.

Benefits: We found no systematic review or RCTs on radiotherapy (see glossary, p 2328) to the ipsilateral supraclavicular fossa. One systematic review (search date not reported) found that postoperative radiotherapy was associated with reduced locoregional recurrence: see radiotherapy after breast conserving surgery, p 2312; radiotherapy after mastectomy, p 2314; and radiotherapy to internal mammary chain irradiation, p 2316.[27] RCTs indicate reduced recurrence in the supraclavicular fossa. One RCT in postmenopausal women at high risk of local recurrence who received tamoxifen (see glossary, p 2329) after mastectomy found that radiotherapy was associated with lower recurrence in the supraclavicular fossa at median follow up of 123 months (9/689 [1.3%] with radiotherapy *v* 37/686 [5.4%] with no radiotherapy; CI not reported).[53]

Harms: The acute morbidity of irradiation to the supraclavicular fossa is mild and includes temporary upper oesophagitis in nearly all women. The risk of radiation pneumonitis increases with the volume of lung irradiated. Treatment irradiates the lung apex in addition to any lung included in the breast or chest wall fields. Possible late morbidity includes brachial plexopathy but this should not exceed 1.8% if attention is paid to limiting total dose to 50 Gy, the limiting of the dose per fraction to 2 Gy or less, and avoiding field junction overlaps.[47,62] Late apical lung fibrosis is common and usually of no clinical importance. Demyelination of the cervical cord is an extremely rare complication of supraclavicular fossa radiotherapy.

Comment: None.

OPTION TOTAL NODAL RADIOTHERAPY

Three RCTs have found that total nodal irradiation improves survival in high risk disease. An earlier systematic review found reduced locoregional recurrence, but no evidence of improved survival.

Benefits: We found one systematic review (search date not reported)[27] and three subsequent RCTs.[49,50,53] The systematic review included RCTs of total nodal irradiation (see glossary, p 2329) to the internal mammary chain, supraclavicular fossa, and axilla.[27] It found that postoperative radiotherapy (see glossary, p 2328) was associated with reduced locoregional recurrence, but no evidence of improved 10 year survival. However, the three RCTs found improved overall survival in women with high risk disease who had a mastectomy, axillary dissection, and systemic adjuvant (see glossary, p 2327) treatment, if total nodal postoperative radiotherapy was given.[49,50,53]

Harms: See harms of radiotherapy to the internal mammary chain, p 2316, supraclavicular fossa, p 2317, and axilla, p 2330. The three RCTs found no increase in cardiac mortality because of radiotherapy.[49–51,53]

Comment: None.

QUESTION What are the effects of adjuvant systemic treatment?

Justin Stebbing

OPTION ADJUVANT COMBINATION CHEMOTHERAPY

One systematic review has found that adjuvant chemotherapy reduces rates of recurrence and improves survival at 10 years for women with early breast cancer. The benefit seems to be independent of nodal or menopausal status, although the absolute improvements are greater in those with node positive disease, and probably greater in younger women. The review found no evidence of a survival advantage from additional months of combination chemotherapy using two or more drugs, nor did RCTs find survival advantage from increased or reduced dosages of combination chemotherapy. Regimens containing anthracycline may modestly improve outcomes compared with the standard CMF regimen.

Breast cancer (non-metastatic)

Benefits:

Versus no chemotherapy: We found one systematic review (search date not reported, 47 RCTs, 18 000 women) comparing prolonged combination chemotherapy (see glossary, p 2328) versus no chemotherapy.[63] Chemotherapy was associated with significantly lower rates of any kind of recurrence and death from all causes (recurrence: women aged < 50 years, OR 0.65, 95% CI 0.61 to 0.69; women aged 50–69 years, OR 0.80, 95% 0.72 to 0.88; death from all causes: women aged < 50 years, OR 0.73, 95% CI 0.68 to 0.78; women aged 50–69 years, OR 0.89, 95% CI 0.86 to 0.92). Proportional benefits were similar for women with node negative and node positive disease. Ten year survival according to nodal and age group is summarised (see table 1, p 2333). **Duration of treatment:** The same review identified 11 RCTs (6104 women), which compared longer regimens (doubling duration of chemotherapy from between 4–6 months to 8–12 months) with shorter regimens.[63] It found no additional benefit from longer treatment duration. **Different doses:** Several RCTs found no significant improvement from enhanced dose regimens, whereas others found little difference from untreated controls when suboptimal doses were used.[64,65] **Anthracycline regimens versus standard CMF regimen:** The systematic review identified 11 RCTs (5942 women) comparing regimens containing anthracycline (see glossary, p 2327) (including the drugs adriamycin [doxorubicin] or 4-epidoxorubicin) versus standard CMF (see glossary, p 2328) regimens.[63] It found a significant reduction in recurrence rates in those on anthracycline regimens (P = 0.006), and a modest but significant improvement in 5 year survival (72% with anthracycline *v* 69% with CMF regimen; P = 0.02).

Harms:

Acute adverse effects: Adverse effects include nausea and vomiting, hair loss, bone marrow suppression, fatigue, and gastrointestinal disturbance. Prolonged chemotherapy is more likely to be associated with lethargy and haematological toxicity (anaemia and neutropenia), and anthracycline regimens cause complete hair loss. **Long term adverse effects:** Fertility and ovarian function may be permanently affected by chemotherapy, especially in women aged over 40 years, although for some women with hormone dependent cancer, reduced ovarian function may contribute to the benefit of adjuvant (see glossary, p 2327) treatment. Other potential long term risks include induction of second cancers (especially haematological malignancies, although the risk is low), and cardiac impairment with cumulative anthracycline dosages. Provided the cumulative dose of adriamycin (doxorubicin) does not exceed 300–350 mg/m^2, the risk of congestive heart failure is less than 1%.

Comment:

The absolute benefits of these regimens need to be balanced against their toxicity for different women. New and highly active cytotoxic agents such as the taxanes are being examined with anthracyclines either in combination or sequence. Alternating sequences of cytotoxic agents may prove an effective way of circumventing acquired drug resistance and thus enhancing the efficacy of a regimen, such as the Milan regimen (see glossary, p 2328) of single agent anthracycline followed by standard CMF chemotherapy.[66]

OPTION ADJUVANT TAMOXIFEN

One systematic review has found that adjuvant tamoxifen taken for up to 5 years reduces the chance of recurrence and death in women with oestrogen receptor positive tumours irrespective of age, menopausal status, nodal involvement, or the addition of chemotherapy. Five years of treatment seems better than shorter durations, but available evidence does not find benefit associated with prolongation beyond 5 years. Tamoxifen carries a slightly increased risk of endometrial cancer, but we found no evidence of an overall adverse effect on non-breast cancer mortality.

Benefits:

Versus placebo: We found one systematic review (search date not reported, 55 RCTs, 37 000 women), which compared adjuvant tamoxifen (see glossary, p 2329) with placebo.[67] It found that 5 years of adjuvant tamoxifen had a similar effect on recurrence and long term survival in all age groups, irrespective of menopausal status or age. Overall tamoxifen for 5 years reduced the annual risk of recurrence by 47%, and of death by 26%. **Oestrogen receptor status:** Five years of tamoxifen treatment was associated with a greater reduction in the recurrence rate for women with oestrogen receptor positive rather than negative tumours (RRR 50% with oestrogen receptor positive *v* 6% with oestrogen receptor negative), and with a slightly greater reduction in the risk of 10 year recurrence in women with node positive compared with node negative disease (ARR 15.2% with node positive *v* 14.9% with node negative). **Duration of treatment:** The review found significantly greater reductions in recurrence with increasing duration of adjuvant tamoxifen (RRR 26% with 5 years of tamoxifen use *v* 12% with 1 year of tamoxifen use; $P < 0.0001$).[67] The absolute improvement in 10 year survival from 5 years of tamoxifen is tabulated (see table 2, p 2333). One RCT (3887 women) comparing 2 and 5 years of treatment found similar results.[68] The effects of prolonged treatment beyond 5 years are unclear. In the largest RCT in the systematic review, 1153 women who had completed 5 years of tamoxifen were randomised to either placebo or 5 more years of tamoxifen.[67,69] Disease free survival (see glossary, p 2328) after 4 years of further follow up was greater for those who switched to placebo rather than continued tamoxifen (92% with placebo *v* 86% with continued tamoxifen; $P = 0.003$), although there was no significant difference in overall survival. Other studies found no detrimental effect or improvement in continuing tamoxifen beyond 5 years.[70] **Versus radiotherapy:** See benefits of tamoxifen plus radiotherapy, p 2305.

Harms:

One systematic review found an increased risk of endometrial cancer with tamoxifen (average HR 2.58, 95% CI 2.23 to 2.93).[67] For 5 years of tamoxifen treatment, this resulted in a cumulative risk over 10 years of two deaths per 1000 women (95% CI 0 deaths per 1000 women to 4 deaths per 1000 women). There was no evidence of an increased incidence of other cancers or of non-breast cancer related deaths (i.e. cardiac or vascular), although one extra death per 5000 women years of tamoxifen was attributed to pulmonary embolus. Bone loss was found in premenopausal women (1.4% bone loss a year) but not in postmenopausal women,

because of the partial agonist effects of tamoxifen.[71] There were mixed effects on cardiovascular risk, with significant reductions in low density lipoprotein cholesterol associated with a reduced incidence of myocardial infarction in some studies, but an increased risk of thrombosis. Overall, no effect has been found on non-breast cancer mortality (HR 0.99, 95% CI 0.88 to 1.16).[67] **Versus radiotherapy:** See harms of tamoxifen plus radiotherapy, p 2306.

Comment: The risk : benefit ratio may vary between women, with oestrogen receptor negative women deriving little benefit. Even in oestrogen receptor positive women, any benefit on breast cancer could be offset with prolonged treatment (beyond 5 years), by drug resistance, and by adverse effects on the endometrium. Two multicentre RCTs of tamoxifen duration are in progress (Cancer Research Campaign, personal communication, 2000); however, because of concerns about long term toxicity with tamoxifen (see harms above) and in the absence of further definitive data, current clinical practice has been to recommend tamoxifen for 5 years.[72] For women with completely oestrogen receptor negative disease, the overall benefit of adjuvant tamoxifen needs further research.

OPTION HIGH DOSE CHEMOTHERAPY New

One systematic review found no significant difference between high dose chemotherapy plus autograft compared with conventional chemotherapy in 5 year survival for women with early, poor prognosis breast cancer. The review found that high dose chemotherapy plus autograft increased treatment related and non-cancer related deaths compared with conventional chemotherapy.

Benefits: We found one systematic review (search date 2002, 9 RCTs, 3525 women with early, poor prognosis breast cancer, multiple positive axillary lymph nodes and no distant metastasis) that compared high dose chemotherapy plus bone marrow or peripheral blood stem cell autograft with conventional chemotherapy (see comment below).[73] It found no significant difference between regimens in overall survival at 3 or 5 years (3 years: RR 1.02, 95% CI 0.98 to 1.06; 5 years: RR 0.98, 95% CI 0.93 to 1.05). It found that high dose chemotherapy significantly increased event free survival at 3 years (RR 1.11, 95% CI 1.05 to 1.18). However, there was no significant difference at 5 years (RR 1.00, 95% CI 0.92 to 1.08). It found that high dose chemotherapy significantly reduced quality of life immediately after treatment but found no significant difference between regimens at 1 year (3 RCTs, data were not reported in the review).

Harms: The systematic review found that high dose chemotherapy significantly increased treatment related mortality and non-cancer related deaths compared with conventional chemotherapy (treatment related deaths, 5 RCTs: 40/1075 [3.7%] with high dose *v* 0/1087 [0%] with conventional; RR 17.05, 95% CI 4.75 to 61.22; non-cancer related deaths: 48 deaths with high dose *v* 4 deaths with conventional dose, RR 7.74, 95% CI 3.43 to 17.50).[73]

Comment: Most of the RCTs included in the systematic review have only been published as abstracts and reporting of follow up is incomplete.[73] Further results are awaited. Overall survival rates quoted in the

review were predominantly based on results to date and showed no differences in overall survival. Quality of life scores were not different between the groups at 1 year but the large excess of non-cancer deaths in the high dose group shows that this intervention is not likely to be beneficial, even in women with poor prognosis primary disease.

OPTION COMBINED CHEMOTHERAPY PLUS TAMOXIFEN

One RCT has found that adding combined chemotherapy to tamoxifen improves survival at 5 years in women with lymph node negative, oestrogen receptor positive early breast cancer.

Benefits: We found no systematic review. We found one RCT (2306 women with lymph node negative, oestrogen receptor positive early breast cancer), which compared tamoxifen (see glossary, p 2329) alone versus tamoxifen plus CMF (see glossary, p 2328) chemotherapy.[74] It found that adding chemotherapy to tamoxifen caused a further absolute improvement in disease free survival (see glossary, p 2328) and overall survival (disease free survival at 5 years' follow up 90% with tamoxifen plus chemotherapy *v* 85% with tamoxifen alone; P = 0.006; overall survival: 97% with tamoxifen plus chemotherapy *v* 94% with tamoxifen alone; P = 0.03).

Harms: Adding CMF chemotherapy to tamoxifen was associated with a greater incidence of grade 3/4 neutropenia (9% with tamoxifen plus chemotherapy *v* 0% with tamoxifen alone), grade 2 or higher nausea (35% with tamoxifen plus chemotherapy *v* 4% with tamoxifen alone), moderate/severe alopecia (35.6% with tamoxifen plus chemotherapy *v* 0.4% with tamoxifen alone), and thromboembolism/phlebitis (7.5% with tamoxifen plus chemotherapy *v* 2.1% with tamoxifen alone).[74]

Comment: None.

OPTION OVARIAN ABLATION

One systematic review in women aged under 50 years with early breast cancer has found that ovarian ablation improves long term survival compared with no ovarian ablation.

Benefits: We found one systematic review (search date not reported, 12 RCTs with at least 15 years' follow up, 2102 premenopausal women with early breast cancer) comparing ovarian ablation (see glossary, p 2328) by irradiation or surgery versus no ablation.[75] Significantly more women with ovarian ablation survived (52% with ablation *v* 46% with no ablation; P = 0.001), and survived recurrence free (45% with ablation *v* 39% with no ablation; P = 0.0007). Benefit was independent of nodal status.

Harms: We found no good evidence on long term adverse effects. Concerns exist about late sequelae of ovarian ablation, especially effects on bone mineral density and cardiovascular risk. Acute adverse effects are likely to be menopausal symptoms

Comment: Five of the RCTs compared ovarian ablation plus chemotherapy with chemotherapy alone.[75] In these, the absolute benefit of ablation was smaller than in RCTs of ovarian ablation alone. It may be that cytotoxic chemotherapy itself suppresses ovarian function, making the effect of ablation difficult to detect in combined RCTs. When only premenopausal women were considered in the absence of chemotherapy, there was a 27% improvement in the odds of recurrence free survival. RCTs are underway of reversible oophorectomy using gonadotrophin releasing hormone analogues, which would allow preservation of fertility in younger women with oestrogen receptor positive tumours.

QUESTION What are the effects of axillary clearance in women with operable primary breast cancer?

J Michael Dixon and Alan Rodger

OPTION AXILLARY MANAGEMENT

RCTs found no evidence that axillary clearance is associated with improved survival at 5–10 years compared with axillary node sampling, axillary radiotherapy, or sampling plus radiotherapy combined. One systematic review of mainly poor quality evidence found that the risk of arm lymphoedema was highest with axillary clearance plus radiotherapy, lower with axillary sampling plus radiotherapy, and lowest with sampling alone.

Benefits: **Versus axillary sampling:** We found no systematic review but found one RCT (466 women) in women having breast conserving surgery (see glossary, p 2328). It found that axillary sampling (see glossary, p 2328) was associated with improved survival compared with axillary clearance (see glossary, p 2328), but the difference was not significant (estimated 5 year survival 88.6% with axillary sampling *v* 82.1% with axillary clearance).[76] Rates of node positivity were similar in both groups. **Versus axillary radiotherapy:** We found one systematic review (search date not reported, 8 RCTs, 4370 women) comparing axillary clearance (level I, II, and III dissection) versus axillary radiotherapy (see glossary, p 2328).[27] It found no significant difference in mortality at 10 years or recurrence (mortality: 54.7% with axillary clearance *v* 54.9% with axillary radiotherapy; recurrence: OR 1.01). Radiotherapy (see glossary, p 2328) was associated with fewer isolated local recurrences (OR 15%, 95% CI 7% to 22%).[27] **Versus sampling plus radiotherapy:** We found no systematic review. Two RCTs compared axillary clearance (level I, II, and III dissection) versus sampling followed by radiotherapy in women with involved axillary nodes.[76,77] They found no significant difference in local, axillary, or distant recurrence. **Versus axillary clearance plus radiotherapy:** We found no studies assessing the effect of radiotherapy in addition to axillary clearance (level I and II, or level I, II, and III dissection) in regional control of disease.

Harms: **Versus axillary sampling:** Adverse effects of axillary surgery include seroma formation, arm swelling, damage to the intercostobrachial nerve, and shoulder stiffness. We found one RCT comparing the morbidity of different axillary procedures.[76] It compared

complete axillary clearance (level I, II, and III dissection) versus four node axillary sampling followed by radiotherapy if the nodes were involved. The rate of arm swelling was higher after clearance than after sampling whether or not women received postoperative radiotherapy (at 3 years, forearm girth was significantly greater; $P = 0.005$). After removal of axillary drains, between a quarter and a half of women who had had a level I and II, or level I, II, and III axillary dissection developed seromas requiring aspiration. **Versus axillary sampling plus radiotherapy:** One RCT comparing clearance with sampling plus radiotherapy for node positive disease found significantly reduced shoulder movement with radiotherapy, even though the shoulder joint was not irradiated.[76] At 6 months, both groups had significantly reduced shoulder movement compared with women receiving axillary sampling alone ($P < 0.004$). However, by 3 years, the axillary clearance group had improved and was not significantly different from the sampling group. **Arm lymphoedema:** One Australian systematic review (search date 1996) of lymphoedema prevalence, risks, and management found that, although current information is of poor quality, the combination of axillary dissection (to or beyond level II) and axillary radiotherapy was associated with a risk of lymphoedema of 12–60%, with most studies suggesting that at least a third of women are affected.[78] Studies of axillary sampling followed by irradiation found lower rates (6–32%), and for axillary sampling alone, lower still (0–21%). Studies of dissection beyond level I found rates between 0–42%, with most studies reporting a rate of 20–30% 1 year after operation.[78] In women who receive axillary radiotherapy without axillary surgery, the overall lymphoedema rate is about 8%.

Comment: **Axillary staging:** Both clearance and sampling provide important prognostic information on which decisions on local and systemic treatment can be based. Further RCTs of less invasive and potentially less morbid staging (see glossary, p 2328) procedures such as sentinel node biopsy are underway. A decision on axillary management should be based on the risk of involvement of axillary nodes (which varies according to tumour size, grade, and the presence of vascular/lymphatic invasion), and potential treatment related morbidity. Two retrospective cohort studies found that level I dissection accurately assessed axillary lymph node status, providing that at least 10 nodes were removed.[79,80] One RCT found that a sample of four nodes provided sufficient information to categorise an axilla as histologically positive or negative.[81] Removal of nodes at level I and II, or removal of all nodes below the axillary vein (level I, II, and III), accurately stages the axilla.[79,80] RCTs comparing sentinel node biopsy with axillary node clearance and sampling are currently underway, and results of these will be incorporated in future *Clinical Evidence* updates (Dixon M, personal communication, 2000).

Breast cancer (non-metastatic)

QUESTION **What are the effects of interventions in locally advanced breast cancer (stage III B)?**

Alan Rodger

OPTION LOCAL TREATMENT FOR LOCALLY ADVANCED BREAST CANCER

Two small RCTs including women with locally advanced disease (stage III B) found that, for locally advanced breast cancer that is rendered operable, radiotherapy or surgery as sole local treatments have similar effects on response rates, duration of response, and overall survival. One RCT found limited evidence that, if surgery is possible and is carried out, postoperative radiotherapy reduced locoregional recurrence. Local skin toxicity (acute and late) after radiotherapy is greater in locally advanced breast cancer than after treatment for less advanced disease, because of the need for a higher radiation dose to skin.

Benefits: We found no systematic review of the role of radiotherapy in locally advanced (stage III B) breast cancer (see glossary, p 2327). We found seven RCTs, including women with stage III B, which compared radiotherapy versus no radiotherapy.[50,53,82–86] Other management options varied across these RCTs. Most RCTs were small, but included more than stage III B women. **Postoperative radiotherapy versus no further local treatment after surgery:** We found two RCTs.[82,85] In one of these RCTs[82] preoperative and postoperative chemo-endocrine treatment was given to all women who also had a mastectomy and half the women were randomised to postmastectomy radiotherapy to the chest wall and regional lymphatics (45–50 Gy in 5 weeks). However, 43% of the 184 women were excluded and there were more exclusions in the radiotherapy group, and it is impossible to ascertain what percentage of women were stage III B. There were numerous chemotherapy complications, including one death. The RCT found no significant difference in local or distant failures. However, it found that overall crude survival was significantly higher with no radiotherapy compared with radiotherapy (28.7 months with no radiotherapy *v* 21.7 months with radiotherapy; $P < 0.05$). Conclusions cannot be drawn from this RCT. The second RCT of operable locally advanced breast cancer (332 women who were recurrence free after modified radical mastectomy [see glossary, p 2328] and 6 cycles of chemohormone treatment; 38% stage T4 and 14% N2)[84] compared postoperative radiotherapy versus no further treatment. It found no significant difference in time to relapse or median overall survival (time to relapse: 4.7 years with radiotherapy *v* 5.2 years with no further treatment; median overall survival: 8.3 years with radiotherapy *v* 8.1 years with no further treatment). Radiotherapy reduced locoregional sites as first recurrence by 9%. **Postmastectomy radiotherapy in women having systemic treatment after surgery:** Two RCTs of "high risk breast cancer" (including women with stage III B disease) studied postmastectomy radiotherapy in women having systemic treatment after surgery.[50,53] One RCT found that, in a subgroup of 189 postmenopausal women with skin invasion who received postmastectomy radiotherapy plus tamoxifen (see glossary, p 2329), 8% developed local

recurrence compared with 34% receiving tamoxifen alone (5 year disease free survival [see glossary, p 2328]: 41% with radiotherapy *v* 37% with tamoxifen; 10 year disease free survival: 23% with radiotherapy *v* 22% with tamoxifen; 5 year survival: 51% with radiotherapy *v* 61% with tamoxifen; 10 year survival: 31% with radiotherapy *v* 27% with tamoxifen). However, the studies used small and retrospective subgroups, making conclusions uncertain.

Surgery alone versus radiotherapy alone: Two RCTs compared surgery alone with radiotherapy alone as local treatment.[83,84] In one RCT (113 women with stage III breast cancer, 67% stage III B) women were given chemotherapy and 81% became operable; then 87 women were randomised to surgery or to radiotherapy.[83] After local treatment, a further 2 years of chemotherapy was given. Both groups had similar duration of disease control (29.2 months with surgery *v* 24.4 months with radiation; P = 0.5), similar overall median survival (39.3 months with surgery *v* 39.0 months with radiation), and similar sites of first relapse. In the other RCT (132 women, 91% stage III B, 9% stage III A) all women received chemotherapy before randomisation to either surgery or radiotherapy.[83] Total response rate was 75% in each group. Duration of remission was not significantly different (15 months with surgery *v* 22 months with radiotherapy; P = 0.58). Survival was similar at 4 years (52 months with radiotherapy *v* 49.1 months with surgery).

Low dose radiotherapy versus tamoxifen: A small RCT (143 women)[86] compared low dose radiotherapy (40 Gy in 15 fractions) versus tamoxifen 20 mg twice daily. Women were given the alternative treatment on relapse. The RCT found no significant difference in response rates (P = 0.34), duration of response (P = 0.76), or survival (P = 0.38).

Harms: The type of harms from radiotherapy for locally advanced breast cancer were similar to those from radiotherapy after mastectomy or breast conserving surgery (see glossary, p 2328). However, in stage III B disease with skin involvement (T4 b, c, d), the skin is usually given a higher dose of radiotherapy. In addition, a higher dose (60 Gy) is often given to more of the breast volume. Acute skin toxicity (including moist desquamation) and late skin toxicity (pigmentation and telangiectasia) are also more likely than in women without skin involvement.

Comment: The lack of good quality, large RCTs addressing directly stage III B breast cancer and the role of radiotherapy render it difficult to draw firm conclusions on its value. Such RCTs are small and have varying approaches to management. From the results of two RCTs,[83,84] it can be concluded that in terms of overall response (which includes the response from local treatments such as surgery, radiotherapy, or both, and the effects of any initial systemic treatment), duration of that response, and overall survival, there is no advantage of either surgery alone or radiotherapy alone as sole local treatment over the other. It is more difficult to detail the possible benefits of postoperative radiotherapy in women whose locally advanced breast cancers have been rendered operable by systemic treatment and who have had surgery, usually modified radical mastectomy. It is likely that such postoperative radiotherapy will reduce the risk of local (and regional if nodal areas are irradiated) recurrence. It is not possible to conclude that it will affect survival.

OPTION SYSTEMIC TREATMENT FOR LOCALLY ADVANCED BREAST CANCER

RCTs found insufficient evidence that cytotoxic chemotherapy of cyclophosphamide, methotrexate, and fluorouracil, or an anthracycline based multidrug regimen improved survival, disease free survival, or long term locoregional control in locally advanced breast cancer. One RCT has found that hormone treatment plus radiotherapy improves survival in locally advanced breast cancer compared with radiotherapy alone. One RCT has found that chemotherapy, hormone treatment, or both, delays locoregional recurrence.

Benefits: We found no systematic review. **Radiotherapy versus radiotherapy plus systemic chemotherapy:** We found three RCTs,[87–89] which compared radiotherapy (see glossary, p 2328) versus radiotherapy plus systemic treatment (hormone treatment, chemotherapy, or both). One RCT (410 women, most stage III B)[87] compared radiotherapy with radiotherapy plus chemotherapy (CMF [see glossary, p 2328]) (for 12 cycles) with radiotherapy plus hormone treatment (ovarian irradiation for premenopausal women, tamoxifen [see glossary, p 2329] for postmenopausal women) and with radiotherapy plus both chemotherapy and hormone treatment. Both chemotherapy ($P = 0.0002$) and hormone treatment ($P = 0.0007$) significantly delayed locoregional recurrence. Combined chemotherapy and hormone treatment had the largest effect ($P = 0.0001$). Locoregional recurrence at 6 years was reduced (about 60% with radiotherapy *v* about 50% with added chemotherapy or hormonal treatment). The effect on distant metastases was similar but less marked. Significantly increased median survival was found only with hormone treatment (4.3 years with hormone treatment *v* 3.3 years without hormone treatment, after 8 years HR death 0.75, 95% CI 0.59 to 0.96; median survival 3.8 years with chemotherapy *v* 3.6 years without chemotherapy, HR 0.84, 95% CI 0.66 to 1.08). Another RCT (118 women with stage III B breast cancer)[88] compared radiotherapy versus radiotherapy plus chemotherapy (CMF for 12 cycles) plus tamoxifen and versus chemotherapy (CMF alternating with adriamycin [doxorubicin] and vincristine — AV) followed by radiotherapy and then further similar chemotherapy and tamoxifen. The radiotherapy in the third arm delivered a lower dose to the skin and a lower total dose. After a minimum follow up of 14 years, the RCT found no significant difference in survival, disease free survival (see glossary, p 2328), or locoregional control. The 10 year survival rates were 13% with radiotherapy alone; 21% with radiotherapy, CMF, and tamoxifen; and 28% for radiotherapy plus CMF, AV, and tamoxifen. Differences in 10 year survival were +8% (95% CI −9% to +25%) for radiotherapy compared with radiotherapy, CMF, and tamoxifen; and 15% (95% CI 3% to 33%) for radiotherapy compared with radiotherapy plus CMF, AV, and tamoxifen. There was no significant difference between the two arms with chemotherapy. Adding CMF and tamoxifen and adding CMF, AV, and tamoxifen significantly increased disease free survival compared with radiotherapy alone at 10 years (4% with radiotherapy alone *v* 15% in each of the other groups; ARI for each of the other groups *v* radiotherapy alone 12%, 95% CI 1% to 25%). Local recurrence was similar in the three arms

(42% with radiotherapy alone *v* 45% with radiotherapy, CMF and tamoxifen *v* 49% with radiotherapy plus CMF, AV, and tamoxifen). The third RCT (52 women with T4 breast cancer) compared an anthracycline (see glossary, p 2327) chemotherapy regimen before radiotherapy versus similar radiotherapy alone.[89] The combined treatment arm achieved a higher initial locoregional control rate (complete response 78.6% with chemotherapy regimen before radiotherapy *v* 45.8% with radiotherapy alone; P = 0.03). However, the number of women free of locoregional spread at death or last follow up was similar (57% with chemotherapy regimen before radiotherapy *v* 50% with radiotherapy alone). Overall survival and time to distant recurrence were not significantly different. **Multimodal treatment versus hormone treatment:** One RCT (108 women) compared multimodal treatment (preoperative chemotherapy, surgery, radiotherapy, and tamoxifen) with initial hormone treatment plus subsequent salvage treatments upon tumour progression.[90,91] The objective remission after 6 months was higher with multimodal treatment than with tamoxifen alone (31/54 [57%] with multimodal treatment *v* 19/53 [36%] with tamoxifen alone; OR 2.4, 95% CI 1.1 to 5.0).[90] However, at a median follow up of 52 months, there was no significant difference in survival, the development of metastases, the time to metastases, or uncontrolled local disease. Women with oestrogen receptor positive tumours had a higher objective response rate (49% with oestrogen receptor positive *v* 7% with oestrogen receptor negative tumours; P value not reported), and increased survival (numbers not reported).[91]

Harms: In many RCTs, harms of treatment were not reported (see harms of adjuvant combination chemotherapy, p 2318).

Comment: The lack of large RCTs and the frequent inclusion of less locally advanced disease (see glossary, p 2327) (T3) with locally advanced breast cancer defined here as stage III B make it difficult to draw conclusions. There is, however, no evidence from the studies using CMF chemotherapy or various regimens incorporating anthracyclines that cytotoxic chemotherapy improves survival, disease free survival, or long term locoregional control in stage III B breast cancer.

GLOSSARY

Adjuvant treatment This usually refers to systemic chemotherapy, hormonal treatment, or both, taken by people after removal of a primary tumour (in this case, surgery for early breast cancer), with the aim of killing any remaining micrometastatic tumour cells and thus preventing recurrence.

Advanced breast cancer Operable locally advanced breast cancer (stage III A) is T3 (tumours > 5 cm) and N1 (non-matted involved axillary nodes). Locally advanced breast cancer (stage III B) is M0 with T4 (skin or chest wall infiltration by tumour), N2 (matted axillary nodes)/N3 (internal mammary node involvement) disease, or both, not classified as non-invasive or early invasive breast cancer. Metastatic breast cancer (stage IV) is M1 (any supraclavicular fossa node involvement or distant metastases to bone, lung, liver, etc.) with any combination of tumour and node parameters.

Anthracyclines Are also known as cytotoxic antibiotics, and are used as adjuvant treatment with radiotherapy. Examples of anthracyclines are aclarubicin, daunorubicin, adriamycin (doxorubicin), epirubicin, and idarubicin.

Breast cancer (non-metastatic)

Axillary clearance Clearance of level I, II, and usually level III axillary lymph nodes. Level I nodes are lateral to the pectoralis minor muscle, level II nodes are under it, and level III nodes are medial to it at the apex of the axilla.

Axillary radiotherapy This usually includes irradiation of the supraclavicular fossa. Irradiation of this area incorporates some underlying lung that increases the risk of radiation pneumonitis. By increasing the volume of the lung irradiated, compared with chest wall or breast radiotherapy alone, the risk of acute pneumonitis is increased.

Axillary sampling Aims to remove the four largest, most easily palpable axillary lymph nodes, for histological examination.

Breast conserving surgery Surgery that consists of lumpectomy (minimal free margins), wide local excision (wider free margins), or segmental or quadrant resection (usually with wide free margins).

CMF (classical) Chemotherapy regimen containing cyclophosphamide, methotrexate, and fluorouracil (5-FU).

Combination chemotherapy Two or more cytotoxic drugs given intravenously every 3–4 weeks for 4–6 months.

Disease free survival Means being alive with no local or distant recurrence or contralateral disease.

Early invasive breast cancer (stage I or II) is M0 with T1 or T2 (tumour diameter ≤ 5 cm, no involvement of skin or chest wall) and N0 or N1 (mobile axillary nodes); or M0 with T3 (tumour diameter > 5 cm, no skin or chest wall involvement), but only N0.

FAC Chemotherapy regimen containing fluorouracil (5-FU), adriamycin (doxorubicin), and cyclophosphamide.

Lumpectomy Gross tumour excision.

Milan regimen A sequential regimen of single agent anthracycline followed by CMF.

Neoadjuvant chemotherapy (also known as primary medical treatment.) Involves the use of chemotherapy to treat breast cancer before locoregional treatment (surgery and or radiotherapy) to the breast to downstage large primary cancers that would require mastectomy to improve chances of survival.

Non-invasive breast cancer (stage 0) is Tis (carcinoma *in situ*, intraductal carcinoma, lobular carcinoma *in situ*, or Paget's disease of the nipple with no associated tumour); N0 (no axillary nodal involvement); and M0 (no metastases).

Ovarian ablation Surgical, medical, or radiation induced suppression of ovarian function in premenopausal women.

Overall objective response rate The proportion of treated people in whom a complete response (disappearance of all known lesions on 2 separate measurements at least 4 weeks apart), or partial response (> 50% reduction in the size of lesions) is observed.

Quadrantectomy Tumour excised with ≥ 2 cm of normal surrounding breast tissue and with a segment of breast tissue from the periphery of the breast to the nipple.

Radical mastectomy Removal of breast and pectoralis major and minor muscles and axillary contents.

Radiotherapy Part of initial local and regional treatment. In early stage disease, it may be an adjunct to surgery; in locally advanced disease (T4, N2), it may be the sole locoregional treatment. Radiotherapy may be delivered to the breast or postmastectomy chest wall, as well as to the lymphatic areas of the axilla, supraclavicular fossa, or internal mammary node chain.

Staging of breast cancer A detailed description by tumour, nodal, and metastatic parameters at a particular time (TNM).[1] These are amalgamated into broader categories called stages (0–IV). Stages can be aggregated into even broader categories (non-invasive, early invasive, and advanced breast cancer) (see table 3, p 2333).

Supraradical mastectomy Removal of breast, pectoralis major and minor muscles, axillary contents, and internal mammary chain of nodes.
Tamoxifen A non-steroidal anti-oestrogen taken as daily oral tablets, usually for between 2–5 years.
TNM staging system See "staging of breast cancer" above.
Total mastectomy Removal of breast.
Total nodal irradiation Radiotherapy to the regional lymph nodes, including supraclavicular, infraclavicular, axillary nodes, and internal mammary nodes in the upper intercostal spaces.
UICC system International Union against Cancer.

Substantive changes

Tamoxifen plus radiotherapy for DCIS Two RCTs added;[8,10] conclusions unchanged.
Radiotherapy after surgery for DCIS One RCT added;[8] conclusions unchanged.
Radiotherapy after breast conserving surgery One RCT added;[46] conclusions unchanged.

QUESTIONS

INTERVENTIONS

Key Messages

- **Diet (low fat, high carbohydrate)** One small RCT found limited evidence that advice to follow a low fat, high carbohydrate diet reduced self reported breast swelling and breast tenderness at 6 months compared with general dietary advice.
- **Danazol** One RCT found that danazol reduced cyclical breast pain after 12 months compared with placebo, but increased adverse effects (weight gain, deepening of the voice, menorrhagia, and muscle cramps). It found no significant difference in pain relief between danazol and tamoxifen.
- **Gestrinone** One RCT found that gestrinone reduced breast pain after 3 months compared with placebo, but increased adverse effects (greasy skin, hirsutism, acne, reduction in breast size, headache, and depression).
- **Tamoxifen** Three RCTs found limited evidence that tamoxifen is more effective than placebo at reducing breast pain. Two of the RCTs found more hot flushes and vaginal discharge with tamoxifen compared with placebo, although differences between groups did not reach significance. The third RCT did not report on adverse events. One RCT found similar efficacy but fewer adverse effects with a lower dose of 10 mg compared with 20 mg. One RCT found no significant difference in pain relief between tamoxifen and danazol. One meta-analysis of four large breast cancer prevention trials found that tamoxifen used long term was associated with an increased risk of venous thromboembolism.
- **Lisuride maleate** One RCT with weak methods found limited evidence that lisuride maleate (a dopamine agonist) reduced breast pain over 2 months compared with placebo.

- **Tibolone** We found no placebo controlled RCTs of tibolone. One small RCT found limited evidence that tibolone reduced breast pain after 1 year compared with hormone replacement therapy.
- **Bromocriptine** One RCT with high withdrawal rates and one small crossover RCT reporting post crossover results found limited evidence that bromocriptine (a dopamine agonist) reduced breast pain compared with placebo. However, both RCTs found a higher incidence of adverse effects with bromocriptine compared with placebo. Adverse events included nausea, dizziness, postural hypotension, and constipation. One of the RCTs found that withdrawals related to adverse effects were more frequent with bromocriptine compared with placebo, although differences between groups did not reach significance.
- **Hormone replacement therapy** We found no placebo controlled RCTs of hormone replacement therapy. One small RCT found limited evidence that women taking hormone replacement therapy had more breast pain after 1 year than women taking tibolone.
- **Progesterones** Two small crossover RCTs found no significant difference between progesterones and placebo in breast pain.
- **Antibiotics; diuretics; evening primrose oil; gonadorelin analogues (luteinising hormone releasing hormone analogues); progestogens; pyridoxine; vitamin E** We found no RCTs of sufficient quality on the effects of these interventions.

DEFINITION Breast pain can be differentiated into cyclical mastalgia (worse before a menstrual period) or non-cyclical mastalgia (unrelated to the menstrual cycle).[1,2] Cyclical pain is often bilateral, usually most severe in the upper outer quadrants of the breast, and may be referred to the medial aspect of the upper arm.[1–3] Non-cyclical pain may be caused by true breast pain or chest wall pain located over the costal cartilages.[1,2,4] Specific breast pathology and referred pain unrelated to the breasts are not included in this chapter.

INCIDENCE/ PREVALENCE Up to 70% of women develop breast pain in their lifetime.[1,2] Of 1171 US women attending a gynaecology clinic, 69% suffered regular discomfort, which was judged as severe in 11% of women, and 36% had consulted a doctor about breast pain.[2]

AETIOLOGY/ RISK FACTORS Breast pain is most common in women aged 30–50 years.[1,2]

PROGNOSIS Cyclical breast pain resolves spontaneously within 3 months of onset in 20–30% of women.[5] The pain tends to relapse and remit, and up to 60% of women develop recurrent symptoms 2 years after treatment.[1] Non-cyclical pain responds poorly to treatment but may resolve spontaneously in about 50% of women.[1]

AIMS OF INTERVENTION To reduce breast pain and improve quality of life, with minimal adverse effects.

OUTCOMES Breast pain score based on the number of days of severe (score 2) or moderate (score 1) pain experienced in each menstrual cycle; visual analogue score of breast pain, heaviness, or breast tenderness; questionnaires.

METHODS *Clinical Evidence* search and appraisal July 2003 using the following keywords: breast tenderness, discomfort, pain, mastalgia, and mastodynia. Overall, the evidence was poor and some studies with

weaker methods were included when higher quality evidence was not found, as indicated in the text. Studies were included whatever the definition of breast pain, as indicated in the text.

QUESTION What are the effects of treatments for breast pain?

OPTION DIET (LOW FAT, HIGH CARBOHYDRATE)

One small RCT found limited evidence that advice to follow a low fat, high carbohydrate diet reduced self reported breast swelling and breast tenderness at 6 months compared with general dietary advice.

Benefits: We found no systematic review. We found one small RCT (21 women attending a clinic in Canada with severe cyclical mastalgia for at least 5 years), which compared instruction to reduce fat content of the diet (to 15% of total calorie intake, while increasing complex carbohydrates to maintain calorie intake) versus general dietary advice (the principles for a healthy diet based on Canada's Food Guide, but not counselled to modify the fat content of their diet) for 6 months.[6] One woman in each group withdrew and was excluded from the analysis. It found that over 6 months, self reported breast swelling was significantly reduced in women with low fat, high carbohydrate diet compared with general dietary advice (breast swelling at 6 months: 5/10 [50%] with low fat diet *v* 9/9 [100%] with general diet; NNT 2, 95% CI 2 to 5). It also found that reported tenderness was significantly reduced in women receiving low fat dietary advice compared with those receiving general dietary advice at 6 months (6/10 [60%] with low fat diet *v* 9/9 [100%] with general diet; NNT 3, 95% CI 2 to 9). However, it found no significant difference between groups in breast swelling, tenderness, and nodularity on physical examination at 6 months (6/10 [60%] with low fat diet *v* 2/9 [22%] with general diet; RR 2.7, 95% CI 0.8 to 4.1).[6]

Harms: The small RCT reported no adverse effects.[6]

Comment: Diets can be difficult to sustain in the long term.

OPTION EVENING PRIMROSE OIL

We found no good quality RCTs on the effects of evening primrose oil.

Benefits: We found no systematic review and no good quality RCTs (see comment below).

Harms: Poor quality RCTs found that adverse effects causing treatment discontinuation were similar with evening primrose oil and placebo (3%), and were largely caused by abdominal bloating.[5,7]

Comment: In one RCT, 72 women received evening primrose oil or placebo for 3 months followed by 3 months of evening primrose oil.[7] It reported that pain, tenderness, and lumpiness improved in cyclical but not non-cyclical breast pain. However, the methods of the RCT were poor and included post hoc revision of the inclusion criteria, subgroup analysis, exclusion of withdrawals, and the use of baseline comparisons (with the best response seen in women who were

symptomatically worse at baseline). We found one survey of randomised and open studies; however, data were reported as overall summary figures, which makes specific data extraction impossible.[5] In the UK, the Committee for Safety of Medicines has withdrawn the prescription licence from evening primrose oil because of lack of efficacy but it is still available over the counter.[8]

OPTION DANAZOL

One RCT found that danazol reduced cyclical breast pain after 12 months compared with placebo, but increased adverse effects (weight gain, deepening of the voice, menorrhagia, and muscle cramps). It found no significant difference in pain relief between danazol and tamoxifen.

Benefits: We found no systematic review. We found one good quality outpatient based RCT in 93 women with severe cyclical mastalgia.[9] **Versus placebo:** The RCT compared three treatments over 6 months: danazol (200 mg/day), tamoxifen (10 mg/day), and placebo. It found that significantly more women achieved greater than 50% pain relief at the end of treatment with danazol compared with placebo (pain relief: 21/32 [66%] with danazol *v* 11/29 [38%] with placebo; RR 1.7, 95% CI 1.0 to 2.9; NNT 4, 95% CI 2 to 29). It found that after 12 months of treatment, the difference between groups remained significant (pain relief after 1 year: 12/32 [38%] with danazol *v* 0/29 [0%] with placebo; NNT 3, 95% CI 2 to 5). **Versus tamoxifen:** The same RCT found no significant difference in pain relief after 6 months of treatment between danazol and tamoxifen (21/32 [66%] with danazol *v* 23/32 [72%] with tamoxifen; RR 0.9, 95% CI 0.7 to 1.3).[9]

Harms: Adverse effects were reported in more women taking danazol than placebo.[9] These included a significant increase in weight gain (10/32 [31%] with danazol *v* 1/29 [3%] with placebo; $P = 0.006$), and non-significant increases for deepening of the voice (4/32 [13%] with danazol *v* 0/29 [0%] with placebo; $P = 0.11$), menorrhagia (4/32 [13%] with danazol *v* 0/29 [0%] with placebo; $P = 0.11$), and muscle cramps (3/32 [9%] with danazol *v* 0/29 [0%] with placebo; $P = 0.24$).[9]

Comment: Although we found no direct evidence, there is consensus that once a response is achieved, adverse effects can be avoided by reducing the dose of danazol to 100 mg daily and confining treatment to the 2 weeks preceding menstruation.[9,10] Non-hormonal contraception is essential with danazol when given in 200 mg doses, as danazol has deleterious androgenic effects in the fetus.[11]

OPTION BROMOCRIPTINE

One RCT with high withdrawal rates and one small crossover RCT reporting post crossover results found limited evidence that bromocriptine (a dopamine agonist) reduced breast pain compared with placebo. However, both RCTs found a higher incidence of adverse effects with bromocriptine compared with placebo. Adverse events included nausea, dizziness, postural hypotension, and constipation. One of the RCTs found that withdrawals related to adverse effects were more frequent with bromocriptine compared with placebo, although differences between groups did not reach significance.

Breast pain

Benefits: We found no systematic review but found two RCTs.[12,13] The first outpatient based, European RCT (272 premenopausal women with diffuse fibrocystic disease of the breast) compared bromocriptine (2.5 mg twice daily) versus placebo.[12] After 3 and 6 months it found that bromocriptine significantly improved symptoms compared with placebo on self assessed visual analogue scoring of breast pain, tenderness, and heaviness (results presented graphically).[12] Results have to be interpreted with care, as overall withdrawal rates were high (see comment below). The second RCT (10 women) used a crossover design, and also found that bromocriptine significantly reduced pain compared with placebo (post crossover: $P < 0.02$; pre-crossover results not reported).[13]

Harms: The larger RCT found that adverse effects were significantly more frequent with bromocriptine than with placebo (61/135 [45%] with bromocriptine *v* 41/137 [30%] with placebo; RR 1.5, 95% CI 1.1 to 1.9; NNH 7, 95% CI 4 to 29).[13] It found that withdrawals related to adverse effects were more frequent in women taking bromocriptine (15/135 [11%] with bromocriptine *v* 8/137 [6%] with placebo; RR 1.9, 95% CI 0.8 to 4.3). Adverse reactions included nausea (32% with bromocriptine *v* 13% with placebo), dizziness (12% with bromocriptine *v* 7% with placebo), postural hypotension, and constipation.[12] Overall, withdrawal rates were high (see comment below). The second RCT found that nausea and dizziness occurred in 8/10 (80%) women on bromocriptine compared with 0/10 (0%) on placebo.[13] Strokes and death have been reported after use of bromocriptine to inhibit lactation, and the US Food and Drug Administration has withdrawn its licence for this indication.[14]

Comment: Bromocriptine is now used rarely because frequent and intolerable adverse effects at the therapeutic dose outweigh the benefits for this indication. In the larger RCT, analysis was not by intention to treat, and overall withdrawal rates were high (withdrawals: 49/135 [36%] with bromocriptine *v* 36/137 [26%] with placebo; RR 1.4, 95% CI 1.0 to 2.0).[12]

OPTION LISURIDE

One RCT with weak methods found limited evidence that lisuride maleate (a dopamine agonist) reduced breast pain over 2 months compared with placebo.

Benefits: One double blind RCT (60 women with premenstrual breast pain) comparing lisuride maleate (200 µg/day) versus placebo over 2 months found significant improvement in visual analogue scores for pain (improved scores in 27/30 [90%] with lisuride maleate *v* 10/30 [33%] with placebo; RR 2.7, 95% CI 1.6 to 4.5; NNT 2, 95% CI 2 to 3) (see comment below).[15]

Harms: During the first month of treatment, nausea was more frequently reported by women taking lisuride maleate; however, the difference was not significant (women reporting nausea: 5/30 [17%] with lisuride maleate *v* 3/30 [10%] with placebo; RR 1.7, 95% CI 0.4 to 6.4).[15]

Comment: Allocation was carried out in blocks of 10 consecutive women. Tablet coding for active treatments and placebo differed, potentially confounding any treatment effect. Response to treatment was defined as a reduction greater than 25% from the baseline score during the first month, or greater than 50% during the second month.[15]

OPTION HORMONE REPLACEMENT THERAPY IN BREAST PAIN

We found no placebo controlled RCTs of hormone replacement therapy. One small RCT found limited evidence that women taking hormone replacement therapy had more breast pain after 1 year than women taking tibolone.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus tibolone:** One RCT (44 postmenopausal women) compared hormone replacement therapy (transdermal oestrogen patches 50 μg twice weekly for 3 weeks/month, plus progestogen 5 mg/day for 12 days/month/cycle); tibolone (2.5 mg/day); and no treatment.[16] The RCT found significantly more breast pain in women on hormone replacement therapy compared with tibolone after 1 year (increase in breast pain as assessed by questionnaire: 53% with hormone replacement therapy *v* 5% with tibolone; $P < 0.02$).[16]

Harms: The RCT did not report on adverse effects.[16] See harms of hormone replacement therapy under secondary prevention of ischaemic cardiac events, p 197.

Comment: Tibolone is a synthetic steroid reported to have oestrogenic, progestogenic, and weak androgenic properties, which can be used as a form of hormone replacement therapy.[17]

OPTION TAMOXIFEN

Three RCTs found limited evidence that tamoxifen is more effective than placebo at reducing breast pain. Two of the RCTs found more hot flushes and vaginal discharge with tamoxifen compared with placebo, although differences between groups did not reach significance. The third RCT did not report on adverse events. One RCT found similar efficacy but fewer adverse effects with a lower dose of 10 mg compared with 20 mg. One RCT found no significant difference in pain relief between tamoxifen and danazol. One meta-analysis of four large breast cancer prevention trials found that tamoxifen used long term was associated with an increased risk of venous thromboembolism.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs.[9,18,19] One double blind RCT (60 premenopausal women with cyclical breast pain) compared tamoxifen (20 mg/day) versus placebo.[19] It found that significantly more women experienced pain relief (measured by visual analogue scale over 3 months) with tamoxifen compared with placebo (22/31 [71%] with tamoxifen *v* 11/29 [38%] with placebo; RR 1.9, 95% CI 1.1 to 3.1; NNT 3, 95% CI 2 to 13). The second RCT (93 women) compared tamoxifen, danazol, and placebo.[9] It found that significantly more women with tamoxifen achieved a good outcome (> 50% reduction in mean pain score) at the end of treatment, 6 months later, and 12 months

later compared with placebo (pain relief after 6 months of treatment: 23/32 [72%] with tamoxifen *v* 11/29 [38%] with placebo; RR 1.9, 95% CI 1.1 to 3.2; NNT 3, 95% CI 1 to 10). The third RCT (88 women, aged 22–44 years) found that 8 months of tamoxifen increased the proportion of women who achieved complete recovery (outcome not clearly defined) compared with placebo (complete recovery: 40/44 [90%] with tamoxifen *v* 0/44 [0%] with placebo).[18] **Dose response:** One RCT (301 women with cyclical breast pain for > 6 months) compared 10 mg versus 20 mg daily doses of tamoxifen from days 15–25 in the menstrual cycle for 3 months. It found no significant difference in pain relief (127/155 [82%] with 10 mg *v* 107/142 [75%] with 20 mg; RR 1.09, 95% CI 0.96 to 1.18).[20] Another RCT (60 women) compared 10 mg versus 20 mg daily doses of tamoxifen for 3 and 6 months in cyclical and non-cyclical mastalgia.[21] It found that 3 month response rates were similar (pain relief: 12/14 [86%] with 10 mg *v* 14/15 [93%] with 20 mg; RR 0.9, 95% CI 0.4 to 1.1). **Versus danazl:** See benefits of danazol, p 2337.

Harms: The first two RCTs found that hot flushes and vaginal discharge were more common with 20 mg tamoxifen daily than with placebo. However, differences were not significant.[18,19] The first RCT found more hot flushes (8/31 [26%] with tamoxifen *v* 3/29 [10%] with placebo; ARI 16%; RR 2.5, 95% CI 0.7 to 8.5) and vaginal discharge (5/31 [16%] with tamoxifen *v* 2/29 [7%] with placebo; ARI 9.2%; RR 2.3, 95% CI 0.5 to 11.0).[19] The second RCT found more hot flushes and vaginal discharge with tamoxifen 20 mg daily compared with placebo (hot flushes 8/32 [25%] with tamoxifen *v* 3/29 [10%] with placebo; RR 2.4, 95% CI 0.7 to 8.3; vaginal discharge 5/32 [16%] with tamoxifen *v* 2/29 [7%] with placebo; RR 2.3, 95% CI 0.5 to 10.8).[9] See adverse effects of tamoxifen under treatment of breast cancer, p 2300. The third RCT did not report any significant adverse events.[18] One meta-analysis of the four largest breast cancer prevention trials found that tamoxifen used long term at 20 mg daily was associated with venothromboembolism.[22] **Dose response:** Adverse effects occurred more frequently with the 20 mg dose than with the 10 mg dose between days 15–25 of the menstrual cycle.[20,21] The largest RCT found that adverse effects were reported significantly more frequently with the 20 mg dose than with the 10 mg dose (adverse effects: 94/142 [66%] with 20 mg/day *v* 80/155 [52%] with 10 mg/day; RR 1.28, 95% CI 1.06 to 1.56; NNT 6, 95% CI 3 to 28).[20] Adverse effects were primarily hot flushes (AR 54/142 [38%] with 20 mg/day *v* 33/155 [21%] with the 10 mg/day; RR 1.79, 95% CI 1.24 to 2.58; NNH 6, 95% CI 3 to 16) and gastrointestinal disturbances (AR 54/142 [38%] with 20 mg/day *v* 30/155 [19%] with 10 mg/day; RR 1.97, 95% CI 1.34 to 2.88; NNH 6, 95% CI 4 to 12).

Comment: Tamoxifen is not licensed for mastalgia in the UK or the USA. There is consensus to limit its use to no more than 6 months at a time under expert supervision and with appropriate non-hormonal contraception because of the high incidence of adverse effects. Tamoxifen is contraindicated in pregnancy because of potential teratogenicity.[23]

OPTION GONADORELIN ANALOGUES (LUTEINISING HORMONE RELEASING HORMONE ANALOGUES)

We found no systematic review or RCTs on the effects of gonadorelin analogues (e.g. goserelin) in women with breast pain.

Benefits: We found no systematic review or RCTs.

Harms: Adverse effects of goserelin can include hot flushes (90%), headaches (57%), nausea and vomiting (29%), depression and irritability (24%), loss of libido (37%), and amenorrhoea (100%).[24]

Comment: None.

OPTION SYNTHETIC STEROIDS (GESTRINONE, TIBOLONE)

One RCT found that gestrinone reduced breast pain after 3 months compared with placebo, but increased adverse effects (greasy skin, hirsutism, acne, reduction in breast size, headache, and depression). We found no placebo controlled RCTs of tibolone. One small RCT found limited evidence that tibolone reduced breast pain after 1 year compared with hormone replacement therapy.

Benefits: We found no systematic review. **Versus placebo:** We found one double blind, outpatient based RCT (145 premenopausal women with cyclical breast pain) comparing gestrinone (2.4 mg twice weekly) with placebo.[25] It found that gestrinone reduced breast pain significantly more than placebo after 3 months (using visual analogue score where 0 = no pain, 100 = worst pain; pain score reduced from 59.5 to 11.0 with gestrinone *v* 58.2 to 36.7 with placebo; $P < 0.0001$). We found no placebo controlled RCTs of tibolone. **Versus hormone replacement therapy:** See hormone replacement therapy versus tibolone, p 2339.[16]

Harms: **Versus placebo:** The RCT found that adverse effects were significantly more common with gestrinone compared with placebo (at least 1 adverse effect, 41% with gestrinone *v* 14% with placebo; ARI 27%; RR 2.96, 95% CI 1.70 to 4.40). Adverse effects included greasy skin (13 with gestrinone *v* 2 with placebo); hirsutism (10 with gestrinone *v* 3 with placebo); acne (9 with gestrinone *v* 2 with placebo); intermenstrual bleeding (7 with gestrinone *v* 0 with placebo); voice change (5 with gestrinone *v* 1 with placebo); reduced libido (5 with gestrinone *v* 3 with placebo); reduction in breast size (3 with gestrinone *v* 0 with placebo); headache (4 with gestrinone *v* 0 with placebo); depression (2 with gestrinone *v* 0 with placebo); and tiredness (2 with gestrinone *v* 0 with placebo).[25] **Versus hormone replacement therapy:** The RCT comparing tibolone versus hormone replacement therapy did not report adverse effects.[16]

Comment: Gestrinone is a synthetic steroid, reported to have androgenic, antioestrogenic, and antiprogestogenic properties.[17]

OPTION PROGESTERONES

Two small crossover RCTs found no significant difference in breast pain between progesterones and placebo.

Benefits: We found two RCTs.[26,27] The first RCT (crossover, 26 women with cyclical breast pain of at least 6 months' duration) treated all included women with daily 20 mg tablets of medroxyprogesterone acetate for 6 months, followed by a 2 month observation period. Women with persistent symptoms were then randomly allocated to oral medroxyprogesterone acetate (20 mg tablets) or placebo given from day 10–26 of the menstrual cycle, for 3 months and then switched group (crossover) for the remaining 3 months.[26] The RCT found no significant differences in the visual analogue scale for pain at the end of each phase before and after the crossover (data presented graphically). The overall withdrawal rate was 15%.[26] The second RCT (crossover, 80 women with breast pain of at least 2 months' duration) identified women who were able to keep an updated diary with visual analogue scales of pain for 2 months and then randomised them to daily applications of cream with progesterone 1% versus placebo, from the 10th day of the cycle to the beginning of the next cycle, for 3 months. The pre-crossover analysis found no significant difference in pain scores between progesterone and placebo cream (numerical results not reported; see comment below).[27]

Harms: The first RCT found that five women reported adverse effects while on medroxyprogesterone acetate, five while on placebo, and one with both. Symptoms were mostly vague premenstrual symptoms.[26] No further details were provided. The second RCT did not report on harms.[27]

Comment: The second RCT provided insufficient details about the analysis. Withdrawals involved 7/32 (22%) women.[27] Both RCTs have small sample size, significant withdrawals, and a selection phase, which may restrict the generalisibility of the evidence.[26,27]

OPTION PROGESTOGENS

We found no RCTs on the effects of progestogens in women with breast pain.

Benefits: We found no systematic review or good quality RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION OTHER AGENTS

We found no RCTs of the effects of pyridoxine, diuretics, antibiotics, or vitamin E compared with placebo for the treatment of breast pain.

Benefits: We found no systematic review or good quality RCTs on the effects of other agents.

Harms: We found no RCTs.

Comment: None.

Candidiasis (vulvovaginal)

Search date March 2003

Des Spence

QUESTIONS

INTERVENTIONS

See glossary, p 2355

Key Messages

Acute vulvovaginal candidiasis

- **Intravaginal imidazoles** RCTs found that intravaginal imidazoles (butoconazole, clotrimazole, miconazole, or terconazole) reduced persistent symptoms of vulvovaginal candidiasis after 9–38 days compared with placebo, and found no clear evidence that effects differ among the various intravaginal imidazoles. RCTs found no clear evidence of any difference in persistent symptoms between shorter and longer durations of treatment (1–14 days). RCTs found no significant difference in symptoms between intravaginal imidazoles and oral

fluconazole, itraconazole, or ketoconazole. RCTs found that intravaginal imidazoles were associated with less nausea, headache, and abdominal pain but more vulvar irritation and vaginal discharge than oral fluconazole or oral ketoconazole. Two RCTs provided insufficient evidence to compare intravaginal imidazoles versus intravaginal nystatin.

- **Oral fluconazole** We found no RCTs comparing oral fluconazole versus placebo or no treatment. One systematic review found no significant difference in persistent symptoms of vulvovaginal candidiasis over 1–12 weeks between oral fluconazole or oral itraconazole and intravaginal imidazoles, and found that oral fluconazole was associated with more nausea, headache, and abdominal pain but less vulvar irritation and vaginal discharge than intravaginal imidazoles. One weak RCT provided insufficient evidence to compare oral fluconazole versus oral itraconazole. One systematic review found no significant difference in persistent symptoms of vulvovaginal candidiasis or in adverse effects between oral fluconazole and oral ketoconazole.
- **Oral itraconazole** One RCT found that oral itraconazole reduced persistent symptoms of vulvovaginal candidiasis at 1 week after treatment compared with placebo. One systematic review found no significant difference in persistent symptoms over 1–12 weeks between oral itraconazole or oral fluconazole and intravaginal imidazoles. One weak RCT provided insufficient evidence to compare oral itraconazole versus oral fluconazole.
- **Intravaginal nystatin** One RCT found that intravaginal nystatin reduced the proportion of women with a poor symptomatic response after 14 days' treatment compared with placebo. Two RCTs provided insufficient evidence to compare intravaginal nystatin versus intravaginal imidazoles. We found no RCTs comparing intravaginal nystatin versus oral fluconazole, itraconazole, or ketoconazole.
- **Oral ketoconazole** We found no RCTs comparing oral ketoconazole versus placebo or no treatment. RCTs found no significant difference between oral ketoconazole and intravaginal imidazoles in persistent symptoms of vulvovaginal candidiasis and found that oral ketoconazole may cause more nausea, fatigue, and headaches but less vulvar irritation. One systematic review found no significant difference in persistent symptoms or adverse effects between oral ketoconazole and oral fluconazole. Case reports have associated ketoconazole with a low risk of fulminant hepatitis (1/12 000 courses of treatment with oral ketoconazole).

Recurrent vulvovaginal candidiasis

- **Regular prophylaxis with oral itraconazole** One RCT found that regular prophylaxis with oral itraconazole reduced the rate of symptomatic recurrence of vulvovaginal candidiasis over 6 months compared with placebo.
- **Intermittent or continuous prophylaxis with oral ketoconazole** One RCT found that oral ketoconazole, reduced symptomatic recurrence of vulvovaginal candidiasis over 6 months compared with placebo. This benefit is associated with an increased risk of harms, including rare cases of fulminant hepatitis (1/12 000 courses of treatment with oral ketoconazole).
- **Regular prophylaxis with intravaginal imidazoles** Two RCTs provided insufficient evidence about the effects of regular prophylaxis with intravaginal clotrimazole versus placebo in preventing recurrence of vulvovaginal candidiasis. One RCT found no significant difference in the number of episodes of

symptomatic vaginitis over 6 months between regular prophylaxis with intravaginal clotrimazole and treatment as required, although women who took regular prophylaxis had fewer episodes. The RCT was too small to exclude a clinically important difference. More women preferred treatment as required. One RCT found insufficient evidence about the effects of regular prophylaxis with intravaginal clotrimazole versus oral itraconazole.

- **Regular prophylaxis with oral fluconazole** We found no RCTs about the effects of regular prophylaxis with oral fluconazole in preventing symptomatic recurrence of vulvovaginal candidiasis.
- **Treating a male sexual partner** Two RCTs found no significant difference between treating and not treating a woman's male sexual partner in the resolution of the woman's symptoms of vulvovaginal candidiasis over 1–4 weeks or in the rate of symptomatic recurrence. The women in the RCTs were not selected because of a history of recurrent vulvovaginal candidiasis.

DEFINITION **Vulvovaginal candidiasis** is symptomatic vaginitis (inflammation of the vagina), which often involves the vulva, caused by infection with a *Candida* yeast. Predominant symptoms are vulvar itching and abnormal vaginal discharge (which may be minimal, a "cheese like" material, or a watery secretion). Differentiation from other forms of vaginitis requires the presence of yeast on microscopy of vaginal fluid. **Recurrent vulvovaginal candidiasis** is commonly defined as four or more symptomatic episodes a year.[1]

INCIDENCE/ PREVALENCE Vulvovaginal candidiasis is the second most common cause of vaginitis (after bacterial vaginosis). Estimates of its incidence are limited and often derived from women who attend hospital clinics. At least one episode of vulvovaginal candidiasis occurs during the lifetime of 50–75% of all women. Vulvovaginal candidiasis is diagnosed in 5–15% of women who attend sexually transmitted disease and family planning clinics.[1] About half of the women who have an episode develop recurrent vulvovaginal candidiasis.[2]

AETIOLOGY/ RISK FACTORS *Candida albicans* accounts for 85–90% of cases of vulvovaginal candidiasis. Development of symptomatic vulvovaginal candidiasis probably represents increased growth of yeast that previously colonised the vagina without causing symptoms. Risk factors for vulvovaginal candidiasis include pregnancy (RR 2–10), diabetes mellitus, and systemic antibiotics. The evidence that different types of contraceptives are risk factors is contradictory. The incidence of vulvovaginal candidiasis rises with initiation of sexual activity, but we found no direct evidence that vulvovaginal candidiasis is sexually transmitted.[3–5]

PROGNOSIS We found few descriptions of the natural history of untreated vulvovaginal candidiasis. Discomfort is the main complication and can include pain while passing urine or during sexual intercourse. Balanitis (see glossary, p 2355) in male partners of women with vulvovaginal candidiasis can occur, but it is rare.

AIMS OF INTERVENTION To alleviate symptoms with minimal adverse effects from treatment.

OUTCOMES **Acute vulvovaginal candidiasis:** clinical cure rates, either measured in the short term (5–15 days) or medium term (3–6 weeks) after treatment. The definition of clinical cure varies among RCTs but often includes both complete resolution of symptoms and negative culture of *Candida*. **Recurrent vulvovaginal candidiasis:** symptomatic recurrence.

METHODS *Clinical Evidence* search and appraisal March 2003, and personal contact with the medical information department of Bristol Myers Squibb to retrieve an RCT on nystatin.[6] We included only those RCTs in which most participants were from the target population (for example, to answer the questions for non-pregnant women, we sought RCTs that excluded pregnant women or RCTs in which pregnant women represented < 20% of the participants). We excluded studies of women with HIV infection. Many RCTs excluded women with diabetes mellitus. We included RCTs only if recruitment was restricted to women with both symptoms of vaginal candidiasis and laboratory confirmation of candidal infection. Studies of asymptomatic women with vaginal colonisation by *Candida* species were excluded.

QUESTION What are the effects of treatments for acute vulvovaginal candidiasis in non-pregnant women?

OPTION INTRAVAGINAL IMIDAZOLES

RCTs found that intravaginal imidazoles (butoconazole, clotrimazole, miconazole, or terconazole) reduced persistent symptoms of vulvovaginal candidiasis after 9–38 days compared with placebo and found no clear evidence that effects differ among the various intravaginal imidazoles. RCTs found no clear evidence of any difference in persistent symptoms between shorter and longer durations of treatment (1–14 days). RCTs found no significant difference in symptoms between intravaginal imidazoles and oral fluconazole, itraconazole, or ketoconazole. RCTs found that intravaginal imidazoles were associated with less nausea, headache, and abdominal pain but more vulvar irritation and vaginal discharge than oral fluconazole or oral ketoconazole. Two RCTs provided insufficient evidence to compare intravaginal imidazoles versus intravaginal nystatin.

Benefits: **Versus placebo:** We found one systematic review (search date 1993,[7] 3 RCTs[8–10]) and three additional RCTs (see table A on web extra).[11–13] The systematic review did not perform a meta-analysis.[7] Five RCTs found that, compared with placebo, intravaginal imidazoles (butoconazole, clotrimazole, miconazole, or terconazole) significantly reduced persistent symptoms of vaginal candidiasis at 9–38 days after treatment.[8–10,12,13] However, only two of these RCTs[12,13] provided intention to treat results. The sixth RCT (95 women) found no significant difference in symptoms after 5 weeks between clotrimazole and placebo, but results were not intention to treat findings and the follow up rate was very low (62/95 [65%]).[11] **Versus each other:** We found one systematic review (search date 1993,[7] 12 RCTs[8,9,14–23]) and 22 additional RCTs (see table B on web extra).[24–45] Many of the RCTs were too small to exclude

clinically important differences in outcomes. The populations selected by each RCT varied considerably in the prevalence of prognostic risk factors (such as diabetes mellitus or a history of recurrent attacks in the previous year), and a variety of outcomes were assessed. The RCTs provided no clear evidence of any consistent difference in effectiveness among the different imidazoles. **Duration of treatment:** We found one systematic review (search date 1993, 13 RCTs)[7] and nine additional RCTs comparing regimens that used the same intravaginal imidazole for different durations.[9,14,16,20,46–61] The RCTs found no consistent difference in the proportion of women with persistent symptoms, but they were too small to exclude a clinically important difference. **Versus oral fluconazole or oral itraconazole:** See benefits of oral fluconazole, p 2349. **Versus oral ketoconazole:** See benefits of oral ketoconazole, p 2351. **Versus intravaginal nystatin:** We found two RCTs.[24,62] The first RCT (70 women) found no significant difference between clotrimazole (100 mg for 14 days) and high strength nystatin vaginal cream (1 million IU, once daily for 7 days) in the proportion of women with persistent symptoms after 4 weeks (2/33 [6%] with nystatin *v* 1/37 [3%] with clotrimazole; OR 2.24, 95% CI 0.23 to 22.40).[24] The second RCT (292 women) compared six interventions: intravaginal clotrimazole, intravaginal econazole, intravaginal miconazole, oral miconazole plus intravaginal nystatin, oral nystatin plus intravaginal nystatin, and intravaginal nystatin alone.[62] It found no significant difference among interventions in symptomatic relapse over 6 months (18/53 [34%] with intravaginal clotrimazole *v* 16/34 [47%] with intravaginal econazole *v* 18/80 [22%] with intravaginal miconazole *v* 6/31 [19%] with oral miconazole plus intravaginal nystatin *v* 14/49 [28%] with oral nystatin plus intravaginal nystatin *v* 26/45 [58%] with intravaginal nystatin alone; reported as non-significant; CI not reported). The RCT is likely to have been underpowered to detect a clinically important difference among treatments.[62]

Harms: **Versus placebo:** In the RCTs of intravaginal imidazoles versus placebo, most women did not report any adverse effects.[8–13] The most common adverse effect was vulvar irritation. Most RCTs did not report frequencies of specific adverse effects in women who took placebo. In one RCT, adverse effects were more common in women who took oral placebo than in women who used intravaginal imidazole (nine adverse events, mainly nausea and headache, in 22 women who received oral placebo *v* one episode of irritation in 23 women who used intravaginal imidazole).[10] **Versus oral fluconazole or oral itraconazole:** See harms of oral fluconazole, p 2349. **Versus intravaginal nystatin:** The first RCT found no adverse effects in women who took intravaginal clotrimazole or intravaginal nystatin.[24] The second RCT gave no information on adverse effects.[62]

Comment: Most RCTs were small and many had weak methods (poorly described randomisation, inadequate concealment and blinding, and definitions of cure based on mycology results rather than symptoms). We excluded all RCTs that defined cure only on the basis of mycology results. Trials in women who obtain intravaginal imidazoles over the counter are needed.

OPTION ORAL FLUCONAZOLE

We found no RCTs comparing oral fluconazole versus placebo or no treatment. One systematic review found no significant difference in persistent symptoms of vulvovaginal candidiasis over 1–12 weeks between oral fluconazole or oral itraconazole and intravaginal imidazoles and found that oral fluconazole was associated with more nausea, headache, and abdominal pain but less vulvar irritation and vaginal discharge than intravaginal imidazoles. One weak RCT provided insufficient evidence to compare oral fluconazole versus oral itraconazole. One systematic review found no significant difference in persistent symptoms of vulvovaginal candidiasis or in adverse effects between oral fluconazole and oral ketoconazole.

Benefits: **Versus placebo:** We found no systematic review or RCTs. **Versus intravaginal imidazoles:** We found one systematic review (search date 2000, 7 RCTs, 1247 women) that found no significant difference between oral fluconazole or oral itraconazole and intravaginal imidazoles (clotrimazole, miconazole, econazole) in persistent symptoms at 5–15 days (124/627 [20%] with oral fluconazole or itraconazole *v* 121/620 [20%] with intravaginal imidazoles; RR 1.00, 95% CI 0.95 to 1.06) or at 2–12 weeks (74/432 [17%] with oral fluconazole or itraconazole *v* 71/404 [18%] with intravaginal imidazoles; RR 1.04, 95% CI 0.95 to 1.07).[63] **Versus oral itraconazole:** We found no systematic review but found one RCT (86 women) that found no significant difference between oral fluconazole 150 mg in a single dose and oral itraconazole 200 mg daily for 3 days in the proportion of women cured at 7 days (13/38 [34%] with fluconazole *v* 16/32 [50%] with itraconazole; P = 0.18) or at 21 days (18/38 [47%] *v* 17/32 [53%]; P = 0.63; see comment below).[64] **Versus oral ketoconazole:** See benefits of oral ketoconazole, p 2351. **Versus intravaginal nystatin:** We found no RCTs.

Harms: **Versus intravaginal imidazoles:** Two large RCTs identified by the review[63] found that oral fluconazole may be associated with increased nausea, headache, and abdominal pain compared with intravaginal imidazoles.[65,66] The first RCT (429 women) found that single dose 150 mg oral fluconazole significantly increased adverse effects over 14 days compared with intravaginal clotrimazole 100 mg daily for 7 days (59/217 [27%] with oral fluconazole *v* 37/212 [17%] with intravaginal clotrimazole; OR 1.75, 95% CI 1.11 to 2.75; NNH 11, 95% CI 6 to 54).[65] The individual events that were more common with oral fluconazole were headache (12% *v* 9%), abdominal pain (7% *v* 3%), and nausea (4% *v* 0%). The second RCT (235 women) found that oral fluconazole significantly increased nausea and other gastrointestinal symptoms compared with intravaginal econazole (9/121 [7%] *v* 2/114 [2%]; OR 3.55, 95% CI 1.06 to 11.90), but intravaginal econazole significantly increased local vulvar burning and vaginal discharge (3/121 [2%] with oral fluconazole *v* 25/114 [22%] with intravaginal econazole; OR 0.16, 95% CI 0.07 to 0.35).[66] A third RCT (369 women) identified by the review found very few adverse effects with either oral fluconazole or clotrimazole (8/188 [4%] *v* 9/181 [5%]).[67] A fourth RCT (double blind, 81 women) identified by the review found

no significant difference between oral itraconazole and intravaginal econazole in the proportion of women who had adverse effects (4/40 [10%] with itraconazole *v* 8/41 [20%] with econazole; OR 0.48, 95% CI 0.14 to 1.61).[68] **Versus oral itraconazole:** The RCT found that oral fluconazole and oral itraconazole were associated with similar rates of adverse effects, including gastrointestinal disturbances, pelvic pain, insomnia, anxiety, and rash.[64] **Versus oral ketoconazole:** See harms of oral ketoconazole, p 2351.

Comment: **Versus oral itraconazole:** In the first RCT, women who received oral fluconazole had significantly higher baseline symptom scores than women who received oral itraconazole (9.03 *v* 7.03; P = 0.003); this makes the results difficult to interpret.[64]

OPTION ORAL ITRACONAZOLE

One RCT found that oral itraconazole reduced persistent symptoms at 1 week after treatment compared with placebo. One systematic review found no significant difference in persistent symptoms over 1–12 weeks between oral itraconazole or oral fluconazole and intravaginal imidazoles. One weak RCT provided insufficient evidence to compare oral itraconazole versus oral fluconazole.

Benefits: **Versus placebo:** We found one systematic review (search date 2000),[63] which identified one RCT (90 women) that compared three interventions: oral itraconazole, oral clotrimazole, and placebo.[10] The RCT found that oral itraconazole (200 mg daily for 3 days) significantly reduced the proportion of women with persistent symptoms at 1 week after treatment compared with placebo (13/48 [27%] with itraconazole *v* 12/22 [55%] with placebo; P < 0.05).[10] **Versus intravaginal imidazoles:** See benefits of oral fluconazole, p 2349. **Versus oral fluconazole:** See benefits of oral fluconazole, p 2349. **Versus oral ketoconazole:** We found no RCTs. **Versus intravaginal nystatin:** We found no RCTs.

Harms: **Versus placebo:** The RCT identified by the review[63] found that itraconazole significantly increased the proportion of women who had adverse effects compared with intravaginal clotrimazole (17/50 [34%] with itraconazole *v* 1/23 [4%] with clotrimazole; OR 4.83, 95% CI 1.55 to 15.1); the adverse effects with increased frequency were nausea (14%), headache (12%), dizziness (6%), and bloating (6%).[10] **Versus intravaginal imidazoles:** See harms of oral fluconazole, p 2349.

Comment: None.

OPTION ORAL KETOCONAZOLE

We found no RCTs comparing oral ketoconazole versus placebo or no treatment. RCTs found no significant difference between oral ketoconazole and intravaginal imidazoles in persistent symptoms and found that oral ketoconazole may cause more nausea, fatigue, and headaches but less vulvar irritation. One systematic review found no significant difference in persistent symptoms or adverse effects between oral ketoconazole and oral fluconazole. Case reports have associated ketoconazole with a low risk of fulminant hepatitis (1/12 000 courses of treatment with oral ketoconazole).

Benefits: **Versus oral placebo:** We found no systematic review or RCTs. **Versus intravaginal imidazoles:** We found one systematic review (search date 1993,[7] 4 RCTs,[69–72] 280 women) and three additional RCTs[73–75] (see table C on web extra). The systematic review concluded that oral treatment is as effective as topical treatment at eliminating *Candida* but did not compare clinical outcomes.[7] Six RCTs found no significant difference in persistent symptoms at 1–4 weeks between oral ketoconazole and intravaginal clotrimazole, miconazole, or tioconazole,[69–74] and one RCT found that significantly more women had persistent symptoms at 4 weeks with oral ketoconazole than with intravaginal isoconazole.[75] **Versus oral itraconazole:** We found no RCTs. **Versus oral fluconazole:** We found one systematic review (search date 1993,[7] 1 RCT,[76] 183 women). The RCT found no significant difference between ketoconazole (400 mg daily for 5 days) and oral fluconazole (1 dose of 150 mg) in the proportion of women with persistent symptoms after 5–16 days (17/72 [24%] with ketoconazole *v* 17/80 [21%] with fluconazole; OR 1.15, 95% CI 0.53 to 2.45) or after 27–62 days (14/72 [19%] with ketoconazole *v* 14/76 [18%] with fluconazole; OR 1.07, 95% CI 0.47 to 2.43).[76] **Versus intravaginal nystatin:** We found no RCTs.

Harms: Observational studies have found that asymptomatic elevation of liver enzymes is common in people who take oral ketoconazole, and fulminant hepatitis was observed in about 1/12 000 courses of treatment.[77] **Versus intravaginal imidazoles:** Most of the RCTs gave little information on adverse effects.[69–73,75] In these RCTs, thirteen women who took oral ketoconazole had nausea, fatigue, headaches, or abdominal pain, and two women who used intravaginal clotrimazole had vulvar irritation or vaginal bleeding. One RCT (151 women) found that oral ketoconazole increased rates of headache (23% *v* 4%), nausea (22% *v* 1%), abdominal discomfort (14% *v* 7%), and fatigue (7% *v* 2%; CIs not reported) compared with intravaginal clotrimazole.[74] **Versus oral fluconazole:** The RCT (183 women) found that nausea was reported by similar proportions of women who took oral fluconazole as those who took oral ketoconazole (9/92 [10%] with fluconazole *v* 13/91 [14%] with ketoconazole; CI not reported).[76]

Comment: The possibility of rare but serious hepatitis has led to a consensus that the risks associated with oral ketoconazole may outweigh its benefits in women with vulvovaginal candidiasis.

OPTION INTRAVAGINAL NYSTATIN

One RCT found that intravaginal nystatin reduced the proportion of women with a poor symptomatic response after 14 days' treatment compared with placebo. Two RCTs provided insufficient evidence to compare intravaginal nystatin versus intravaginal imidazoles. We found no RCTs that compared intravaginal nystatin versus oral fluconazole, itraconazole, or ketoconazole.

Benefits: **Versus placebo:** We found no systematic review but found one RCT that compared intravaginal nystatin versus placebo.[6] The RCT (double blind, 50 women) found that, compared with placebo,

intravaginal nystatin (500 000 IU twice daily for 14 days) significantly reduced the proportion of women with a symptomatic response categorised as "poor" (2/25 [8%] with nystatin *v* 10/25 [40%] with placebo; ARR 32%, 95% CI 8% to 56%; OR 0.18, 95% CI 0.05 to 0.65; NNT 3, 95% CI 2 to 12). **Versus intravaginal imidazoles:** See benefits of intravaginal imidazoles, p 2347. **Versus oral fluconazole, itraconazole, or ketoconazole:** We found no RCTs.

Harms: **Versus placebo:** The RCT found no reports of adverse effects among 52 women who used intravaginal nystatin.[6]

Comment: None.

QUESTION What are the effects of treatments for recurrent vulvovaginal candidiasis in non-pregnant women?

OPTION REGULAR PROPHYLAXIS WITH INTRAVAGINAL IMIDAZOLES

Two RCTs provided insufficient evidence about the effects of regular prophylaxis with intravaginal clotrimazole compared with placebo in preventing recurrence of vulvovaginal candidiasis. One RCT found no significant difference in the number of episodes of symptomatic vaginitis over 6 months between regular prophylaxis with intravaginal clotrimazole and treatment as required, although women who took regular prophylaxis had fewer episodes. The RCT was too small to exclude a clinically important difference. More women preferred treatment as required. One RCT found insufficient evidence about the effects of regular prophylaxis with intravaginal clotrimazole versus oral itraconazole.

Benefits: **Versus placebo:** We found one systematic review (search date 1993,[7] 2 RCTs,[78,79] 89 women with recurrent vulvovaginal candidiasis) that compared intravaginal clotrimazole 500 mg monthly versus intravaginal placebo monthly for 6 months. Both RCTs found that intravaginal clotrimazole reduced the proportion of women with symptomatic recurrence over 6 months compared with placebo, although in one RCT the difference was significant and in the other RCT it was not.[78,79] **Versus as required treatment:** We found one crossover RCT (unblinded, 23 women with recurrent vaginal candidiasis) that compared regular prophylactic intravaginal clotrimazole 500 mg each month versus intravaginal clotrimazole 500 mg at the onset of symptoms for 12 months.[80] It found that women who took regular clotrimazole had fewer symptomatic episodes of vaginitis over 6 months than women who took clotrimazole as required, but the difference was not significant (2.2 episodes per woman with regular treatment *v* 3.7 with as needed treatment; P = 0.05). It found that significantly more women preferred treatment as required compared with prophylactic treatment (17/23 [74%] *v* 4/23 [17%]; P = 0.001). The RCT is likely to have been too small to exclude a clinically important difference. **Versus oral itraconazole:** See benefits of oral itraconazole, p 2353.

Harms: See harms of intravaginal imidazoles, p 2348.

Comment: None.

OPTION REGULAR PROPHYLAXIS WITH ORAL FLUCONAZOLE

We found no RCTs about the effects of regular prophylaxis with oral fluconazole in prevention of recurrent vulvovaginal candidiasis.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION REGULAR PROPHYLAXIS WITH ORAL ITRACONAZOLE

One RCT found that regular prophylaxis with oral itraconazole reduced the rate of symptomatic recurrence of vulvovaginal candidiasis over 6 months compared with placebo. One RCT found insufficient evidence about the effects of regular prophylaxis with oral itraconazole versus intravaginal clotrimazole.

Benefits: We found no systematic review. **Versus placebo:** One RCT (single blind, 114 women with recurrent vulvovaginal candidiasis) found that regular prophylaxis with oral itraconazole (400 mg monthly) significantly reduced recurrence of symptoms of vulvovaginal candidiasis compared with placebo (recurrence during 6 months' follow up: 20/55 [36%] with itraconazole *v* 34/53 [64%] with placebo; ARR 28%, 95% CI 9% to 47%; OR 0.33, 95% CI 0.16 to 0.71; NNT 4, 95% CI 3 to 11).[83] After discontinuation of oral itraconazole, recurrence rates were similar.[83] **Versus intravaginal imidazoles:** We found one RCT (unblinded, 44 women) that compared oral itraconazole (200 mg twice weekly) versus intravaginal clotrimazole (200 mg twice weekly) for 6 months.[84] One woman withdrew from itraconazole treatment and five withdrew from clotrimazole treatment. The RCT found that oral itraconazole versus intravaginal clotrimazole increased the proportion of women with symptomatic recurrences over 6 months (7/21 [33%] with itraconazole *v* 0/17 [0%] with clotrimazole; see comment below). **Versus as required treatment:** We found no RCTs.

Harms: The first RCT gave no information on adverse effects (see oral itraconazole, p 2350).[83]

Comment: **Versus intravaginal imidazoles:** The results of the RCT are difficult to interpret because it was unblinded, and the unbalanced withdrawal from the RCT could explain the observed difference between groups.[84]

OPTION ORAL KETOCONAZOLE

One RCT found that oral ketoconazole, reduced symptomatic recurrence of vulvovaginal candidiasis over 6 months compared with placebo. This benefit is associated with an increased risk of harms, including rare cases of fulminant hepatitis (1/12 000 courses of treatment with oral ketoconazole).

Benefits: **Versus placebo:** We found one systematic review (search date 1993,[7] 1 RCT,[85] 63 women). The RCT (74 women) compared three interventions: intermittent oral ketoconazole (400 mg daily for 5

days of each menstrual cycle), continuous low dose ketoconazole (100 mg daily for 6 months), and placebo over 6 months.[85] It found that intermittent oral ketoconazole significantly reduced symptomatic recurrence over 6 months compared with placebo (6/21 [29%] with intermittent ketoconazole *v* 15/21 [71%] with placebo; OR 0.19, 95% CI 0.06 to 0.62). It also found that continuous low dose oral ketoconazole reduced symptomatic recurrence over 6 months compared with placebo (1/21 [5%] with continuous ketoconazole v 15/21 [71%] with placebo; OR 0.06, 95% CI 0.02 to 0.22). **Versus intravaginal imidazoles:** We found no RCTs. **Regular prophylaxis versus as required treatment:** We found no RCTs.

Harms: Ketoconazole is associated with an increased frequency of gastrointestinal adverse effects and case reports of rare fulminant hepatitis (see ketoconazole, p 2350).

Comment: The possibility of rare but serious hepatitis has led to a consensus that the risks associated with oral ketoconazole may outweigh its benefits in women with vulvovaginal candidiasis.

OPTION EFFECTS OF TREATING A MALE SEXUAL PARTNER IN WOMEN WITH RECURRENT VULVOVAGINITIS

Two RCTs found no significant difference between treating and not treating a woman's male sexual partner in the resolution of the woman's symptoms of vulvovaginal candidiasis over 1–4 weeks or in the rate of symptomatic recurrence. The women in the RCTs were not selected because of a history of recurrent vulvovaginal candidiasis.

Benefits: We found no systematic review but found two RCTs.[81,82] In the first RCT (40 women with acute vulvovaginal candidiasis and their male partners), all the women received oral itraconazole 100 mg daily for 5 days.[81] Their male partners were randomised to receive oral itraconazole 100 mg daily for 5 days or placebo. The RCT found no significant difference between treating the male partner with oral itraconazole and placebo in the proportion of women with persistent symptoms after 30 days (2/19 [11%] with partners who received itraconazole *v* 4/18 [22%] with partners who received placebo; OR 0.43, 95% CI 0.08 to 2.43). The second RCT (117 women with acute or recurrent vaginal candidiasis and their male partners) treated all of the women with oral ketoconazole 200–600 mg daily for 3 days. Their male partners were randomised to oral ketoconazole 400 mg daily versus placebo for 3 days. The RCT found no significant difference in the proportion of women cured 1 week after treatment (48/57 [84%] with partners receiving ketoconazole *v* 53/60 [88%] with partners receiving placebo; OR 0.71, 95% CI 0.25 to 2.02) or the proportion of initially cured women who relapsed by 4 weeks after treatment (13/48 [27%] with ketoconazole *v* 19/53 [36%] with placebo; OR 0.67, 95% CI 0.29 to 1.54; see comment below).

Harms: The RCTs gave no information on harms.[81,82]

Comment: The women in the RCTs were not selected because of a history of recurrent vulvovaginal candidiasis.[81,82] The definition of "cured" and "relapsed" in the second RCT is not clear, but it seems to be a combination of improved symptoms and negative cultures.[82] Only a small number of men in the RCT had any penile symptoms, and these were distributed equally between the ketoconazole and placebo groups.

GLOSSARY

Balanitis is inflammation of the glans of the penis. The foreskin is often involved (balanoposthitis).

Interventions focusing on men and on children witnessing intimate partner violence

See glossary, p 2367

Key Messages

- **Advocacy** One RCT and one non-randomised controlled trial found that advocacy reduced reabuse compared with no treatment. The RCT also found an improvement in women's quality of life with advocacy compared with no treatment. One controlled trial in pregnant Hispanic women found no significant difference in rates of reabuse between combined counselling plus mentoring (similar to advocacy) and a resource card, but found that counselling plus mentoring slightly reduced rates of reabuse compared with unlimited counselling.
- **Safety planning** One RCT found that providing telephone sessions on safe behaviour in addition to usual care increased safe behaviour at 6 months compared with usual care alone. We found limited evidence from one non-randomised controlled trial in pregnant women that helping participants to make a safety plan reduced spouse abuse and increased safe behaviour at 12 months.
- **Cognitive behaviour orientated counselling** One controlled trial found that cognitive behaviour orientated therapy improved women's assertiveness and reduced their exposure to abuse compared with baseline levels, whereas non-specific support did not. However, the study did not directly compare effects of interventions.
- **Couple counselling** Controlled trials found that both gender specific counselling and couple counselling reduced physical aggression, psychological aggression and depression in wives from baseline levels, but they found no significant differences between treatments. One controlled trial found no significant difference between group and individual couple counselling on reduction in physical violence or on psychological wellbeing.

- **Grief resolution orientated counselling** One controlled trial found that grief resolution orientated counselling improved self esteem and self efficacy from baseline, whereas feminist orientated counselling did not. However, the study did not directly compare effects of interventions.
- **Peer support groups** We found no systematic reviews or controlled trials on the effect of peer support groups.
- **Shelters** We found no reliable controlled trials. One cohort study found a reduced incidence of violence in the weeks following shelter stay for women choosing to use the shelter when they were also engaged in other types of help seeking behaviour compared with women not choosing to stay at the shelter. Women choosing to stay at the shelter who had not sought help elsewhere experienced an increase in violence.
- **Non-specific counselling** Two controlled trials and one comparative cohort study found no effect of counselling compared with no treatment on medical care utilisation rates, reported exposure to violence and threats of violence, or depression, anxiety, and self esteem.

DEFINITION

Domestic violence, also called intimate partner violence, is actual or threatened physical or sexual violence, or emotional or psychological abuse (including coercive tactics) by a current or former spouse or dating partner (including same sex partners).[1] Other terms commonly used to describe domestic violence include domestic abuse, spouse abuse, marital violence, and battering.

INCIDENCE/PREVALENCE

Between 10–69% of women participating in population based surveys in 48 countries from around the world reported being physically assaulted by a partner during their lifetime.[2] Rates of assault by a partner are 4.3 times higher among women than men.[3] Nearly 25% of surveyed women in the USA reported being physically and/or sexually assaulted by a current or former partner at some time during their lives, and 1.5% were victimised during the previous 12 months.[3] Rates of violence against pregnant women range from 0.9–20%.[4] Between 11.7–24.5% of women in prenatal clinics[5–8] and 5.5–17% of women in primary or ambulatory care reported being abused by a partner in the past year.[9–12]

AETIOLOGY/RISK FACTORS

A recent systematic review found that physical domestic violence toward women is associated with lower levels of education and unemployment, low family income, marital discord, and with the partner's lower level of occupation, childhood experiences of abuse, witnessing interparental violence, higher levels of anger, depression, heavy or problem drinking, drug use, jealousy, and lack of assertiveness with spouse.[13] A similar review of research on psychological aggression found that the few demographic and psychological variables assessed were either inconsistently associated with psychological domestic violence or were found to be associated with psychological domestic violence in studies with serious methodological limitations.[14]

PROGNOSIS

There are few prospective studies documenting the course of domestic violence and its outcomes. Cross sectional surveys suggest that domestic violence persists for at least two thirds of women.[15,16] Among black and Hispanic people, persistence of domestic violence seems to be dependent on initial severity.[17] For

all ethnic groups, half of those reporting moderate domestic violence did not report occurrences of domestic violence at the 5 year follow up, but for people of black or Hispanic origin reporting severe domestic violence only a third did not report occurrences of domestic violence at the 5 year follow up. A case control study conducted in middle class working women found that, compared with non-abused women, women abused by their partners during the previous 9 years were significantly more likely to have or report headaches (48% *v* 35%), back pain (40% *v* 25%), sexually transmitted diseases (6% *v* 2%), vaginal bleeding (17% *v* 6%), vaginal infections (30% *v* 21%), pelvic pain (17% *v* 9%), painful intercourse (13% *v* 7%), urinary tract infections (22% *v* 12%), appetite loss (9% *v* 3%), digestive problems (35% *v* 19%), abdominal pain (22% *v* 11%), and facial injuries (8% *v* 1%).[18] After adjusting for age, race, insurance status, and cigarette smoking, a cross sectional survey found that women experiencing psychological abuse are also more likely to report poor physical and mental health, disability preventing work, arthritis, chronic pain, migraine and other frequent headaches, sexually transmitted infections, chronic pelvic pain, stomach ulcers, spastic colon, frequent indigestion, diarrhoea, or constipation (see table 1, p 2369).[19]

AIMS OF INTERVENTION To improve quality of life and psychological and physical wellbeing; to reduce risk of physical and mental illness, injury, or death.

OUTCOMES Self reported rates of domestic violence, mortality, non-fatal injuries, gynaecological and reproductive/obstetrical complications (e.g. chronic pelvic pain, miscarriage, recurrent vaginal infections), chronic disorders that may have a psychosomatic component (e.g. chronic pain, sleep or eating disorders, or hypertension), and psychological conditions (e.g. depression, suicide, substance abuse, anxiety, low self esteem, low self efficacy, or poor assertiveness) associated with intimate partner violence, as well as quality of life, physical and functional status, and adverse effects of treatment. Utilisation of domestic violence services was also considered as an intermediate outcome. Scales frequently used were the Severity of Violence Against Women Scale, Spielberger's 20 item State-Trait Anxiety Inventory, Hudson's Index of Self-esteem, Self-efficacy Scale, Modified Conflict Tactics Scale, Beck Depression Inventory, and Index of Spouse Abuse Scale (see glossary, p 2367).

METHODS *Clinical Evidence* search and appraisal July 2003. *Clinical Evidence* searched Medline from 1966, Embase from 1980, PsycINFO from 1985, ASSIA from 1987, Cinahl from 1982, MIDIRS from 1990; Cochrane Library 2002 issue 4 and TRIP database; and identified systematic reviews, RCTs, other controlled trials, and observational studies using the following search terms: intimate partner violence, domestic violence, battered women, woman abuse, woman battering, family violence, husband to wife violence, marital violence, battered wives, conjugal violence, spouse abuse, violence against women, and abused women; and prevention, treatment, or intervention. We excluded public education, system level interventions, civil protection orders, screening for domestic violence or protocols focusing on identification of domestic violence victims, as well as interventions targeting only men (e.g. batterer treatment). Couple interventions were included only if women participated regularly in

the intervention and reoccurrence of violence or other outcomes among women were measured. Given the paucity of studies, none were excluded because of methodological limitations; however, when high non-participation, attrition, or high rates of loss to follow up were found, these are mentioned in the comment sections.

QUESTION **What are the effects of interventions initiated by health care professionals, aimed at female victims of domestic violence?**

OPTION **INDIVIDUAL, COUPLE, OR GROUP COUNSELLING**

Two controlled trials and one cohort study found no effect of counselling compared with no treatment on medical care utilisation rates, reported exposure to violence and threats of violence, or depression, state anxiety, and self esteem. One controlled trial found that grief resolution orientated counselling improved self esteem and self efficacy from baseline, whereas feminist orientated counselling did not. Similarly, one controlled trial found that cognitive behaviour orientated therapy improved women's assertiveness and reduced exposure to abuse from baseline, whereas non-specific support did not. One RCT and one controlled trial reported that gender specific or couple therapy reduced subsequent exposure to violence among couples from baseline, but found no significant differences between these two types of counselling.

Benefits:

Versus no treatment: We found three systematic reviews (search dates 1997[20] and 2001[21,22]), which between them identified one cohort study[23] and one controlled trial.[24] We found one additional controlled trial.[25] The cohort study (117 women), conducted in Sweden, evaluated an intervention comprising emergency room counselling (see glossary, p 2367) by a social worker and psychiatrist, overnight hospital stay even if not warranted by injuries, counselling after release, and referrals to social and legal services offered to women self identified as battered.[23] Women receiving counselling had similar rates of utilisation of somatic and psychiatric care during the 5 year period after treatment compared with those who declined treatment or withdrew. No numbers or description of types of services were reported. The controlled trial identified by the systematic reviews (290 pregnant Hispanic women) compared three interventions: unlimited counselling, unlimited counselling plus a mentor, or a wallet sized resource card.[24] Clinics were assigned randomly (see comment). Women in all three groups reported a decrease in levels of violence and threats of violence at follow up 2 months postpartum, which was sustained through follow up at 6, 12, and 18 months. The trial found no significant difference in severity of violence between either type of counselling group and resource card intervention (mean on the Severity of Violence Against Women Scale [see glossary, p 2368]: 34.7 for counselling plus mentor *v* 39.5 for unlimited counselling only *v* 38.2 for resource card; see note below for explanation of this score). Physical violence and threats of violence scores remained consistently lower at each follow up for the counselling plus mentor group (but not reaching statistical significance), whereas scores for women in the counselling only group were consistently higher than

those in the resource card group. The additional controlled trial (33 women in two shelters in South Korea) compared a problem solving/empowerment group intervention versus no intervention.[25] Anxiety proneness scores (measured using Spielberger's 20 item State Trait Anxiety Inventory [see glossary, p 2368]) decreased significantly in the intervention group compared with the control group (size of change from pre-test to post-test: –11.81 *v* –0.35; $P < 0.01$), but there were no significant differences between groups in current levels of anxiety (–9.88 *v* –9.35; $P = 0.91$), self esteem (measured using Rosenberg's Self-esteem Scale [see glossary, p 2367]: 1.56 *v* 1.29; $P = 0.84$), or depression (measured using the CES-D [see glossary, p 2367]: –13.31 *v* –5.76; $P = 0.13$). **Grief resolution orientated counselling versus feminist orientated counselling:** We found one systematic review[22] (search date 2001, 1 quasi-randomised trial, 20 women). In the trial included in the review,[26] women requesting counselling at a battered women's programme were alternately allocated to grief resolution or feminist orientated individual counselling for 8 weeks. Women in both groups improved based on pre–post evaluation with Hudson's Index of Self-esteem (see glossary, p 2367) and a Self-efficacy Scale (see glossary, p 2368). Pre–post score differences were statistically significant only for women in the grief resolution orientated group for both self esteem (66.9 *v* 53.5; $P < 0.01$) and self efficacy (63.3 *v* 74.7; $P < 0.01$), whereas women in the feminist orientated group showed no significant changes between pre- and post-intervention scores (self esteem: 45.7 *v* 39.5; self efficacy: 68.4 *v* 77.7). Differences between treatments were not reported. **Cognitive behaviour orientated counselling** We found one controlled trial (20 women in Colombia, aged 19–50 years) that compared 20 twice weekly 3 hour sessions of cognitive behavioural treatment versus non-structured support group.[27] Two women in the cognitive behavioural therapy group and four in the non-structured support group reported new episodes of domestic violence after the intervention began. Levels of assertiveness improved significantly in the intervention group (from pre- to post-intervention; $P < 0.05$), whereas in the control group they did not. Differences between treatments were not reported. **Group counselling versus individual couple counselling:** One systematic review (search date 1997) identified one controlled trial (68 couples).[20] It found no difference between group and individual couple intervention in reduction in physical violence or in psychological wellbeing. Withdrawal rates were higher in the group programme. **Gender specific versus couple counselling:** We identified one RCT[28] and one non-randomised controlled trial (124 couples) comparing gender specific counselling versus couple counselling.[29] In the RCT, 49 couples who indicated a desire to remain in their current relationship were randomly assigned to gender specific counselling or couple counselling.[28] There were no differences in victims' reports of subsequent physical violence at 6 month follow up for 26 (62%) of the couples (reports: 8.3% among couple therapy participants *v* 7.1% for gender specific therapy; $P = 0.91$). In the non-randomised controlled trial, volunteer married and intact couples who reported at least two acts of

husband to wife physical aggression (75 couples), excluding couples with alcohol dependence, mental disease, and who reported severe injuries, or women who feared their partner, were alternately assigned to couple therapy or gender specific therapy.[29] The past year prevalence of husband to wife physical aggression was reduced from 100% before treatment to 74% after treatment ($P < 0.01$) in both groups, based on the Modified Conflict Tactics Scale (see glossary, p 2367). With both treatments, there were significant decreases from pre-treatment scores to 1 year follow up in husband to wife psychological aggression (93.37 to 44.79; $P < 0.005$) and mild (19.31 to 8.63; $P < 0.001$) and severe physical aggression (3.34 to 1.71; $P < 0.05$), as well as wives' depression on the Beck Depression Inventory (see glossary, p 2367) (12.39 to 8.79; $P < 0.005$), with no differences between treatments. Women in couples group therapy reported that physical aggression resulted from content discussed in 2% of the sessions, with no differences between treatments.

Harms: No harms were reported for individual or group counselling. However, a potential harm of any intervention targeting victims of domestic violence is escalation of violence as a result of reprisal. Qualitative assessment of weekly reports did not support the belief that women who received couple counselling were placed in any further danger than those who attended individual therapy.[28]

Comment: It is unclear whether the controlled trial comparing counselling versus no intervention was an RCT because the allocation method was not described.[24] Rotating assignment to groups may have increased the possibility of contamination across groups. In the quasi-randomised trial comparing grief orientated versus feminist orientated counselling, the scoring range was unclear, and the authors did not indicate whether the original 14 point Lickert scale was used.[26] The trial conducted in South Korea, comparing a group problem solving/empowering intervention versus no intervention, had high withdrawal rates (47% in group intervention *v* 43% in the no intervention group).[25] In the second trial comparing gender specific interventions versus couple intervention, two thirds of eligible couples declined to participate.[29] In addition, 67% of the participants withdrew at the start or dropped out during treatment or before follow up.

OPTION ADVOCACY

One RCT and one non-randomised controlled trial found that advocacy reduced reabuse compared with no treatment. The RCT also found an improvement in women's quality of life with advocacy compared with no treatment. One controlled trial in pregnant Hispanic women found no significant difference in rates of reabuse between combined counselling plus mentoring (similar to advocacy) and a resource card, but found that counselling plus mentoring slightly reduced rates of reabuse compared with unlimited counselling.

Benefits: **Versus no treatment:** We found one systematic review[30] (search date 2002, 1 RCT,[31] 278 women) and one additional non-randomised controlled trial.[32] The RCT included in the review

allocated 278 battered women leaving shelter stay either to a trainee advocate or to a control group.[31] Advocates worked with participants for about 6.4 hours each week over a 10 week period. It found significant reductions in psychological abuse and increases in quality of life at 6, 12, 18, and 24 months of follow up, but it found no significant change from baseline for depression. The RCT reported no significant differences between groups for psychological abuse or depression, but found that advocacy significantly improved quality of life ($P = 0.01$) and reduced reabuse at 24 months compared with control (reabuse rate: 76% with advocacy *v* 89% with control; $P < 0.01$). The additional non-randomised controlled trial (81 women seeking temporary restraining orders with incomes below the poverty line and access to a telephone, who had no obvious mental disorder, were not already represented by an attorney, or receiving extensive violence related resources) allocated 22 women to law school advocates and 59 to standard court services without an advocate.[32] Women assisted by advocates reported less physical reabuse (5% *v* 25%) and psychological reabuse (10% *v* 47%) compared with women receiving standard court services at 6 months of follow up. **Versus counselling:** We found one systematic review (search date 2001, 1 controlled trial,[24] 290 pregnant Hispanic women).[22] The controlled trial compared unlimited counselling plus a mentor (who might be considered to have acted as an advocate) versus unlimited counselling only versus a resource card.[24] Participants in all three groups reported a reduction in levels of violence and threats of violence at follow up 2 months postpartum. Although women receiving unlimited counselling plus mentoring reported less physical violence than women receiving unlimited counselling only (mean on the Severity of Violence Against Women Scale [see glossary, p 2368] adjusted for entry scores: 34.7 *v* 39.5; $P < 0.05$), neither of these interventions had significantly different results compared with women receiving only a resource card. There were no differences at 6, 12, or 18 month follow up assessments.

Harms: No harms were reported. However, a potential harm for any intervention targeting victims of domestic violence is escalation of violence as a result of reprisal.

Comment: In the additional controlled trial (81 women below the poverty line), 41% of those approached did not consent to participate.[32] An additional 13% did not appear for their first appointment. Assignment to the intervention group was based on women's acceptance of free legal representation from a law student. The RCT[31] evaluated the effect of advocacy for women exiting shelters, and the controlled trial involving women below the poverty line utilised law school advocates in a legal setting (interventions not available in a healthcare setting).[32] Although referral to an advocate (usually available at community based intimate partner violence services) at any time was considered an intervention to which a healthcare professional could potentially refer a victim; the extent to which the effectiveness of these interventions for women exiting shelter or women seeking restraining orders can be generalised to women in other conditions is unknown.

OPTION SHELTERS

We found no reliable controlled trials. One cohort study found a reduced incidence of violence in the weeks after shelter stay for women choosing to use the shelter when they were also engaged in other types of help seeking behaviour compared with women not choosing to stay at the shelter. Women choosing to stay at the shelter who had not sought help elsewhere experienced an increase in violence.

Benefits: We found one systematic review (search date 1997), which found no reliable studies.[20]

Harms: The systematic review identified one cohort study (243 women), which found that violence increased among women staying at shelters who had not sought other types of help.[33] However, women choosing shelters had previously experienced twice as much violence as those not choosing shelters.

Comment: The systematic review identified one cohort study (243 women) in women who spontaneously went to a shelter (see glossary, p 2368) and women sent by the prosecutors' offices compared those who voluntarily chose to stay at the shelter compared with those who chose not to stay. [33] Stay ranged from 1–30 days. The study found that women choosing shelter and not seeking any other help were more likely to experience new episodes of violence during the 6 weeks after leaving the shelter compared with those who did not choose to stay at the shelter (OR 1.8; $P = 0.13$, after adjusting for initial risk of violence, days outside the shelter, and attrition). However, in women who engaged in at least one other type of help seeking behaviour, shelter use reduced the risk of new violence compared with shelter non-use (OR 0.6; $P < 0.05$), suggesting that shelter stay is only effective when women use other resources. Conclusions must be drawn carefully from this study because losses to follow up were 36%, and results were based on subgroup analyses.[33] In the study, help seeking behaviour was defined as the number of distinct kinds of help seeking actions taken during the 6 months before the baseline interview and included previous shelter stay, calling the police, trying to get a restraining order, seeking criminal justice prosecution, seeking counselling, and trying to get help from legal aid or a private attorney.[20]

OPTION PEER SUPPORT GROUPS

We found no systematic reviews, RCTs, non-randomised controlled trials, or cohort studies of peer support groups in women experiencing domestic violence.

Benefits: We found no RCTs, non-randomised controlled trials, or cohort studies of peer support groups (see glossary, p 2367) in women experiencing domestic violence.

Harms: We found no RCTs, non-randomised controlled trials, or cohort studies.

Comment: None.

OPTION SAFETY PLANNING

One RCT found that providing telephone sessions on safe behaviour in addition to usual care increased safe behaviour at 6 months compared with usual care alone. We found limited evidence from one non-randomised controlled trial in pregnant women that helping participants to make a safety plan reduced spouse abuse and increased safe behaviour at 12 months.

Benefits: We found one systematic review (search date 2002, 1 RCT, and 1 non-randomised trial).[30] The RCT (150 English and Spanish speaking women recruited from a family violence unit in an urban District Attorney's office) compared standard services offered by the District Attorney's office versus standard services plus six telephone sessions on safety behaviours.[34] The RCT found that additional sessions on safety behaviours improved safety behaviour compared with standard treatment at 3 and 6 months (safety behaviours were assessed using the Safety Behaviour Checklist of 15 behaviours, adjusted for relevance [e.g. if no firearms in the home, adopting the safety behaviour of removing the firearm was not applicable]; mean increase of two safety behaviours for sessions *v* standard care; effect size 0.91 at 3 months and 0.64 at 6 months). In the non-randomised trial included in the review, 199 pregnant women attending public prenatal clinics who had been physically or sexually assaulted in the past year by their partner were recruited consecutively first into the control group to receive standard prenatal care (67 women) and then into the safety planning group (132 women).[35] Women in the control group received a wallet sized resource card with information on community resources. In the safety planning group, trained nurses helped participants to prepare a safety plan and provided them with information on applying for legal protection orders and filing for criminal charges, as well as community resource phone numbers. This information was provided during three evenly spaced sessions throughout pregnancy and was reinforced with a brochure at the end of each session. After adjusting for entry levels of violence, women in the safety planning group reported less ongoing physical and non-physical abuse on the Index of Spouse Abuse Scale (see glossary, p 2367) at 12 months (37.6 *v* 56.9; $P = 0.007$), and fewer threats and instances of actual violence on the Severity of Violence Against Women Scale (see glossary, p 2368) at 6 months (threats score 27.3 *v* 33.4; actual violence 33.1 *v* 35.9) and 12 months (threats score 27.0 *v* 33.6; actual violence 32.6 *v* 37.1) compared with women in the control group ($P = 0.052$), although it is unclear to which comparison the statistical test refers to. At 12 months, the safety planning group had used significantly more relevant safety behaviours than women in the control group ($P < 0.001$).

Harms: None reported. However, a potential harm for any intervention targeting victims of domestic violence is escalation of violence as a result of reprisal. In the RCT, one woman committed suicide after 3 weeks. The study did not report which treatment she was assigned. However, it is not clear that the suicide was related to treatment.[34]

Comment: The RCT recruited participants from a district attorney's office, a setting to which healthcare providers may refer people who have experienced domestic violence.[34] Less than 3% of women refused to participate (4/154). Nearly all women completed the study at 6 months (149/150). The occurrence of intimate partner violence during the trial was not assessed. The intervention ceased at 8 weeks, and a subsequent assessment of effect size showed a decrease between 3–6 months. The authors noted that this may reflect a ceiling effect or a need for reinforcement with additional intervention services. In the non-randomised study, the intervention group was recruited during prenatal care, whereas the comparison group was recruited postpartum.[35] The influence of different periods of recruitment on recall of abuse was not explored.

GLOSSARY

Advocacy involves providing information to a client on her legal, medical, and financial options; facilitating her access to and utilisation of community resources such as shelters, counselling, and protection orders; accessing and mobilising her natural support networks; assisting in goal setting and making choices; validating her feelings of being victimised; and providing emotional support.[6]

Beck Depression Inventory in its short version has 13 items. Scores above 4 indicate increasing levels of depression.

CES-D (Centers for Epidemiological Studies Depression) Scale Twenty item 4 point Lickert scale, with scores that range from 0 to 60. Higher scores indicate more symptoms of depression.

Counselling usually involves professional guidance in solving a client's problems. Counselling services tend to focus on providing information rather than the use of psychological techniques. However, counselling, as used in one of the controlled trials referred to above,[25] may also include referral to services and assistance in accessing these services (overlapping with advocacy).

Hudson's Index of Self-esteem Scores vary from 0–100. Higher scores indicate lower self esteem.

Index of Spouse Abuse Scale is a 30 item, self report scale measuring the frequency with which respondents have experienced 11 types of physical abuse and 19 types of non-physical abuse inflicted by a male partner. In scoring the measure, items are weighted differentially based on severity. Scores range from 0–100 on each subscale, with high scores indicating high frequency of severe abuse and low scores indicating relative absence of abuse.

Modified Conflict Tactics Scale (CTS2) has 78 items measuring the frequency (on an 8 point scale from never to more than 20 times) with which partners engage in psychological and physical attacks on each other.

Peer support groups Sometimes facilitated by a professional, peer support groups are hypothesised to help women exposed to domestic violence by reducing social isolation (risk factor for or effect of domestic violence) and providing encouragement and support, for example by allowing women to see that they are not alone in their experience and that there are available alternatives to changing their situation.

Rosenberg's Self-esteem Scale A 10 item scale with a four point response format resulting in a score range of 10 to 40, with higher scores representing higher self steem.

Safety planning helps participants to identify behaviours that might signal increased danger and prepare, ahead of time, codes of communication with family or friends, as well as needed documents, keys, and clothing should a quick exit become necessary.

Domestic violence towards women

Self-efficacy Scale Scores on the original 23 item scale vary from 14 to 322, with a mean of 230 ± 39. Higher scores indicate higher self efficacy.[27]

Severity of Violence Against Women Scale Scores on the physical violence component range from 27 to 108, where 27 would equal never being exposed to any of the behaviours and 108 would equal being exposed many times to all of the behaviours in the inventory.

Shelters provide housing, food, and clothing, usually for 30–90 days, to victims and their children under 12 who leave their abuser. Many shelters also offer individual or group therapy or counselling, advocacy, child care, job training, and assistance in finding transitional housing.

Spielberger's 20 item State-Trait Anxiety Inventory Scores range from 20–80, where 20 equals not feeling like that at all (state anxiety) or ever (trait anxiety) and 80 would equal feeling like that very much (state anxiety) or always (trait anxiety).

Substantive changes

Advocacy One systematic review added;[30] conclusions unchanged.

Safety planning One RCT added.[34] Intervention recategorised as Likely to be beneficial.

TABLE 1 **Risks for reported conditions in women experiencing psychological abuse (see text, p 2359).[19]**

Complaint	RR (95% CI)
Poor physical health	1.69 (1.20 to 2.29)
Poor mental health	1.74 (1.07 to 2.73)
Disability preventing work	1.49 (1.06 to 2.14)
Arthritis	1.67 (0.20 to 2.22)
Chronic pain	1.91 (1.49 to 2.36)
Migraine	1.54 (1.16 to 1.93)
Other frequent headaches	1.41 (1.05 to 1.82)
Sexually transmitted infections	1.82 (1.19 to 2.68)
Chronic pelvic pain	1.62 (1.03 to 2.48)
Stomach ulcers	1.72 (1.02 to 2.84)
Spastic colon	3.62 (1.63 to 7.50)
Frequent indigestion, diarrhoea, or constipation	1.30 (1.03 to 1.63)

Dysmenorrhoea

QUESTIONS

INTERVENTIONS

See glossary, p 2386

Key Messages

- **Non-steroidal anti-inflammatory drugs (other than aspirin)** Two systematic reviews have found that naproxen, ibuprofen, mefenamic acid, valdecoxib, and rofecoxib reduce pain compared with placebo. It remains unclear from direct comparisons which non-steroidal anti-inflammatory drugs have better efficacy or safety. One systematic review found that naproxen reduced pain more and was associated with fewer adverse effects than co-proxamol. It also found that mefenamic acid reduced symptoms more than co-proxamol.
- **Aspirin, paracetamol, and compound analgesics** One systematic review found that aspirin was more effective for pain relief than placebo, but less effective than naproxen or ibuprofen. The review found no significant difference between paracetamol compared with placebo, aspirin, or ibuprofen in pain relief, although some of the RCTs may have been too small to rule out clinically important differences. It found limited evidence that co-proxamol reduced pain compared with placebo.
- **Magnesium** One systematic review found limited evidence from two out of three small RCTs that magnesium reduced pain after 5–6 months compared with placebo. A third RCT found no significant difference.
- **Thiamine** One large RCT identified by a systematic review found that thiamine reduced pain after 60 days compared with placebo.
- **Toki-shakuyaku-san (herbal remedy)** One systematic review found limited evidence that toki-shakuyaku-san reduced pain after 6 months compared with placebo and that it reduced the need for additional medication with diclofenac.
- **Topical heat** One RCT found topical heat (about 39 °C) treatment to be as effective as ibuprofen and more effective than placebo in reducing pain.

- **Transcutaneous electrical nerve stimulation** One systematic review found limited evidence from small RCTs that high frequency transcutaneous electrical nerve stimulation reduced pain compared with placebo transcutaneous electrical nerve stimulation. We found insufficient evidence from small RCTs to assess effects of low frequency transcutaneous electrical nerve stimulation compared with other or no treatment.
- **Vitamin E** One RCT found limited evidence that vitamin E reduced pain compared with placebo.
- **Acupuncture** One systematic review of one small RCT found insufficient evidence to compare acupuncture with placebo or no treatment.
- **Behavioural interventions** We found insufficient evidence from two poor quality RCTs about the effects of behavioural interventions.
- **Combined oral contraceptives** One systematic review found insufficient evidence about the effects of combined oral contraceptives versus placebo for pain relief.
- **Fish oil** One small RCT identified by a systematic review and one additional RCT found limited evidence that fish oil reduced pain and symptoms after 1–3 months compared with placebo.
- **Herbal remedies (other than toki-shakuyaku-san)** We found no RCTs of other herbal remedies.
- **Surgical interruption of pelvic nerve pathways** One small RCT found limited evidence suggesting that laparoscopic uterine nerve ablation increased pain relief compared with diagnostic laparoscopy. Another RCT found that laparoscopic uterine nerve ablation reduced pain at 12 months compared with laparoscopic presacral neurectomy. It found no significant difference in pain relief between treatments at 3 months. It also found increased constipation with laparoscopic uterine nerve ablation.
- **Vitamin B_{12}** We found no RCTs that compared vitamin B_{12} with placebo. One small RCT found insufficient evidence for vitamin B_{12} compared with advice to follow a low fat vegetarian diet.
- **Spinal manipulation** One systematic review has found inconclusive evidence on the effects of spinal manipulation compared with placebo or no treatment in pain relief.

DEFINITION

Dysmenorrhoea is painful menstrual cramps of uterine origin. It is commonly divided into primary dysmenorrhoea (pain without organic pathology) and secondary dysmenorrhoea (pelvic pain associated with an identifiable pathological condition, such as endometriosis [see endometriosis, p 2391] or ovarian cysts). The initial onset of primary dysmenorrhoea is usually shortly after menarche (6–12 months) when ovulatory cycles are established. Pain duration is commonly 8–72 hours and is usually associated with the onset of menstrual flow. Secondary dysmenorrhoea can also occur at any time after menarche, but may arise as a new symptom during a woman's fourth and fifth decade, after the onset of an underlying causative condition.[1]

INCIDENCE/ PREVALENCE

Variations in the definition of dysmenorrhoea make it difficult to determine prevalence precisely. However, various types of study have found a consistently high prevalence in women of different ages and nationalities. One systematic review (search date 1996)

of the prevalence of chronic pelvic pain, summarising both community and hospital surveys, estimated prevalence to be 45–95%.[2] Reports focus on adolescent girls and generally include only primary dysmenorrhoea, although this is not always specified. Studies of prevalence are summarised in table 1, p 2389.

AETIOLOGY/ RISK FACTORS A longitudinal study of a representative sample of women born in 1962 found that severity of dysmenorrhoea was significantly associated with duration of menstrual flow (average duration of menstrual flow was 5.0 days for women with no dysmenorrhoea and 5.8 days for women with severe dysmenorrhoea: where severe dysmenorrhoea was defined as pain that did not respond well to analgesics and clearly inhibited daily activity; $P < 0.001$; WMD –0.80, 95% CI –1.36 to –0.24); younger average menarcheal age (13.1 years in women without dysmenorrhoea *v* 12.6 years in women with severe dysmenorrhoea; $P < 0.01$; WMD 0.50, 95% CI 0.09 to 0.91); and cigarette smoking (41% of smokers and 26% of non-smokers experienced moderate or severe dysmenorrhoea).[9] There is also some evidence of a dose–response relationship between exposure to environmental tobacco smoke and increased incidence of dysmenorrhoea.[10]

PROGNOSIS Primary dysmenorrhoea is a chronic recurring condition that affects most young women. Studies of the natural history of this condition are sparse. One longitudinal study in Scandinavia found that primary dysmenorrhoea often improves in the third decade of a woman's reproductive life, and is also reduced after childbirth.[9] We found no studies that reliably examined the relationship between the prognosis of secondary dysmenorrhoea and the severity of underlying pathology such as endometriosis.

AIMS OF INTERVENTION To relieve pain from dysmenorrhoea, with minimal adverse effects.

OUTCOMES Pain relief, measured either by a visual analogue scale (see glossary, p 2387), other pain scales, or as a dichotomous outcome (pain relief achieved yes/no); overall improvement in dysmenorrhoea measured by change in dysmenorrhoeic symptoms either self reported or observed, quality of life scales, or other similar measures such as the Menstrual Distress or Menstrual Symptom Questionnaires; adverse effects of treatment (incidence and type of adverse effects); proportion of women requiring analgesics in addition to their assigned treatment; proportion of women reporting activity restriction or absences from work or school and hours or days of absence as a more selective measure.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION What are the effects of treatments for dysmenorrhoea?

OPTION ACUPUNCTURE

One systematic review of one small RCT found insufficient evidence to compare acupuncture with placebo or no treatment.

Benefits: We found one systematic review of acupuncture for primary dysmenorrhoea (search date 2001, 1 RCT, 43 women).[11] The RCT included in the systematic review compared weekly acupuncture during three menstrual cycles a month for 3 months versus three other treatments: placebo acupuncture (see glossary, p 2387); monthly medical visits; or no medical visits. Outcomes were assessed after 3 months using non-validated pain scales and symptom questionnaires, and improvement was defined as a reduction in pain by more than half the admission score. It found that acupuncture significantly increased the proportion of women with reduced pain compared with other treatment (10/11 [91%] with acupuncture *v* 4/11 [36%] with placebo acupuncture *v* 1/10 [10%] with monthly medical visits *v* 2/11 [18%] with no medical treatment; $P < 0.05$ for acupuncture *v* all other treatments).

Harms: The RCT identified by the review did not address harms of acupuncture.[12]

Comment: The scale used to assess outcomes in the RCT identified by the review does not seem to be validated.[11] We found no evidence of statistical adjustment for multiple comparisons (such as Bonferroni's correction) in the published paper.[12] The review identified a second RCT comparing different modalities of acupuncture.[11]

OPTION ASPIRIN, PARACETAMOL, AND COMPOUND ANALGESICS

One systematic review found that aspirin was more effective for pain relief than placebo, but less effective than naproxen or ibuprofen. The review found no significant difference between paracetamol compared with placebo, aspirin, or ibuprofen in pain relief, although some of the RCTs may have been too small to rule out clinically important differences. It found limited evidence that co-proxamol reduced pain compared with placebo.

Benefits: We found one systematic review (search date 1997, 13 RCTs) of the effects of analgesics in primary dysmenorrhoea (see table 2, p 2390), which compared analgesics versus placebo, versus each other, or versus non-steroidal anti-inflammatory drugs.[13] **Aspirin versus placebo:** The review identified eight RCTs comparing aspirin versus placebo (486 women, 650 mg 4 times daily). The review found that aspirin was significantly more effective than placebo for pain relief (proportion of women with at least moderate pain relief, 5 RCTs: RR 1.60, 95% CI 1.12 to 2.29; NNT 10, 95% CI 5 to 50). It also found no significant difference between aspirin and placebo in the need for additional medication or restriction of daily activity and absence from work (additional medications, 3 RCTs: RR 0.79, 95% CI 0.58 to 1.08; restriction of activity, 3 RCTs: RR 0.82, 95% CI 0.64 to 1.04; absence from work, 1 RCT: RR 1.28, 95% CI 0.24 to 6.76).[13] **Paracetamol versus placebo:** One RCT identified by the review found no significant difference between paracetamol (500 mg 4 times daily) and placebo in pain relief (proportion of women with at least moderate pain relief; 35 women; RR 1.00, 95% CI 0.28 to 3.63).[13] **Co-proxamol versus placebo:** One RCT identified by the review found that co-proxamol (see glossary, p 2386) significantly increased the proportion of women with at

least moderate pain relief compared with placebo (72 women; 650 mg/65 mg 4 times daily; RR 3.72, 95% CI 2.13 to 6.52).[13] **Paracetamol versus aspirin:** One RCT (35 women) identified by the review compared aspirin (500 mg 4 times daily) versus paracetamol (500 mg 4 times daily). It found no significant difference in pain relief (10 cm visual analogue scale (see glossary, p 2387): median change from baseline 1.6 cm, 95% CI 0.4 cm to 3.3 cm with paracetamol *v* 1.2 cm, 95% CI 0 cm to 2.7 cm with aspirin). **Aspirin or paracetamol or co-proxamol versus non-steroidal anti-inflammatory drugs:** See benefits of non-steroidal anti-inflammatory drugs, p 2374.

Harms: The most common adverse effects described by the review were nausea or abdominal discomfort, headaches, and dizziness.[13] Adverse effects occurred in 7–17% of women taking aspirin versus 3–17% of women taking placebo. The review found no difference between aspirin or paracetamol compared with placebo in the frequency of adverse effects (any adverse effect for aspirin *v* placebo: RR 1.31, 95% CI 0.79 to 2.17; any adverse effect for paracetamol *v* placebo: RR 1.00, 95% CI 0.36 to 2.75).

Comment: Most RCTs included in the systematic review were short (usually only 1 menstrual cycle on each treatment), small, and used a crossover design without a washout period. All of the RCTs (except 1 of co-proxamol versus naproxen) used double blinding. All the RCTs used oral administration of treatment in the form of tablets or capsules. Negative RCTs may have been too small to rule out clinically important differences.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (OTHER THAN ASPIRIN)

Two systematic reviews and subsequent RCTs have found that naproxen, ibuprofen, mefenamic acid, valdecoxib, and rofecoxib reduced pain compared with placebo. It remains unclear from direct comparisons which non-steroidal anti-inflammatory drugs have better efficacy or safety. One systematic review found that naproxen reduced pain more and was associated with fewer adverse effects than co-proxamol. It also found that mefenamic acid reduced symptoms more than co-proxamol.

Benefits: We found two systematic reviews[13,14] and six subsequent RCTs of the effects of non-steroidal anti-inflammatory drugs (NSAIDs) in primary dysmenorrhoea.[15–20] The first systematic review (search date 1997, 46 RCTs, 2733 women) evaluated the effects of naproxen (23 RCTs, 1728 women), ibuprofen (18 RCTs, 748 women), and mefenamic acid (5 RCTs, 257 women).[13] The second systematic review (search date not stated, 1 RCT) assessed rofecoxib, a cyclo-oxygenase-2 selective NSAID, versus placebo or versus naproxen in people with primary dysmenorrhoea.[14] **Versus placebo:** The first systematic review found that all three NSAIDs significantly increased proportion of women with at least moderate pain relief compared with placebo (naproxen, 13 RCTs: RR 3.17, 95% CI 2.72 to 3.67; NNT 3, 95% CI 2 to 4; ibuprofen, 9 RCTs: RR 2.41, 95% CI 1.58 to 3.68; NNT 3, 95% CI 2 to 4; mefenamic acid, 3 RCTs: RR 2.03, 95% CI 1.65 to 2.48; NNT 3, 95% CI 2 to 5). The use of additional analgesics was significantly reduced for all

NSAIDs versus placebo. Women taking naproxen were 60% less likely to use additional analgesics (10 RCTs; RR 0.4, 95% CI 0.3 to 0.4); those taking ibuprofen were 70% less likely (2 RCTs; RR 0.23, 95% CI 0.13 to 0.41); and those on mefenamic acid were 35% less likely (1 RCT; RR 0.65, 95% CI 0.52 to 0.80). Restriction of daily life was significantly less for naproxen and ibuprofen (naproxen, 1 RCT: RR 0.65, 95% CI 0.52 to 0.80; ibuprofen, 3 RCTs: RR 0.26, 95% CI 0.16 to 0.42). Absence from work or school was significantly reduced with naproxen but not with ibuprofen (naproxen, 7 RCTs: RR 0.29, 95% CI 0.13 to 0.66; ibuprofen, 1 RCT: RR 0.14, 95% CI 0.02 to 1.10).[13] The RCT identified by the second review (127 women) compared four treatments: rofecoxib 25 mg/day; rofecoxib (50 mg loading dose then 25 mg/day); naproxen sodium (550 mg every 12 hours); and placebo over four consecutive cycles.[14] It found that both doses of rofecoxib and naproxen provided more pain relief compared with placebo (pain relief measured by combining the TOPAR8 scales over 4 menstrual cycles [total pain relief scores to 8 hours]; $P < 0.006$ for all treatments *v* placebo). The first subsequent RCT (69 women) found that niflumic acid (750 mg/day for 3 days) significantly increased the proportion of women who had complete remission or more than 50% remission of pain on day 3 of treatment compared with placebo (26/30 [87%] with niflumic acid *v* 15/31 [48%] with placebo; RR 1.73, 95% CI 1.17 to 2.57; NNT 3, 95% CI 2 to 5).[15] The second subsequent RCT (crossover design; 57 women) compared four treatments: bromfenac (10 or 50 mg/day), naproxen (550 mg loading dose, then 275 mg repeat doses 4 hourly as needed), and placebo.[16] It found that women taking bromfenac (10 or 50 mg/day) or naproxen had significantly less pain than women taking placebo after three days of treatment in one cycle ($P < 0.05$ for all comparisons *v* placebo). The third subsequent RCT (crossover design; 52 women) compared six hourly doses of dexketoprofen 12.5 or 25 mg, racemic ketoprofen 25 mg, and placebo.[17] It found that after 1 day of treatment pain relief was better in the three treatment groups compared to placebo ($P < 0.05$ for all treatment groups *v* placebo). The fourth subsequent RCT (crossover design; 24 women) found that lysine clonixinate or ibuprofen increased the proportion of women with total pain relief compared with placebo (10/24 [42%] with lysine clonixinate *v* 9/24 [38%] with ibuprofen *v* 2/24 [8%] with placebo; active treatment versus placebo; $P < 0.001$).[18] However, results were difficult to interpret because no pre-crossover results were reported. The sixth subsequent RCT (crossover design; 96 women) compared valdecoxib (20 mg or 40 mg every 12 hours) versus naproxen sodium (550 mg every 12 hours) versus placebo.[20] It found that valdecoxib significantly reduced pain 8 and 12 hours after the first dose compared with placebo ($P < 0.01$ for 20 mg dose and $P < 0.001$ for 40 mg dose). It also found that naproxen sodium significantly reduced pain compared with placebo ($P < 0.001$). However, results were difficult to interpret because no pre-crossover results were reported. **Comparison of NSAIDs:** The first systematic review identified 5 RCTs comparing different NSAIDs.[13] Three RCTs identified by the review found no significant difference in pain relief between naproxen (550 mg loading dose followed by 275 mg) and ibuprofen (400 mg) (proportion of women with at least moderate

pain relief: pooled RR 1.1, 95% CI 0.8 to 1.5). One RCT identified by the review found that naproxen (550 mg loading dose followed by 275 mg) significantly increased pain relief compared with mefenamic acid (500 mg followed by 250 mg) (proportion of women with at least moderate pain relief: RR 2.4, 95% CI 1.4 to 4.1). Another RCT identified by the review found no significant difference in pain relief between ibuprofen 400 mg and mefenamic acid 250 mg (no RR or P values provided). The second subsequent RCT (crossover design; 57 women) compared bromfenac 50 mg/day, bromfenac 10 mg/day, naproxen sodium (550 mg loading dose, then 275 mg repeat doses 4 hourly as needed), and placebo measuring outcomes with a categorical scale (described in the study, no information of validation).[16] No significant differences were found in pain scores between the three treatment groups after day one of treatment ($P > 0.05$). The third subsequent RCT (crossover design; 52 women) compared six hourly doses of dexketoprofen 12.5 mg, dexketoprofen 25 mg, racemic ketoprofen 25 mg, and placebo using a visual analogue scale (see glossary, p 2387).[17] It found no difference in pain scores between the three treatment groups after 3 days of treatment in one cycle ($P > 0.05$), and all treatments reduced pain significantly more than placebo ($P < 0.05$). The fourth subsequent RCT (crossover design; 24 women) found no significant difference in the proportion of women with total pain relief between lysine clonixinate and ibuprofen (10/24 [42%] with lysine clonixinate *v* 9/24 [38%] with ibuprofen; $P > 0.05$). However, results were difficult to interpret because no pre-crossover results were reported. The fifth subsequent RCT (308 women) compared nimesulide 100 mg and diclofenac 50 mg taken up to three times daily as needed over two menstrual cycles. It found no significant difference in the proportion of women who rated the treatment as "good" or "very good" at the end of each menstrual cycle (85.5% with nimesulide *v* 81.0% with diclofenac; RR 1.05, 95% CI 0.95 to 1.16).[19] The sixth subsequent RCT (crossover design; 96 women) found no significant difference in pain relief between valdecoxib 40 mg and naproxen sodium 550 mg ($P > 0.05$). However, results were difficult to interpret because no pre-crossover results were reported.[20] **Versus aspirin or paracetamol:** The first systematic review identified three RCTs comparing NSAIDs versus aspirin or paracetamol.[13] It found that both naproxen (275 mg 4 times daily) and ibuprofen (400 mg 4 times daily) reduced pain more than aspirin (650 mg 4 times daily) (excellent or moderate pain relief: naproxen *v* aspirin, 1 RCT: RR 2.29, 95% CI 1.09 to 4.79; ibuprofen *v* aspirin, 1 RCT: RR 1.90, 95% CI 1.13 to 2.78). It found no significant difference in pain relief between ibuprofen and paracetamol (1 RCT, results presented graphically).[13] **Versus co-proxamol:** The first systematic review identified three RCTs comparing NSAIDs versus co-proxamol (see glossary, p 2386).[13] One RCT identified by the review compared mefenamic acid (500 mg 3 times daily) versus co-proxamol (650 mg/65 mg 3 times daily). It found that mefenamic acid was significantly more effective in reducing dysmenorrhoea related symptoms than co-proxamol ($P < 0.01$). Mefenamic acid also reduced the need for additional medication compared with co-proxamol (mean number of tablets of additional medication 2.6

with mefenamic acid *v* 6.8 with co-proxamol; P value not provided). The RCT found no difference between treatments in absence from work or school. Two RCTs (98 women) identified by the review compared naproxen (275 mg 3 times daily) versus co-proxamol (650 mg/65 mg 3 times daily). Neither RCT found a significant difference in pain severity.[13]

Harms: The most commonly reported adverse effects in the RCTs identified by the review were nausea, dizziness, and headaches.[13] Naproxen significantly increased the number of adverse effects compared with placebo (number of RCTs not specified; RR 1.45, 95% CI 1.03 to 2.04). The review found no difference between ibuprofen and placebo in the number of adverse effects (RR 1.12, 95% CI 0.85 to 1.47) or between mefenamic acid and placebo (RR 0.59, 95% CI 0.28 to 1.23). The review also found that co-proxamol significantly increased adverse effects compared with naproxen (23–58% with co-proxamol *v* 15–25% with naproxen; RR 1.94, 95% CI 1.11 to 3.41). It also found that naproxen significantly increased adverse effects compared with placebo (RR 1.45, 95% CI 1.03 to 2.04) and marginally increased nausea (RR 2.71, 95% CI 1.00 to 7.36). The second RCT (57 women) found adverse effects in 13/57 (23%) women taking bromfenac 50 mg, 15/57 (26%) women taking bromfenac 10 mg, 20/57 (35%) women taking naproxen (550 mg loading dose, then 275 mg repeat doses 4 hourly as needed), and 19/57 (33%) women taking placebo.[16] The fifth RCT (308 women) found gastrointestinal adverse effects in 7/149 (4.8%) women taking nimesulide and 16/155 (10.3%) women taking diclofenac.[19] The systematic review of rofecoxib[14] did not describe fully the adverse effects found in the RCT it identified.[21] The RCT found that minor adverse effects including nausea and dry mouth were reported by: 4/127 (3%) with placebo; 7/127 (6%) with rofecoxib (25 mg followed by 25 mg/day); 13/127 (11%) with rofecoxib (50 mg followed by 25 mg/day); and 11/127 (9%) with naproxen sodium (550 mg twice daily for 3 days) ($P < 0.05$ for rofecoxib [50 mg followed by 25 mg/day] *v* placebo).[21] The RCT (crossover design; 96 women) that compared valdecoxib (20 or 40 mg every 12 hours) versus naproxen sodium (550 mg every 12 hours) versus placebo reported minor adverse events in all groups.[20] Adverse events included abdominal pain, diarrhoea, dizziness, fever, headache, nausea, and pain. People taking valdecoxib 20 mg reported 27 adverse events (16 were headache). Those taking valdecoxib 40 mg reported 19 adverse events (9 were headaches). People taking naproxen sodium reported 12 adverse events (8 were headaches) and people taking placebo reported 23 adverse events (20 were headaches). However, results were difficult to interpret because no pre-crossover results were reported.

Comment: All the RCTs identified by the review used oral treatment.[13] NSAIDs can be given as suppositories, which seem to have a similar effect on overall pain relief but less effect than oral treatment for spasmodic pain.[22] Most RCTs in the first systematic review used a crossover design without a washout period and were brief (usually only 1 menstrual cycle/treatment). Nine of the included RCTs did not blind the researchers to treatment allocation. Many of the trials on NSAIDs were sponsored by the pharmaceutical industry. The

pain relief figures used above (see benefits above) refer to RCTs that include women with primary dysmenorrhoea only. However, some of the figures regarding the use of additional medication included data from women with undefined dysmenorrhoea. A systematic review with stricter inclusion criteria and methodological quality assessment is underway.[23] Some RCTs used a scale with categories (categorical scale) to measure outcomes.[16,18] There is no evidence that those scales were validated. Variations in pain measured in the categorical scales were summarised using parametric statistics, making those results difficult to interpret.[16,18] The second systematic review also identified one crossover clinical trial (63 women) that compared rofecoxib (50 mg loading dose then 25 mg/day), naproxen (550 mg every 12 hours), and placebo as needed.[14] It found no difference in outcomes between rofecoxib and naproxen, but found that rofecoxib significantly reduced pain as measured by TOPAR8 scores ($P < 0.002$) and time to remedication ($P < 0.009$) compared with placebo.

OPTION BEHAVIOURAL INTERVENTIONS

We found insufficient evidence from two poor quality RCTs about the effects of behavioural interventions.

Benefits: We found no systematic review. We found two small RCTs on behavioural interventions (see glossary, p 2386). One involved relaxation and imagery for women with congestive or spasmodic (see glossary, p 2387) dysmenorrhoea,[24] and the other involved aerobic exercise for women with primary dysmenorrhoea.[25] **Relaxation treatment:** The first RCT (69 women) compared relaxation treatment plus positive imagery regarding menstruation versus self directed group discussion about menstruation versus waiting list control. The groups were divided into women with congestive or spasmodic dysmenorrhoea using the Menstrual Symptom Questionnaire. It found that in women with spasmodic or congestive dysmenorrhoea, relaxation treatment significantly improved symptoms compared with waiting list control ($P < 0.01$). However, it found that only the women with spasmodic dysmenorrhoea experienced significantly less pain with relaxation compared with group discussion or waiting list control ($P < 0.001$).[24] **Aerobic exercise:** The second RCT (36 women) comparing a training group that participated in 30 minutes of exercise 3 days a week with a sedentary control group found that aerobic exercise significantly lowered Menstrual Distress Questionnaire scores ($P < 0.05$; results presented graphically).[25]

Harms: The RCTs gave no information on adverse effects.

Comment: Both RCTs were small and of poor methodological quality.[24,25] In one RCT, spasmodic dysmenorrhoea was defined as spasms of pain mainly in the abdomen, and congestive dysmenorrhoea was defined as a dull aching pain in the lower abdomen and other areas of the body.[24] However, the classification of dysmenorrhoea into spasmodic and congestive categories is no longer commonly used

and has little meaning.[25] The RCT (36 women) comparing aerobic exercise with a sedentary control analysed results for the 26 women (72%) who completed the trial (11 in the exercise group and 15 in the control group).[25] A systematic review is underway.[26]

OPTION COMBINED ORAL CONTRACEPTIVES

One systematic review found insufficient evidence of the effects of oral contraceptives for pain relief.

Benefits: We found one systematic review of combined oral contraceptives for primary dysmenorrhoea (search date 1999, 5 RCTs, 379 women).[27] It found no significant difference between medium dose oestrogen (> 35 μg) plus first or second generation progestogens compared with placebo in pain relief at 1–3 months (4 RCTs, 320 women; RR 1.40, 95% CI 0.58 to 3.42). It found that oral contraceptives reduced the proportion of women absent from work or school compared with placebo but the difference was of borderline statistical significance (1 RCT; 19/49 [39%] with contraceptives *v* 24/40 [60%] with placebo; RR 0.65, 95% CI 0.42 to 1.00).[27]

Harms: The review found no significant difference between combined oral contraceptives and placebo in adverse effects, such as nausea, vomiting, depression, and abdominal pain (1 RCT, 89 women: 15/49 [31%] with contraceptives *v* 8/40 [20%] with placebo; RR 1.53, 95% CI 0.72 to 3.24).[27] The results of two RCTs are difficult to interpret and could not be included in the meta-analysis of adverse effects performed by the review because the RCTs randomised menstrual cycles and not women.[28,29] One small RCT (18 women) identified by the review comparing combined oral contraceptives with placebo found that more women receiving oral contraceptives experienced breakthrough bleeding (2/12 [17%] with contraceptives *v* 0/6 [0%] with placebo).[28] Another RCT (59 women) identified by the review found that combined oral contraceptives increased weight gain, nausea, and vomiting compared with placebo (no further data provided).[29]

Comment: Most of the RCTs identified by the review had weak methods.[27] Because of the small number of included trials and participants, the results of the systematic review are sensitive to the statistical methods of calculation used. One of the RCTs identified by the review could not be included in the meta-analysis because of poor reporting of data.[29] All of the RCTs identified by the review used oral contraceptives that are no longer commonly prescribed, so the results may not be applicable to women today who take different preparations.[27]

OPTION FISH OIL

One small RCT identified by a systematic review and one additional RCT found limited evidence that fish oil reduced pain and symptoms after 1–3 months compared with placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 1 RCT, 42 women)[30] and one additional RCT[31] that compared fish oil versus placebo. The RCT (crossover design; 42

women) identified by the review compared fish oil capsules with placebo twice daily for 1 month. It found that menstrual symptom scores were significantly lower with fish oil compared with placebo but this refers to the average of the two groups after the allocated treatments were crossed over.[30] Less additional medication (ibuprofen 200 mg) was used in the fish oil group (mean 4.7 tablets with fish oil *v* 10.1 with placebo; P = 0.015). One additional RCT (78 women) compared four interventions: fish oil (0.5–1.0 g 5 times daily); fish oil plus vitamin B_{12}; seal oil (higher in saturated fat than fish oil); and placebo for a minimum of 3 months.[31] It found that pain measured on a visual analogue scale (see glossary, p 2387) significantly decreased only in the fish oil with vitamin B_{12} group (reduction in mean scores: fish oil –0.15, fish oil plus vitamin B_{12} –0.73, seal oil –0.2, placebo –0.19; P = 0.015 for fish oil plus vitamin B_{12} *v* placebo). However, all three active treatment groups experienced significant change in the number of other menstrual symptoms and the amount of interference with daily activities (P < 0.05).

Harms: **Versus placebo:** One RCT (42 women) identified by the review found that two women taking fish oils reported nausea and one woman reported acne.[30] No adverse effects were reported in women receiving placebo.

Comment: Both RCTs included women with dysmenorrhoea and no additional health problems.[30,31] This could include women with either primary or secondary dysmenorrhoea.

OPTION MAGNESIUM

One systematic review found limited evidence from two out of three small RCTs that magnesium reduced pain after 5–6 months compared with placebo. The third RCT found no significant difference between treatments.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 3 RCTs).[30] The first RCT (50 women) identified by the review compared magnesium aspartate three times daily with placebo. It found that magnesium aspartate significantly increased the proportion of women without pain after 6 months compared with placebo (21/25 [84%] with magnesium *v* 7/25 [28%] with placebo; RR 3.0, 95% CI 1.6 to 5.8; NNT 2, 95% CI 2 to 3). The second RCT (27 women) identified by the review found no significant difference between magnesium (5 mmol 3 times daily) and placebo in reducing pain as measured by visual analogue scale (see glossary, p 2387) pain scores, or in the number of ibuprofen tablets taken after 6 months (P = 0.07; no further data provided). The third RCT (21 women) identified by the review found that magnesium (500 mg/day during menses) significantly reduced pain after 5 months compared with placebo (P < 0.01).[30]

Harms: One RCT identified by the review found that magnesium significantly increased the proportion of women who experienced intestinal discomfort and other minor adverse effects compared with placebo (5/25 [20%] with magnesium *v* 0/25 [0%] with placebo; NNH 5, 95% CI 2 to 38), although relief of these symptoms occurred when the dose was reduced from three to two tablets daily.[30]

Comment: None.

OPTION THIAMINE

One large RCT identified by a systematic review has found that thiamine reduces pain after 60 days compared with placebo.

Benefits: We found one systematic review (search date 2000, 1 RCT).[30] The RCT identified by the review (crossover, 556 Indian adolescents attending school) compared thiamine 100 mg/day with placebo for 3 months. It found that thiamine significantly increased the proportion of women with no pain before crossover after 60 days compared with placebo (142/277 [51%] with thiamine *v* 0/279 [0%] with placebo; NNT 2, 95% CI 2 to 3).[18] After completion of the RCT, 87% of all women experienced no pain.

Harms: The review did not report any harms of thiamine.[30]

Comment: None.

OPTION VITAMIN B_{12}

One small RCT found insufficient evidence for vitamin B_{12} compared with a low fat vegetarian diet.

Benefits: **Versus dietary change:** We found no systematic review. We found one RCT (crossover design; 33 women) that compared a supplement tablet containing vitamin B_{12} (0.02 mg/day) with advice to follow a low fat vegetarian diet.[32] However, results were difficult to interpret because no pre-crossover results were reported.

Harms: The RCT comparing a vitamin B_{12} tablet with advice to follow a low fat vegetarian diet found that stomach upset, slight nausea, burping, and a bad taste in the mouth were reported by eight women across the different treatment groups.[32] No additional information was reported in the trial.

Comment: The RCT comparing vitamin B_{12} with dietary advice may have been too small to rule out clinically important differences.[32]

OPTION VITAMIN E

One RCT found limited evidence that vitamin E reduced pain compared with placebo.

Benefits: We found one systematic review (search date 2000, 1 RCT)[30] and one subsequent RCT.[33] **Versus placebo:** The subsequent RCT (100 women, aged 16–18 years) compared vitamin E (500 units/day for 5 days/cycle, which is about 333 mg) with placebo.[33] It found that vitamin E reduced pain significantly more than placebo (median visual analogue scale (see glossary, p 2387) pain scores, 3.5 with vitamin E *v* 4.3 with placebo; P = 0.02). **Vitamin E plus ibuprofen versus ibuprofen alone:** One RCT identified by the review (crossover design; 50 women) compared vitamin E (100 mg/day for 20 days before menses) plus ibuprofen (400 mg 3 times daily at the outset of painful menstruation) versus ibuprofen alone (400 mg 3 times daily at the onset of pain).[30] It found no significant difference between vitamin E plus ibuprofen and ibuprofen alone in pain relief (23/26 [88%] with vitamin E plus ibuprofen *v* 17/24 [71%] with ibuprofen; RR 1.25, 95% CI 0.93 to 1.67).

Harms: The RCTs did not report harms.[30,33]

Comment: None.

OPTION HERBAL REMEDIES

One systematic review found limited evidence that toki-shakuyaku-san reduced pain after 6 months compared with placebo and that it reduced the need for additional medication with diclofenac.

Benefits: We found one systematic review (1 RCT, search date 2000, 50 women) comparing a herbal remedy versus placebo.[30] It found that the Japanese herbal remedy toki-shakuyaku-san (2.5 g 3 times daily) significantly reduced pain as measured by a visual analogue scale (see glossary, p 2387) after 6 months compared with placebo ($P < 0.005$), and reduced the need for additional medication (diclofenac sodium) ($P < 0.01$; results presented graphically).

Harms: The RCT gave no information on adverse effects.[30]

Comment: Toki-shakuyaku-san is a mixture of six herbs, including angelica and peony root. Allocation method is not clearly described in the RCT.[30]

OPTION SPINAL MANIPULATION

One systematic review has found inconclusive evidence on the effects of spinal manipulation compared with placebo or no treatment for pain relief.

Benefits: We found one systematic review (search date 2000, 5 RCTs) comparing spinal manipulation versus placebo or no treatment.[34] The review did not perform a meta-analysis because of heterogeneity. The first RCT (11 women) identified by the review compared high velocity, low amplitude manipulation (see glossary, p 2386) versus no treatment versus placebo manipulation (see glossary, p 2387). It found no significant difference between HVLA in pain relief after 1 month compared with either no treatment or placebo (7/8 [87%] with HVLA *v* 0/2 [0%] with no treatment; RR 5.00, 95% CI 0.39 to 63.85; 7/8 [87%] with HVLA *v* 0/1 [0%] with placebo treatment; RR 3.33, 95% CI 0.30 to 37.42). The second RCT identified by the review (44 women) comparing HVLA with placebo manipulation found that HVLA significantly reduced pain intensity as measured by a 10 cm visual analogue scale (see glossary, p 2387) pain score after one treatment and one menstrual cycle (WMD −1.41, 95% CI −2.55 to −0.27). The third RCT (138 women) identified by the review found no difference between HVLA and placebo manipulation in pain as measured by mean change in visual analogue scale pain score after one menstrual cycle (WMD +2.08, 95% CI −3.20 to +7.36). The fourth RCT (12 women) identified by the review found that HVLA improved pain after one treatment during one menstrual cycle compared with placebo manipulation (no further data provided). The fifth RCT (26 women) identified by the review compared 3 months of Toftness manipulation (see glossary, p 2387) with placebo manipulation.[34] It found that manipulation significantly reduced pain intensity after 6 months compared with placebo, but not at 3 months (WMD at 6 months −1.40, 95% CI −2.21 to −0.59; WMD at 3 months 2.20, 95% CI 1.38 to 3.02).[34]

Harms: One RCT identified by the review (138 women) found no significant difference between HVLA and placebo manipulation in the proportion of women experiencing soreness in the lower back region within 48 hours of the intervention (3/69 [4%] with HVLA *v* 2/69 [3%] with placebo; RR 1.50, 95% CI 0.26 to 8.70).[34] Soreness resolved within 24 hours. No other adverse effects were reported. The other RCTs identified by the review gave no information on adverse effects.

Comment: The overall methodological quality of the RCTs identified by the review was good: low withdrawal rate (2%), adequate randomisation method, blinding of the outcome assessor, and potential blinding of the participants as the control procedure was similar to the treatment.

OPTION TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

One systematic review found limited evidence from small RCTs that high frequency transcutaneous electrical nerve stimulation reduced pain compared with placebo transcutaneous electrical nerve stimulation. We found insufficient evidence from small RCTs to assess effects of low frequency, transcutaneous electrical nerve stimulation compared with other or no treatment.

Benefits: We found one systematic review including women with primary dysmenorrhoea (search date 2001, 8 RCTs, 172 women).[11] **High frequency transcutaneous electrical nerve stimulation (TENS) versus placebo TENS:** It found that high frequency TENS (see glossary, p 2387) significantly increased pain relief compared with placebo TENS as measured by subjective assessment or by a visual analogue scale (see glossary, p 2387) (pain relief by subjective assessment, 2 RCTs, 53 women: OR 7.2, 95% CI 3.1 to 16.5; pain relief by visual analogue scale range 0–100 [0 meaning no pain relief and 100 total pain relief] 1 RCT, 18 women: WMD 45.0 scale units, 95% CI 22.5 scale units to 67.5 scale units). The review found no significant difference in the proportion of women needing additional analgesics between high frequency TENS and placebo TENS (1 RCT, 64 women: OR 0.3, 95% CI 0.1 to 1.1). It also found no significant difference in the number of analgesic tablets taken between high frequency TENS and placebo TENS (1 RCT, 24 women, mean number of tablets taken each day 6.92 with high frequency TENS *v* 6.78 with placebo, WMD +0.1 tablets, 95% CI –2.1 tablets to +2.4 tablets). It found no difference between high frequency and placebo TENS in absence from work or school as measured by the number of lost hours each menstrual cycle (1 RCT, 24 women: WMD +0.04 hours, 95% CI –0.4 hours to +0.5 hours). **Low frequency TENS versus placebo TENS:** The review found no significant difference in pain relief between low frequency TENS and placebo TENS (pain relief by subjective assessment, 2 RCTs, 29 women: OR 1.3, 95% CI 0.4 to 4.1; pain relief by visual analogue scale 0–100, 1 RCT, 18 women: WMD +24.1 scale units, 95% CI –2.9 scale units to +51.1 scale units). One additional RCT (24 women) that could not be included in the meta-analysis because of the way in which results were reported found that pain relief was significantly increased by low frequency TENS compared to placebo TENS ($P < 0.05$). Low frequency TENS reduced the number of

additional tablets of analgesic used compared with placebo TENS (1 RCT, 24 women; WMD –3.1 tablets, 95% CI –5.5 tablets to –0.7 tablets). However, there was no difference between the two groups for hours of absence from work or school (1 RCT, 24 women; WMD –0.2 hours, 95% CI –0.6 hours to +0.2 hours). **Low frequency TENS versus placebo tablets:** The review found no difference in pain relief between low frequency TENS and placebo tablets (1 RCT, 21 women; OR 2.9, 95% CI 0.4 to 24.4). One additional RCT (20 women) that could not be included in the meta-analysis found low frequency TENS increased pain relief compared to placebo tablets ($P < 0.05$). **High frequency TENS versus low frequency TENS:** The review found that high frequency TENS was more effective than low frequency TENS for pain relief measured by subjective assessment (1 RCT, 21 women; OR 3.9, 95% CI 1.1 to 13.0), but not for pain relief measured with a visual analogue scale (1 RCT, 18 women; WMD +21, 95% CI –4.4 to +46). One additional RCT that could not be included in the meta-analysis found that low frequency TENS versus high frequency TENS significantly reduced pain ($P < 0.05$). The review found that low frequency TENS versus high frequency TENS significantly reduced the number of additional analgesic tablets taken (WMD 3.2 tablets, 95% CI 0.5 tablets to 5.9 tablets). There was no difference between the two groups for the outcome of absence from work or school (WMD +0.2 hours, 95% CI –0.2 hours to +0.6 hours). **TENS versus non-steroidal anti-inflammatory drugs:** One RCT (32 women) comparing high frequency TENS, ibuprofen, and placebo found that high frequency TENS was significantly less effective than ibuprofen in achieving pain relief (14/32 [44%] with TENS *v* 24/32 [75%] using ibuprofen; OR 0.26, 95% CI 0.09 to 0.75).[35] Another unblinded RCT (12 women, crossover) found no significant difference between naproxen and high frequency/high intensity TENS in pain relief (data presented in graphic form but no OR or P values provided) but both significantly reduced pain from baseline ($P < 0.001$).[36]

Harms: Adverse effects of muscle vibrations, tightness, headaches, and slight burning or redness after use were experienced by four women on treatment and none on placebo (OR 10.0, 95% CI 0.5 to 199.0; $P = 0.12$).[35] In the unblinded crossover RCT, 10/12 (83%) women considered TENS to be temporarily painful but were prepared to accept this effect for the pain relief achieved.[36] None of the 12 women reported any adverse effects during treatment with naproxen. One RCT found that 4/32 (13%) women using high frequency TENS experienced muscle vibrations, tightness, headaches after use, and slight redness or burning of the skin (OR 8.2, 95% CI 1.1 to 60.9). There were no reported adverse effects from low frequency TENS or placebo TENS. The systematic review identified one RCT comparing high frequency TENS and naproxen reported an increase in the number of adverse effects experienced by participants (OR 26.7, 95% CI 5.5 to 130.9). In the TENS group, 10/12 (83%) experienced pain from the treatment whereas those taking naproxen reported no adverse effects. The women who reported pain from TENS stated that they were prepared to accept the short term pain from the treatment in return for relief of dysmenorrhoea.[11]

Comment: None.

OPTION TOPICAL HEAT

One RCT found topical heat (about 39 °C) treatment to be as effective as ibuprofen and significantly more effective than placebo for pain relief.

Benefits: We found no systematic review. We found one efficacy RCT (see glossary, p 2386) (84 volunteer women with moderate or greater pain in at least four of their last six cycles who experienced pain relief with non-prescription analgesics and a history consistent with a diagnosis of primary dysmenorrhoea) of topically applied heat that used a double dummy (see glossary, p 2386) design with a heated or unheated patch and oral ibuprofen or placebo.[37] An abdominal patch (heated to 38.9 °C or unheated) was applied for about 12 hours daily for 2 days from the start of menses. In addition, oral medication (placebo or ibuprofen 400 mg) was given three times daily for 2 days. There were four treatment groups: heated patch plus placebo, heated patch plus ibuprofen, unheated patch plus placebo, and unheated patch plus ibuprofen. Pain relief was measured on a scale from 0 to 5; 0 was no relief and 5 complete relief of pain. After 2 days of treatment, significant pain relief was obtained with the heated patch plus placebo (mean pain score 3.27; $P < 0.001$), the heated patch plus ibuprofen (mean pain score 3.55; $P < 0.001$), and the unheated patch plus ibuprofen (mean pain score 3.07; $P = 0.001$) compared with the unheated patch plus placebo group (mean pain score 1.95). There was no difference in pain relief between the heated patch plus ibuprofen and the unheated patch plus ibuprofen groups ($P = 0.09$). However, the "time to noticeable pain relief" was significantly shorter for the heated patch plus placebo compared to the unheated patch plus placebo group (median 1.5 hours with heated patch plus placebo *v* 2.79 hours with unheated patch plus placebo; $P = 0.01$; no further data were provided).

Harms: The RCT found that women with a heated patch were more likely to report pinkness or redness of the skin than those with an unheated patch at the end of day 2 after women had used the patch for 12 continuous hours (23/40 [58%] with a heated patch *v* 5/41 [12%] with an unheated patch; OR 9.74, 95% CI 3.16 to 30.04). All women reported normal skin 3–7 days after starting treatment.

Comment: Participants in the RCT included volunteer women. Disease in these women may have a different pattern and response to treatment than disease in women seeking health care.

OPTION SURGICAL TREATMENTS

One small RCT found limited evidence suggesting that laparoscopic uterine nerve ablation increased pain relief compared with diagnostic laparoscopy. Another RCT found that laparoscopic uterine nerve ablation reduced pain at 12 months compared with laparoscopic presacral neurectomy but found no significant difference in pain relief between treatments at 3 months. It also found increased constipation with laparoscopic uterine nerve ablation.

Benefits: We found one systematic review (search date 1998, 6 RCTs) of surgical pelvic nerve interruption for primary and secondary dysmenorrhoea.[38] Only two of the six RCTs included women with

primary dysmenorrhoea. Meta-analysis was not performed because of RCT heterogeneity. One RCT identified by the review (21 women) compared laparoscopic uterine nerve ablation (see glossary, p 2387) with diagnostic laparoscopy and found that LUNA significantly increased pain relief at 3 months (OR 15.5, 95% CI 2.9 to 83.0) and at 12 months (OR 10.9, 95% CI 1.5 to 77.0). The other RCT (68 women) found no significant difference between LUNA and laparoscopic presacral neurectomy (see glossary, p 2386) in pain relief at 3 months' follow up (OR 0.7, 95% CI 0.2 to 2.7). However, at 12 months' follow up, the LPSN group had significantly better pain relief scores (OR 0.26, 95% CI 0.10 to 0.71).[38]

Harms: One RCT identified by the review found that LPSN versus LUNA increased constipation (31/33 [94%] with LPSN *v* 0/35 [0%] with LUNA; RR 0.01, 95% CI 0 to 0.24).[38]

Comment: Two larger RCTs of LUNA are underway, and data will be included in an update of the systematic review (Proctor M, personal communication, 2002).[39] We found a second relevant systematic review but we have not included it because it includes lower levels of evidence, such as case studies.[40]

GLOSSARY

Behavioural interventions Treatments that attempt modification of thought and beliefs (cognition) about symptoms and pain, modification of behavioural or physiological responses to symptoms, pain, or both.

Co-proxamol Non-proprietary label for a dextropropoxyphene hydrochloride and paracetamol combination. The most common presentation is tablets containing dextropropoxyphene hydrochloride 32.5 mg and paracetamol 325 mg.

Double dummy Design pertaining to an RCT in which multiple treatments are compared (usually against a placebo) and the treatments have dissimilar presentation. Each participant will receive either active treatment or placebo for each treatment. Because multiple treatments are being compared (at least two), it allows identification of treatment effects against placebo as well as the additive effects of treatments.

Efficacy trial A trial designed to study if an intervention works in ideal conditions (e.g. when people receive treatments exactly as prescribed). In contrast, effectiveness trials evaluate the effects of treatments in "real life" conditions. Analysis in efficacy trials usually involves only the participants who had full compliance with the therapeutic scheme. The applicability of the results from efficacy trials may be limited because conditions were artificial and hence response may be different in real life situations.

High velocity, low amplitude manipulation (HVLA) A technique of spinal manipulation that uses high velocity, low amplitude thrusts to manipulate vertebral joints. The technique is designed to restore motion to a restricted joint and improve function. The physician positions the person at the barrier of restricted motion and then gives a rapid, accurate thrust in the direction of the restricted barrier to resolve the restriction and improve motion.

Laparoscopic presacral neurectomy (LPSN) Involves the total removal of the presacral nerves lying within the boundaries of the interiliac triangle. This procedure interrupts most of the cervical sensory nerve fibres and is used to diminish uterine pain.

Laparoscopic uterine nerve ablation (LUNA) Involves laparoscopic surgery to transect (usually they are cut and then electrocauterised) the uterosacral ligaments at their insertion into the cervix. This procedure interrupts most of the cervical sensory nerve fibres and is used to diminish uterine pain.

Placebo acupuncture Also known as sham acupuncture, a commonly used control intervention involving the use of acupuncture needles to stimulate non-acupuncture points in areas outside of Chinese meridians. These points can be identified by a point detector as areas of the skin that do not have skin electrical activity similar to acupuncture points. There is some disagreement over correct needle placement, as placement of a needle in any position may elicit some biological response that can complicate interpretation of results.

Placebo manipulation Also known as sham manipulation, it is a control intervention. The main principle is to use a non-therapeutic level of torque. There are two common techniques for placebo manipulation. In one, thrust is administered but the posture of the participant is such that the mechanical torque of the manipulation is substantially reduced. In the other, an activator adjusting tool is used, which can make spinal adjustments using spring recoil, where the spring is set so no force is exerted in the spine.

Toftness manipulation A low force technique of chiropractic adjusting that uses a sensometer to detect sites of abnormal electromagnetic radiation, and to determine which sites to adjust. Adjustment is then delivered using a metered, handheld pressure applicator.

Transcutaneous electrical nerve stimulation (TENS) Electrodes are placed on the skin and different electrical pulse rates and intensities are used to stimulate the area. Low frequency TENS (also referred to as acupuncture-like TENS) usually consists of pulses delivered at 1–4 Hz at high intensity so they evoke visible muscle fibre contractions. High frequency TENS (conventional TENS) usually consists of pulses delivered at 50–120 Hz at a low intensity, so there are no muscle contractions.

Visual analogue scale A commonly used scale in pain assessment. It is a 10 cm horizontal or vertical line with word anchors at each end, such as "no pain" and "pain as bad as it could be". The person is asked to make a mark on the line to represent pain intensity. This mark is converted to distance in millimetres from the "no pain" anchor to give a pain score that can range from 0–100.

Spasmodic dysmenorrhoea Spasms of acute pain that typically begin on the first day of menstruation.[41]

Congestive dysmenorrhoea A dull aching pain in the lower abdomen as well as other areas of the body that may begin several days before menstruation and can include other premenstrual symptoms such as irritability.[41]

TABLE 1 **Prevalence of dysmenorrhoea: results of community and hospital surveys (see text, p 2371).[3–8]**

Study population	Population size	Location	Year	Prevalence
College students aged 17–19 years[3]	165	USA	1996	72% (13% severe)
High school students aged 14–21 years[4]	291	Canada	1997	93% (5% severe)
Adolescents attending an inner city family planning clinic[5]	308	USA	1992	80% (18% severe)
Women from an urban population aged 19 years[6]	596	Sweden	1982	73% (15% severe)
Students aged 12–24 years[7]	1066	Mexico	1998	52–64%
Adolescents aged 12–17 years[8]	2699	USA	1981	60% (14% severe)

TABLE 2 **Effects of aspirin, paracetamol, and compound analgesics for dysmenorrhoea: results of a systematic review (see text, p 2373).[13]**

Comparison	Usual dosage	Number of RCTs	Number of women	Pain relief	Adverse effects	Conclusion
Aspirin *v* placebo	650 mg four times daily	8	486	RR 1.60 (95% CI 1.12 to 2.29)	More frequent on aspirin (7–17% *v* 3–17% on placebo; RR 1.3, 95% CI 0.79 to 2.17)	Aspirin more effective than placebo (NNT 10, 95% CI 5 to 50)
Aspirin *v* paracetamol	650 mg *v* 500 mg four times daily	1	35	Median pain relief: paracetamol 1.6 (95% CI 0.4 to 3.3); aspirin 1.2 (95% CI 0 to 2.7)	NA	No significant difference
Aspirin *v* naproxen	650 mg *v* 275 mg four times daily	1	32	RR 2.29 (95% CI 1.09 to 4.79)	NA	Naproxen more effective than aspirin
Aspirin *v* ibuprofen	650 mg *v* 400 mg four times daily	1	56	RR 1.9 (95% CI 1.13 to 2.78)	NA	Ibuprofen more effective than placebo
Paracetamol *v* placebo	500 mg four times daily	1	35	RR 1.00 (95% CI 0.28 to 3.63)	No significant difference (RR 1.00, 95% CI 0.36 to 2.75)	No significant difference
Paracetamol *v* ibuprofen	1000 mg *v* 400 mg three times daily	1	67	RR 0.86 (95% CI 0.68 to 1.10)	NA	No significant difference
Co-proxamol *v* placebo	650 mg/65 mg four times daily	1	72	RR 3.72 (95% CI 2.13 to 6.52)	NA	Co-proxamol more effective than placebo
Co-proxamol *v* naproxen	650 mg/65 mg *v* 275 mg three times daily	2	98	$P > 0.05$ (no other data could be obtained from the report)	More frequent on co-proxamol (23–58% *v* 15–25% on naproxen; RR 1.94, 95% CI 1.11 to 3.41)	No significant difference
Co-proxamol *v* mefenamic acid	650 mg/65 mg *v* 500 mg three times daily	1	30	$P < 0.01$ (no other evidence can be obtained from the trial)	NA	Mefenamic acid more effective than co-proxamol

Subfertility in women with endometriosis (see infertility and subfertility, p 2427)

Key Messages

- We found no RCTs comparing medical versus surgical treatments.
- **Hormonal treatment at diagnosis (combined oral contraceptives, medroxyprogesterone)** RCTs have found that hormonal treatments at diagnosis (except for dydrogesterone) reduce pain attributed to endometriosis over 3–6 months of treatment and are all similarly effective. One systematic review found that combined low dose oral contraceptives reduced dysmenorrhoea compared with goserelin during 6 months of treatment, but all women improved 6 months after stopping treatment. Two RCTs found no significant difference in overall pain relief between combined oral contraceptives and gonadorelin analogues. Adverse effects of hormonal treatments are common. One RCT found that combined oral contraceptives are associated with less hot flushes, insomnia and vaginal dryness than gonadorelin analogues.

Endometriosis

- **Combined laparoscopic ablation of endometrial deposits and uterine nerve** One RCT found limited evidence that laparoscopic ablation of deposits plus laparoscopic uterine nerve ablation reduced pain at 6 months compared with diagnostic laparoscopy, and that pain reduction persisted for up to 5 years in more than 50% of the women. One systematic review of two small RCTs provided insufficient evidence to compare laparoscopic ablation of endometrial deposits plus laparoscopic uterine nerve ablation versus laparoscopic ablation alone.
- **Hormonal treatment after conservative surgery** RCTs have found that, compared with placebo or expectant management, hormonal treatment with danazol or gonadorelin analogues for 6 months after surgery reduces pain and delays the recurrence of pain at 12 and 24 months. Treatment for 3 months or treatment with combined oral contraceptives for 6 months does not seem to be effective. Adverse effects of hormonal treatment are common and include hot flushes and bone loss with gonadorelin analogues and androgenic adverse effects with danazol.
- **Laparoscopic cystectomy for ovarian endometrioma** One RCT found that laparoscopic cystectomy reduced pain caused by ovarian endometrioma at 2 years compared with laparoscopic drainage. Complication rates were similar.
- **Hormonal treatment at diagnosis (danazol, gestrinone, gonadorelin analogues)** RCTs have found that hormonal treatments at diagnosis (except for dydrogesterone) reduce pain attributed to endometriosis over 3–6 months of treatment and are all similarly effective. Adverse effects of hormonal treatments are common and include hot flushes and bone loss with gonadorelin analogues or gestrinone and androgenic adverse effects with danazol.
- **Hormonal treatment after oophorectomy** One RCT in women who previously had an oophorectomy found insufficient evidence on the effects of hormone replacement therapy in recurrence of endometriosis compared with no treatment.
- **Hormonal treatment at diagnosis (dydrogesterone)** One small RCT provided insufficient evidence to compare dydrogesterone versus placebo.
- **Hormonal treatment before surgery** Two RCTs provided insufficient evidence on the effects of hormonal treatment before surgery in women with pain attributed to endometriosis.
- **Laparoscopic ablation of endometrial deposits alone** We found no RCTs comparing laparoscopic ablation of endometrial deposits alone versus diagnostic laparoscopy or no treatment in women with pain attributed to endometriosis. One systematic review of two small RCTs provided insufficient evidence to compare laparoscopic ablation alone versus laparoscopic ablation of endometrial deposits plus laparoscopic uterine nerve ablation.
- **Laparoscopic uterine nerve ablation (LUNA) alone** We found no RCTs evaluating LUNA alone in women with pain attributed to endometriosis.

DEFINITION Endometriosis is characterised by ectopic endometrial tissue, which can causes dysmenorrhoea, dyspareunia, non-cyclical pelvic pain, and subfertility. Diagnosis is made by laparoscopy. Most endometrial deposits are found in the pelvis (ovaries, peritoneum, uterosacral ligaments, pouch of Douglas, and rectovaginal septum). Extrapelvic deposits, including those in the umbilicus and diaphragm, are rare. Severity of endometriosis (see glossary, p 2402) is defined by the American Fertility Society: this review uses the terms mild (stage I and II), moderate (stage III), and severe (stage IV).[1] Endometriomas are cysts of endometriosis within the ovary.

This review assesses dysmenorrhoea, dyspareunia, and non-cyclical pelvic pain associated with endometriosis. For subfertility associated with endometriosis see infertility and subfertility, p 2427.

INCIDENCE/ PREVALENCE In asymptomatic women, the prevalence of endometriosis is 2–22%, depending on the diagnostic criteria used and the populations studied.[2–5] In women with dysmenorrhoea, the incidence of endometriosis is 40–60%, and in women with subfertility is 20–30%.[3,6,7] The severity of symptoms and the probability of diagnosis increase with age.[8] Incidence peaks at about 40 years of age.[9] Symptoms and laparoscopic appearance do not always correlate.[10]

AETIOLOGY/ RISK FACTORS The cause of endometriosis is unknown. Risk factors include early menarche and late menopause. Embryonic cells may give rise to deposits in the umbilicus, whereas retrograde menstruation may deposit endometrial cells in the diaphragm.[11,12] Use of oral contraceptives reduces the risk of endometriosis, and this protective effect persists for up to 1 year after their discontinuation.[9]

PROGNOSIS We found two RCTs in which laparoscopy was repeated after treatment in women given placebo.[13,14] Over 6–12 months, endometrial deposits resolved spontaneously in up to a third of women, deteriorated in nearly half, and were unchanged in the remainder.

AIMS OF INTERVENTION To relieve pain (dysmenorrhoea, dyspareunia, and other pelvic pain), with minimal adverse effects.

OUTCOMES American Fertility Society scores for size and number of deposits;[1] recurrence rates; time between stopping treatment and recurrence; rate of adverse effects of treatment. **In women with pain:** Relief of pain, assessed by a visual analogue scale ranging from 0 to 10, and subjective improvement. **In women undergoing surgery:** Ease of surgical intervention (rated by the surgeon as easy, average, difficult, or very difficult).[15]

METHODS *Clinical Evidence* search and appraisal July 2003. The author also sought RCTs by electronic searching of databases, hand searching of 30 key journals, searching the reference lists of other RCTs, and identifying unpublished studies from abstracts, proceedings, and pharmaceutical companies. She used the search strategy and database of the Cochrane Menstrual Disorders and Subfertility Group, updated on a monthly basis, to identify RCTs on Medline and Embase. She included RCTs that used adequate diagnostic criteria for inclusion of participants (endometriosis diagnosed either by laparoscopy or laparotomy in association with dysmenorrhoea, dyspareunia, other pelvic pain, or infertility) and clinical outcomes (see outcomes above). Trials comparing different hormonal treatments of the same class were not assessed.

QUESTION What are the effects of hormonal treatments given at diagnosis?

OPTION HORMONAL TREATMENTS AT DIAGNOSIS

RCTs have found that hormonal treatments at diagnosis (combined oral contraceptives, danazol, gestrinone, gonadorelin analogues, or medroxyprogesterone acetate) reduce pain attributed to endometriosis over 3–6 months of treatment and are all similarly effective. One small RCT provided insufficient evidence to compare dydrogesterone with placebo. One systematic review found that combined low dose oral contraceptive reduced dysmenorrhoea compared with goserelin during 6 months of treatment, but all women improved 6 months after stopping treatment. Two RCTs found no significant difference in overall pain relief between gonadorelin analogues and combined oral contraceptives. Adverse effects of hormonal treatments are common and include hot flushes and bone loss with gonadorelin analogues or gestrinone and androgenic adverse effects with danazol. One RCT found that combined oral contraceptives are associated with less hot flushes, insomnia and vaginal dryness than gonadorelin analogues.

Benefits: We found four systematic reviews (search dates 1998,[16] 2000,[17] and 2001[18,19]) of 6 months of continuous ovulation suppression (using combined oral contraceptives, danazol, gestrinone, gonadorelin analogues, or medroxyprogesterone acetate). The reviews found that all treatments were similarly effective in reducing severe and moderate (see glossary, p 2402) pain at 6 months. **Versus placebo or no treatment:** Three RCTs (155 women) identified by the reviews[16–19] found that danazol, gonadorelin analogues, and medroxyprogesterone acetate all significantly reduced pain at 3–6 months compared with placebo (see table 1, p 2405). One RCT (59 women) identified by the second review[17] compared three interventions: dydrogesterone, medroxyprogesterone acetate, and placebo. It found no significant difference between dydrogesterone and placebo in the proportion of woman who had pain relief but it may have been underpowered to detect a clinically important difference. Additional placebo-controlled RCTs found that, in women who received 12 months of leuprolide (a gonadorelin agonist) or norethisterone (a progestogen) with or without oestrogen, pain relief was maintained for the duration of treatment and up to 8 months after treatment was stopped.[20,21] **Combined oral contraceptives versus gonadorelin analogues:** The fourth review[19] (1 RCT,[22] 57 women with laparoscopically diagnosed endometriosis and moderate or severe pain) found that cyclic low dose monophasic combined oral contraceptive was significantly more effective for relief of dysmenorrhoea than goserelin (3.6 mg subcutaneous depot formulation monthly for 6 months of treatment; 21/24 [88%] with combined oral contraceptive *v* 0/25 [0%] with goserelin; OR 33.1, 95% CI 10.8 to 101.0).[19] After 6 months of follow up without treatment, all women improved (24/24 [100%] with combined oral contraceptive *v* 25/25 [100%] with goserelin). The review found no significant difference between combined cyclic low dose monophasic oral contraceptives and goserelin in the relief of dyspareunia or non-menstrual pain at the end of 6 months of treatment (OR 0.93,

95% CI 0.25 to 3.53).[19] One subsequent RCT (102 women) compared combined oral contraceptive for 12 months versus combined oral contraceptive for 4 months plus gonadorelin analogues for 8 months.[23] It found no difference in the proportion of women with pain (either menstrual or non-menstrual) at 12 months (menstrual pain: 14/47 [29.8%] with combined oral contraceptive *v* 16/55 [29.1%] with combined oral contraceptive + gonadorelin analogues; non-menstrual pain: 15/47 [31.9%] with combined oral contraceptive *v* 17/55 [30.9%] with combined oral contraceptive + gonadorelin analogues; reported as non-significant, CI not reported). **Danazol versus gestrinone:** The second review identified one RCT (269 women) comparing danazol 200 mg daily versus gestrinone 2.5 mg twice weekly.[24] It found no significant difference in dysmenorrhoea over 6 months of treatment between danazol and gestrinone (reported as non-significant, results presented graphically), although both groups significantly improved from baseline ($P < 0.001$). **Danazol versus gonadorelin analogues:** The first systematic review identified 15 RCTs (1299 women) comparing gonadorelin analogues versus danazol.[16] After 6 months of treatment, the review found no significant difference in menstrual pain (5 RCTs, 386 women; RR 1.09, 95% CI 0.99 to 1.20), dyspareunia (6 RCTs, 476 women; RR 0.98, 95% CI 0.93 to 1.02), or resolution of endometrial deposits (3 RCTs, 426 women; RR 0.84, 95% CI 0.56 to 1.26).[16] **Gestrinone versus gonadorelin analogues:** One RCT identified by the second systematic review[17] found that both gestrinone and gonadorelin analogues significantly reduced all types of pain from baseline over 3 months. It found that gestrinone modestly, but significantly, reduced dyspareunia after 6 months' treatment compared with gonadorelin analogues (measured by a visual analogue scale: WMD −1.16, 95% CI −2.08 to −0.24), but gonadorelin analogues significantly reduced dysmenorrhoea (WMD 0.82, 95% CI 0.15 to 1.49). It found no significant difference in non-menstrual pain between gestrinone and gonadorelin analogues (WMD −0.41, 95% CI −1.76 to +0.94). **Medroxyprogesterone acetate versus combined oral contraceptives plus danazol:** One RCT (80 women) identified by the second review[17] compared medroxyprogesterone acetate (150 mg every 3 months) versus combined oral contraceptive plus danazol 50 mg daily. It found that medroxyprogesterone acetate was more effective at reducing dysmenorrhoea, but not dyspareunia or non-menstrual pain (CI not reported). **Medroxyprogesterone acetate versus gonadorelin analogues:** We found one RCT (double blind; 48 women with endometriosis treated for 6 months and followed for 1 year after allocation) that compared medroxyprogesterone versus gonadorelin analogues.[25] It found that either treatment significantly improved symptoms attributable to endometriosis, sleep disturbances and anxiety–depression scores from baseline measurements ($P < 0.05$ for all outcomes). It found no significant difference between treatments (reported as non-significant, CI not reported).

Harms:

Versus placebo or no treatment: One review found that gonadorelin analogues were associated with more hot flushes than placebo (about 80% with gonadorelin analogues *v* 30% with placebo; RR 2.7, 95% CI 1.5 to 4.8) and more headaches (33%

gonadorelin analogues *v* 10% with placebo; RR 3.6, 95% CI 1.1 to 11.5).[16] Gonadorelin analogues are associated with hypo-oestrogenic symptoms, such as hot flushes and vaginal dryness. RCTs have found that adding oestrogen, progestogens, or tibolone significantly relieves hot flushes caused by gonadorelin analogues (reducing symptom scores by 50% or more).[20,21,26–28] In one RCT comparing 6 months of danazol 100 mg daily after surgery versus no treatment, danazol was associated with more adverse effects: spotting (12% with danazol *v* 7% with no treatment), bloating (16% with danazol *v* 9% with no treatment), headache (21% with danazol *v* 13% with no treatment), and weight gain (22% with danazol *v* 14% with no treatment) (see hormonal treatment after surgery, p 2399).[29] **Combined oral contraceptives versus gonadorelin analogues:** The fourth review found that, compared with combined oral contraceptives, women receiving goserelin (a gonadorelin analogue) reported a significantly higher incidence of hot flushes (1 RCT; 1/28 v 24/29; OR 0.04, 95% CI 0.02 to 0.12), insomnia (1 RCT; 0/28 [0%] with combined oral contraceptives *v* 7/29 [24%] with goserelin; OR 0.11, 95% CI 0.02 to 0.53) and vaginal dryness (0/28 [0%] with combined oral contraceptives *v* 5/29 [17%] with goserelin; OR 0.12, 95% CI 0.02 to 0.74).[19] **Danazol versus gestrinone:** RCTs identified by the second review found greater frequency of greasy skin and hirsutism with gestrinone than with danazol, but less reduction in breast size, muscle cramps, and hunger.[17] **Gestrinone versus gonadorelin analogues:** One RCT identified by the second systematic review[17] found a significantly higher frequency of hot flushes with gestrinone compared with gonadorelin analogues. **Medroxyprogesterone versus combined oral contraceptives plus danazol:** One RCT (80 women) found that women taking medroxyprogesterone had more bloating (OR 4.04, 95% CI 1.68 to 9.70) and spotting (OR 16.3, 95% CI 6.8 to 39.2) than women taking combined oral contraceptives plus danazol.[17] One RCT (28 women with previous laparoscopic surgery) found more adverse events with medroxyprogesterone acetate compared with combined oral contraceptives plus danazol: amenorrhoea (20% with medroxyprogesterone acetate *v* 0% with combined oral contraceptives plus danazol), breakthrough bleeding (15% with medroxyprogesterone acetate *v* 0% with combined oral contraceptives plus danazol), bloating (63% with medroxyprogesterone acetate *v* 28% with combined oral contraceptives plus danazol), and weight gain (53% with medroxyprogesterone acetate *v* 30% with combined oral contraceptives plus danazol).[29] **Medroxyprogesterone acetate versus gonadorelin analogues:** The RCT gave no information on adverse effects.[25]

Comment: The RCTs were mainly small with no long term follow up. The RCT addressing quality of life had high withdrawal rates (18/48 [38%]).[25] One RCT suggested that bone loss associated with prolonged use of gonadorelin analogue (12 months) may be prevented by using norethisterone with or without oestrogen.[21]

QUESTION **What are the effects of hormonal treatments before surgery?**

OPTION **PREOPERATIVE HORMONAL TREATMENT**

Two RCTs provided insufficient evidence on the effects of hormonal treatment before surgery in women with pain attributed to endometriosis.

Benefits: We found no systematic review but found two RCTs comparing treatment with a gonadorelin analogue before surgery versus no treatment.[15,30] The first RCT (75 women with moderate or severe (see glossary, p 2402) endometriosis) compared 6 months of nafarelin before surgery versus surgery plus 6 months of nafarelin.[15] It found that 6 months of nafarelin 200 μg before surgery significantly reduced symptom scores compared with 6 months of nafarelin after surgery (mean score 0 with nafarelin before surgery *v* 6 with nafarelin after surgery; P = 0.007).[15] It found no significant difference in ease of surgery as assessed by the surgeon (proportion of women judged easy to treat: 14/25 [56%] with nafarelin before surgery *v* 10/28 [36%] with no treatment before surgery; RR 1.60, 95% CI 0.86 to 2.90).[15] The second RCT (48 women with moderate or severe endometriosis) found similar symptoms at 6 months after surgery between 3 months of treatment with goserelin before surgery and no treatment before surgery.[30] It also found no significant difference in the proportion of women whose surgery was rated as "moderately" or "very" difficult (14/20 [70%] with goserelin before surgery *v* 20/27 [74%] with no treatment before surgery; RR 0.94, 95% CI 0.60 to 1.50).

Harms: The first RCT found that nafarelin was associated with hot flushes (96% with nafarelin before surgery *v* 92% with nafarelin after surgery), vaginal dryness (43% with nafarelin before surgery *v* 32% with nafarelin after surgery), and decreased libido (36% with nafarelin before surgery *v* 36% with nafarelin after surgery).[15] In the second RCT, adverse events were also experienced frequently both in women receiving gonadorelin analogues before surgery and in women receiving no treatment (at least one adverse event: 18/21 [86%] with gonadorelin analogue *v* 21/27 [78%] with no treatment; RR 1.1, 95% CI 0.8 to 1.4).[30] The most frequently reported adverse effects were hot flushes and headaches, and these happened only in women receiving gonadorelin analogue (hot flushes 13/21 [62%], headaches 6/21 [29%]). See also harms of hormonal treatments, p 2394.

Comment: The trial may have been too small to exclude a clinically important effect.

QUESTION **What are the effects of surgical treatments?**

OPTION **LAPAROSCOPIC ABLATION OF ENDOMETRIAL DEPOSITS**

We found no RCTs evaluating laparoscopic ablation of endometrial deposits alone. One RCT found limited evidence that ablation of deposits plus laparoscopic uterine nerve ablation reduced pain at 6 months

compared with diagnostic laparoscopy, and that pain reduction persisted for up to 5 years in more than half of the women. One systematic review of two small RCTs provided insufficient evidence to compare laparoscopic ablation of endometrial deposits plus laparoscopic uterine nerve ablation versus laparoscopic ablation alone.

Benefits: We found no RCTs evaluating laparoscopic ablation of endometrial deposits (see glossary, p 2402) alone in women with pain attributed to endometriosis. **Plus laparoscopic uterine nerve ablation (LUNA):** We found two systematic reviews of laparoscopic ablation of endometrial deposits plus LUNA (see glossary, p 2402).[31,32] The first review (search date 1999) identified one RCT (63 women with mild to moderate (see glossary, p 2402) endometriosis) comparing laparoscopic ablation of deposits plus LUNA versus diagnostic laparoscopy.[31,33,34] The RCT found that ablation plus LUNA significantly reduced pain at 6 months[31] (median decrease in pain score on a visual analogue scale: 2.85 with ablation *v* 0.05 with diagnostic laparoscopy; P = 0.01). Follow up of the RCT suggested that 90% of the women who responded continued to have pain improvement at 1 year,[33] and 55% at 5 years.[34] The second review (search date 1998) identified two RCTs (132 women with mild to severe endometriosis; age range 18–40 years) comparing laparoscopic ablation plus LUNA versus laparoscopic ablation alone.[32] The RCTs found no clinically important difference in pain relief at 6–9 months after laparoscopic ablation plus LUNA and laparoscopic ablation alone (pain measured by a visual analogue scale; P = 0.12 in one RCT, CI not reported in the other). The largest RCT (81 women) identified by the review found that satisfaction with treatment was high in both groups (73% with control *v* 68% with laparoscopic uterine nerve ablation). **Laser versus diathermy ablation:** We found no RCTs.

Harms: The RCT identified by the second review reported no complications in women receiving laparoscopic ablation or LUNA.[31] The RCTs identified by the second review gave no information on adverse effects.[32] Potential harms of laparoscopic ablation include adhesions, reduced fertility, and damage to other pelvic structures.

Comment: The RCTs included in the review may have been underpowered to exclude a clinically important difference in outcomes.[32] Further trials are needed. An RCT of LUNA is underway in Auckland, New Zealand. One hundred and ten women were randomised and 12 months of follow up data were due by the end of 2003 (Farquhar C, personal communication, 2003).

OPTION LAPAROSCOPIC UTERINE NERVE ABLATION (LUNA)

We found no RCTs evaluating laparoscopic uterine nerve ablation alone. One RCT found limited evidence that laparoscopic uterine nerve ablation plus laparoscopic ablation of endometrial deposits reduced pain at 6 months compared with diagnostic laparoscopy, and that pain reduction persisted for several years in more than half the women. One systematic review of two small RCTs provided insufficient evidence to compare laparoscopic uterine nerve ablation plus laparoscopic ablation of endometrial deposits versus laparoscopic ablation alone.

Benefits: We found no RCTs evaluating laparoscopic uterine nerve ablation (see glossary, p 2402) alone in women with pain attributed to endometriosis. **Plus laparoscopic ablation of endometrial deposits:** See benefits of laparoscopic ablation of endometrial deposits, p 2399.

Harms: Potential harms of laparoscopic uterine nerve ablation include denervation of pelvic structures and uterine prolapse (see harms of laparoscopic ablation of endometrial deposits, p 2399).

Comment: None.

QUESTION What are the effects of hormonal treatment after conservative surgery?

OPTION HORMONAL TREATMENTS AFTER CONSERVATIVE SURGERY

RCTs have found that, compared with placebo or expectant management, 6 months of hormonal treatment with danazol or gonadorelin analogues after surgery reduces pain and delays the recurrence of pain at 12 and 24 months. Treatment for 3 months with danazol or gonadorelin analogues or treatment with combined oral contraceptives for 6 months does not seem to be effective. One RCT found that cyproterone acetate and combined oral contraceptives were similarly effective in women with modest and severe pain. Adverse effects of hormonal treatment are common and include hot flushes and bone loss with gonadorelin analogues and androgenic adverse effects with danazol.

Benefits: We found no systematic review. We found eight RCTs.[29,35–41] Four RCTs found that 6 months of treatment with danazol, medroxyprogesterone acetate or gonadorelin analogues after laparoscopic conservative surgery (see glossary, p 2402) significantly reduced pain over 1–2 years compared with placebo or expectant management. However, three RCTs found no significant difference in pain relief if treatment was given for 3 months. One RCT found no significant difference between 6 months of treatment with a monophasic combined oral contraceptive and placebo in pain at 22 months. **Combined oral contraceptive versus placebo for 6 months:** One RCT (70 women who had had laparoscopic conservative surgery) comparing combined contraceptives after surgery versus placebo for 6 months found no significant difference in pain associated with endometriosis (mean follow up 22 months; recurrences 2/33 [6%] with oral contraceptives *v* 1/35 [3%] with no treatment; RR 2.1, 95% CI 0.2 to 22.3).[40] The RCT may have been underpowered to detect a clinically important difference. **Danazol versus placebo or versus expectant management for 6 months:** We found two RCTs.[29,37] The first RCT (28 women with moderate (see glossary, p 2402) endometriosis who had had conservative surgery followed by monthly injections of decapeptyl for 6 months) compared danazol 100 mg daily for 6 months versus expectant management.[29] It found that danazol significantly reduced pain at both 12 months ($P < 0.01$) and 24 months ($P < 0.05$). Overall, recurrence at 24 months was 44% with danazol compared with 67% with expectant management ($P < 0.05$). The

second RCT (60 women with mild to severe endometriosis who had undergone conservative surgery) compared three interventions: danazol 600 mg daily, medroxyprogesterone 100 mg daily, or placebo for 180 days after surgery. It found that danazol significantly reduced pain compared with placebo at 6 months (absolute results presented graphically; $P < 0.05$).[37] **Danazol versus placebo for 3 months:** One RCT (77 women with moderate to severe endometriosis who had had laparoscopic conservative surgery) compared danazol 600 mg daily after surgery versus placebo for 3 months.[36] It found no significant difference in pain relief 6 months after finishing treatment (moderate to severe pain: 7/31 [23%] with danazol *v* 9/29 [31%] with no treatment; RR 0.73, 95% CI 0.31 to 1.70). **Gonadorelin (gonadotrophin releasing hormone) analogues versus placebo or expectant management for 6 months:** We found two RCTs.[38,39] The first RCT (109 women with mild to moderate symptomatic endometriosis who had had laparoscopic conservative surgery) found that nafarelin 200 μg twice daily after surgery significantly reduced pain after 6 months of treatment compared with placebo ($P = 0.001$).[38] The second RCT (269 women with mild to moderate symptomatic endometriosis who had had laparoscopic conservative surgery) compared 6 months of open label allocation of 3.6 mg of subcutaneous goserelin versus expectant management with 2 years of follow up.[39] It found that goserelin significantly reduced pain scores over 2 years ($P = 0.008$) and delayed the recurrence of pain by more than 12 months.[39] **Gonadorelin analogues versus placebo or expectant management for 3 months:** We found two RCTs.[35,41] The first RCT (75 women with mild to moderate endometriosis who had had laparotomy) compared nafarelin after surgery versus placebo for 3 months.[35] It found no significant difference in pain at 12 months (assessed by a visual analogue scale: 7.0 with nafarelin *v* 6.9 with placebo; reported as non-significant, CI not reported).[35] The second RCT (89 women with moderate to severe endometriosis who had had laparoscopic conservative surgery) compared monthly intramuscular leuprolide acetate depot injections after surgery for 3 months versus expectant management with 36 months of follow up.[41] It found no significant difference in pain (moderate to severe pain recurrence during follow up, 10/44 [23%] with leuprolide acetate *v* 11/45 [24%] with expectant management; cumulative pain recurrence rates at 18 months, 23% with leuprolide acetate *v* 29% with no treatment; log rank test not significant). **Medroxyprogesterone acetate versus placebo for 6 months:** We found one RCT (60 women with mild to severe endometriosis who had undergone conservative surgery) comparing three interventions: medroxyprogesterone 100 mg daily, danazol 600 mg daily, or placebo for 180 days after surgery. It found that medroxyprogesterone significantly reduced pain compared with placebo at 6 months (absolute results presented graphically; $P < 0.05$).[37] **Cyproterone acetate versus combined oral contraceptive:** One RCT (open label, 90 women with recurrent pelvic pain of more than 6 months of duration after complete surgical eradication of endometriosis) compared low dose continuous cyproterone acetate after surgery versus a continuous monophasic combined oral contraceptive.[42] It found that both treatments were similarly effective in

women with modest and severe pain. It found no significant difference between treatments in the proportion of women who were satisfied with treatment (33/45 [73%] with cyproterone acetate *v* 30/45 [67%] with oral contraceptive; RR 1.1, 95% CI 0.8 to 1.4).

Harms: See harms of hormonal treatments, p 2394.

Comment: The RCTs were mainly small with no long term follow up.

QUESTION **What are the effects of hormonal treatment after oophorectomy (with or without hysterectomy)?**

OPTION **HORMONAL TREATMENTS AFTER OOPHORECTOMY**

One RCT in women who previously had an oophorectomy found insufficient evidence on the effects of hormone replacement therapy compared with no treatment.

Benefits: We found no systematic review. We found one RCT (172 women who previously had bilateral salpingo-oophorectomy 91.8% of whom had total abdominal hysterectomy (see glossary, p 2402)) comparing hormone replacement therapy (HRT; 115 women) versus no treatment (57 women).[43] HRT consisted of two weekly 1.5 mg oestradiol patches and 200 mg daily of micronised progesterone given orally during 14 days followed by a 16 day interval free of treatment. HRT was started 4 weeks after the salpingo-oophorectomy. It found no significant difference in recurrence rates at a mean of 45 months (0/57 [0%] without HRT *v* 4/115 [4%] with HRT; ARI +3.5%, 95% CI –3.2% to +8.6%). The risk factors for recurrence were women who had endometriotic peritoneal involvement > 3 cm (2.4% recurrence a year with HRT *v* 0.3% with no HRT) and incomplete hysterectomy (22.2% with HRT *v* 1.9% with no HRT).

Harms: The RCT found that surgical re-interventions were more frequent with HRT but this difference was not significant (2.6% with HRT *v* 0% with no HRT; OR 4.5, 95% CI 0.4 to 60.0).[43]

Comment: The RCT had insufficient power to exclude clinically important differences.[43]

QUESTION **What are the effects of treatments for ovarian endometrioma?**

OPTION **LAPAROSCOPIC DRAINAGE VERSUS LAPAROSCOPIC CYSTECTOMY**

One RCT found that laparoscopic cystectomy reduced pain caused by ovarian endometrioma at 2 years compared with laparoscopic drainage. Complication rates were similar.

Benefits: We found no systematic review. We found one RCT (64 women) comparing laparoscopic cystectomy versus laparoscopic drainage (see glossary, p 2402) and coagulation.[44] **In women with pain**

attributed to endometrioma: The RCT found that cystectomy significantly reduced the recurrence of pain at 2 years (OR 0.2, 95% CI 0.1 to 0.8) and increased the pain free interval after operation compared with drainage (median interval; 19 months with cystectomy *v* 9.5 months with drainage; $P < 0.05$).[44]

Harms: The RCT reported no intraoperative or postoperative complications in either group.[44]

Comment: None.

GLOSSARY

Severity of endometriosis Determination of the stage or degree of endometrial involvement is based on the American Fertility Society Scale of weighted point scale of estimations, evaluating the degree of involvement of the peritoneum, ovaries, and fallopian tubes.[1] According to the allocated score, endometriosis is categorised as:

Mild (stage I and II) American Fertility Society score of 1–15 points
Moderate (stage III) American Fertility Society score of 16–40 points
Severe (stage IV) American Fertility Society score of > 40 points

Conservative surgery Surgery to conserve the pelvic organs.

Laparoscopic ablation of endometrial deposits A surgical procedure where a long tube with a fibre-optic telescope (the laparoscope) is inserted into a woman's abdomen to ablate (destroy) the endometrial deposits around the ovaries and uterus in order to relieve pain.

Laparoscopic cystectomy During laparoscopy the cyst wall of the endometrioma is excised or stripped.

Laparoscopic drainage During laparoscopy the endometrioma contents are drained out.

Laparoscopic uterine nerve ablation (LUNA) The cutting of nerves in the uterus to stop chronic pain. This is carried out laparoscopically through a small incision in the abdomen so the outside surface of the uterus and uterine nerves can be seen.

Total abdominal hysterectomy Open operation through the abdominal wall to remove the uterus. In some situations, this is performed in conjunction with a bilateral salpingo-oophorectomy, the removal of both ovaries and fallopian tubes.

Substantive changes

Hormonal treatment at diagnosis Evidence on harms of danazol, gestrinone, gonadorelin analogues reassessed; recategorised as tradeoff between benefits and harms.

QUESTIONS

INTERVENTIONS

MEDICAL TREATMENT ALONE

Likely to be beneficial

Gonadorelin analogues (GnRHa) plus progestogen (reduced heavy bleeding and hot flushes associated with GnRHa compared with GnRHa alone) 2412

Gonadorelin analogues (GnRHa) plus tibolone (no significant difference in fibroid symptoms compared with GnRHa alone but adding tibolone reduces hot flushes and prevents loss in bone mineral density associated with GnRHa) 2412

Trade off between benefits and harms

Gonadorelin analogues alone .2410

Unknown effectiveness

Gestrinone 2414

Gonadorelin analogue (GnRHa) plus raloxifene (insufficient evidence on effects compared with GnRHa alone 2412

Gonadorelin analogues (GnRHa) plus combined oestrogen–progestogen (insufficient evidence on effects compared with GnRHa plus progesterone) 2412

Levonorgestrel intrauterine system 2415

Mifepristone 2415

Non-steroidal anti-inflammatory drugs 2414

PREOPERATIVE MEDICAL TREATMENT

Likely to be beneficial

Gonadorelin analogues 2415

SURGICAL TREATMENTS

Beneficial

Laparoscopic myomectomy (reduces recovery time and postoperative pain compared with abdominal myomectomy) 2421

Likely to be beneficial

Laparoscopically assisted vaginal hysterectomy (reduces recovery time and postoperative pain but increases operating time and blood loss compared with total abdominal hysterectomy) . .2419

Total abdominal hysterectomy* 2417

Total laparoscopic hysterectomy (reduces postoperative fever, hospital stay, and recovery time compared with total abdominal hysterectomy) New 2421

Total vaginal hysterectomy (reduces operation time, less blood loss, pain, fever, and hospital stay compared with total abdominal hysterectomy and increases satisfaction with operation) New 2425

Unknown effectiveness

Thermal balloon endometrial ablation 2422

To be covered in future updates

Total abdominal myomectomy

Covered elsewhere in *Clinical Evidence*

Menorrhagia (many women with fibroids experience symptoms of heavy menstrual bleeding) (see menorrhagia, p 2474)

*Based on consensus. RCTs unlikely to be conducted.

See glossary, p 2423

Key Messages

Medical treatment alone

- **Gonadorelin analogues (GnRHa) plus progestogen (reduced heavy bleeding and hot flushes associated with GnRHa compared with GnRHa alone)** One small RCT found that leuprorelin (leuprolide) acetate plus progesterone reduced heavy bleeding compared with leuprorelin acetate alone, and reduced the proportion of women who had hot flushes.
- **Gonadorelin analogues plus tibolone (no significant difference in fibroid symptoms compared with GnRHa alone but adding tibolone reduces hot flushes and prevents loss in bone mineral density associated with GnRHa)** Two small RCTs found no significant difference between GnRHa alone and GnRHa plus tibolone in fibroid related symptoms or uterine and fibroid size. They found that adding tibolone reduced hot flushes, vaginal dryness, and night sweats and prevented loss in bone mineral density.
- **Gonadorelin analogues alone** RCTs have found that GnRHa reduce fibroid related symptoms compared with placebo, but are associated with important adverse effects. One RCT found that nafarelin increased amenorrhoea at 12 weeks compared with placebo. One RCT provided insufficient evidence to compare nafarelin versus buserelin. One RCT found that higher doses of nafarelin increased amenorrhoea at 16 weeks compared with lower doses. Two RCTs found that nafarelin reduced bone density from baseline after 16 weeks' treatment compared with placebo, but that bone density returned to pretreatment levels 6 months after treatment was stopped. Two RCTs found that hot flushes were more common with nafarelin than with placebo or buserelin.
- **Gonadorelin analogue plus raloxifene (insufficient evidence on effects compared with GnRHa alone)** One RCT found that adding raloxifene to GnRHa reduced fibroid size compared with GnRHa alone. It found no significant difference in fibroid related symptoms or hot flushes.
- **Gonadorelin analogues plus combined oestrogen–progestogen (insufficient evidence on effects compared with GnRHa plus progesterone)** One RCT provided insufficient evidence to compare GnRHa plus oestrogen–progestogen hormone replacement therapy versus GnRHa plus progesterone hormone replacement therapy.
- **Non-steroidal anti-inflammatory drugs** Two small RCTs provided insufficient evidence to assess non-steroidal anti-inflammatory drugs in women with fibroids.
- **Gestrinone; levonorgestrel intrauterine system; mifepristone** We found no RCTs on the effects of these interventions.

Preoperative medical treatment

- **Gonadorelin analogues** One systematic review has found that GnRHa for at least 3 months before fibroid surgery improve preoperative haemoglobin concentration and haematocrit, and reduce uterine and pelvic symptoms compared with placebo or no pretreatment. Preoperative gonadorelin also reduced blood loss and the rate of vertical incisions during laparotomy. Women

having hysterectomy were more likely to have a vaginal rather than an abdominal procedure after GnRHa pretreatment compared with placebo or no pretreatment. Another small RCT found that GnRHa combined with endometrial resection reduced the need for further treatment (either medical or surgical) over 1 year compared with GnRHa alone. However, women were more likely to experience adverse hypo-oestrogenic effects from preoperative treatment, such as hot flushes, vaginal symptoms, and sweating, and were more likely to withdraw from treatment because of adverse effects.

Surgical treatments

- **Laparoscopic myomectomy (reduces recovery time and postoperative pain compared with abdominal myomectomy)** One RCT found that laparoscopic myomectomy resulted in lower postoperative pain, and a shorter recovery time compared with abdominal myomectomy.
- **Laparoscopically assisted vaginal hysterectomy (reduces recovery time and postoperative pain but increases operating time and blood loss compared with total abdominal hysterectomy)** We found no RCTs comparing long term effects of laparoscopic assisted vaginal hysterectomy versus other treatments. Two RCTs found that women having laparoscopically assisted vaginal hysterectomy had shorter recovery times and less postoperative pain compared with women having total abdominal hysterectomy.One RCT found that women having laparoscopically assisted vaginal hysterectomy had longer operating time and more blood loss than women having total vaginal hysterectomy.
- **Total abdominal hysterectomy** We found no RCTs and an RCT is unlikely to be conducted. There is consensus that total abdominal hysterectomy is superior to no treatment in reducing fibroid related symptoms.
- **Total laparoscopic hysterectomy (reduces postoperative fever, hospital stay, and recovery time compared with total abdominal hysterectomy)** One RCT found that women having total laparoscopic hysterectomy had less postoperative fever, shorter hospital stay, and shorter recovery times compared with women having total abdominal hysterectomy.
- **Total vaginal hysterectomy (reduces operation time, less blood loss, pain, fever, and hospital stay compared with total abdominal hysterectomy and increases satisfaction with operation)** Two RCTs found that women having total vaginal hysterectomy had shorter operation time, less blood loss, pain and fever, shorter hospital stay, earlier return to work, and greater satisfaction than women having total abdominal hysterectomy. One RCT found that women having total vaginal hysterectomy had shorter operation times and less blood loss than women having laparoscopically assisted vaginal hysterectomy.
- **Thermal balloon endometrial ablation** We found no RCTs comparing thermal balloon ablation versus non-surgical treatment or hysterectomy. One RCT compared thermal balloon ablation versus rollerball endometrial ablation in women with fibroids smaller than the average size of a 12 week pregnancy, all of whom had been pretreated with gonadorelin analogues. It found no significant difference between thermal balloon and rollerball ablation in amenorrhoea rates, pictorial bleeding assessment chart score, haemoglobin, or hysterectomy rates at 12 months. It found that thermal balloon ablation reduced operation time and intraoperative complication rate compared with rollerball ablation. About one third of women reported being "not very satisfied" with either operation.

DEFINITION Fibroids (uterine leiomyomas) are benign tumours of the smooth muscle cells of the uterus. Women with fibroids can be asymptomatic or may present with menorrhagia (30%), pelvic pain with or without dysmenorrhoea or pressure symptoms (34%), infertility (27%), and recurrent pregnancy loss (3%).[1] Much of the data describing the relationship between the presence of fibroids and symptoms are based on uncontrolled studies that have assessed the effect of myomectomy (see glossary, p 2423) on the presenting symptoms.[2] The prevalence of fibroids in infertile women can be as high as 13%, but no direct causal relationship between fibroids and infertility has been established.[3]

INCIDENCE/ PREVALENCE The reported incidence of fibroids varies from 5.4–77.0% depending on the method of diagnosis (the gold standard is histological evidence). A random sample of 335 Swedish women aged 25–40 years was reported to have an incidence of fibroids of 5.4% (95% CI 3.0% to 7.8%) based on transvaginal ultrasound examination.[4] The prevalence of these tumours increased with age (age 25–32 years: 3.3%, 95% CI 0.7% to 6.0%; 33–40 years: 7.8%, 95% CI 3.6% to 12.0%).[4] Another large case control study found that the rate of fibroids was higher in women aged less than 50 years; it found a rate of pathologically confirmed fibroids of 4.24/1000 woman years in women aged 50 years or more compared with 6.20/1000 in women aged 45–50 years, 4.63/1000 in women aged 40–45 years, 2.67/1000 in women aged 35–40 years, 0.96/1000 in women aged 30–35 years and 0.31/1000 in women aged 25–30 years.[5] Based on postmortem examination, 50% of women were found to have these tumours.[6] Gross serial sectioning at 2 mm intervals of 100 consecutive hysterectomy specimens revealed the presence of fibroids in 50/68 [73%] premenopausal women and 27/32 [84%] postmenopausal women. These women were having hysterectomies for reasons other than fibroids.[7] The incidence of fibroids in black women is three times greater than that in white women, based on ultrasound or hysterectomy diagnosis.[8] Submucosal fibroids have been diagnosed in 6–34% of women having a hysteroscopy for abnormal bleeding, and in 2–7% of women having infertility investigations.[9]

AETIOLOGY/ RISK FACTORS The cause of fibroids is unknown. It is known that each fibroid is of monoclonal origin and arises independently.[10,11] Factors thought to be involved include the sex steroid hormones oestrogen and progesterone as well as the insulin-like growth factors, epidermal growth factor and transforming growth factor. Risk factors for fibroid growth include nulliparity and obesity. There is a risk reduction to a fifth with five term pregnancies, compared with nulliparous women ($P < 0.001$).[5] Obesity increases the risk of fibroid development by 21% with each 10 kg weight gain ($P = 0.008$).[5] The combined oral contraceptive pill also reduces the risk of fibroids with increasing duration of use (women who have taken oral contraceptives for 4–6 years compared with women who have never taken oral contraceptives: OR 0.8, 95% CI 0.5 to 1.2; women who have taken oral contraceptives for ≥ 7 years compared with women who have never taken oral contraceptives: OR 0.5, 95% CI 0.3 to 0.9).[12] Women

who have had injections containing 150 mg depot medroxyprogesterone acetate also have a reduced incidence compared with women who have never had injections of this drug (OR 0.44, 95% CI 0.36 to 0.55).[13]

PROGNOSIS There are few data on the long term untreated prognosis of these tumours, particularly in women who are asymptomatic at diagnosis. One small case control study reported that in a group of 106 women treated with observation alone over 1 year there was no significant change in symptoms and quality of life over that time.[14] Fibroids tend to shrink or fibrose after the menopause.[5]

AIMS OF INTERVENTION To reduce menstrual bleeding; prevent or correct iron deficiency anaemia; reduce pressure symptoms; reduce pelvic pain; and induce a change in fertility status, with minimal adverse effects.

OUTCOMES Menstrual blood flow (assessed objectively [mL/cycle] or subjectively); haemoglobin and haematocrit concentration; pelvic pain, pressure, or both (measured by a validated scale or subjective report); reduction in fibroid and uterine volume; pregnancy rate; quality of life. Some of the outcomes relate to surgery: ease of surgery as assessed by the surgeon, complication rates during and after surgery; blood loss during surgery; duration of surgery; length of hospital stay; rate of blood transfusions; probability of transverse versus vertical incisions during surgery; probability of vaginal versus abdominal hysterectomy; recurrence rate; patient satisfaction rate.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of medical treatment alone?

OPTION GONADORELIN ANALOGUES ALONE

RCTs have found that gonadorelin analogues reduce fibroid related symptoms compared with placebo, but are associated with important adverse effects. One RCT found that nafarelin increased amenorrhoea at 12 weeks compared with placebo. One RCT provided insufficient evidence to compare nafarelin versus buserelin. One RCT found that higher doses of nafarelin increased amenorrhoea at 16 weeks compared with lower doses. Two RCTs found that nafarelin reduced bone density from baseline after 16 weeks' treatment compared with placebo, but that bone density returned to pretreatment levels 6 months after treatment was stopped. Two RCTs found that hot flushes were more common with nafarelin than with placebo or buserelin.

Benefits: **Versus placebo:** We found one systematic review of nafarelin (search date 1997, 1 RCT, 101 women).[15] The RCT identified by the review found that intranasal nafarelin (200 μg twice daily) significantly increased the proportion of women with amenorrhoea at 3 months compared with placebo (33/64 [51%] women amenorrhoeic with nafarelin *v* 3/37 [8%] with placebo, $P \leq 0.05$).[15] **Versus each other:** We found one systematic review (search date 1997) that identified one RCT (211 women enrolled) comparing intranasal nafarelin (200 μg twice daily) versus intranasal buserelin (300 μg 3 times daily).[15] The RCT found that nafarelin significantly increased haemoglobin at 16 weeks compared with buserelin (haemoglobin

12.8 g/dL with nafarelin *v* 12.3 g/dL with buserelin; P = 0.03). However, the RCT did not describe the clinical importance of this difference. **Different doses:** We found one systematic review (search date 1997) that identified one RCT (257 women) comparing different doses of nafarelin (50, 100, 200, and 400 μg twice daily).[15] The RCT found that higher doses of nafarelin significantly increased the proportion of women who were amenorrhoeic at 16 weeks compared with lower doses (women amenorrhoeic 41/59 [69.5%] with 50 μg *v* 46/54 [85.2%] with 100 μg *v* 40/48 [83.3%] with 200 μg *v* 52/57 [91.2%] with 400 μg; P = 0.0053 for dose-response effect). **Different modes of administration:** We found no systematic review and no RCTs that measured clinical outcomes (see comment below). **Versus gonadorelin analogues (GnRHa) plus hormonal treatment:** See benefits of GnRHa plus hormone replacement therapy, p 2412.

Harms:

Versus placebo: The systematic review identified two RCTs, which found that intranasal nafarelin (200 μg twice daily) reduced bone density by 2.5% from baseline after 16 weeks' treatment compared with placebo.[15] Six months after treatment was withdrawn, bone density had increased to values that were not significantly different from baseline. Many women reported hot flushes during nafarelin treatment (rates ranged from 39% to 100% across 5 RCTs in the review). One RCT found that nafarelin significantly increased the proportion of women who had hot flushes compared with placebo (61% with nafarelin *v* 36% with placebo; P = 0.02).[15] **Versus each other:** The RCT identified by the review found that nafarelin significantly increased the proportion of women who had hot flushes compared with buserelin (38.5% with nafarelin *v* 23.4% with buserelin; P = 0.025), but few women discontinued treatment (data not reported).[15] **Versus GnRHa plus hormonal treatment:** See harms of GnRHa plus hormone replacement, p 2414.

Comment:

The RCTs did not assess effects on pregnancy rates. GnRHa control bleeding, reduce some fibroid related symptoms, and reduce fibroid and uterine size. However, they may cause menopausal symptoms and bone loss, which make them unacceptable for long term use. **Versus placebo:** We found four additional RCTs (154 women) comparing GnRHa versus placebo.[16–19] All had important methodological weaknesses. The first RCT (13 participating centres, 128 women, 24 weeks' treatment) had high withdrawal rates, precluding reliable comparison of the benefits of treatments.[16] It found that leuprorelin was associated with vasomotor flushes, vaginitis, arthralgia/myalgia, asthenia, peripheral oedema, insomnia, nausea, and nervousness compared with placebo (see table 1, p 2426).[16] It found no significant difference between nafarelin and placebo in the risk of developing emotional lability/nervousness, depression, headaches, or decreased libido, although sample size may have been insufficient to rule out clinically important differences for these outcomes (see table 1, p 2426).[16] The second RCT (38 premenopausal women) did not assess clinical outcomes.[17] The other two RCTs were too small to yield reliable results (12 women[18] and 15 women[19]). Two of these RCTs found that fibroids returned to their previous size after stopping treatment.[16,17] **Versus each other:** We found two additional small RCTs.[20,21] The first RCT

(67 women) compared buserelin (1.8 mg every 4 weeks) versus leuprorelin (1.88 mg every 4 weeks) by subcutaneous injection.[20] The second RCT (27 women) compared triptorelin standard dose treatment plus three different types of dosage regimen.[21] Neither of the RCTs compared clinical outcomes among treatment groups. **Different doses:** Two RCTs (77 women) compared two different doses of leuprorelin (leuprolide) acetate (1.88 mg *v* 3.75 mg every 4 weeks for 24 weeks).[22,23] Neither of the RCTs compared clinical outcomes among treatment groups, but one RCT reported that all women experienced partial or complete relief from symptoms throughout their treatment.[22] **Different modes of administration:** We found three RCTs (96 women) comparing intranasal versus subcutaneous GnRHa, none of which reported quantitative results for clinical outcomes.[24–26] One RCT reported that all women had a subjective improvement in menstrual symptoms after 6 months' treatment, especially menorrhagia and dysmenorrhoea, but no figures were reported.[24] The RCTs found no differences in uterine and fibroid shrinkage depending on how GnRHa treatment was given.[24–26]

OPTION GONADORELIN ANALOGUES PLUS HORMONE REPLACEMENT

One small RCT found no significant difference between leuprorelin (leuprolide) acetate plus progesterone and leuprorelin acetate alone in the proportion of women who had heavy bleeding at 12 months. Two small RCTs found no significant difference between gonadorelin analogues alone and gonadorelin analogues plus tibolone in fibroid related symptoms or uterine and fibroid size. They found that adding tibolone reduced hot flushes, vaginal dryness, and night sweats, and prevented loss in bone mineral density. One small RCT provided insufficient evidence to compare gonadorelin analogues plus oestrogen–progestogen hormone replacement versus gonadorelin analogues plus progesterone only hormone replacement. Another RCT found that adding raloxifene to gonadorelin analogues reduced fibroid size compared with gonadorelin analogues alone. It found no significant difference in fibroid related symptoms or hot flushes.

Benefits:

Gonadorelin analogue (GnRHa) plus progestogen versus GnRHa alone: We found no systematic review but found one RCT (41 women).[27] It found no significant difference between leuprorelin (leuprolide) acetate plus progesterone and leuprorelin acetate plus placebo in heavy bleeding at 12 months (proportion of women with bleeding for ≤ 7 days/month or self reported improvement in bleeding assessed by menstrual calendar: 8/21 [38%] with added progesterone *v* 11/20 [55%] with added placebo; RR 0.69, 95% CI 0.35 to 1.36). We found two RCTs that did not assess effects on fibroid related symptoms.[28,29] The first RCT (24 women) assessing harms found that GnRHa plus medroxyprogesterone acetate significantly reduced vasomotor symptoms over 12 months compared with GnRHa alone ($P < 0.05$; absolute numbers not reported).[28] The second RCT (16 women) found that leuprorelin acetate plus progestogen hormone replacement significantly reduced the proportion of women with hot flushes over 24 weeks compared with leuprorelin acetate alone (1/9 [11%] with leuprorelin acetate plus

progestogen *v* 6/7 [86%] with leuprorelin acetate alone; RR 0.13, 95% CI 0.02 to 0.84).[29] **GnRHa plus tibolone versus GnRHa alone:** We found two RCTs.[30,31] Both RCTs found no significant difference in symptoms at 6 months between adding tibolone to GnRHa and GnRHa alone. They found that fewer women taking tibolone had hot flushes. The first RCT (50 women) found no significant difference between GnRHa plus tibolone and GnRHa plus placebo in uterine and fibroid size or fibroid related symptoms at 6 months (mean uterine volume 415 cm^3 with added tibolone *v* 386 cm^3 with added placebo; mean fibroid volume 139 cm^3 with added tibolone *v* 133 cm^3 with added placebo; symptom intensity on a visual analogue scale from 0–10: 3.3 with added tibolone *v* 3.5 with added placebo for pelvic pressure; 2.0 with added tibolone *v* 2.5 with added placebo for pelvic pain; 3.0 in both groups for urinary frequency; P value for all comparisons reported as non-significant).[30] It found that, after 6 months' treatment, GnRHa plus tibolone significantly reduced the mean number of hot flushes each day compared with GnRHa alone (1.5 with added tibolone *v* 4.6 with added placebo; $P < 0.01$; data presented graphically).[30] The RCT also found that the significant reduction in bone mineral density after 6 months' treatment with gonadorelin alone was prevented with the concurrent administration of tibolone (mean difference $P < 0.01$).[30] The risk of fractures was not assessed. The second RCT (20 women) comparing GnRHa (triptoreline) plus tibolone versus GnRHa alone also found no significant difference in fibroid volume at 6 months (reduction in volume 64% with GnRHa plus tibolone *v* 60% with GnRHa alone; reported as non-significant, CI not reported).[31] The RCT is likely to have been too small to detect a clinically important difference. It found that fewer women taking tibolone plus GnRHa had hot flushes (30% with GnRHa plus tibolone *v* 80% with GnRHa alone), vaginal dryness (20% with GnRHa plus tibolone *v* 50% with GnRHa alone), and night sweats (20% with GnRHa plus tibolone *v* 30% with GnRHa alone) compared with women taking GnRHa alone.[31] The RCT did not assess the significance of the difference between groups. **GnRHa plus progestogen versus GnRHa plus combined oestrogen–progestogen:** We found one RCT (51 women) that compared GnRHa plus progestogen hormone replacement versus GnRHa plus combined oestrogen–progestogen hormone replacement over a 2 year period.[32] After 3 months of leuprorelin treatment, it found a decrease in the mean uterine volume in both groups compared with baseline estimates (416 cm^3 with oestrogen–progestogen *v* 440 cm^3 with progestogen alone; CI of the difference not reported). After 21 months of treatment, the mean uterine volume was reduced only in women taking oestrogen–progestogen hormone replacement (414 cm^3 with oestrogen–progestogen *v* 647 cm^3 with progestogen alone; CI not reported). Most women experienced a reduction in fibroid related symptoms (comparison of results between groups not reported). Menorrhagia improved or resolved in 85%, pelvic pressure in 63%, and pelvic pain in 100% of women. **GnRHa plus raloxifene versus GnRHa alone:** We found one RCT (100 women) that compared adding raloxifene to GnRHa versus GnRHa alone for 6 months.[33] It found that both treatments were associated with a reduction in both uterine and fibroid size from

baseline, and found that raloxifene plus GnRHa caused a significantly greater reduction in fibroid size at 6 months compared with GnRHa alone (reduction 7% with raloxifene plus GnRHa *v* 4% with GnRHa alone, absolute data read from graph, $P < 0.05$). It found no significant difference between groups in fibroid related symptoms (menorrhagia or constipation: no women in either group; pelvic pressure: 6.7% with raloxifene plus GnRHa *v* 6.5% with GnRHa alone; pelvic pain: 4.4% with raloxifene plus GnRHa *v* 6.5% with GnRHa alone; urinary frequency: 6.7% with raloxifene plus GnRHa *v* 4.3% with GnRHa alone; reported as non-significant, CI not reported).[33]

Harms: See harms of hormone replacement therapy under menopausal symptoms topic, p 2459. **GnRHa plus progestogen versus GnRHa alone:** The first RCT gave no information on adverse effects.[27] **GnRHa plus tibolone versus GnRHa alone:** See also GnRHa without hormonal replacement therapy, p 2410. **GnRHa plus raloxifene versus GnRHa alone:** The RCT found that both GnRHa alone and raloxifene plus GnRHa significantly increased the mean number of hot flushes a day after 15 days' treatment (mean 3–6 flushes a day; $P < 0.05$). However, it found no significant difference between groups (reported as non-significant, CI not reported).

Comment: Most of the RCTs were small. There is insufficient evidence to determine the optimum hormone replacement regimen that minimises the adverse effects of GnRHa. The RCTs did not assess effects on pregnancy rates.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

Two small RCTs provided insufficient evidence to assess non-steroidal anti-inflammatory drugs in women with fibroids.

Benefits: We found two small RCTs, which assessed the effects of non-steroidal anti-inflammatory drugs (ibuprofen and naproxen) on heavy menstrual bleeding in women with fibroids.[34,35] The first RCT (25 women with menorrhagia; 11 with fibroids) found no significant difference in menstrual blood loss over 4 months between naproxen and placebo in women with fibroids (total menstrual blood loss over 4 cycles 221 mL with placebo *v* 196 mL with naproxen; P value not reported).[34] The second RCT (24 women; 10 with fibroids) also found no significant difference in menstrual blood loss over 2 months between ibuprofen 600–1200 mg/day and placebo (34 women: total menstrual blood loss over 2 cycles about 130 mL in all groups; P value not reported).[35] Both RCTs may have been underpowered to assess a clinically important difference in outcomes.[34,35]

Harms: See harms under non-steroidal anti-inflammatory drugs, p 1551.

Comment: The RCTs did not assess effects on pregnancy rates.

OPTION GESTRINONE

We found no RCTs about the effects of gestrinone on fibroid related symptoms. Androgenic adverse effects limit its use.

Benefits: We found no systematic review and no RCTs that assessed clinical outcomes (see comment below).

Harms: Two uncontrolled trials found that gestrinone was associated with seborrhoea and acne, which increased with duration of treatment.[36,37] One RCT found that after 1 year of treatment, seborrhoea affected 71–93% of women, and acne was reported by 31–63% of women after 2 years of treatment. Myalgia and arthralgia, mild hirsutism, and hoarseness were also reported. Body weight also increased after 2 years of treatment, from a mean of 57.4 kg to 60.9 kg. These changes reversed when treatment was discontinued.

Comment: We found two uncontrolled trials (197 women) that assessed the mode of administration of gestrinone in reducing uterine volume.[36,37] The effects of gestrinone were assessed as comparisons with baseline values. After 3 months of treatment in one trial, 76–86% of women reported amenorrhoea. Pelvic pain was resolved in 76–98% of women.[36] Haemoglobin increased from a mean of 12.38 g/dL to 13.26 g/dL and haematocrit increased from 36.9% to 38.4%.[36] The trials did not assess effects on pregnancy rates.

OPTION MIFEPRISTONE

We found no RCTs of mifepristone in women with fibroids.

Benefits: We found no systematic review or RCTs.

Harms: Mild atypical hot flushes were reported in 28–40% of women in one observational study.[38]

Comment: None.

OPTION LEVONORGESTREL INTRAUTERINE SYSTEM

We found no RCTs of the levonorgestrel intrauterine system in women with fibroids.

Benefits: **Versus no treatment:** One systematic review (search date 2000) identified no RCTs.[39] We found no additional RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION In women scheduled for fibroid surgery, what are the effects of preoperative medical treatments?

OPTION GONADORELIN ANALOGUES

One systematic review has found that gonadorelin analogues for at least 3 months before fibroid surgery improve preoperative haemoglobin concentration and haematocrit, and reduce uterine and pelvic symptoms compared with placebo or no pretreatment. Preoperative gonadorelin also reduced blood loss and the rate of vertical incisions during laparotomy. Women having hysterectomy were more likely to have a vaginal rather than an abdominal procedure after gonadorelin analogue pretreatment

compared with placebo or no pretreatment. Another small RCT found that gonadorelin analogues combined with endometrial resection reduced the need for further treatment (either medical or surgical) over 1 year compared with gonadorelin analogues alone. However, women were more likely to experience adverse hypo-oestrogenic effects from preoperative treatment, such as hot flushes, vaginal symptoms, and sweating, and were more likely to withdraw from treatment because of adverse effects.

Benefits:

Versus placebo or no preoperative treatment: We found one systematic review (search date 2000, 21 RCTs, 1886 women)[40] and one additional RCT.[41] The systematic review assessed gonadorelin analogue (GnRHa) pretreatment (given at least 3 months before surgery) compared with placebo or no treatment, in separate categories: before, during, and after myomectomy (see glossary, p 2423) or hysterectomy. The review found that, compared with placebo or no treatment, pretreatment with GnRHa significantly improved preoperative haemoglobin concentration (9 RCTs, 541 women: WMD 0.98 g/dL, 95% CI 0.74 g/dL to 1.22 g/dL) and haematocrit (4 RCTs, 138 women: 3.14%, 95% CI 1.78% to 4.51%). It also found that GnRHa significantly improved preoperative pelvic symptoms when measured on a symptom scale (pelvic symptom score (see glossary, p 2423): 3 RCTs, 372 women: WMD −2.12, 95% CI −2.38 to −1.87). It found that significantly fewer women receiving GnRHa pretreatment had no improvement in pelvic symptoms compared with women receiving no pretreatment (1 RCT: OR 0.38, 95% CI 0.22 to 0.60). It found that pretreatment with GnRHa significantly reduced intraoperative blood loss (estimated by measuring the weight of swabs and the volume of blood collected in receptacles) compared with placebo or no treatment (8 RCTs, 263 women: WMD 67 mL, 95% CI 44 mL to 91 mL during myomectomy; 6 RCTs, 419 women: WMD 58 mL, 95% CI 40 mL to 76 mL during hysterectomy). The review also found that GnRHa significantly reduced the duration of operation in women having hysterectomy (8 RCTs, 748 women: WMD 5.2 minutes, 95% CI 1.8 minutes to 8.6 minutes) and reduced hospital stay compared with placebo or no treatment (4 RCTs, 392 women: WMD 1.0 day, 95% CI 0.9 days to 1.2 days). GnRHa pretreatment significantly reduced vertical incision rate in women having laparotomy compared with placebo or no treatment (myomectomy; 1 RCT, 28 women: OR 0.11, 95% CI 0.02 to 0.75; hysterectomy; 4 RCTs, 529 women: OR 0.36, 95% CI 0.23 to 0.55). There was also a suggestion that hysterectomy was subjectively graded by the surgeons as "not as difficult" in the pretreated women (2 RCTs: OR 0.73, 95% CI 0.25 to 0.97). A significantly higher proportion of these women also converted to a vaginal procedure (3 RCTs: OR 4.7, 95% CI 3.0 to 7.5). The review found that pretreated compared with non-pretreated women maintained marginally but significantly higher postoperative blood counts (postoperative haemoglobin: 3 RCTs, 240 women: WMD 0.8 g/dL, 95% CI 0.5 g/dL to 1.1 g/dL) for both types of surgery and higher haematocrit levels after hysterectomy (2 RCTs, 173 women: WMD 1.8%, 95% CI 1.1% to 2.4%), although the clinical significance of these results is unclear. One small RCT (60 women, 18 infertile, 6 with recurrent abortion) identified by the review[40] assessed pregnancy rate in infertile women who had had myomectomy for fibroids at a mean follow up of 13 months.[42] Pregnancy

rate was higher for pretreated versus non-pretreated women, although the difference was not significant (AR 7/11 [64%] for pretreated *v* 6/13 [46%] for non-pretreated; RR 1.4, 95% CI 0.7 to 2.9). The RCT may have been too small to detect a clinically important difference. **Versus GnRHa alone:** We found one RCT (25 women) comparing goserelin acetate plus endometrial resection (see glossary, p 2423) versus goserelin acetate alone.[43] It found that, compared with goserelin acetate alone, combined treatment reduced the proportion of women who required further treatment (either medical or surgical) over 1 year (17% with combined treatment *v* 69% with goserelin acetate alone; RR 4.3, 95% CI 1.1 to 15.4).

Harms: **Versus placebo or no preoperative treatment:** The review found that women pretreated with GnRHa versus placebo or no treatment were significantly more likely to experience hypo-oestrogenic symptoms, such as hot flushes (534 women: OR 6.5, 95% CI 4.6 to 9.2), change in breast size (261 women: OR 7.7, 95% CI 2.4 to 24.9), and vaginal symptoms (534 women: OR 4.0, 95% CI 2.1 to 7.6).[40] Women were also more likely to withdraw from treatment because of adverse effects (4 RCTs, 628 women: OR 2.5, 95% CI 1.0 to 5.9). The systematic review identified two small RCTs that evaluated long term follow up in women receiving pretreatment with GnRHa before myomectomy. In one of these, all 24 women were checked for fibroid recurrence at 6 months and 63% of the pretreated group had a recurrence of their fibroids compared with 13% of the control group. Fibroid recurrence 2–3 years after surgery was over 50% in the 18 women from the second RCT, but no significant difference was found between pretreated and non-pretreated women. No other adverse effects were assessed. **Versus GnRHa alone:** The RCT gave no information on harms.[43]

Comment: Only one of the RCTs[42] assessed effects on pregnancy rates. **Versus other preoperative treatments:** One RCT was not included in the systematic review because the outcome of avoiding scheduled hysterectomy was assessed in the GnRHa group only.[41]

QUESTION What are the effects of surgical treatments?

OPTION TOTAL ABDOMINAL HYSTERECTOMY

We found no RCTs comparing total abdominal hysterectomy versus no treatment or sham surgery. An RCT is unlikely to be conducted. There is consensus that abdominal hysterectomy is superior to no treatment in improving fibroid related symptoms. RCTs found that women having total abdominal hysterectomy had longer surgery, more blood loss, pain and fever, longer hospital stay, later return to work, and less satisfaction than women having total vaginal hysterectomy. Two RCTs found that women having total abdominal hysterectomy had longer recovery times and more postoperative pain but shorter operating times and less blood loss than women having laparoscopically assisted vaginal hysterectomy. One RCT found that women having total abdominal hysterectomy had more postoperative fever, longer hospital stay, and recovery times than women having total laparoscopic hysterectomy.

Fibroids (uterine myomatosis, leiomyomas)

Benefits: We found no systematic review. We found no RCTs comparing total abdominal hysterectomy (see glossary, p 2424) versus no intervention or sham surgery (see comment below). **Versus total vaginal hysterectomy:** See glossary, p 2424. See benefits of total vaginal hysterectomy, p 2418. **Versus laparoscopically assisted vaginal hysterectomy:** See glossary, p 2424. See benefits of laparoscopically assisted vaginal hysterectomy, p 2419. **Versus laparoscopic myomectomy:** See benefits of laparoscopic myomectomy, p 2421.[44]

Harms: **Versus total vaginal hysterectomy:** See harms of total vaginal hysterectomy, p 2419. **Versus laparoscopically assisted vaginal hysterectomy:** See harms of laparoscopically assisted vaginal hysterectomy, p 2420. **Versus laparoscopic myomectomy:** See harms of laparoscopic myomectomy, p 2422.

Comment: There is consensus that abdominal hysterectomy is superior to no treatment in improving fibroid related symptoms. An RCT is unlikely to be conducted. Other RCTs have compared different types of hysterectomy in various groups of women but results from these RCTs are not generalisable to women with fibroids.

OPTION TOTAL VAGINAL HYSTERECTOMY New

Two RCTs found that women having total vaginal hysterectomy had shorter operation times, less blood loss, pain and fever, shorter hospital stay, earlier return to work, and greater satisfaction than women having total abdominal hysterectomy. One RCT found that women having total vaginal hysterectomy had shorter operation times and less blood loss than women having laparoscopically assisted vaginal hysterectomy.

Benefits: We found no systematic review. We found no RCTs comparing total vaginal hysterectomy (see glossary, p 2424) versus no intervention or sham surgery. **Versus total abdominal hysterectomy:** We found no systematic review. We found two RCTs (179 women) comparing total vaginal hysterectomy versus total abdominal hysterectomy.[45,46] Both RCTs found that vaginal hysterectomy improved intraoperative and postoperative outcomes compared with abdominal hysterectomy. The first RCT (90 women) compared three interventions: total vaginal hysterectomy, total abdominal hysterectomy, and laparoscopically assisted vaginal hysterectomy (LAVH) (see glossary, p 2424).[45] The women in each group did not differ significantly in age, weight, or other relevant demographic characteristics. The RCT found that, compared with either total abdominal hysterectomy or LAVH, total vaginal hysterectomy significantly reduced intraoperative blood loss (215 mL with vaginal hysterectomy *v* 293 mL with abdominal hysterectomy *v* 343 mL with LAVH; $P = 0.04$). It found that, compared with total abdominal hysterectomy, both total vaginal hysterectomy and LAVH significantly reduced postoperative pain scores at 24 hours (measured on a scale from 0–10; 3 with vaginal hysterectomy *v* 6 with abdominal hysterectomy *v* 4 with LAVH; $P < 0.001$), and the number of days of postoperative antibiotic use (1.3 days with vaginal hysterectomy *v* 1.7 days with abdominal hysterectomy *v* 1.3 days with LAVH; $P < 0.001$). It also found that both total vaginal hysterectomy and LAVH significantly reduced the time to return to work (mean: 29 days with vaginal

hysterectomy *v* 41 with abdominal hysterectomy *v* 30 with LAVH; P < 0.001), reduced the proportion of women with febrile morbidity (13% with vaginal hysterectomy *v* 27% with total abdominal hysterectomy *v* 3% with LAVH; P < 0.05), and reduced mean hospital stay (4.7 days with vaginal hysterectomy *v* 5 days with abdominal hysterectomy *v* 4.7 days with LAVH; P = 0.003). The second RCT found that, compared with total abdominal hysterectomy, total vaginal hysterectomy significantly reduced the duration of operation (86 minutes with vaginal hysterectomy *v* 102 minutes with abdominal hysterectomy; P < 0.001), reduced the proportion of women with postoperative fever (17% with vaginal hysterectomy *v* 30% with abdominal hysterectomy; P < 0.05), and reduced the proportion of women who needed postoperative analgesics (66% with vaginal hysterectomy *v* 8% with abdominal hysterectomy; P < 0.05). It found that total vaginal hysterectomy significantly reduced hospital stay compared with abdominal hysterectomy (3.4 days with vaginal hysterectomy *v* 4.3 days with abdominal hysterectomy; P < 0.001). More women having vaginal hysterectomy rated treatment as "good" or "very good" (83% with vaginal hysterectomy *v* 32% with total hysterectomy [see glossary, p 2424], P value not reported). **Versus laparoscopically assisted vaginal hysterectomy:** See benefits of laparoscopically assisted vaginal hysterectomy, p 2419.

Harms: The RCTs found no major complications associated with total vaginal hysterectomy.[45,46]

Comment: Other RCTs have compared different types of hysterectomy in various groups of women but results from these RCTs are not generalisable to women with fibroids. The RCTs did not assess effects on pregnancy rates.

OPTION LAPAROSCOPICALLY ASSISTED VAGINAL HYSTERECTOMY

We found no RCTs comparing long term effects of laparoscopically assisted vaginal hysterectomy versus other treatments. Two RCTs found that women having laparoscopically assisted vaginal hysterectomy had shorter recovery times and less postoperative pain but longer operating time and more blood loss than women having total abdominal hysterectomy. One RCT found that women having laparoscopically assisted vaginal hysterectomy had longer operating time and more blood loss than women having total vaginal hysterectomy.

Benefits: We found no systematic review. We found no RCTs comparing laparoscopically assisted vaginal hysterectomy (LAVH) (see glossary, p 2424) versus no intervention or sham surgery. **Versus total abdominal hysterectomy or total vaginal hysterectomy:** We found two RCTs in women with symptomatic fibroids scheduled for hysterectomy comparing the effects of LAVH versus total abdominal hysterectomy (TAH) on operating time, blood loss, complications (not clearly specified), febrile morbidity, postoperative analgesic requirement, and hospital stay.[44,45] Both RCTs found that LAVH improved intraoperative and postoperative outcomes compared with abdominal hysterectomy. The first RCT (62 women) found that LAVH significantly reduced hospital stay and analgesic use compared with TAH (mean hospital stay 3.8 days with LAVH *v* 5.8 days

with TAH; P < 0.001; analgesic use for > 24 hours postoperatively 23% with LAVH *v* 77% with TAH; CI not reported). Post hoc subgroup analyses found limited evidence that relative effects of LAVH and TAH depended on uterine weight (see comment below). The second RCT (90 women) compared three interventions: LAVH, total vaginal hysterectomy, and TAH.[45] There was no significant difference in age, weight, or other relevant demographic characteristics among groups. The RCT found that, compared with either LAVH or TAH, total vaginal hysterectomy significantly reduced intraoperative blood loss (343 mL with LAVH *v* 215 mL with vaginal hysterectomy *v* 293 mL with TAH; P = 0.04). It found that, compared with TAH, both LAVH and total vaginal hysterectomy significantly reduced postoperative pain scores at 24 hours (measured on a scale from 0–10; 4 with LAVH *v* 3 with total vaginal hysterectomy *v* 6 with TAH; P < 0.001), and the number of days of postoperative antibiotic use (1.3 days with LAVH *v* 1.3 days with total vaginal hysterectomy *v* 1.7 days with TAH; P < 0.001). It also found that both LAVH and total vaginal hysterectomy significantly reduced the time to return to work (mean 30 days with LAVH *v* 29 days with vaginal hysterectomy *v* 41 days with TAH; P < 0.001), reduced the proportion of women with febrile morbidity (3% with LAVH *v* 13% with total vaginal hysterectomy *v* 27% with TAH; P < 0.05), and reduced mean hospital stay (4.7 days with LAVH *v* 4.7 days with vaginal hysterectomy *v* 5 days with TAH; P = 0.003). The second RCT found no significant difference in postoperative pain, time to return to work, or febrile morbidity between LAVH and vaginal hysterectomy.[45]

Harms:

Versus total abdominal hysterectomy: The first RCT found that LAVH significantly increased operating time (in women who did not have a second operation [oophorectomy and/or adhesiolysis]) compared with TAH (mean operating time 135 minutes with LAVH *v* 120 minutes with TAH; P = 0.001).[44] The second RCT also found that LAVH significantly increased mean operating time (without second procedure) and blood loss compared with TAH (mean 109 minutes with LAVH *v* 98 minutes with TAH; P < 0.001; mean blood loss 343 mL with LAVH *v* 293 mL with TAH; P = 0.04).[45] No major complications were reported in either RCT, although there was insufficient information to determine which complications were addressed.

Comment:

The RCTs did not assess effects on pregnancy rates. **In women with uterus estimated to weigh 500 g or less:** Subgroup analysis of the first RCT in 41 women with uterus estimated to weigh 500 g or less in the preoperative assessment found that LAVH and TAH required comparable operating times (130 minutes on average with LAVH *v* 120 minutes with TAH).[44] They had less postoperative pain and shorter recovery compared with the TAH group. Sonograms were used to estimate uterine weight. Analgesia requirement was reduced with LAVH (1/20 [5%] with LAVH *v* 6/11 [55%] with TAH; RR 0.09, 95% CI 0.01 to 0.67; NNT 2, 95% CI 1 to 6). Hospital stay was also reduced with LAVH (3.8 days, 95% CI 3.2 days to 4.0 days with LAVH *v* 5.8 days, 95% CI 5.0 days to 6.4 days with TAH; P < 0.0001). **In women with uterus estimated to weigh more than 500 g:** Subgroup analysis of the RCT in 21 women with uteri weighing more than 500 g found that LAVH was associated with a shorter recovery but a longer operating time compared with TAH.[44]

About 27% of women randomised to LAVH converted to laparotomy. Mean operating time was increased with LAVH (150 minutes, 95% CI 125 minutes to 173 minutes with LAVH *v* 108 minutes, 95% CI 83 minutes to 120 minutes with TAH; P = 0.002). Mean hospital stay was reduced with LAVH (4.0 days, 95% CI 3.9 days to 5.8 days with LAVH *v* 6.0 days, 95% CI 5.8 days to 6.0 days with TAH). **Extrapolating results of hysterectomy for other disorders to women with fibroids:** Other RCTs have compared different types of hysterectomy in other groups of women but results from these RCTs are not generalisable to women with fibroids.

OPTION TOTAL LAPAROSCOPIC HYSTERECTOMY New

One RCT found that women having total laparoscopic hysterectomy had less postoperative fever, shorter hospital stay, and shorter recovery times compared than women having total abdominal hysterectomy.

Benefits: We found no systematic review. We found no RCTs comparing total laparoscopic hysterectomy (see glossary, p 2424) versus no intervention or sham surgery. **Versus total abdominal hysterectomy:** We found no systematic review but found one RCT (122 women with an enlarged uterus [equivalent to > 14 weeks' gestation] because of fibroids) comparing total laparoscopic hysterectomy versus total abdominal hysterectomy.[47] It found that, compared with total abdominal hysterectomy, total laparoscopic hysterectomy significantly reduced the proportion of women who had postoperative fever (13% with total laparoscopic hysterectomy *v* 29% with total abdominal hysterectomy; P < 0.05), and reduced duration of hospital stay (mean 76.4 hours with total laparoscopic hysterectomy *v* 121.8 hours with total abdominal hysterectomy) and recovery times (mean 22 days with total laparoscopic hysterectomy *v* 36 days with total abdominal hysterectomy; P < 0.001 for both outcomes).

Harms: The RCT reported that one woman randomised to total laparoscopic hysterectomy converted to abdominal hysterectomy because of incidental bowel injury.[47] It found no other major complications associated with laparoscopic or abdominal hysterectomy.

Comment: Women were only included in the RCT if they had an enlarged uterus.[47] This would usually be a contraindication to total laparoscopic hysterectomy. Other RCTs have compared different types of hysterectomy in various groups of women but results from these RCTs are not generalisable to women with fibroids. The RCT did not assess effects on pregnancy rates.

OPTION LAPAROSCOPIC MYOMECTOMY

Limited evidence from RCTs suggests that laparoscopic myomectomy is associated with less postoperative pain and fever, and shorter recovery times compared with abdominal myomectomy.

Benefits: We found no systematic review. We found no RCTs against no intervention or sham surgery. **Versus abdominal myomectomy:** We found two RCTs comparing laparoscopic versus abdominal myomectomy (see glossary, p 2423) by laparotomy.[48,49] The first RCT (40 women with < 5 myomas and the size of the largest myoma

< 7 cm) found no differences in length of surgery, blood loss, or postoperative complications (fever). Women having laparoscopic myomectomy reported a lower intensity of postoperative pain (unlabelled scale), required less analgesia, and had a shorter recovery time than women having abdominal myomectomy by laparotomy. Two days after surgery, a significantly smaller proportion of women required analgesia with laparoscopic myomectomy versus abdominal myomectomy (analgesia free women: 17/20 [85%] with laparoscopy *v* 3/20 [15%] with abdominal; RR 5.7, 95% CI 2.0 to 16.4; NNT 2, 95% CI 1 to 3), and by day 15 more women were fully recovered after laparoscopic myomectomy (18/20 [90%] with laparoscopy *v* 1/20 [5%] with abdominal; RR 18.0, 95% CI 2.7 to 122.0; NNT 2, 95% CI 1 to 2). The second RCT (131 women with at least 1 myoma ≥ 5 cm) found similar length of surgery with laparoscopic and abdominal myomectomy.[49] However, it found a significantly greater drop in haemoglobin with abdominal than with laparoscopy (1.33 g/dL with laparoscopy *v* 2.17 g/dL with abdominal; P < 0.001). Women who had laparoscopic myomectomy were marginally but significantly less likely to experience postoperative fever than women who had abdominal myomectomy (8/66 [12%] with laparoscopy *v* 17/65 [26%] with abdominal; RR 0.46, 95% CI 0.22 to 1.00; NNT 9, 95% CI 4 to 116) and were more likely to have a shorter hospital stay (75.6 hours with laparoscopy *v* 142.8 hours with abdominal; CI not reported; P < 0.001). It found no significant difference in pregnancy rate after surgery between laparoscopic and abdominal myomectomy (53.6% with laparoscopy *v* 55.9% with abdominal; reported as non-significant, CI not reported).

Harms: No major complications were reported in the two RCTs.[48,49] The second RCT found that more people having abdominal compared with laparoscopic myomectomy had transfusions (transfusion risk: 3/65 [5%] with abdominal *v* 0/66 [0%] with laparoscopy; CI not reported).[49]

Comment: Other RCTs have compared different types of hysterectomy in various groups of women but results from these RCTs are not generalisable to women with fibroids.

OPTION THERMAL BALLOON ABLATION

We found no RCTs comparing thermal balloon ablation versus non-surgical treatment or versus hysterectomy. One RCT compared thermal balloon ablation versus rollerball endometrial ablation in women with fibroids smaller than the average size of a 12 week pregnancy, all of whom had been pretreated with gonadorelin analogues. It found no significant difference between thermal balloon and rollerball ablation in amenorrhoea rates, pictorial bleeding assessment chart score, haemoglobin, or hysterectomy rates at 12 months. It found that thermal balloon ablation reduced operation time and intraoperative complication rate compared with rollerball ablation. About one third of women reported being "not very satisfied" with either operation.

Benefits: **Versus other surgical treatment:** We found no RCTs comparing thermal balloon ablation (see glossary, p 2423) versus hysterectomy. We found one RCT (96 women with fibroids smaller than the

average size of a 12 week pregnancy who had received 2 months of preoperative treatment with gonadorelin analogues) that compared thermal balloon ablation versus rollerball endometrial ablation (see glossary, p 2423).[50] Thermal balloon ablation was performed by staff surgeons or supervised residents under local intracervical and paracervical anaesthesia with intravenous sedation. Rollerball ablation was performed under general anaesthesia by experienced surgeons. The RCT found no significant difference with thermal balloon ablation versus rollerball endometrial ablation in hysterectomy rates, amenorrhoea rates, pictorial bleeding assessment chart score (see glossary, p 2423), or haemoglobin at 12 months (women having hysterectomy: 4/45 [9%] with thermal balloon *v* 4/48 [8%] with rollerball; amenorrhoea: 5 women with thermal balloon *v* 8 women with rollerball; mean decrease in pictorial bleeding assessment chart score: 343 with thermal balloon *v* 345 with rollerball; mean increase in haemoglobin: 2.7 g/dL with thermal balloon *v* 3.0 g/dL with rollerball; P values reported as non-significant for all comparisons; CI not reported). Operating time was significantly shorter in the thermal balloon group compared with the rollerball group (11.5 minutes with thermal balloon *v* 37.3 minutes with rollerball, $P < 0.0001$). About a third of women in both groups reported that they were "not very satisfied" with their operation (33% with thermal balloon *v* 39% with rollerball).[50]

Harms: The RCT found that a significantly higher proportion of women had intraoperative complications with rollerball ablation than with thermal balloon ablation (5/45 [11%] with rollerball *v* 0/48 [0%] with thermal balloon, $P < 0.05$; 2 women had fluid overload, 2 had major bleeding, and 1 had injury to the cervix).[50] It found no significant difference between rollerball ablation and thermal balloon ablation in postoperative complications (3 women in each group) or postoperative pain score at 12 hours.

Comment: The RCT did not assess effects on pregnancy rates.

GLOSSARY

Endometrial resection Destruction of the endometrium using a cutting tool.

Myomectomy Removal of fibroids from the uterus. The mode of removal may be abdominal, laparoscopic, or hysteroscopic.

Pelvic symptom score scale An ordinal scale that adds the results of pelvic pain and pelvic pressure. Each symptom is evaluated in a scale ranging of 0–3, where 0 means absence of pain, and increasing numbers represent mild, moderate, and severe pain. Because both results are added, absence of symptoms is represented by 0 and severe pain and pelvic pressure by 6. We found no data on validation of the scale. However, it is commonly used in studies evaluating pelvic pain.

Pictorial bleeding assessment chart (PBAC) Used to measure menstrual bleeding. Validation studies indicate that a PBAC score of 100–185 is suggestive of menorrhagia (heavy menstrual bleeding) which is objectively defined by the alkaline haematin test as a menstrual blood loss greater than 80 mL.

Rollerball endometrial ablation Destruction of the endometrium using electrical coagulation with a rollerball electrode applied through the cervical os.

Thermal balloon ablation Destruction of the endometrium using pressure from a balloon catheter inserted through the cervical os and then filled with fluid to a pressure of 160–180 mm Hg and heated to about 87 °C.

Fibroids (uterine myomatosis, leiomyomas)

Total hysterectomy Removal of the uterus. The mode of removal may be through the abdominal wall (total abdominal hysterectomy), through the vagina (total vaginal hysterectomy), partially through the vagina and partially morcellated and removed by laparoscopic incision (laparoscopically assisted vaginal hysterectomy), or entirely by laparoscopic excision (total laparoscopic hysterectomy). In some situations, total abdominal hysterectomy is performed in conjunction with a bilateral salpingo-oophorectomy, the removal of both ovaries and fallopian tubes.

Substantive changes

Gonadorelin analogues plus hormone replacement Two RCTs added;[31,33] conclusions unchanged.

Preoperative gonadorelin analogues One small RCT found that gonadorelin analogues combined with endometrial resection reduced the need for further treatment (either medical or surgical) over 1 year compared with gonadorelin analogues alone.[43]

Key Messages

In women with infertility caused by ovulation disorders

- **Clomifene** One systematic review has found that clomifene (clomiphene) increases pregnancy rate compared with placebo in women who ovulate infrequently. Four other studies, including two RCTs, have found no significant difference in ovulation or pregnancy rates between clomifene and tamoxifen. One RCT found that clomifene plus metformin increased pregnancy rates after 6 months' treatment compared with clomifene alone.

- **Gonadotrophins** We found no RCTs comparing gonadotrophins versus placebo or clomifene. One systematic review found that pregnancy rates with human menopausal gonadotrophins or urofollitropin (urofollitrophin, urinary follicle stimulating hormone) ranged from 10–12%. The review found no significant difference in pregnancy rates between treatments. Two RCTs found that pregnancy rates with follitropin (recombinant follicle stimulating hormone) or urofollitropin ranged from 24–27%. It found no significant difference between treatments. The review found that urofollitropin reduced the risk of ovarian hyperstimulation syndrome compared with human menopausal gonadotrophins, although this was confined to women who were not treated with concomitant gonadotrophin releasing hormone analogues. One systematic review and one subsequent RCT found no significant difference in pregnancy rates between gonadotrophins and laparoscopic ovarian drilling but found that gonadotrophins increased rates of multiple pregnancies. Observational evidence suggests that gonadotrophins may be associated with an increased risk of non-invasive ovarian tumours and multiple pregnancies.

- **Cyclofenil** One RCT provided insufficient evidence about the effects of cyclofenil in women with ovulatory disorders.

- **Laparoscopic ovarian drilling** We found no RCTs comparing laparoscopic ovarian drilling versus no treatment. One systematic review and one subsequent small RCT found no significant difference in pregnancy rates between laparoscopic ovarian drilling and gonadotrophins. They found that laparoscopic ovarian drilling reduced rates of multiple pregnancies.

- **Pulsatile gonadotrophin releasing hormone** One systematic review of small, weak RCTs provided insufficient evidence to assess pulsatile gonadotrophin releasing hormone treatment.

In women with tubal infertility

- **In vitro fertilisation** We found no RCTs comparing in vitro fertilisation versus no treatment. RCTs are unlikely to be conducted. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. One RCT found that immediate compared with delayed in vitro fertilisation increased pregnancy and live birth rates. Three RCTs found no significant difference in numbers of live births between in vitro fertilisation and intracytoplasmic sperm injection. Observational evidence suggests that adverse effects associated with in vitro fertilisation include multiple pregnancies and ovarian hyperstimulation syndrome.
- **Tubal flushing with oil soluble media** One systematic review found that tubal flushing with oil soluble media increased pregnancy rates compared with no intervention. It found that tubal flushing with oil soluble media increased the live birth rate compared with flushing with water soluble media.
- **Tubal surgery before in vitro fertilisation** One systematic review in women with hydrosalpinges undergoing in vitro fertilisation has found that tubal surgery increases pregnancy and live birth rates compared with no treatment or medical treatment. One systematic review found no significant difference in pregnancy rates among different types of tubal surgery. One systematic review found no significant difference in pregnancy rates between tubal surgery plus additional treatments to prevent adhesion formation (steroids, dextran, noxytioline) and tubal surgery alone. Another systematic review provided insufficient evidence to assess postoperative hydrotubation or second look laparoscopy.
- **Selective salpingography plus tubal catheterisation** We found no RCTs on the effects of selective salpingography plus tubal catheterisation.
- **Tubal flushing with water soluble media** One systematic review identified no RCTs comparing tubal flushing with water soluble media versus no intervention. It found that tubal flushing with water soluble media decreased live birth rate compared with flushing with oil soluble media.

In women with infertility associated with endometriosis

- **Intrauterine insemination plus gonadotrophins** One RCT found that intrauterine insemination plus gonadotrophins increased live birth rates compared with no treatment. A second RCT found no significant difference in birth rates between intrauterine insemination plus pituitary down regulation plus gonadotrophins and expectant management, but it is likely to have been underpowered to detect a clinically important difference. A third RCT found that intrauterine insemination plus gonadotrophins increased pregnancy rates after the first treatment cycle compared with intrauterine insemination alone.
- **In vitro fertilisation** We found no RCTs comparing in vitro fertilisation versus no treatment in women with endometriosis related infertility. RCTs are unlikely to be conducted. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. Observational studies found inconclusive evidence about whether in vitro fertilisation is as effective in women with endometriosis as in women with tubal infertility.

Infertility and subfertility

- **Laparoscopic ablation of endometrial deposits** We found no RCTs comparing laparoscopic surgery versus no treatment or versus ovarian suppression. One systematic review has found that laparoscopic resection or ablation of endometrial deposits increases live birth rates and ongoing pregnancy rates compared with diagnostic laparoscopy. Operative complications were not increased with laparoscopic surgery.
- **Drug induced ovarian suppression** One systematic review found no significant difference in pregnancy rates between drugs that induce ovarian suppression and placebo. The review found that ovulation suppression agents (medroxyprogesterone, gestrinone, combined oral contraceptives, and gonadotrophin releasing hormone analogues) cause adverse effects, including weight gain, hot flushes, and osteoporosis, and that danazol may cause dose related weight gain and androgenic effects.

In couples with male factor infertility

- **Intracytoplasmic sperm injection plus in vitro fertilisation** We found no RCTs of intracytoplasmic sperm injection plus in vitro fertilisation that assessed pregnancy and live birth rates. Observational evidence in the UK suggests an average live birth rate of 22% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account.
- **Intrauterine insemination** Two systematic reviews have found that intrauterine insemination increases pregnancy rates per cycle compared with intracervical insemination or timed intercourse.
- **Donor insemination** We found no RCTs on the effects of donor insemination. Observational evidence suggests an average live birth rate of 11%, but it is sometimes unclear whether ovarian stimulation was used in addition to donor insemination.
- **In vitro fertilisation versus gamete intrafallopian transfer** One small RCT provided insufficient evidence to compare in vitro fertilisation versus gamete intrafallopian transfer.

In couples with unexplained infertility

- **Intrauterine insemination plus gonadotrophins** Two systematic reviews and one subsequent RCT have found that intrauterine insemination plus gonadotrophins increases pregnancy rates compared with timed intercourse or intracervical insemination. One systematic review found no significant difference between intrauterine insemination and timed intercourse or intracervical insemination in pregnancy rates. However, it found that adding gonadotrophins to any of the three interventions increased pregnancy rates per cycle. One systematic review and one subsequent RCT have found that fallopian tube sperm perfusion increases pregnancy rates compared with intrauterine insemination. One systematic review found no significant difference in live birth rate between intrauterine insemination with or without ovarian stimulation and in vitro fertilisation.
- **Clomifene** One systematic review found limited evidence that clomifene (clomiphene) increased rates of pregnancy per cycle compared with placebo.
- **Fallopian tube sperm perfusion** One systematic review and one subsequent RCT have found that fallopian tube sperm perfusion increases pregnancy rates compared with intrauterine insemination.
- **Gamete intrafallopian transfer** We found no RCTs comparing gamete intrafallopian transfer versus no treatment. RCTs found conflicting effects on pregnancy rates of gamete intrafallopian transfer versus other treatments (intrauterine insemination, timed intercourse, and in vitro fertilisation).

- **In vitro fertilisation** Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle. However, one systematic review identified one RCT in couples with unexplained infertility that found no significant difference in pregnancy rates between in vitro fertilisation and expectant management. RCTs included in the review found no significant difference in live birth rate between in vitro fertilisation and either gamete intrafallopian transfer or intrauterine insemination with or without ovarian stimulation.

DEFINITION Normal fertility has been defined as achieving a pregnancy within 2 years by regular sexual intercourse.[1] However, many define infertility as the failure to conceive after 1 year of unprotected intercourse. Infertility can be primary, in couples who have never conceived, or secondary, in couples who have previously conceived. Infertile couples include those who are sterile (who will never achieve a natural pregnancy) and those who are subfertile (who could eventually achieve a natural pregnancy).

INCIDENCE/ PREVALENCE Although there is no evidence of a major change in the prevalence of infertility, many more couples are seeking help than previously. Currently, about 1/7 couples in industrialised countries will seek medical advice for infertility.[2] Rates of primary infertility vary widely between countries, ranging from 10% in Africa to about 6% in North America and Europe.[1] Reported rates of secondary infertility are less reliable.

AETIOLOGY/ RISK FACTORS In the UK, nearly a third of infertility cases are unexplained.[3] The rest are caused by ovulatory failure (27%), low sperm count or quality (19%), tubal damage (14%), endometriosis (5%), and other causes (5%).[3]

PROGNOSIS In developed countries, 80–90% of couples attempting to conceive are successful after 1 year and 95% after 2 years.[3] The chances of becoming pregnant vary with the cause and duration of infertility, the woman's age, the couple's previous pregnancy history, and the availability of different treatment options.[2,4] For the first 2–3 years of unexplained infertility, cumulative conception rates remain high (27–46%) but decrease with increasing age of the woman and duration of infertility.[4] The background rates of spontaneous pregnancy in infertile couples can be calculated from longitudinal studies of infertile couples who have been observed without treatment.[4]

AIMS OF INTERVENTION To achieve the delivery of one healthy baby; to reduce the distress associated with infertility, with minimal adverse effects.

OUTCOMES Live births, miscarriages, multiple pregnancies, incidence of ovarian hyperstimulation syndrome (see glossary, p 2452), satisfaction with services and treatments, acceptance of childlessness if treatment is unsuccessful, and pregnancy rate. Pregnancy rate is an intermediate outcome, but one that is important in itself to many people. Ovulation is an intermediate outcome. Pregnancies in infertile couples will occur spontaneously without treatment.[4] Effectiveness of treatments for infertility should be assessed on the basis of pregnancy rates over and above the spontaneous pregnancy rates, otherwise the impacts of treatments may be overestimated.

METHODS *Clinical Evidence* search and appraisal June 2003. **Crossover design:** For infertility, RCTs with a crossover design may overestimate the treatment effect because pregnancies occurring in the first half of the trial will remove couples from the second half.[5] Crossover trials were included in some systematic reviews where no or few RCTs using a parallel group design were available. Ideally, only data from the first half of the trial, before crossover, should be used. However, a study that used a computer model to compare the results of crossover and parallel designed trials suggests that any overestimation may be clinically irrelevant.[6]

QUESTION **What are the effects of treatments for infertility caused by ovulation disorders?**

OPTION CLOMIFENE

One systematic review has found that clomifene (clomiphene) increases pregnancy rate compared with placebo in women who ovulate infrequently. Four other studies, including two RCTs, have found no significant difference in ovulation or pregnancy rates between clomifene and tamoxifen. One RCT found that clomifene plus metformin increased pregnancy rates alone after 6 months' treatment compared with clomifene alone.

Benefits: **Versus placebo:** We found one systematic review (search date not reported, 3 crossover RCTs) that compared clomifene 50–200 mg versus placebo in 217 cycles in women who ovulate infrequently (see table 1, p 2457).[7] It found that clomifene significantly increased pregnancy rates compared with placebo (OR 3.4, 95% CI 1.2 to 9.5). **Versus tamoxifen:** We found no systematic review, but found four studies (2 RCTs, 1 quasi-randomised study, and 1 observational study; 197 anovulatory or infrequently ovulating women; see comment below).[32–35] The first RCT (86 anovulatory women aged < 40 years) compared tamoxifen (maximum 60 mg daily) versus clomifene (maximum 150 mg daily).[33] It found no significant difference in the overall rate of ovulation between tamoxifen and clomifene (50/113 [44%] ovulatory cycles with tamoxifen *v* 41/91 [45%] ovulatory cycles with clomifene; P > 0.05; see comment below) or in the number of pregnancies (10/46 [22%] with tamoxifen *v* 6/40 [15%] with clomifene; RR 1.7, 95% CI 0.7 to 4.2). The other studies found similar results.[32,34,35] **Versus other drug combinations:** We found no systematic review but found one RCT (90 infertile women with polycystic ovary syndrome, infrequent menstruation, high insulin levels, and body mass indexes > 28) comparing clomifene (at its lowest effective dose; see comment below) plus metformin (500 mg orally 3 times daily) versus clomifene alone (at its lowest effective dose; see comment below).[36] The RCT found that clomifene plus metformin significantly increased pregnancy rates per person after 6 months' treatment compared with clomifene alone (13/45 [29%] with clomifene plus metformin *v* 4/45 [9%] with clomifene alone; RR 3.3, 95% CI 1.2 to 9.2; NNT 5, 95% CI 3 to 22).

Harms: **Ovarian cancer:** In a cohort study of 3837 infertile women, 11 women were found to have ovarian cancer.[14] In 135 women that were randomly selected as a subcohort from these 3837 women,

there was an 11-fold increase in risk of ovarian cancer in women using clomifene for 12 or more cycles (RR 11.1, 95% CI 1.5 to 82.3). The association was present for both gravid and nulligravid women, and for infertile women both with ovulatory disorders and with infertility from other causes. Subsequent cohort[37] and case-control[38–40] studies have found no association between clomifene and ovarian cancer. **Multiple pregnancy:** Multiple pregnancy occurs in 2–13% of women with all causes of infertility taking clomifene compared with a spontaneous multiple pregnancy rate of about 1–2% of women in North American and European populations.[41,42] In a 1 year survey in the UK, 25/44 (57%) triplet pregnancies reported were attributable to clomifene.[43] Clomifene was also implicated in 2/8 sets of quadruplets and quintuplets reported. **Ovarian hyperstimulation syndrome:** See glossary, p 2452. Clomifene tends to cause only mild ovarian hyperstimulation that does not require treatment.

Comment: Clomifene was first introduced in the 1960s and most of the trials testing its efficacy took place in the 1970s before more recent quality standards for RCTs were established. Three of the studies comparing clomifene versus tamoxifen based estimates of pregnancy rates on fewer than 30 pregnancies.[32,33,35] In the first RCT comparing tamoxifen versus clomifene, the different number of treatment cycles between groups could potentially bias the results.[33] In the RCT comparing clomifene plus metformin versus clomifene alone, the dose of clomifene was initially 50 mg daily for 5 days and only increased to 100 mg or 150 mg daily for 5 days if the lower dose was insufficient to enable ovulation to be triggered with human chorionic gonadotrophin.[36] In the cohort study, 5/11 (45%) people with ovarian cancer were diagnosed with borderline epithelial tumours that had low malignant potential, and two with granulosa cell tumours that had different embryological, pathological, and epidemiological features from epithelial tumours.[14] Borderline and malignant tumours pose different risks that are not easy to combine and excluding the two granulosa cell tumours from the number of ovarian cancers found diminishes the increased risk attributed to clomifene treatment.

OPTION CYCLOFENIL

One RCT provided insufficient evidence about the effects of cyclofenil in women with ovulatory disorders.

Benefits: **Versus placebo:** We found one RCT (213 women with either ovulatory disorders or unexplained infertility) comparing three cycles of cyclofenil (800 mg daily) versus placebo from days 4–8 of the ovulatory cycle (see comment below).[44] It found no significant difference in cumulative pregnancy rates (26/114 [23%] with cyclofenil *v* 21/99 [21%] with placebo; RR 1.1, 95% CI 0.7 to 1.8).

Harms: The RCT gave no information on adverse effects.[44]

Comment: Only 123/213 (58%) women in the RCT had ovulatory disorders and the results for these women were not presented separately.[44] The RCT does not, therefore, exclude a possible benefit of cyclofenil.

OPTION GONADOTROPHINS

We found no RCTs comparing gonadotrophins versus placebo or clomifene (clomiphene). One systematic review found that pregnancy rates with human menopausal gonadotrophins or urofollitropin (urofollitrophin, urinary follicle stimulating hormone) ranged from 10–12% and found no significant difference in pregnancy rates between treatments. Two RCTs found that pregnancy rates with follitropin (recombinant follicle stimulating hormone) or urofollitropin ranged from 24–27% and found no significant difference between treatments. The review found that urofollitropin reduced the risk of ovarian hyperstimulation syndrome compared with human menopausal gonadotrophins, although this was confined to women who were not treated with concomitant gonadotrophin releasing hormone analogues. One systematic review and one subsequent RCT found no significant difference in pregnancy rates between gondaotrophins and laparoscopic ovarian drilling but found that gonadotrophins increased rates of multiple pregnancies. Observational evidence suggests that gonadotrophins may be associated with an increased risk of non-invasive ovarian tumours and multiple pregnancies.

Benefits:

Versus placebo: We found no RCTs. **Versus clomifene:** We found no RCTs. **Human menopausal gonadotrophins versus urofollitropin:** We found one systematic review (search date not reported, 14 RCTs, 388 women with subfertility associated with polycystic ovary syndrome) that compared human menopausal gonadotrophins versus urofollitropin.[15] It found no significant difference in pregnancy rates (19/183 [10%] with human menopausal gonadotrophins *v* 26/213 [12%] with urofollitropin; OR 0.8, 95 % CI 0.4 to 1.5) (see table 1, p 2457). **Follitropin versus urofollitropin:** We found no systematic review, but found two RCTs comparing urofollitropin versus follitropin.[16,45] The first RCT (172 women with clomifene resistant, normogonadotrophic anovulation) found no significant difference between follitropin and urofollitropin in cumulative ovulation rates (95% with follitropin *v* 96% with urofollitropin), cumulative pregnancy rates (27% with follitropin *v* 24% with urofollitropin), or miscarriage rates (31% with follitropin *v* 32% with urofollitropin).[16] The second RCT (51 women with clomifene resistant, normogonadotrophic anovulation) found similar results, although a much lower total dose and shorter duration of follitropin was used to achieve ovulation.[45] **Versus laparoscopic ovarian drilling:** See glossary, p 2451. See benefits of laparoscopic ovarian drilling, p 2435.

Harms:

Ovarian cancer: One case control study (200 women with ovarian cancer and 408 area matched controls) found that women with non-invasive ovarian tumours were more than three times more likely to have been exposed to an ovulation induction agent (adjusted OR 3.5, 95% CI 1.2 to 10.1), particularly to human menopausal gonadotrophins (adjusted OR 9.4, 95% CI 1.7 to 52.1).[40] Women with invasive ovarian tumours were no more likely to have been exposed to any ovulation induction agents. **Multiple pregnancy:** One case series found that multiple pregnancy occurred in 29% of women with polycystic ovary syndrome when conventional regimens of gonadotrophins were used to induce ovulation.[17] The first RCT comparing urofollitropin versus follitropin

found no significant difference in the risk of multiple pregnancy, although the low event rates found with either treatment limit the usefulness of the result.[17] **Ovarian hyperstimulation:** The systematic review (search date not reported, 7 RCTs) found that urofollitropin significantly reduced the risk of ovarian hyperstimulation compared with human menopausal gonadotrophins (OR 0.3, 95% CI 0.2 to 0.7).[15] However, this effect was only present where no concomitant gonadotrophin releasing hormone analogue was used (5 RCTs; OR 0.2, 95% CI 0.1 to 0.5). The review found that concomitant use of a gonadotrophin releasing hormone analogue increased the risk of ovarian hyperstimulation (2 RCTs; OR 3.2, 95% CI 1.5 to 6.7).[15] The first RCT comparing urofollitropin versus follitropin found no significant difference in the risk of ovarian hyperstimulation syndrome (see glossary, p 2452), although the low event rates found with either treatment limit the usefulness of the result.[16]

Comment: Despite not being placebo controlled, trials in the review of gonadotrophins often included women who were not ovulating and, therefore, provide some evidence that treatment is effective.[15] Follitropin is not derived from human tissues.

OPTION LAPAROSCOPIC OVARIAN DRILLING

We found no RCTs comparing laparoscopic ovarian drilling versus no treatment. One systematic review and one subsequent small RCT found no significant difference in pregnancy rate between laparoscopic ovarian drilling and gonadotrophins. It found that laparoscopic ovarian drilling reduced rates of multiple pregnancies.

Benefits: **Versus no treatment:** We found no RCTs. **Versus gonadotrophins:** We found one systematic review (search date 2001, 4 RCTs, 303 women with anovulatory clomifene [clomiphene] resistant polycystic ovary syndrome)[18] (see table 1, p 2457) and one subsequent RCT (see comment below) comparing laparoscopic ovarian drilling (see glossary, p 2451) versus gonadotrophins.[19] The review found no significant difference between laparoscopic ovarian drilling and gonadotrophins in pregnancy rates after 6–12 months' follow up (81/127 [64%] with laparoscopic ovarian drilling *v* 72/126 [57%] with gonadotrophins; OR 1.42, 95% CI 0.84 to 2.42).[18] The subsequent RCT (18 women with polycystic ovary syndrome who had failed to ovulate after treatment with clomifene or purified follicle stimulating hormone) compared laparoscopic ovarian drilling versus a gonadotrophin releasing hormone analogue plus a combined oral contraceptive.[19] All the women also received three cycles of follitropin plus intrauterine insemination. The RCT found no significant difference in the number of pregnancies or live births after 6 months' treatment (pregnancies: 5/10 [50%] with laparoscopic ovarian drilling *v* 5/8 [63%] with gonadotrophin releasing hormone analogue plus combined oral contraceptive; RR 0.8, 95% CI 0.4 to 1.8; live births: 5/10 [50%] with laparoscopic ovarian drilling *v* 4/8 [50%] with gonadotrophin releasing hormone analogue plus combined oral contraceptive; RR 1.00, 95% CI 0.34 to 2.93).

Harms: **Versus gonadotrophins:** The systematic review found that laparoscopic ovarian drilling significantly reduced rates of multiple pregnancies compared with gonadotrophins (OR 0.16, 95% CI 0.03 to 0.98).[18] Adverse effects associated with laparoscopic ovarian drilling include the risks of general anaesthesia, postoperative adhesion formation,[46] and pelvic infection.[47] We found no evidence to support the suggestion that laparoscopic drilling increases the long term risk of premature ovarian failure. Laparoscopic drilling is thought not to increase the risk of multiple pregnancy as it usually induces spontaneous ovulation, in contrast to the multifollicular ovulation that may be induced by the use of gonadotrophins.

Comment: The trials of laparoscopic ovarian drilling included women who were not ovulating and, therefore, provide some evidence that treatment is effective despite the lack of placebo controls.[18,19]

OPTION PULSATILE GONADOTROPHIN RELEASING HORMONE

One systematic review of small, weak RCTs provided insufficient evidence to assess pulsatile gonadotrophin releasing hormone treatment.

Benefits: We found one systematic review (search date not reported, 3 RCTs, 29 women with subfertility and clomifene [clomiphene] resistant polycystic ovary syndrome) that compared pulsatile gonadotrophin releasing hormone (GnRH) versus other treatments to induce ovulation.[48] The RCTs included in the review assessed three different comparisons: pulsatile GnRH plus follicle stimulating hormone versus pulsatile GnRH alone; pulsatile GnRH plus 3 weeks' pretreatment with GnRH versus pulsatile GnRH alone; and pulsatile GnRH versus human menopausal gonadotrophins. The RCTs were also small (each reporting 1–4 pregnancies) and of short duration (1–3 cycles), and therefore provided insufficient evidence to assess pulsatile GnRH in women with polycystic ovary syndrome.

Harms: One retrospective analysis (229 cycles in 71 women) compared pulsatile GnRH versus gonadotrophins alone and found no significant difference in multiple pregnancy rates after six cycles.[49] However, 75% of the multiple pregnancies in the gonadotrophin group were triplets or higher order multiple pregnancies, whereas all multiple pregnancies in the GnRH group were twins.

Comment: Pulsatile GnRH is used in women with anovulation caused by low serum gonadotrophins and oestrogen concentrations (hypogonadotropic hypogonadism). Hypogonadotropic hypogonadism is a well defined condition and so evidence from case series should be generalisable to most affected women. Case series (256 anovulatory women with hypogonadotropic hypogonadism undergoing 1043 treatment cycles) found cumulative pregnancy rates of 59–73% at 6 months and 81–92% at 12 months.[50–53] Only one series reported the live birth rate; this was 65% after 12 treatment cycles.[53]

QUESTION What are the effects of treatments for tubal infertility?

OPTION SELECTIVE SALPINGOGRAPHY PLUS TUBAL CATHETERISATION

We found no RCTs on the effects of selective salpingography plus tubal catheterisation in women with tubal infertility.

Benefits: We found no systematic review or RCTs.

Harms: Observational studies found that ectopic pregnancy occurred in 3–9% of women undergoing selective salpingography and tubal catheterisation and that tubal perforation, which does not seem to be clinically important, occurred in 2%.[52,54]

Comment: One systematic review (search date not reported) combined data from 10 cohort and other observational studies of selective salpingography and tubal cannulation (482 women), and four observational studies of hysteroscopic cannulation for proximal tubal blockage (133 women).[52] It found that hysteroscopy was associated with a higher pregnancy rate compared with selective salpingography and tubal catheterisation (pregnancies exceeding 20 weeks' gestation: 65/133 [49%] with hysteroscopy *v* 103/482 [21%] with salpingography). None of the observational studies included an untreated group, so it is not possible to estimate the treatment related pregnancy rate over and above the spontaneous pregnancy rate. Tubal patency and pregnancy without treatment have been reported in women diagnosed with bilateral proximal tube obstruction.[55]

OPTION TUBAL FLUSHING

One systematic review identified no RCTs comparing tubal flushing with water soluble media versus no intervention. It found that tubal flushing with oil soluble media increased pregnancy rates compared with no intervention. It also found that tubal flushing with oil soluble media increased the live birth rate compared with flushing with water soluble media.

Benefits: We found no RCTs reporting solely on women with tubal infertility. We found one systematic review (search date 2001, 8 RCTs, 1706 women) that evaluated flushing of the woman's fallopian tubes with oil or water soluble media in couples with infertility.[56] **Versus no intervention:** The review found no RCTs comparing tubal flushing with water soluble media versus no intervention.[56] It found that tubal flushing with oil soluble media significantly increased the chance of pregnancy compared with no intervention (2 RCTs; 224 women; OR 3.57, 95% CI 1.76 to 7.23). **Oil soluble versus water soluble media:** The review found no significant difference in pregnancy rates between tubal flushing with oil soluble versus water soluble media.[56] However, oil soluble media significantly increased live birth rates (live birth: 2 RCTs; 951 women; OR 1.49, 95% CI 1.05 to 2.11; pregnancy: 5 RCTs; 1241 women; OR 1.23, 95% CI 0.95 to 1.60).

Harms: **Versus no intervention:** The RCTs included in the review gave no information on miscarriage, ectopic pregnancy, procedural pain, or short or long term procedural complications.[56] **Oil soluble versus water soluble media:** The systematic review found that oil soluble media reduced procedural pain and procedural complications compared with water soluble media (pain: 2 RCTs; 834 women; OR 0.40, 95% CI 0.28 to 0.57; procedural complications: 4 RCTs; 1357 women; OR 0.22, 95% CI 0.14 to 0.34).[56] It found no significant difference in miscarriage or ectopic pregnancy (miscarriage per pregnancy: 1 RCT; 158 women; OR 0.82, 95% CI 0.41 to 1.64; ectopic pregnancy: 2 RCTs; 562 women; OR 0.49, 95% CI 0.10 to 2.42).

Comment: RCTs comparing oil soluble versus water soluble media were statistically heterogeneous.[56] The RCTs were not solely in women with tubal infertility and so may also be relevant to couples with unexplained infertility. One RCT included in the review only included women with unexplained infertility or mild endometriosis.[57]

OPTION TUBAL SURGERY

One systematic review in women with hydrosalpinges undergoing in vitro fertilisation has found that tubal surgery increases pregnancy and live birth rates compared with no treatment or medical treatment. One systematic review found no significant difference in pregnancy rates among different types of tubal surgery. One systematic review found no significant difference in pregnancy rates between tubal surgery plus additional treatments to prevent adhesion formation (steroids, dextran, noxytioline) and tubal surgery alone. Another systematic review provided insufficient evidence to assess postoperative hydrotubation or second look laparoscopy.

Benefits: **Versus no treatment or medical treatment:** We found one systematic review (search date 2000, 3 RCTs, 295 women with hydrosalpinges undergoing in vitro fertilisation [IVF]; see comment below), which found that tubal surgery significantly increased pregnancy rates compared with no treatment or medical treatment (OR 1.75, 95% CI 1.07 to 2.86) and the live birth rate (OR 2.13, 95% CI 1.24 to 3.65; see comment below).[58] **Different types of tubal surgery versus each other:** We found one systematic review (search date not reported, 8 RCTs, 557 women).[59] Two RCTs (130 women) identified by the review found no significant difference in pregnancy rates between CO_2 laser adhesiolysis (see glossary, p 2451) and diathermy adhesiolysis (1 RCT; 16/30 [53%] with laser *v* 17/33 [52%] with diathermy; RR 1.04, 95% CI 0.65 to 1.67) or between CO_2 laser salpingostomy and diathermy salpingostomy (1 RCT; 26/75 [35%] with laser *v* 16/60 [27%] with diathermy; RR 1.30, 95% CI 0.77 to 2.19).[59] A third RCT (72 women) identified by the first review found no significant difference in pregnancies after 2 years between the use of an operating microscope and the use of magnifying lenses (loupes) during microsurgical reversal of sterilisations (26/36 [72%] with microscope *v* 28/36 [78%] with loupes; OR 0.75, 95% CI 0.26 to 2.15).[59] **Adding postoperative treatments to tubal surgery:** We found two systematic reviews (search date not reported, 10 RCTs,

1086 women;[60] search date not reported, 5 RCTs, 588 women[61]). The first review compared tubal surgery plus additional treatments to prevent adhesion formation (steroids, dextran, and noxytioline) versus tubal surgery alone.[60] It found no significant difference in pregnancy rates between tubal surgery plus steroids (systemic or intraperitoneal) and no steroids (4 RCTs; OR 1.10, 95% CI 0.74 to 1.64), tubal surgery plus dextran (intraperitoneal) and no dextran (3 RCTs; OR 0.65, 95% CI 0.37 to 1.14), or tubal surgery plus noxytioline (intraperitoneal) and no noxytioline (1 RCT; OR 0.67, 95% CI 0.30 to 1.47). The second review compared early postoperative hydrotubation (see glossary, p 2451) or second look laparoscopy (see glossary, p 2452) plus adhesiolysis after tubal surgery versus control (late postoperative hydrotubation, postoperative irrigation with antibiotics plus late postoperative hydrotubation, no postoperative hydrotubation, or no second look laparoscopy).[61] It found that all the RCTs were either poor quality or underpowered. It found insufficient evidence to support the routine practice of hydrotubation (1 RCT; OR 1.12, 95% CI 0.57 to 2.21) or second look laparoscopy (2 RCTs; OR 0.96 95% CI 0.44 to 2.07) after tubal surgery. **Versus IVF:** We found no RCTs (see comment below).

Harms:

Versus no treatment or medical treatment: The review found no significant difference between tubal surgery and no treatment or medical treatment in the rate of ectopic pregnancy (OR 0.42, 95% CI 0.08 to 2.14), miscarriage per pregnancy (OR 0.49, 95% CI 0.16 to 1.52), or treatment related complications (OR 5.80, 95% CI 0.35 to 96.79).[58] Tubal surgery involves general anaesthesia and admission to hospital. There is a risk of ectopic pregnancy caused by pre-existing tubal damage; retrospective studies have reported rates of 7–9% with tubal surgery, compared with 1–3% with IVF.[9,10] IVF carries the risk of multiple pregnancy and ovarian hyperstimulation syndrome (see glossary, p 2452) (see harms of IVF under treatments for tubal infertility, p 2440).

Comment:

Success rates with tubal surgery depend on the severity and site of disease. The best figures from surgery in women with distal tubal occlusion are live birth rates of 20–30%, with rates of 40–60% reported for the less common proximal occlusion (see table 1, p 2457).[20–24] Success rates with reversal of female sterilisation vary depending on the method used for sterilisation, with live birth rates of 50–90%.[25] **Versus no treatment or medical treatment:** In the systematic review comparing tubal surgery versus non-surgical treatment, although a variety of different surgical techniques were used, laparoscopic unilateral or bilateral salpingectomy were the most common (numerical data not reported).[58] **Different types of tubal surgery versus each other:** Of the eight RCTs included in the review, five used outdated surgical techniques, were small, and had problems relating to methods of randomisation.[59] These data precede recent improvements in case selection and laparoscopic training. One additional systematic review (search date not reported, 7 observational studies, 279 women with proximal tubal blockage) compared microsurgery (see glossary, p 2452) (275 women) versus macrosurgery (see glossary, p 2452) (104 women).[52] It found that microsurgery significantly increased pregnancy rates compared with macrosurgery (RR 2.2, 95% CI 1.5 to

3.2). **Versus IVF:** Fertility rates from case series of tubal surgery and from large databases of couples undergoing IVF suggest that tubal surgery is as effective as IVF in women with filmy adhesions, mild distal tubal occlusion, or proximal obstruction.[20,62–66] If successful, tubal surgery allows women to have more pregnancies without further medical intervention and without the risks associated with IVF.[67]

OPTION IN VITRO FERTILISATION

We found no RCTs comparing in vitro fertilisation versus no treatment. RCTs are unlikely to be conducted. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. One RCT found that immediate compared with delayed in vitro fertilisation increased pregnancy and live birth rates. Three RCTs found no significant difference in numbers of live births between in vitro fertilisation and intracytoplasmic sperm injection. Observational evidence suggests that adverse effects associated with in vitro fertilisation include multiple pregnancies and ovarian hyperstimulation syndrome.

Benefits: We found no systematic review. **In vitro fertilisation (IVF) versus no treatment:** We found no RCTs. **Immediate versus delayed IVF:** We found one RCT (399 couples with any cause of infertility; the couples who received delayed IVF acted as untreated controls for at least 6 months), which found that immediate IVF (see glossary, p 2451) compared with delayed IVF (see glossary, p 2451) significantly increased the pregnancy rate (33/190 [17%] with immediate IVF *v* 13/163 [8%] with delayed IVF; RR 2.18, 95% CI 1.19 to 4.0), and significantly increased the numbers of live births (22/190 [12%] with immediate IVF *v* 8/163 [5%] with delayed IVF; RR 2.36, 95% CI 1.08 to 5.16).[68] **Versus tubal surgery:** See benefits of tubal surgery, p 2438. **Plus intracytoplasmic sperm injection (ICSI):** We found one systematic review (search date 2002, 1 RCT, 415 couples) that found no significant difference in pregnancy rates between IVF plus ICSI and IVF alone in couples with non-male subfertility (70/213 [33%] with IVF alone *v* 51/202 [25%] with IVF plus ICSI; OR 1.4, 95% CI 0.95 to 2.2).[69]

Harms: **Multiple pregnancy:** One RCT did not report on multiple pregnancy rates,[70] and the other RCTs were underpowered to detect clinically important differences in multiple pregnancy rates between treatments.[68,71,72] However, of the 6309 live births after IVF in the UK in 2000–2001, 27% were multiple, including 109 (2%) triplets.[8] In the UK, the number of embryos that can be replaced is restricted to two (see table 1, p 2457).[8] In the USA, where there are no such restrictions, 15 367 live births included 38% multiple births, 6% of which were triplets and above.[11] **Ovarian hyperstimulation syndrome:** The RCT comparing IVF versus ICSI found that ovarian hyperstimulation occurred in seven (4%) IVF cycles and nine (5%) ICSI cycles.[71] The other RCTs gave no information about rates of ovarian hyperstimulation syndrome (see glossary, p 2452).[68,70,72] One non-systematic review suggests that severe ovarian hyperstimulation syndrome occurs in 0.5–2.0% of all IVF cycles.[12]

Obstetric outcome: We found one systematic review (search date 1998, 42 high quality observational studies) that compared obstetric outcome in mothers receiving IVF versus either a population based control group or a selected control group matched for different variables.[73] It found that children born after IVF had a considerably higher risk of being born preterm and with a lower birth weight than children conceived naturally, although this was likely to be because of the high incidence of multiple births and maternal characteristics such as nulliparity, increased age, previous infertility, and obstetric history (absolute numbers not reported). There was no evidence of an increased overall incidence of congenital malformations in children born after conventional IVF or after embryo cryopreservation.

Comment: The success of IVF is influenced by a woman's age, duration of infertility, and previous pregnancy history.[2] Pregnancy rates are highest between the ages of 25 and 35 years and decline steeply after 35 years . Similar clinics, which describe the same methods, report different success rates for IVF.[2] In the UK Human Fertilisation and Embryology Authority database, the average live birth rate per IVF cycle over 2000–2001 was 22% if ICSI cycles were taken into account (see table 1, p 2457).[8] The equivalent average figure in the USA is 25%, but again results vary among centres.[11,74] In the UK, larger centres (≥200 cycles a year) report slightly higher live birth rates than smaller centres (20% per cycle started compared with 16%).[75] Such a difference has not been reported consistently in the USA.

QUESTION What are the effects of treatment for infertility associated with endometriosis?

OPTION DRUG INDUCED OVARIAN SUPPRESSION

One systematic review found no significant difference in pregnancy rates between drugs that induce ovarian suppression and placebo. The review found that ovulation suppression agents (medroxyprogesterone, gestrinone, combined oral contraceptives, and gonadotrophin releasing hormone analogues) cause adverse effects, including weight gain, hot flushes, and osteoporosis, and that danazol may cause dose related weight gain and androgenic effects.

Benefits: We found one systematic review (search date not reported, 13 RCTs).[76] **Versus placebo:** The review identified five RCTs (244 women with visually diagnosed endometriosis who had been attempting conception for < 12 months) comparing ovulation suppression agents (medroxyprogesterone, gestrinone, combined oral contraceptives, and gonadotrophin releasing hormone analogues) versus placebo. It found no significant difference in pregnancy rates between ovulation suppression agents and placebo (OR 0.8, 95% CI 0.5 to 1.4).[76] **Versus danazol:** The review identified eight RCTs (658 women with visually diagnosed endometriosis who had been attempting conception for < 12 months).[76] It found no significant difference in pregnancy rates between ovulation suppression agents and danazol (OR 1.2, 95% CI 0.9 to 1.7).[76] **Versus surgery:** See benefits of laparoscopic ablation of endometrial depositis, p 2450.

Harms: The review found that ovulation suppression agents caused adverse effects that included weight gain, hot flushes, and osteoporosis.[76] Adverse effects of danazol were dose related and included an average weight gain of 2–4 kg with 3 months' treatment; androgenic effects such as acne, seborrhoea, hirsutism, voice changes; and general complaints, including irritability, musculoskeletal pains, and tiredness. Hot flushes and breast atrophy were sometimes observed. One RCT (40 women with menorrhagia) comparing danazol versus mefenamic acid found that most of these adverse effects were reversible on stopping treatment.[77]

Comment: In the review, three of the RCTs used a combination of clomifene (clomiphene) plus ovarian suppression agents.[76] Treatment using ovulation suppression could waste valuable time for women who are trying to get pregnant, as the opportunity for spontaneous conceptions is lost during treatment.

OPTION INTRAUTERINE INSEMINATION PLUS GONADOTROPHINS

One RCT found that intrauterine insemination plus gonadotrophins increased live birth rates compared with no treatment. A second RCT found no significant difference in birth rates between intrauterine insemination plus pituitary down regulation plus gonadotrophins and expectant management, but it is likely to have been underpowered to detect a clinically important difference. A third RCT found that intrauterine insemination plus gonadotrophins increased pregnancy rates after the first treatment cycle compared with intrauterine insemination alone.

Benefits: We found no systematic review but found three RCTs.[78–80] The first RCT (103 couples with infertility associated with minimal or mild endometriosis) compared intrauterine insemination plus gonadotrophins (53 couples, 127 cycles) versus no treatment (50 couples, 184 cycles).[78] It found that intrauterine insemination plus follicle stimulating hormone (FSH) significantly increased live birth rates compared with no treatment (14/53 [26%] with intrauterine insemination plus FSH *v* 4/50 [8%] with no treatment; RR 3.3, 95% CI 1.2 to 9.4; NNT 6, 95% CI 3 to 28).[78] The second RCT (49 women with minimal or mild endometriosis) compared three cycles of pituitary down regulation plus gonadotrophins plus intrauterine insemination versus 6 months of expectant management.[79] It found no significant difference in birth rates (7/24 [29%] with intrauterine insemination plus pituitary down regulation plus gonadotrophins *v* 5/25 [20%] with expectant management; RR 1.5, 95% CI 0.5 to 4.0). The RCT is likely to have been underpowered to detect a clinically important difference in pregnancy rates between the two groups. The third RCT (119 couples with primary pelvic or cervical factor infertility for a mean of 3.7 years, 57 couples with infertility associated with endometriosis) compared alternate cycles of gonadotrophins plus intrauterine insemination versus intrauterine insemination alone.[80] It found that gonadotrophins plus intrauterine insemination significantly increased the pregnancy rate after the first treatment cycle compared with intrauterine insemination alone (11/58 [19%] with gonadotrophins plus intrauterine insemination *v* 0/61 [0%] with intrauterine insemination alone; NNT 5, 95% CI 4 to

14). The 119 couples were subsequently followed up longitudinally and it was found that, in the 57 couples with a diagnosis of endometriosis, gonadotrophins plus intrauterine insemination significantly increased the probability of pregnancy over a total of 127 cycles compared with intrauterine insemination alone (RR 5.1, 95% CI 1.1 to 22.5).[80]

Harms: No cases of severe ovarian hyperstimulation or hospital admission were reported in the first or third RCTs.[78,80] In the second RCT, one severe case (1/24 [4%]), one moderate case (1/24 [4%]), and three mild cases (3/24 [13%]) of ovarian hyperstimulation syndrome (see glossary, p 2452) were reported.[79]

Comment: We found one systematic review (search date 2002, 3 RCTs, 386 women) that compared single versus double inseminations in stimulated cycles of intrauterine insemination.[81] Although live birth rates per couple could not be estimated, the pregnancy rates per couple were not significantly increased by performing an additional insemination (OR 1.45, 95% CI 0.78 to 2.68). One small crossover RCT assessed the timing of insemination in clomifene (clomiphene) stimulated cycles.[82] It found similar pregnancy rates per cycle whether insemination was timed with a urinary luteinising hormone kit or whether ultrasound monitoring with human chorionic gonadotrophin induction of ovulation was used.

OPTION LAPAROSCOPIC ABLATION OF ENDOMETRIAL DEPOSITS

We found no RCTs comparing laparoscopic surgery versus no treatment or versus ovarian suppression. One systematic review has found that laparoscopic ablation or resection of endometrial deposits increases live births and ongoing pregnancy rates compared with diagnostic laparoscopy. Operative complications were not increased with laparoscopic surgery.

Benefits: **Versus no treatment or ovarian suppression:** We found no RCTs (see comment below). **Laparoscopic surgery versus diagnostic laparoscopy:** We found one systematic review (search date 2000–2001, 2 RCTs, 437 women) comparing laparoscopic surgery (ablation or resection of endometrial deposits) versus diagnostic laparoscopy.[26] It found that laparoscopic surgery significantly increased the proportion of women who had a live birth or pregnancy continuing beyond 20 weeks compared with diagnostic laparoscopy (60/223 [27%] with laparoscopic surgery *v* 39/214 [18%] with diagnostic laparoscopy; OR 1.65, 95% CI 1.05 to 2.60) (see table 1, p 2457). See also laparoscopic ablation of endometrial deposits under endometriosis, p 2391.

Harms: The review found no significant difference in the proportion of women who had intraoperative complications between laparoscopic surgery and diagnostic laparoscopy (3/172 [1.7%] with laparoscopic surgery *v* 1/169 [0.6%] with diagnostic laparoscopy; OR 2.69, 95% CI 0.38 to 19.30).[26] One multicentre series of 29 966 diagnostic and operative gynaecological laparoscopies found a mortality of 3.3/100 000 laparoscopies and a complication rate of 3.2/1000 laparoscopies.[27]

Comment: The risks and morbidity of surgery under general anaesthesia and of postoperative adhesion formation need to be balanced against the adverse effects of treatments involving ovarian suppression or stimulation. In the larger RCT comparing laparoscopic surgery versus diagnostic laparoscopy, 48/341 (14%) women who received laparoscopic surgery for their endometriosis also had periadnexal adhesions treated, which may have affected their fertility.[26] We found one systematic review (search date not reported)[83] and one non-systematic review,[84] which together identified 21 cohort studies and one quasi-randomised trial in a total of 3879 women with all stages of endometriosis. Interventions were laparoscopic or open surgery versus medical treatment or no treatment. The non-systematic review combined data from all 21 studies and found that surgery significantly increased pregnancy rates compared with medical treatment or no treatment (RR 1.4, 95% CI 1.3 to 1.5).[84] It found no significant difference in pregnancy rates between laparoscopic and open surgery (RR 0.9, 95% CI 0.8 to 1.0). It found that, in women with mild or minimal endometriosis, laparoscopic surgery significantly increased pregnancy rates compared with danazol or no treatment (OR 2.7, 95% CI 2.1 to 3.5; absolute results presented graphically).

OPTION IN VITRO FERTILISATION

We found no RCTs comparing in vitro fertilisation versus no treatment in women with endometriosis related infertility. RCTs are unlikely to be conducted. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. Observational studies found inconclusive evidence about whether in vitro fertilisation is as effective in women with endometriosis as in women with tubal infertility.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: See harms of in vitro fertilisation under treatments for tubal infertility, p 2440.

Comment: In the UK Human Fertilisation and Embryology Authority database, the live average birth rate per in vitro fertilisation cycle over 2000–2001 was 22% if intracytoplasmic sperm injection cycles were taken into account.[8] We found one systematic review[85] and two retrospective cohort studies[86,87] that examined the effects of endometriosis compared with other causes of infertility, or the effects of severity of endometriosis, on in vitro fertilisation outcome. The cohort studies found no significant difference in pregnancy rates among groups.[86,87] The systematic review (search date 1999, 22 non-randomised studies) found that women with endometriosis were less likely to become pregnant than women with infertility because of blocked or damaged tubes (pregnancy assessed by human chorionic gonadotrophin levels; adjusted OR 0.56, 95% CI 0.44 to 0.70).[85] There is a need for properly controlled prospective randomised studies that present fertility rates with in vitro fertilisation in different stages of endometriosis using a validated classification system. Comparisons with assisted reproductive techniques are also required.

QUESTION **What are the effects of treatments for male factor infertility?**

OPTION INTRAUTERINE INSEMINATION

Two systematic reviews have found that intrauterine insemination increases pregnancy rates per cycle compared with intracervical insemination or timed intercourse.

Benefits: We found two systematic reviews (search date not reported[28] and search date 1996–1997[88]). The first review (10 RCTs, 2082 treatment cycles in couples with male infertility) compared intrauterine insemination with or without gonadotrophins versus intracervical insemination or timed intercourse.[28] It found that intrauterine insemination significantly increased the pregnancy rate per cycle compared with other treatments (6.5% with intrauterine insemination *v* 3.1% with intracervical insemination or timed intercourse; OR for intrauterine insemination *v* either intracervical insemination or timed intercourse 2.2, 95% CI 1.4 to 3.4) (see table 1, p 2457).[28] The second review (17 RCTs including 8 RCTs identified by the first review, 3662 completed treatment cycles in couples with male subfertility) found that, compared with timed intercourse, intrauterine insemination with or without ovarian stimulation significantly increased conception rates both in natural cycles (OR 2.4, 95% CI 1.5 to 3.8) and in controlled cycles (OR 2.1, 95% CI 1.3 to 3.5).[88] The review found that intrauterine insemination in controlled cycles also significantly increased the probability of conception compared with timed intercourse in natural cycles (OR 6.2, 95% CI 2.4 to 16.5). It found no significant difference in conception rates between intrauterine insemination in controlled cycles and intrauterine insemination in natural cycles (OR 1.8, 95% CI 1.0 to 3.3).[88]

Harms: Apart from the risks of ovarian hyperstimulation syndrome (see glossary, p 2452) and multiple pregnancy associated with ovarian stimulation, intrauterine insemination may increase the likelihood of infection and may cause discomfort. However, data from RCTs are scarce.

Comment: The evidence from RCTs for timing and the optimum number of inseminations per cycle is inconclusive (see comments on intrauterine insemination under treatments for infertility associated with endometriosis, p 2443).

OPTION INTRACYTOPLASMIC SPERM INJECTION PLUS IN VITRO FERTILISATION

We found no RCTs of intracytoplasmic sperm injection plus in vitro fertilisation that assessed pregnancy and live birth rates. Observational evidence in the UK suggests an average live birth rate of 22% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account.

Benefits: **Versus in vitro fertilisation alone:** We found no RCTs of intracytoplasmic sperm injection (ICSI) plus in vitro fertilisation that assessed pregnancy and live birth rates (see comment below).

Harms: Observational studies have found conflicting reports of congenital abnormalities[89,90] and sex chromosomal abnormalities in children born after ICSI (see comment below).[91,92] One systematic review (search date 2001, 30 observational studies) concluded that although there was a small increased risk of major birth defects in children born after ICSI, this increase was not significant and no particular type of malformation was increased.[93] It could not clarify whether ICSI increased the occurrence of chromosomal abnormalities in the offspring of infertile couples with normal karyotypes.

Comment: The data on congenital and chromosome abnormalities with ICSI are constantly being revised as experience increases. Many couples have a strong preference for a child that is genetically related to both partners.[94] In the UK Human Fertilisation and Embryology Authority database, the average live birth rate per in vitro fertilisation cycle over 2000–2001 was 22% if ICSI cycles were taken into account (see table 1, p 2457).[8]

OPTION IN VITRO FERTILISATION VERSUS GAMETE INTRAFALLOPIAN TRANSFER

One small RCT provided insufficient evidence to compare in vitro fertilisation versus gamete intrafallopian transfer.

Benefits: We found no systematic review. We found one RCT (13 couples with male infertility), which found no significant difference between in vitro fertilisation and gamete intrafallopian transfer in pregnancy rates over 1 year (2/7 [29%] with in vitro fertilisation *v* 2/6 [33%] with gamete intrafallopian transfer; RR 1.20, 95% CI 0.23 to 5.95).[95]

Harms: See harms of in vitro fertilisation under treatments for tubal infertility, p 2440.

Comment: Data from large databases suggest the live birth rate per cycle of gamete intrafallopian transfer in women with infertility other than tubal infertility is 23% and the risk of ectopic pregnancy 5% (see table 1, p 2457).[13]

OPTION DONOR INSEMINATION

We found no RCTs on the effects of donor insemination. Observational evidence suggests an average live birth rate of 11%, but it is sometimes unclear whether ovarian stimulation was used in addition to donor insemination.

Benefits: **Versus no treatment:** We found no systematic review or RCTs in couples with male infertility that compared donor insemination versus no treatment or other interventions (see comment below).

Harms: We found no RCTs.

Comment: One systematic review (search date 1996, 12 RCTs, 2215 treatment cycles) found limited evidence that intrauterine compared with intracervical insemination of frozen donor sperm increased pregnancy rates.[96] The review included RCTs that were poor in their

methodology, contained several different treatment variations making direct comparisons difficult, and included a mixture of women with and without fertility problems. Data are available from large databases, but it is sometimes unclear whether ovarian stimulation was used in addition to donor insemination. The average live birth rate per cycle in the UK Human Fertilisation and Embryology Authority database in 2000–2001 was 11% with donor insemination (see table 1, p 2457).[8] Similar rates are reported from the French donor insemination database (23 700 women over 4 years), with a mean pregnancy rate of 10% per cycle, and the Sheffield database (UK, 343 women, 980 treatment cycles), with an 11% overall live birth rate.[29,30] Comparisons of donor insemination versus no treatment or other interventions may be inappropriate as, for many couples, donor insemination is not an acceptable option. RCTs have tended to concentrate on comparisons between different techniques of donor insemination.

QUESTION What are the effects of treatments for unexplained infertility?

OPTION CLOMIFENE

One systematic review found limited evidence that clomifene (clomiphene) increased rates of pregnancy per cycle compared with placebo.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 4 using crossover designs; 458 cycles in women with unexplained infertility), which found that clomifene significantly increased pregnancy rates per cycle compared with placebo (OR 2.5, 95% CI 1.4 to 4.6; see comment below).[97] When only cycles before crossover were analysed (which was only possible with the data from 3 of the RCTs), the positive effect increased (OR 5.0, 95% CI 1.8 to 14.3).

Harms: See harms of clomifene under treatments for infertility caused by ovulation disorders, p 2432.

Comment: The systematic review[97] excluded one RCT[98] because of the risk of selection bias with a pseudo-random allocation method based on odd or even chart numbers. The other RCTs identified by the review were generally poor and it is possible that if one further medium sized RCT was performed, the direction of the overall effect found with meta-analysis could change again.[97] The review highlighted important differences between the trials: two RCTs included women with surgically treated endometriosis, one included only couples with primary infertility, and one included couples with a short duration of infertility (median of 28 months). Three of the RCTs included co-intervention with intrauterine insemination or cervicovaginal insemination. The RCTs also differed in their design (4 were crossover trials) and in the quality of randomisation (only 1 used properly concealed randomisation). The authors of the review commented that, as the baseline cycle fecundity of the women included in these trials would only be about 1–2%, even with clomifene their cycle fecundity would be unlikely to exceed 5%.[97]

OPTION INTRAUTERINE INSEMINATION PLUS GONADOTROPHINS

Two systematic reviews and one subsequent RCT have found that intrauterine insemination plus gonadotrophins increases pregnancy rates compared with timed intercourse or intracervical insemination. One systematic review found no significant difference between intrauterine insemination and timed intercourse or intracervical insemination in pregnancy rates. It found that adding ovarian stimulation to any of the three interventions increased pregnancy rates per cycle. One systematic review and one subsequent RCT have found that fallopian tube sperm perfusion increases pregnancy rates compared with intrauterine insemination. One systematic review found no significant difference in live birth rate between intrauterine insemination with or without ovarian stimulation and in vitro fertilisation.

Benefits:

Versus timed intercourse or intracervical insemination: We found three systematic reviews,[28,31,99] which between them identified 12 RCTs and we found one subsequent RCT,[100] in couples with unexplained infertility. The first review (search date not reported, 8 RCTs, number of treatment cycles not reported) compared intrauterine insemination plus gonadotrophins versus timed intercourse plus gonadotrophins.[99] It found that intrauterine insemination plus ovarian stimulation significantly increased pregnancy rates (OR 2.4, 95% CI 1.4 to 3.9). The second review (search date 1997, 7 RCTs including 6 RCTs identified by the first review, 980 treatment cycles) compared intrauterine insemination plus ovarian stimulation with gonadotrophins versus timed intercourse plus ovarian stimulation with gonadotrophins.[31] It found that intrauterine insemination plus ovarian stimulation significantly increased the pregnancy rate per cycle (110/549 [20%] with intrauterine insemination plus ovarian stimulation *v* 49/431 [11%] with timed intercourse plus ovarian stimulation; RR 0.20, 95% CI 0.08 to 0.31). The third systematic review (search date not reported, 7 RCTs, including 4 RCTs identified by the first or second reviews, 934 treatment cycles) compared intrauterine insemination versus timed intercourse or intracervical insemination.[28] Four RCTs used gonadotrophins, two used clomifene (clomiphene), and three used no ovarian stimulation. The review found no significant difference between intrauterine insemination and intracervical insemination or timed intercourse in pregnancy rates (OR 1.5, 95% CI 1.0 to 2.2). The review also found that the addition of ovarian stimulation with gonadotrophins to any of the three interventions significantly increased the overall pregnancy rates (45/249 [18%] with intrauterine insemination or favourable timed intracervical insemination or timed intercourse plus gonadotrophin stimulation *v* 9/108 [8%] with intrauterine insemination or favourable timed intracervical insemination or timed intercourse alone; RR 2.17, 95% CI 1.10 to 4.28; NNT 11, 95% CI 7 to 58).[28] The subsequent RCT (932 couples) compared intracervical insemination alone, intrauterine insemination alone, intracervical insemination plus ovarian stimulation, and intrauterine insemination plus ovarian stimulation for four cycles or until pregnancy was achieved.[100] It found that intrauterine insemination plus ovarian stimulation versus intracervical insemination alone significantly increased the chance of becoming pregnant (OR 3.2, 95% CI 2.0 to 5.3). The RCT also found pregnancy rates of 14/233 (6%) with

intracervical insemination, 35/234 (15%) with intrauterine insemination, 26/234 (11%) with ovarian stimulation plus intracervical insemination, and 54/231 (23%) with ovarian stimulation plus intrauterine insemination.[100] **Versus intrauterine insemination alone:** We found one RCT (932 couples), which found that intrauterine insemination plus ovarian stimulation versus intrauterine insemination alone significantly increased the chance of becoming pregnant (OR 1.7, 95% CI 1.2 to 2.6).[100] **Versus fallopian tube sperm perfusion:** See glossary, p 2451. See benefits of fallopian tube sperm perfusion, p 2449. **Versus gamete intrafallopian transfer:** See benefits of gamete intrafallopian transfer, p 2450. **Versus in vitro fertilisation:** See in vitro fertilisation for unexplained infertility, p 2451.

Harms: Apart from the risks of ovarian hyperstimulation syndrome (see glossary, p 2452) and multiple pregnancy, intrauterine insemination may increase the likelihood of infection and may be associated with some discomfort. However, data from RCTs are scarce. **Versus in vitro fertilisation:** See in vitro fertilisation for unexplained infertility, p 2451. **Different gonadotrophins:** One RCT (97 couples with unexplained infertility) compared intrauterine insemination plus low dose, step up follicle stimulating hormone (FSH) versus intrauterine insemination plus a conventional FSH regimen.[101] It found no significant difference in pregnancy rates (7/49 [14%] with low dose FSH plus intrauterine insemination *v* 7/48 [15%] with conventional FSH plus intrauterine insemination; RR 0.98, 95% CI 0.37 to 2.58). Low dose FSH versus conventional FSH significantly reduced the proportion of women with ovarian hyperstimulation syndrome (4/49 [8%] with low dose FSH *v* 13/48 [27%] with conventional FSH; RR 0.30, 95% CI 0.11 to 0.86; NNT 6, 95% 3 to 28), and ovarian hyperstimulation syndrome requiring hospital admission (0% with low dose FSH *v* 16.7% with conventional FSH). However, the low dose regimen did not completely prevent multiple pregnancies.

Comment: Only three of the RCTs were common to all three systematic reviews. One of the reviews scored the included studies for validity.[31] They scored from 49–70% when 100% was taken as the ideal study. The evidence from RCTs for timing and the optimum number of inseminations per cycle is inconclusive (see comments on intrauterine insemination under treatments for infertility associated with endometriosis, p 2443).

OPTION FALLOPIAN TUBE SPERM PERFUSION

One systematic review and one subsequent RCT have found that fallopian tube sperm perfusion increases pregnancy rates compared with intrauterine insemination.

Benefits: **Versus intrauterine insemination:** We found one non-systematic review (search date not reported, 5 RCTs in couples with unexplained infertility)[102] and one subsequent RCT that compared fallopian tube sperm perfusion (see glossary, p 2451) versus intrauterine insemination.[103] All five RCTs in the review used gonadotrophins or gonadotrophins plus clomifene (clomiphene), and in

total 293 cycles of intrauterine insemination and 317 cycles of fallopian tube sperm perfusion were assessed.[102] The review found that fallopian tube sperm perfusion significantly increased pregnancy rate per cycle compared with intrauterine insemination (70/317 [22%] with fallopian tube sperm perfusion *v* 38/293 [13%] with intrauterine insemination; RR 1.70, 95% CI 1.19 to 2.44; NNT 11, 95% CI 7 to 33). The subsequent RCT (132 cycles in 65 couples) also found that, compared with intrauterine insemination, fallopian tube sperm perfusion significantly increased pregnancy rates per cycle (16/66 [24%] with fallopian tube sperm perfusion *v* 6/66 [9%] with intrauterine insemination; RR 2.67, 95% CI 1.11 to 6.40; NNT 7, 95% CI 4 to 38) and pregnancy rates per person after a maximum of three treatment cycles (16/33 [48%] with fallopian tube sperm perfusion *v* 6/32 [19%] with intrauterine insemination; RR 2.59, 95% CI 1.16 to 5.77; NNT 4, 95% CI 2 to 9).[103]

Harms: See harms of intrauterine insemination, p 2449. The non-systematic review did not report on harms.[102] The subsequent RCT reported that complications, including cervical bleeding, vasovagal episodes, uterine cramping, or pelvic infections, were not reported with either treatment.[103]

Comment: None.

OPTION GAMETE INTRAFALLOPIAN TRANSFER

We found no RCTs comparing gamete intrafallopian transfer versus no treatment. RCTs found conflicting results with gamete intrafallopian transfer versus other treatments (intrauterine insemination, timed intercourse, and in vitro fertilisation in pregnancy rates).

Benefits: **Versus no treatment:** We found no systematic review or RCTs. **Versus intrauterine insemination or timed intercourse:** We found no systematic review. We found three RCTs (283 couples with unexplained infertility).[104–106] The first RCT (50 couples) compared gamete intrafallopian transfer (GIFT) versus ovarian stimulation plus either timed intercourse or timed cervical donor insemination and found no significant difference in pregnancy rates (2/24 [8%] with GIFT cycles *v* 2/15 [13%] with ovarian stimulation plus either timed intercourse or timed cervical donor insemination; RR 0.63, 95% CI 0.10 to 3.98).[104] Of the other two RCTs, one (174 couples) found that GIFT increased pregnancy rates compared with ovarian stimulation with or without intrauterine insemination, and the other (59 couples) found no significant difference in pregnancy rates.[105,106] **Versus in vitro fertilisation:** See benefits of in vitro fertilisation for the treatment of unexplained infertility, p 2451.

Harms: Potential harms include the risks attributable to general anaesthesia and laparoscopy. One of the RCTs found that multiple pregnancy rates varied with the number of oocytes transferred.[106]

Comment: One prospective cohort study (99 treatment cycles, 53 couples) found that GIFT versus no treatment increased numbers of pregnancies.[107] GIFT, unlike in vitro fertilisation, gives no diagnostic information regarding fertilisation, and involves a laparoscopy and general anaesthetic, both of which are usually avoided with in vitro fertilisation. Observational data suggest that success rates decrease with increasing age.[108,109]

OPTION IN VITRO FERTILISATION

Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle. However, one systematic review identified one RCT in couples with unexplained infertility that found no significant difference in pregnancy rates between in vitro fertilisation and expectant management. RCTs included in the review found no significant difference in live birth rate between in vitro fertilisation and either gamete intrafallopian transfer or intrauterine insemination with or without ovarian stimulation.

Benefits: We found one systematic review (search date 2001, 5 RCTs, 353 women).[110] **Versus expectant management:** The review found no significant difference between in vitro fertilisation (IVF) and expectant management in pregnancy rates (1 RCT; 35 women; OR 0.30, 95% CI 0.02 to 3.67).[110] **Versus intrauterine insemination:** Three included RCTs found no significant difference in live birth rate between IVF and intrauterine insemination with or without ovarian stimulation (without ovarian stimulation: 1 RCT, 113 women; OR for live birth 1.96, 95% CI 0.88 to 4.36; with ovarian stimulation: 1 RCT, 118 women; OR 1.15, 95% CI 0.55 to 2.42).[110] **Versus gamete intrafallopian transfer:** One included RCT (69 women) found no significant difference between IVF and gamete intrafallopian transfer in live birth rate (OR 2.57, 95% CI 0.93 to 7.08).[110]

Harms: **Versus intrauterine insemination:** In one RCT (113 women) comparing intrauterine insemination versus IVF identified by the review, multiple pregnancy rates were 4% with intrauterine insemination in natural cycles, 29% with intrauterine insemination in stimulated cycles, and 21% with IVF (see harms of gonadotrophins, p 2434).[110] Mild ovarian hyperstimulation syndrome (see glossary, p 2452) occurred in two women in the stimulated intrauterine insemination group, and severe ovarian hyperstimulation syndrome occurred in three women in the IVF group. See also harms of in vitro fertilisation under treatments for tubal infertility, p 2440.

Comment: The RCTs included in the systematic review may have lacked power to detect clinically important differences between treatments.[110]

GLOSSARY

Adhesiolysis Division of adhesions, which are bands of scar tissue that form after infection or surgery.

Delayed in vitro fertilisation In vitro fertilisation treatment after 6 months of being assessed in an infertility clinic after at least 12 months of infertility.

Fallopian tube sperm perfusion Fallopian tube sperm perfusion is based on a pressure injection of 4 mL sperm suspension with an attempt to seal the cervix to prevent semen reflux. It attempts to ensure a sperm flushing of the fallopian tubes and an overflowing of the inseminate into the pouch of Douglas.

Hydrotubation Flushing of the fallopian tubes through the cervix and uterine cavity to remove surgical debris and reduce the incidence of tubal reocclusion.

Immediate in vitro fertilisation In vitro fertilisation treatment within 6 months of being assessed in an infertility clinic after at least 12 months of infertility.

Laparoscopic ovarian drilling Ovarian drilling can be performed laparoscopically by either cautery or laser vapourisation (using CO_2, argon, or Nd:YAG lasers), which are used to create multiple perforations (about 10 holes per ovary) of the ovarian

surface and stroma (inner area of the ovary). This is thought to cause ovulation by restoring the intra-ovarian hormonal environment to normal, which in turn beneficially affects the hypothalamic–pituitary–ovarian axis.

Macrosurgery Surgery without dedicated optical magnification.

Microsurgery Surgery involving optical magnification to allow the use of much finer instruments and suture material in addition to a non-touch technique, with the aim of minimising tissue handling and damage.

Ovarian hyperstimulation syndrome Can occur in mild, moderate, and severe forms. Mild ovarian hyperstimulation syndrome is characterised by fluid accumulation, as shown by weight gain, abdominal distension, and discomfort. Moderate ovarian hyperstimulation syndrome is associated with nausea and vomiting, ovarian enlargement, abdominal distension, discomfort, and dyspnoea. Severe ovarian hyperstimulation syndrome is a life threatening condition, in which there is contraction of the intravascular volume, tense ascites, pleural and pericardial effusions, severe haemoconcentration, and the development of hepatorenal failure. Deaths have occurred, caused usually by cerebrovascular thrombosis, renal failure, or cardiac tamponade.

Second look laparoscopy Laparoscopy performed some time after tubal surgery (either open or laparoscopic) with the aim of dividing adhesions relating to the initial procedure.

Substantive changes

In vitro fertilisation in women with tubal infertility We found no RCTs. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. Evidence reassessed. Recategorised as Beneficial.

Intrauterine insemination plus gonadotrophins One systematic review added;[81] categorisation unchanged.

Laparoscopic ablation of endometrial deposits in women with endometriosis One systematic review has found that laparoscopic ablation or resection of endometrial deposits increases the live birth rate and ongoing pregnancy rates compared with diagnostic laparoscopy.[26] Operative complications were not increased with laparoscopic surgery. Recategorised as Likely to be beneficial.

In vitro fertilisation in women with infertility associated with endometriosis We found no RCTs. Observational evidence in the UK and the USA suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. Observational studies found inconclusive evidence about whether in vitro fertilisation is as effective in women with endometriosis as in women with tubal infertility. Evidence reassessed. Recategorised as Likely to be beneficial.

Intracytoplasmic sperm injection plus in vitro fertilisation One systematic review assessing harms added.[93] Observational evidence in the UK suggests an average live birth rate of 22–25% per in vitro fertilisation cycle if intracytoplasmic sperm injection is taken into account. Evidence reassessed. Recategorised as Beneficial.

TABLE 1 **Success rates of treatments for infertility: evidence from RCTs and observational studies.**

Treatment	Live birth rates	Pregnancy rates	Adverse effects
All causes of infertility			
IVF (per treated cycle)	UK 22%[8]; USA 20%[2]		Ectopic pregnancy 1–3%[9,10]; MB 27%[8]; Severe OHSS 0.5–2.0%[11,12]
GIFT (per cycle) (not including tubal infertility)	23%[13]		Ectopic pregnancy 5%
Infertility caused by ovulation disorders			
Clomifene in amenorrhoeic women (after 2–4 cycles of treatment)		Ovulation rate 61%; pregnancy rate 14%[7]	Risk of ovarian cancer unproved. MP 2–13%, mostly twins[14] OHSS infrequent and mild
Gonadotrophins in women with clomifene resistant PCOS (per cycle)		Human menopausal gonadotrophin 10%;[15] urofollitropin/follitropin 12–27%[15,16]	Risk of ovarian cancer unproved. MP 29%[17]
Laparoscopic drilling in women with clomifene resistant PCOS (per cycle) (cumulative rate 6–12 months after treatment)		50–57%[18,19]	Risks of laparoscopy, general anaesthesia, adhesions, and pelvic infection. Risk of premature ovarian failure unproved
Tubal infertility			
Tubal surgery for distal occlusion (cumulative rate 2 years after surgery)	20–30%[20–22]		Risks of general anaesthesia. Ectopic pregnancy 7–9%[9,10]
Tubal surgery for proximal occlusion (cumulative rate)	40–60%[23,24]		
Reversal of female sterilisation (cumulative live birth rate 1–2 years after surgery)	50–90% depending on method used for sterilisation[25]		

TABLE 1 continued

Treatment	Live birth rates	Pregnancy rates	Adverse effects
Infertility associated with endometriosis			
Surgery (per cycle)	27%[26]		Risks of surgery and general anaesthesia. Mortality 3.33/100 000; complication rate 3.2/1000[27]
Male infertility			
IUI ± gonadotrophins (per cycle)		6.5%[28]	
ICSI plus IVF (per cycle)	22%[8]		
Donor insemination (per cycle)	10–11%[8,29,30]		No adverse effects if no ovarian stimulation is given, but child is not male partner's genetic offspring
Unexplained infertility			
IUI ± gonadotrophins (per cycle)		9–12% without stimulation; 19–20% with stimulation[28,31]	

FSH, follicle stimulating hormone; GIFT, gamete intrafallopian transfer; ICSI, intracytoplasmic sperm injection; IUI, intrauterine insemination; IVF, in vitro fertilisation; MB, multiple birth; MP, multiple pregnancy; OHSS, ovarian hyperstimulation syndrome; PCOS, polycystic ovary syndrome.

Menopausal symptoms

Search date July 2003

Edward Morris and Janice Rymer

QUESTIONS

INTERVENTIONS

Key Messages

- **Progestogens** One systematic review and four additional RCTs have found that progestogen with or without oestrogen reduces vasomotor symptoms compared with placebo. One RCT found no significant difference in vasomotor symptoms between progesterone alone and placebo. Two RCTs found that reduction in vasomotor symptoms was similar with progesterone with or without oestrogen compared with oestrogen alone. Two RCTs found no significant difference in psychological symptoms or quality of life between progesterone with or without oestrogen and placebo or oestrogen alone. The combination of oestrogen and progestogen is associated with an increased risk of breast cancer, stroke, and venous thromboembolic disease.
- **Tibolone** Three RCTs have found that tibolone improves vasomotor symptoms and sexual function compared with placebo. Two RCTs provided limited evidence that tibolone was not as effective for reducing vasomotor symptoms compared with oestrogen plus progestogen. Two RCTs found that tibolone improved sexual function compared with oestrogen plus progestogen.
- **Phyto-oestrogens** We found limited evidence from seven RCTs that phyto-oestrogens reduced vasomotor symptoms compared with placebo.
- **Antidepressants** We found no RCTs on the effects of antidepressants on menopausal symptoms.
- **Clonidine** One small RCT found that transdermal clonidine reduced the number and intensity of hot flushes after 8 weeks compared with placebo. However, we were unable to draw reliable conclusions from that study.

Menopausal symptoms

- **Testosterone** We found no RCTs comparing testosterone versus placebo. Small RCTs provided no consistent evidence about the effects of testosterone plus oestrogens on vasomotor symptoms or sexual function compared with oestrogen alone.
- **Oestrogens** Systematic reviews and subsequent RCTs provide evidence that oestrogen with or without progestogens improves vasomotor symptoms, urogenital symptoms, psychological symptoms, and quality of life in the short term compared with placebo. However, important adverse effects include increased risk of breast cancer, endometrial cancer, stroke, and venous thromboembolic disease. Adding progestogen reduces the risk of endometrial cancer.

DEFINITION Menopause is defined as the end of the last menstrual period. A woman is deemed to be postmenopausal 1 year after her last period. For practical purposes, most women are diagnosed as menopausal after 1 year of amenorrhoea. Menopausal symptoms often begin in the perimenopausal years.

INCIDENCE/ PREVALENCE In the UK, the mean age for the start of the menopause is 50 years and 9 months. The median onset of the perimenopause is 45.5–47.5 years. One Scottish survey (6096 women aged 45–54 years) found that 84% of women had experienced at least one of the classic menopausal symptoms, with 45% finding one or more symptoms a problem.[1]

AETIOLOGY/ RISK FACTORS Urogenital symptoms of menopause are caused by decreased oestrogen concentrations, but the cause of vasomotor symptoms and psychological effects is complex and remains unclear.

PROGNOSIS Menopause is a physiological event. Timing of the natural menopause in healthy women may be determined genetically. Although endocrine changes are permanent, menopausal symptoms such as hot flushes, which are experienced by about 70% of women, usually resolve with time.[2] Some symptoms, however, such as genital atrophy, may remain the same or worsen.

AIMS OF INTERVENTION To reduce or prevent menopausal symptoms; and to improve quality of life, with minimum adverse effects.

OUTCOMES Frequency and severity of vasomotor, urogenital, and psychological symptoms; quality of life.

METHODS *Clinical Evidence* search and appraisal July 2003. Many of the RCTs included were crossover trials, which may have important limitations because treatment effects may persist after crossover, confounding the results for each treatment. Where results are reported only for comparisons with pretreatment values, they have been omitted because these comparisons may be influenced in many (often unquantifiable) ways by other factors apart from treatment effect.

QUESTION What are the effects of medical treatments?

OPTION OESTROGENS

Systematic reviews and subsequent RCTs provide evidence that oestrogen with or without progestogens improves vasomotor symptoms, urogenital symptoms, psychological symptoms, and quality of life in the

short term compared with placebo. However, important adverse effects include increased risk of breast cancer, endometrial cancer, stroke, and venous thromboembolic disease. Adding progestogen reduces the risk of endometrial cancer.

Benefits:

Vasomotor symptoms: We found one systematic review[3] and four subsequent RCTs.[4–7] The systematic review (search date 2000, 21 RCTs, 2511 women) found that oestrogen only hormone replacement therapy (HRT) significantly reduced the frequency of hot flushes compared with placebo (6 RCTs, 371 women: RR of a hot flush in 1 week 0.23, 95% CI 0.12 to 0.42; WMD −15.7, 95% CI −20.0 to −11.5 flushes/week).[3] It also found that oestrogen only HRT significantly reduced the number of women with hot flushes at the end of the study compared with placebo (8 RCTs, 1240 women: 139/906 [15%] with oestrogen *v* 158/334 [47%] with placebo; RR 0.37, 95% CI 0.30 to 0.45; NNT 4, 95% CI 3 to 4). There was a wide variation in the frequency of hot flushes in both placebo and treatment groups among the RCTs (range of means for each RCT 0.9–13.8 flushes/week with oestrogen *v* 12.6–33.5 with placebo). The first subsequent RCT (2673 women entered, 2152 analysed) compared eight combinations of different doses of oral conjugated equine oestrogen (0.625 mg, 0.45 mg, and 0.3 mg) either alone or plus different doses of medroxyprogesterone acetate (2.5 mg or 1.5 mg) versus placebo.[4] It found that daily doses of 0.3 mg, 0.45 mg, or 0.625 mg conjugated equine oestrogens (with or without medroxyprogesterone acetate 2.5 mg/day) significantly reduced vasomotor symptoms from weeks 3–12, as assessed using diary cards to record number and severity of hot flushes, compared with placebo ($P < 0.05$). There was no significant difference in the number or severity of hot flushes between different doses of medroxyprogesterone acetate. There were significant reductions in the number of hot flushes with oestrogen alone by week 3, and for 0.625 mg conjugated oestrogen alone compared with the 0.45 mg and 0.3 mg oestrogen dosages (data presented graphically). The second subsequent RCT (165 women) compared two doses of intranasal estradiol (oestradiol; 150 or 300 μg/day) versus placebo over 12 weeks.[5] Symptoms were assessed with diaries and the Kupperman index (see glossary, p 2470). It found that both doses of oestrogen reduced moderate to severe symptoms at 12 weeks compared with placebo (mean reduction from baseline in number of moderate to severe vasomotor symptoms per day: 9.39 with 300 μg estradiol *v* 7.86 with 150 μg estradiol *v* 5.22 with placebo; $P = 0.002$ for high dose *v* placebo and $P < 0.001$ for low dose *v* placebo). The third subsequent RCT (43 menopausal women) compared oral oestrogen alone versus progestin (150 mg depot medroxyprogesterone for 25 days/month).[6] It found a similar reduction in vasomotor symptoms between treatments at 3 months (P value not reported). The fourth subsequent RCT (351 women) compared oestrogen alone versus oestrogen plus progestogen.[7] It found a reduction in hot flushes with both preparations with small differences between them (data not reported). **Urogenital system:** We found one systematic review (search date 1998, 6 RCTs, 334 people[8]) and four subsequent RCTs.[5,9–11] The systematic review found a significant reduction in the incidence of urinary tract infection with oral or vaginal oestrogen HRT compared with placebo

or no treatment (OR for infection; no HRT *v* HRT: 2.51, 95% CI 1.48 to 4.25).[8] Vaginal oestrogens were superior to oral oestrogens in reducing urinary tract infections ($P < 0.008$). The first subsequent RCT (136 women) found that low dose transdermal oestrogen (25 μg/day) plus norethisterone acetate significantly reduced vaginal dryness and dyspareunia over 6 months compared with placebo ($P < 0.001$).[9] The second subsequent RCT (145 women) found that low dose estradiol (oestradiol) reduced vaginal dryness at weeks 9–12 compared with placebo (86% of days free of vaginal dryness with 1 mg estradiol *v* 76% with 0.5 mg estradiol *v* 74% with placebo), but significance was not tested.[10] The third RCT (multicentre, 84 women treated for 24 weeks, 20% withdrawals) found that an estradiol ring significantly increased relief from dyspareunia compared with placebo (freedom from dyspareunia: 90% with estradiol ring *v* 45% with placebo; $P = 0.028$).[11] The fourth RCT (165 women) compared the effects of two doses of intranasal estradiol (150 or 300 μg/day) versus placebo on dyspareunia and "urinary troubles" (measured on a visual analogue scales).[5] It found that the 150 μg dose significantly reduced symptoms compared with placebo at 12 weeks ($P < 0.001$), and that the 300 μg dose significantly reduced urogenital symptoms compared with placebo at 4 weeks ($P = 0.014$). **Psychological, cognitive, and sleep symptoms:** We found one systematic review on the effect of HRT upon menopausal depressed mood (search date 1995, 14 RCTs including several crossover RCTs, 12 cohort studies; duration of treatment ranged from 1 month to 2 years),[12] one systematic review of the effects of oestrogen on cognitive function in postmenopausal women (search date 1996, 10 controlled trials, and 9 observational studies),[13] and one large subsequent RCT.[14] We found no RCTs of oestrogen treatment in women with clinically proven depression. The first review found that oestrogen significantly reduced depressed mood (measured using different scales) compared with placebo or no treatment ($P < 0.0001$).[12] The second review found that studies were too weak to allow reliable conclusions to be drawn.[13] The subsequent large RCT (16 608 postmenopausal women with an intact uterus aged 50–79 years of age) compared conjugated equine oestrogens (0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) versus placebo.[14] It found that oestrogen plus progestin did not significantly improve mental health or depressive symptoms (assessed using the RAND 36-Item Health Survey) compared with placebo after 1 year (range in mean change of scores from baseline: –0.1 to +0.6 with oestrogen plus progestin *v* –0.1 to +0.7 with placebo; P value ranged from 0.40–0.81). However, it did find significant improvements in sleep disturbance (mean change of scores from baseline: 0.5 with oestrogen plus progestin *v* 0.1 with placebo; $P < 0.001$), although the generalisability of these results may be limited (see comment).[15] **Quality of life:** We found no systematic review. We found one RCT of transdermal estradiol versus placebo,[16] one RCT of oral estradiol versus placebo,[17] one RCT of oral conjugated equine oestrogen plus medroxyprogesterone acetate versus transdermal estradiol plus medroxyprogesterone acetate,[18] one RCT of cyclical progestogen plus oestrogen versus oestrogen alone,[7] and one large RCT of oral conjugated equine oestrogen plus

medroxyprogesterone acetate versus placebo.[14] The first RCT (242 postmenopausal women) found that estradiol transdermal patches (50 μg/24 hours) significantly improved quality of life (P = 0.0003) and wellbeing (P = 0.003) over 12 weeks compared with placebo patches.[16] The second RCT (82 women aged 40–60 years) found that oral estradiol significantly improved quality of life scores compared with placebo (assessed using the Kupperman scale [P = 0.0015]; 3-Factor Green Index [P = 0.0037; P = 0.0026; P = 0.0003], and the Beck Depression Inventory [P = 0.0242]).[17] The third RCT (74 women with an intact uterus and ovaries, 2–7 years after menopause) found that quality of life was similarly improved with either oral conjugated equine oestrogen (0.625 mg/day for four 4 week cycles) plus medroxyprogesterone acetate (10 mg for the last 12 days of each cycle) or with continuous transdermal estradiol-17 beta (50 μg twice weekly for four 4 week cycles) plus medroxyprogesterone acetate (10 mg for the last 12 days of each cycle).[18] The fourth RCT (351 women) found no significant difference in quality of life between progestogen plus oestrogen compared with oestrogen alone at 6 months.[7] The fifth and largest RCT (16 608 postmenopausal women with an intact uterus aged 50–79 years of age) compared conjugated equine oestrogens (0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) versus placebo.[14] It found that oestrogen plus progestin did not significantly improve general health, social functioning, vitality, or sexual satisfaction (assessed using the RAND 36-Item Health Survey) compared with placebo after 1 year (range in mean change in quality of life scores from baseline: −1.9 to +0.2 with oestrogen plus progestin *v* −2.3 to 0.0 with placebo; P value ranged from 0.08–0.76). However, it did find significant improvements in physical functioning and bodily pain (P < 0.001 for both outcomes), although the generalisability of these results may be limited (see comment below).[15]

Harms: Women often report an increase in weight when starting oestrogen, but we found no evidence from RCTs that oestrogen causes significant weight gain in the long term. One systematic review (search date 1998; 22 RCTs) found no effect of either oestrogen alone or combined hormone replacement therapy (HRT) on body weight.[19] The most important long term adverse effects with oestrogens are increased risk of venous thromboembolic disease (see hormone replacement therapy under secondary prevention of ischaemic cardiac events, p 197), endometrial cancer, and breast cancer.[19–22] One systematic review (search date not reported, 51 RCTs, > 160 000 women) found that the relative risk of breast cancer increased by 2.3% (95% CI 1.1% to 3.6%) each year in women using HRT.[23] Five or more years after HRT was stopped, there was no significant excess of breast cancer. One systematic review (search date not reported; 18 RCTs, 5247 women) of the effects of HRT found significantly increased risks of endometrial hyperplasia in women taking unopposed oestrogen (RR 8.14, 95% CI 1.05 to 63.1 for 6 months of treatment; RR 37.0, 95% CI 9.3 to 147 for 36 months of treatment).[22] The review also found significant reductions in the incidence of endometrial hyperplasia when women are given progestogens either cyclically or continuously, with continuous combined HRT having the greatest effect at 36 months

(RR 0.17, 95% CI 0.02 to 1.26). Meta-analysis of four large RCTs (> 20 000 women) found that long term combined HRT or oestrogen only HRT significantly increased the risk of developing breast cancer (RR 1.27,95% CI 1.03 to 1.56) and pulmonary embolism (RR 2.16,95% CI 1.47 to 3.18) compared with placebo, but decreased the risk of colorectal cancer (RR 0.64, 95% CI 0.45 to 0.92) and fractured neck of femur (RR 0.72, 95% CI 0.52 to 0.98) (see harms of hormone replacement therapy in fracture prevention in postmenopausal women, p 1450).[24] However, it found no significant difference between combined HRT and placebo in risk of endometrial cancer 0.76 (95% CI 0.45 to 1.31) or coronary heart disease (slight increase but not significant; RR 1.11, 95% CI 0.96 to 1.30).[24] The large RCT[14] (described above) found similar results (HR for coronary heart disease: 1.29, 95% CI 1.02 to 1.63; HR for breast cancer: 1.26, 95% CI 1.00 to 1.59; HR for stroke: 1.41, 95% CI 1.07 to 1.85; HR for pulmonary embolus: 2.13, 95% CI 1.39 to 3.25). Although the intended duration of the large RCT study was 8.5 years, it was stopped after a mean follow up of 5.2 years due to a significant increase in risks of treatment compared with placebo.[14]

Comment: Based on the evidence of important adverse effects, there has been a change in prescribing attitude toward HRT. Before starting HRT, it is now considered important for prescribers to discuss with women the excess risks associated with HRT. Based on the evidence in the harms section, it remains important that women with an intact uterus who are prescribed any form of oestrogen take either continuous or cyclic progestogens. Applicability of the large RCT[14] may be limited because the average age of women enrolled in the study (63.3 years) is much older than that of women who typically start HRT. A parallel study of the effects of oestrogen alone in women who have had a hysterectomy continues.

OPTION PROGESTOGENS

One systematic review and four additional RCTs have found that progestogen with or without oestrogen reduces vasomotor symptoms compared with placebo. One RCT found no significant difference in vasomotor symptoms between progesterone alone compared with placebo. Two RCTs found that reduction in vasomotor symptoms was similar with progesterone with or without oestrogen compared with oestrogen alone. Two RCTs found no significant difference in psychological symptoms or quality of life between progesterone with or without oestrogen compared with placebo or oestrogen alone. The combination of oestrogen and progestogen is associated with an increased risk of breast cancer, stroke and venous thromboembolic disease.

Benefits: **Vasomotor symptoms:** We found no systematic review of progestogens alone versus placebo. We found one systematic review (search date 2000, 21 RCTs, 2511 women, follow up for 3–36 months), which included comparisons of progesterone plus oestrogen hormone replacement therapy (HRT) versus placebo,[3] three additional RCTs of oral progestogens versus placebo,[25–27] two additional RCTs of transdermal progesterone versus placebo,[28,29]

and two additional RCTs of oral progestogens versus other interventions.[6,7] The systematic review found that progesterone plus oestrogen significantly reduced hot flush severity compared with placebo (OR 0.1, 95% CI 0.06 to 0.19).[3] Three additional RCTs comparing oral progestogens alone versus placebo (all ≤ 24 weeks in duration) found that progestogens significantly reduced vasomotor symptoms (see table 1, p 2473).[25–27] Two additional RCTs comparing transdermal progesterone alone versus placebo found different results.[28,29] One RCT found that progesterone significantly reduced vasomotor symptoms (see table 1, p 2473).[28] The second RCT found no significant difference in vasomotor symptoms (assessed using the Greene climacteric scale [see glossary, p 2470]) between treatments (see table 1, p 2473).[29] The sixth additional RCT (43 menopausal women) compared oral progesterone versus oral oestrogen alone.[6] It found a similar reduction in vasomotor symptoms between treatments at 3 months (no decrease in vasomotor symptoms in 18% of women in each group, P value not reported). The seventh additional RCT (351 women) compared progestogen plus oestrogen versus oestrogen alone.[7] It found a reduction in hot flushes with both preparations, with small differences between them (data not reported) **Urogenital system:** We found no RCTs evaluating the effects of progestogens alone on urinary incontinence, the lower genital tract, or libido. **Psychological symptoms:** We found one RCT (described above [see table 1, p 2473]).[29] It found no significant difference in depression or anxiety symptoms between transdermal progesterone compared with placebo after 12 weeks (anxiety: P = 0.10; depression: P = 0.56). **Quality of life:** We found two RCTs. The first RCT (described above [see table 1, p 2473])[29] found no significant difference between transdermal progesterone and placebo for each of four quality of life domains (vasomotor, physical, psychosocial, sex-related; P value ranged from 0.28–0.94). The second RCT (351 women) compared cyclical progestogen plus oestrogen versus oestrogen alone, and found no significant difference in quality of life between treatments at 6 months (P < 0.001).[7]

Harms: We found three RCTs that evaluated harms of progestogens.[30–32] The first RCT (321 women who had undergone hysterectomy and were already taking conjugated oestrogen) compared continuous progestogen (norgestrel) versus placebo.[30] It found no difference in adverse effects of treatments (including weight gain and bloating). The second RCT (875 women) compared various oestrogen/progestogen combinations over 3 years.[31] It found that addition of progestogen to oestrogen therapy increased breast discomfort compared with oestrogen alone (OR 1.92, 95% CI 1.16 to 3.09). Neither RCT found evidence of an effect on cardiovascular events. The third RCT (51 women receiving 2 mg estradiol, crossover design) compared adverse effects of medroxyprogesterone acetate 10 mg versus norethisterone 1 mg.[32] It found that medroxyprogesterone acetate induced significantly fewer negative mood symptoms and more positive mood symptoms compared with norethisterone in women without a history of premenstrual syndrome than

norethisterone, but that medroxyprogesterone acetate induced more physical symptoms, such as breast tenderness and bloating. Adding oestrogen to progestogen is associated with an increased risk of of breast cancer, stroke, and venous thromboembolic disease (see harms of oestrogen, p 2463).[14,24]

Comment: Progestogens are seldom given alone, which makes it hard to isolate their effects. When given without oestrogen, doses of progestogens were high, the lowest dose being 20 mg medroxyprogesterone acetate daily. We found one further RCT, which compared depomedroxyprogesterone acetate versus placebo, but the disparity in size between the experimental and control groups (57 *v* 12 women), and lack of detail on randomisation strategies make the results difficult to interpret.[33] Three of the placebo controlled RCTs had crossover comparisons, which make conclusions difficult to interpret.[25–27] Based on the evidence for harms associated with oestrogen (see harms of oestrogen, p 2463) it remains important that women with an intact uterus who are prescribed any form of oestrogen take either continuous or cyclical progestogens.

OPTION TIBOLONE

Three RCTs have found that tibolone improves vasomotor symptoms and sexual function compared with placebo. Two RCTs provided limited evidence that tibolone was not as effective for reducing vasomotor symptoms compared with oestrogen plus progestogen. Two RCTs found that tibolone improved sexual function compared with oestrogen plus progestogen.

Benefits: We found no systematic review. **Vasomotor symptoms:** We found two RCTs. which compared tibolone versus placebo,[34,35] and two RCTs that compared tibolone versus oestrogen/progestogen combinations.[36,37] The first RCT (82 women with menopausal symptoms) found that tibolone significantly reduced vasomotor symptoms at 16 weeks compared with placebo (39% reduction in mean score; $P = 0.001$).[34] The second RCT (775 women) compared four different doses of tibolone (0.625, 1.25, 2.5, or 5 mg/day) versus placebo.[35] It found that 1.25 mg, 2.5 mg, and 5 mg tibolone reduced the frequency of hot flushes and sweating episodes compared with placebo (assessed using symptom diaries; results presented graphically; $P < 0.0001$). It found no significant difference in frequency of hot flushes and sweating episodes between 0.625 mg tibolone and placebo. The third RCT (437 women with menopausal symptoms) compared combined oestrogen and progestogen versus tibolone.[36] It found that combined oestrogen/progestogen significantly reduced hot flushes over 48 weeks compared with tibolone ($P = 0.01$). The fourth RCT (235 postmenopausal women) found no significant difference in vasomotor symptoms between combined oestrogen/progestogen and tibolone at 52 weeks (figures not reported).[37] **Urogenital system:** We found three RCTs published in four reports.[36,38–40] The first RCT (crossover, 38 women) found that tibolone significantly increased sexual fantasies ($P < 0.03$) and arousability over 3 months compared with placebo ($P < 0.01$).[40] The second RCT (437 women) found that tibolone significantly improved vaginal dryness from

baseline compared with estradiol (oestradiol) plus norethisterone after 48 weeks of treatment (assessed using a five point scoring system: 2.16 at baseline to 1.33 after treatment with tibolone *v* 2.12 at baseline to 1.27 after treatment with hormone replacement therapy; $P < 0.001$).[36] The RCT also found that tibolone improved sexual satisfaction as measured with McCoy's Sex Scale Questionnaire compared with estradiol (oestradiol) plus norethisterone ($P < 0.05$).[38] The third RCT (50 women attending a university gynaecology clinic) found that tibolone significantly improved sexual desire and coital frequency as measured by a questionnaire compared with conjugated oestrogen (0.625 mg) plus medroxyprogesterone acetate (2.5 mg) after 12 months ($P < 0.05$ for both outcomes).[39] We found no RCTs examining the effects on urinary incontinence. **Psychological symptoms:** We found no RCTs. **Quality of life:** We found no RCTs.

Harms: One RCT reported that two women randomised to receive tibolone (at 1.25 mg and 5.0 mg daily doses) discontinued treatment because of vaginal bleeding.[35] One non-randomised controlled trial found that the main adverse effect of tibolone was breakthrough bleeding, which occurred in about 10% of users.[41] We found no good evidence of androgenic adverse effects, such as hair growth and greasiness of the skin. Two RCTs of short term use found a 33% reduction in plasma high density lipoproteins with tibolone,[42,43] although the long term effects on cardiovascular disease are unknown.

Comment: None.

OPTION PHYTO-OESTROGENS

We found limited evidence from seven RCTs that phyto-oestrogens reduced vasomotor symptoms compared with placebo.

Benefits: We found no systematic review. **Vasomotor symptoms:** We found seven placebo controlled RCTs.[44–50] The first RCT (58 postmenopausal women) compared soy flour (which contains phyto-oestrogens) versus wheat flour for 12 weeks.[44] It found no significant difference between soy flour and wheat flour in hot flushes at 12 weeks (reduction in hot flushes: 40% with soy flour *v* 25% with wheat flour; $P = 0.82$). The second RCT (crossover, 51 women) compared a daily dietary supplement containing no phyto-oestrogens versus a supplement containing 34 mg soy protein.[45] It found that soy protein reduced the severity ($P < 0.001$) but not the frequency of vasomotor symptoms at 6 weeks. The third RCT (unblinded crossover, 51 women) compared isoflavone 40 mg daily versus placebo.[46] It found no significant difference between isoflavone and placebo in vasomotor symptoms assessed after 12 weeks by flush count (mean hot flush count: 3.72 in 46 women receiving placebo *v* 4.22 in 42 women receiving isoflavone; SMD –0.5, 95% CI –8.9 to +7.9) Greene climacteric scale (see glossary, p 2470) (mean 7.23 in 42 women with isoflavone *v* 6.93 in 46 women with placebo; SMD –0.3, 95% CI –19.2 to +18.6). The fourth RCT (39 women) found that soy flour significantly reduced mean flushes per week compared with placebo (45% reduction with soy flour *v* 25%

with placebo tablets after 12 weeks; P < 0.01), although women taking soy extract had a greater number of vasomotor symptoms at baseline than the placebo group.[47] The fifth RCT (94 women) found no significant difference between soy protein and placebo at 3 months for vasomotor symptoms as assessed using a four point subjective rating scale.[48] The sixth RCT (177 women) found that a 50 mg daily dose of an isoflavone extract significantly reduced hot flush severity over 12 weeks compared with placebo (P = 0.01).[49] It found no significant difference between groups in hot flush frequency. The seventh RCT (80 women) found that 100 mg soy isoflavone daily significantly reduced menopausal symptoms compared with placebo (change in Kupperman index [see glossary, p 2470]) from baseline to 16 weeks: 44.6 at baseline to 24.9 at 16 weeks with isoflavone *v* 40.3 at baseline to 41.6 with placebo; P < 0.01).[50] **Other symptoms:** One RCT (94 women) found no significant difference between soy protein and placebo at 3 months for psychological, musculoskeletal, and genitourinary symptoms as assessed using a four point subjective rating scale.[48] **Quality of life:** We found no RCTs.

Harms: We found no evidence of significant adverse effects.

Comment: Few studies have specifically investigated adverse effects of phyto-oestrogens. Results of studies are difficult to interpret because phyto-oestrogen preparations are not standardised. One recent RCT (80 women) compared the effects of 100 mg soy isoflavone daily versus placebo on blood pressure, plasma glucose, serum lipid and lipoprotein concentrations, and endometrial thickness.[50] It found that phyto-oestrogens reduced serum total cholesterol and low density lipoprotein compared with placebo (P < 0.01).

OPTION CLONIDINE

One small RCT found that transdermal clonidine reduced the number and intensity of hot flushes after 8 weeks compared with placebo. However, we were unable to draw reliable conclusions from this study.

Benefits: We found no systematic review. **Vasomotor symptoms:** One RCT (30 women) found that transdermal clonidine (3.5 cm^2 patch delivering 0.1 mg clonidine/day for 7 days) significantly reduced the proportion of women with hot flushes and increased the proportion of women perceiving a reduction in severity of the hot flushes compared with placebo at 8 weeks (women reporting reduction in number of hot flushes: 12/15 [80%] with clonidine *v* 5/14 [35%] with placebo; RR 2.4, 95% CI 1.1 to 4.7; NNT 3, 95% CI 2 to 12; women reporting reduction in severity of hot flushes: 11/15 [73%] with transdermal clonidine *v* 4/14 [29%] with placebo; RR 2.7, 95% CI 1.09 to 6.6; NNT 3, 95% CI 2 to 5).[51] **Psychological symptoms:** We found no RCTs. **Quality of life:** We found no RCTs.

Harms: The RCT found no significant difference in the incidence of adverse effects between clonidine and placebo.[51] The analysed adverse effects included transient local skin reactions (4/15 [27%] with clonidine patch *v* 3/14 [21%] with placebo; RR 1.2, 95% CI 0.34 to 4.6).

Comment: Transdermal patches of clonidine are not widely available. Results may not be generalisable; extrapolating results to oral clonidine is potentially misleading.

OPTION TESTOSTERONE

We found no RCTs comparing testosterone versus placebo. Small RCTs provided no consistent evidence about the effects of testosterone plus oestrogens on vasomotor symptoms or sexual function compared with oestrogen alone.

Benefits: We found no systematic review. **Vasomotor symptoms:** We found no RCTs comparing testosterone alone versus placebo. We found two RCTs comparing testosterone/oestrogen combinations versus oestrogen alone.[52,53] The first RCT (93 postmenopausal women) compared oestrogen plus methyltestosterone (1.25 mg/day or 2.5 mg/day) versus oestrogen alone (0.625 mg/day or 1.25 mg/day).[52] It found that adding a small dose of methyltestosterone significantly reduced hot flushes ($P = 0.008$) and also reduced the oestrogen dose required to control menopausal symptoms. The second RCT (40 women) compared estradiol plus testosterone versus estradiol alone.[53] It found no significant difference in vasomotor symptoms after 2 and 6 months of treatment (numbers not reported). **Urogenital system:** We found one RCT (40 women; described above).[53] It found no significant difference between estradiol alone and estradiol plus testosterone in level of self reported sexual enjoyment and desire.[53] The second RCT (crossover, 53 surgically menopausal women; see comment below) compared four treatments: oestrogen alone; testosterone plus oestrogen; testosterone alone, and placebo.[54] It found that testosterone with or without oestrogen significantly increased sexual desire ($P < 0.01$), sexual arousal ($P < 0.01$), and number of sexual fantasies ($P < 0.01$) compared with placebo or oestrogen alone during the treatment months. **Psychological symptoms:** We found no RCTs. **Quality of life:** We found no RCTs.

Harms: We found no evidence from RCTs or other controlled studies on the incidence of androgenic adverse effects with testosterone in women with menopausal symptoms.

Comment: The crossover RCT addressing urogenital symptoms did not provide an analysis before crossover.[54] Results are therefore likely to be confounded by carry over effects of treatments.

OPTION ANTIDEPRESSANTS

We found no RCTs on the effects of antidepressants on menopausal symptoms.

Benefits: We found no systematic review or RCTs on the effects of antidepressants on menopausal symptoms or quality of life in menopausal women.

Menopausal symptoms

Harms: We found no evidence on adverse effects in postmenopausal women. Antidepressants as a group can cause many central nervous system adverse effects, including sedation and agitation, as well as urinary and vision problems, liver dysfunction, and cardiac dysrhythmias (see antidepressants under depressive disorders, p 1278).

Comment: None.

GLOSSARY

Greene climacteric scale A numerical index that scores 21 menopausal symptoms in three domains: psychological, somatic, and vasomotor. Each symptom is rated from 0–3 where 0 = no symptoms and 3 = extreme symptoms.

Kupperman index A numerical index that scores 11 menopausal symptoms: hot flushes, paraesthesia, insomnia, nervousness, melancholia, vertigo, weakness, arthralgia or myalgias, headache, palpitations, and formication. Each symptom is rated from 0–3 according to severity and symptoms (where 0 = no symptoms and 3 = most severe) are then weighted and the total sum calculated. The maximum score is 51 points.

Substantive changes

Oestrogens One large RCT added comparing conjugated equine oestrogens plus medroxyprogesterone acetate versus placebo.[14] Quality of life outcomes were reported in a separate publication;[15] categorisation unchanged.

Progestogens One RCT added comparing transdermal progesterone alone versus placebo;[29] categorisation unchanged.

Tibolone One RCT added, comparing four different doses of tibolone versus placebo;[35] categorisation unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 2490

Key Messages

Treatments

- **Endometrial thinning before hysteroscopic surgery** One systematic review has found that preoperative gonadorelin (gonadotrophin releasing hormone) analogues reduce moderate or heavy periods and increase amenorrhoea compared with placebo, no preoperative treatment, or preoperative danazol. We found insufficient evidence about effects of preoperative danazol or progestogens compared with placebo or no preoperative treatment.
- **Hysterectomy (*v* endometrial destruction) after medical failure** Systematic reviews have found that hysterectomy reduces menstrual blood loss and the number of women requiring further operations, and increases satisfaction compared with endometrial destruction. RCTs found no differences in effectiveness between different types of hysterectomy. One large cohort study reported major or minor complications in about a third of women undergoing hysterectomy.

- **Non-steroidal anti-inflammatory drugs** One systematic review has found that non-steroidal anti-inflammatory drugs reduce mean menstrual blood loss compared with placebo. One systematic review found no significant difference in menstrual blood loss between mefenamic acid and naproxen, or between non-steroidal anti-inflammatory drugs and oral progestogens, oral contraceptives, or progesterone releasing intrauterine devices.
- **Tranexamic acid** Systematic reviews have found that tranexamic acid reduces menstrual blood loss compared with placebo or other drugs (oral progestogens, mefenamic acid, etamsylate, flurbiprofen, and diclofenac). Adverse effects of tranexamic acid include leg cramps and nausea, which occur in about a third of women using this drug. One long term population based observational study found no evidence that tranexamic acid increases the risk of thromboembolism.
- **Hysteroscopic versus non-hysteroscopic endometrial destruction after medical failure** One systematic review found that hysteroscopic methods of endometrial destruction increased amenorrhoea at 12 months compared with non-hysteroscopic methods. We found no consistent evidence of a difference in amenorrhoea or satisfaction rates among different types of hysteroscopic procedure. RCTs found that complications, such as infection, haemorrhage, or uterine perforation occurred in up to 15% of women undergoing endometrial destruction.
- **Danazol** Systematic reviews found limited evidence that danazol reduced blood loss compared with placebo, luteal phase oral progestogens, mefenamic acid, naproxen, or oral contraceptives, but found that danazol increased adverse effects compared with either non-steroidal anti-inflammatory drugs or oral progestogens.
- **Combined oral contraceptives** One systematic review found insufficient evidence about effects of oral contraceptives in women with menorrhagia.
- **Endometrial resection versus medical treatment** One systematic review and one additional RCT found no consistent evidence of a difference in blood loss or satisfaction between transcervical endometrial resection and medical treatment. RCTs found that complications, such as infection, haemorrhage, or uterine perforation occurred in up to 15% of women undergoing endometrial destruction.
- **Etamsylate** We found insufficient evidence from one systematic review about effects of etamsylate compared with placebo, mefenamic acid, aminocaproic acid, or tranexamic acid.
- **Intrauterine progestogens** We found no systematic review or RCTs comparing intrauterine progestogens versus placebo. Two systematic reviews and three subsequent RCTs found conflicting evidence about menstrual blood loss, satisfaction rates, and quality of life scores with levonorgestrel releasing intrauterine devices compared with other treatments (endometrial resection, thermal balloon ablation, norethisterone, medical treatment, non-steroidal anti-inflammatory drugs, and hysterectomy).
- **Oral progestogens (longer cycle)** We found no RCTs comparing oral progestogens versus placebo. One RCT identified by a systematic review found no significant difference in menstrual blood loss between a longer treatment cycle of oral progestogen and a levonorgestrel releasing intrauterine device.
- **Oral progestogens in luteal phase only** We found no RCTs comparing oral progestogens versus placebo. One systematic review has found that luteal phase oral progestogens increase mean menstrual blood loss compared with danazol, tranexamic acid, or a progesterone releasing intrauterine device.

Menorrhagia

- **Dilatation and curettage after medical failure; gonadorelin (gonadotrophin releasing hormone) analogues; myomectomy after medical failure** We found no RCTs on the effects of these interventions.

DEFINITION Menorrhagia is defined as heavy but regular menstrual bleeding. Idiopathic ovulatory menorrhagia is regular heavy bleeding in the absence of recognisable pelvic pathology or a general bleeding disorder. Objective menorrhagia is taken to be a total menstrual blood loss of 80 mL or more in each menstruation.[1] Subjectively, menorrhagia may be defined as a complaint of regular excessive menstrual blood loss occurring over several consecutive cycles in a woman of reproductive years.

INCIDENCE/ PREVALENCE In the UK, 5% of women (aged 30–49 years) consult their general practitioner each year with menorrhagia.[2] In New Zealand, 2–4% of primary care consultations by premenopausal women are for menstrual problems.[3]

AETIOLOGY/ RISK FACTORS Idiopathic ovulatory menorrhagia is thought to be caused by disordered prostaglandin production within the endometrium.[4] Prostaglandins may also be implicated in menorrhagia associated with uterine fibroids, adenomyosis, or the presence of an intrauterine device. Fibroids have been reported in 10% of women with menorrhagia (80–100 mL/cycle) and 40% of those with severe menorrhagia (≥ 200 mL/cycle).[5]

PROGNOSIS Menorrhagia limits normal activities and causes iron deficiency anaemia in two thirds of women proved to have objective menorrhagia.[1,6,7] One in five of all women in the UK and one in three women in the USA have a hysterectomy before the age of 60 years; menorrhagia is the main presenting problem in at least 50% of these women.[8–10] About 50% of the women who have a hysterectomy for menorrhagia are found to have a normal uterus.[11]

AIMS OF INTERVENTION To reduce menstrual bleeding; improve quality of life; and prevent or correct iron deficiency anaemia, with minimum adverse effects. Women may regard amenorrhea as a benefit or a harm of treatment depending on their perspective.

OUTCOMES Menstrual blood flow (assessed objectively [mL/cycle] or subjectively); haemoglobin concentration; quality of life; patient satisfaction; incidence of adverse drug effects; and incidence of postoperative complications. Whether a particular percentage reduction in menstrual blood loss is considered clinically important will depend on pretreatment menstrual loss and the individual woman's perception of acceptable menstrual loss.

METHODS *Clinical Evidence* search and appraisal February 2003. The author also hand searched reference lists of non-systematic reviews and studies obtained from the initial search, and recent issues of key journals.

QUESTION What are the effects of medical treatments?

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One systematic review has found that non-steroidal anti-inflammatory drugs reduce mean menstrual blood loss compared with placebo. One systematic review found no significant difference in menstrual blood loss between mefenamic acid and naproxen, or between non-steroidal anti-inflammatory drugs and oral progestogens, oral contraceptives, or progesterone releasing intrauterine devices.

Benefits: **Versus placebo:** We found one systematic review (search date 1996, 12 RCTs, 313 women) comparing non-steroidal anti-inflammatory drugs (NSAIDs: mefenamic acid, naproxen, meclofenamic acid, ibuprofen, and diclofenac) versus placebo.[3] Treatment was taken only during menstruation, but doses varied depending on the drug used. The review found that NSAIDs significantly reduced mean menstrual blood loss compared with placebo (WMD for blood loss for all NSAIDs *v* placebo −35 mL, 95% CI −43 mL to −27 mL). **Versus other NSAIDs and other drugs:** We found one systematic review (search date 2001, 16 RCTs) comparing different NSAIDs versus each other, and NSAIDs versus other drugs.[12] It found no significant difference in menstrual blood loss between mefenamic acid and naproxen (WMD for blood loss +21.0 mL, 95% CI −5.9 mL to +47.9 mL); between NSAIDs and oral progestogens given in the luteal phase (WMD for blood loss −23.0 mL, 95% CI −46.6 mL to +0.625 mL); between NSAIDs and the combined oral contraceptive (WMD for blood loss +25.3 mL, 95% CI −22.3 mL to +72.8 mL), or between NSAIDs and a progesterone releasing intrauterine device (WMD for blood loss −4.0 mL, 95% CI −31.2 mL to +23.2 mL). However, many of these comparisons may have lacked power to exclude clinically important differences between treatments.

Harms: The reviews found that commonly reported adverse effects included headaches and gastrointestinal disturbances, including indigestion, nausea, vomiting, and diarrhoea.[3,12] These occurred in at least 50% of women taking NSAIDs in the RCTs that reported data on adverse effects, but similar levels of adverse effects were found in placebo cycles (see non-steroidal anti-inflammatory drugs, p 1551).

Comment: NSAIDs have the additional benefit of relieving dysmenorrhoea (see dysmenorrhoea, p 2370).

OPTION TRANEXAMIC ACID

Systematic reviews have found that tranexamic acid reduces menstrual blood loss compared with placebo or other drugs (oral progestogens, mefenamic acid, etamsylate, flurbiprofen, and diclofenac). Adverse effects of tranexamic acid include leg cramps and nausea, which occur in about a third of women using this drug. One long term population based observational study found no evidence that tranexamic acid increases the risk of thromboembolism.

Benefits: **Versus placebo:** We found two systematic reviews.[3,13] The first review (search date 1996, 5 RCTs, 153 women) found that tranexamic acid (250–500 mg 4 times daily during menstruation) significantly reduced mean menstrual blood loss compared with placebo (WMD −52 mL; other results and significance presented graphically).[3] Few studies in the review measured patient satisfaction. The second systematic review (search date 1997, 7 RCTs) identified two RCTs that compared tranexamic acid (1 g 4 times daily) or a prodrug of tranexamic acid (Kabi 2161, 1.2 g twice daily) versus placebo.[13] It found that either active drug significantly reduced mean menstrual blood loss compared with placebo (WMD −94 mL, 95% CI −151 mL to −37 mL). **Versus other drugs:** We found two systematic reviews.[3,13] One review (search date 1997) found that tranexamic acid significantly reduced mean menstrual blood loss compared with luteal phase oral progestogens or mefenamic acid (WMD for tranexamic acid *v* oral progestogens −111 mL, 95% CI −179 mL to −44 mL; WMD for tranexamic acid *v* mefenamic acid −73 mL, 95% CI −123 mL to −23 mL).[13] The second review (search date 1996) did not pool data from several RCTs comparing tranexamic acid versus other drugs.[3] The RCTs consistently found that tranexamic acid significantly improved outcomes compared with mefenamic acid, etamsylate (ethamsylate), flurbiprofen, diclofenac, and norethisterone. One of the RCTs (46 women) identified by the review found that tranexamic acid significantly reduced limitations on social activities (proportion of people who reported reduced limitation of social activities compared with placebo cycles: 67% with tranexamic acid *v* 45% with norethisterone) and increased the proportion of people with improved sex life (proportion of people reporting improved sex life compared with placebo cycles: 46% with tranexamic acid *v* 15% with norethisterone) compared with norethisterone.[14]

Harms: Nausea and leg cramps occur in a third of women taking tranexamic acid. One systematic review (search date 1997) found no increase in gastrointestinal adverse effects compared with either placebo or other drugs.[13] Isolated case reports have suggested a risk of thromboembolism associated with tranexamic acid, but a large population based study over 19 years found no evidence that this was higher than expected in the normal population.[15]

Comment: Unlike non-steroidal anti-inflammatory drugs, tranexamic acid has no effect on dysmenorrhoea.

OPTION ETAMSYLATE

We found insufficient evidence from one systematic review about effects of etamsylate compared with placebo, mefenamic acid, aminocaproic acid, or tranexamic acid.

Benefits: We found one systematic review (search date not stated, 4 RCTs) comparing etamsylate (ethamsylate) versus placebo, mefenamic acid, aminocaproic acid, or tranexamic acid.[16] Most results were presented as comparison with baseline. However, one RCT (double blind, 81 women; see comment below) identified by the review compared three treatments directly: etamsylate, tranexamic acid,

and mefenamic acid. The RCT found that both tranexamic acid and mefenamic acid significantly reduced mean menstrual blood loss compared with etamsylate (WMD tranexamic acid *v* etamsylate –97 mL, 95% CI –140 mL to –54 mL; WMD mefenamic acid *v* etamsylate –51 mL, 95% CI –96 mL to –6 mL). The review found that etamsylate achieved an overall reduction in menstrual blood loss compared with baseline of 13% (95% CI 11% to 15%), which may not be clinically significant.[16]

Harms: The review found no significant difference in the rate of adverse effects (nausea, headaches, and dizziness) between different drug regimens, and these adverse effects seldom caused women to withdraw from studies.[16]

Comment: The RCT reported that 27% of women had withdrawn from the study before its completion, and made no adjustment for the multiple treatment comparisons involved.[17]

OPTION DANAZOL

Systematic reviews found limited evidence that danazol reduced blood loss compared with placebo, luteal phase oral progestogens, mefenamic acid, naproxen, or oral contraceptives, but found that danazol increased adverse effects compared with either non-steroidal anti-inflammatory drugs or oral progestogens.

Benefits: We found two systematic reviews (search date 2001, 9 RCTs, 353 women;[18] search date 1996, 3 RCTs, 127 women;[3] see comment below) comparing danazol versus placebo, other medical treatments, or different doses of danazol. **Versus placebo:** The first review identified one RCT (66 women), which compared danazol versus placebo. It found that danazol significantly improved blood loss scores from baseline whereas placebo had no significant effect at 3 months.[18] However, it was unclear how this result was calculated. The second review found that danazol (200 mg daily continuously for 2–3 months) significantly reduced mean menstrual blood loss compared with placebo (WMD danazol *v* placebo –108 mL; CI presented graphically).[3] **Versus other drugs:** The first review found that danazol reduced blood loss more than progestogens (OR for mean blood loss < 80 mL at the end of the intervention 7.20; 95% CI 1.28 to 40.40), non-steroidal anti-inflammatory drugs (WMD for mean menstrual blood loss –96.7 mL, 95% CI –138.0 mL to –54.6 mL), and the combined oral contraceptive pill, although confidence intervals were wide. Results were based on a small number of trials, all of which were small and may have lacked power to detect clinically important effects.[18] We found no randomised trials comparing danazol with tranexamic acid or the levonorgestrel releasing intrauterine system. **Different danazol regimens:** The first review included two small RCTs that compared different danazol regimens: standard dose danazol 200 mg daily; lower dose danazol 100 mg daily; and a reducing dose regimen.[18] It found no significant differences in blood loss (WMD for mean menstrual blood loss +33.5 mL, 95% CI –32.4 mL to +99.4 mL), frequency of adverse

events (OR for number of women reporting adverse events 1.13, 95% CI 0.14 to 9.07), or duration of menstruation (WMD for duration of menstruation +1.3 days, 95% CI –0.76 days to +3.36 days) when a dose of 200 mg daily was compared with a reducing dose regimen.

Harms: The first review found that adverse events were more frequent with danazol than non-steroidal anti-inflammatory drugs (OR 7.0, 95% CI 1.7 to 28.2) or progestogens (OR 4.05, 95% CI 1.6 to 10.2). However, the review reported no significant differences in adherence to treatment.[18] RCTs included in the review reported that danazol may be associated with weight gain; androgenic effects such as acne, seborrhoea, hirsutism, and voice changes; and general complaints including irritability, musculoskeletal pains, and tiredness. Hot flushes and breast atrophy can sometimes occur. Most of these adverse effects are reversible on cessation of treatment (see harms of hormonal treatments under endometriosis, p 2391, and harms of danazol under breast pain, p 2334).

Comment: The second systematic review comparing danazol with placebo had less rigorous inclusion criteria and included two RCTs that were excluded by the first review.[3] Women using danazol may be advised to use barrier methods of contraception because of potential virilisation of the fetus if pregnancy occurs during treatment with this drug.

OPTION COMBINED ORAL CONTRACEPTIVES

One systematic review found insufficient evidence about effects of oral contraceptives in women with menorrhagia.

Benefits: We found one systematic review (search date 1997), which identified one small RCT (38 women) comparing a combined oral contraceptive versus danazol, mefenamic acid, or naproxen.[19] It found no significant difference between any of the treatments (doses not provided) but was too small to rule out a clinically important difference.

Harms: Minor adverse effects are common and include nausea, headache, breast tenderness, changes in body weight, hypertension, changes in libido, and depression.

Comment: One non-randomised controlled trial (164 women) found that a 50 mg oral contraceptive pill led to a 53% reduction in menstrual blood loss compared with baseline.[20] The trial also found that aminocaproic acid (85 women) led to a 54% reduction and tranexamic acid (172 women) led to a 47% reduction in menstrual blood loss.[20] Two longitudinal case control studies found that women taking the contraceptive pill were less likely than those not taking the pill to experience heavy menstrual bleeding or anaemia.[21,22]

OPTION ORAL PROGESTOGENS

We found no RCTs comparing oral progestogens with placebo. One systematic review has found that luteal phase oral progestogens increase mean menstrual blood loss compared with danazol, tranexamic acid, or a

progesterone releasing intrauterine device. One RCT identified by the review found no significant difference in menstrual blood loss between a longer treatment cycle of oral progestogen and a levonorgestrel releasing intrauterine device.

Benefits: **Versus placebo:** We found no RCTs. **Versus other drugs:** We found one systematic review (search date not stated; 7 RCTs), which compared four treatments: luteal phase oral progestogens, danazol, tranexamic acid, and progesterone releasing intrauterine devices (IUDs).[23] It found that oral progestogens significantly increased mean menstrual blood loss compared with any of the other treatments (progestogen *v* danazol WMD −56 mL, 95% CI −96 mL to −15 mL; progestogen *v* tranexamic acid WMD −111 mL, 95% CI −179 mL to −44 mL; and progestogen *v* progesterone releasing IUD WMD −51 mL, 95% CI −84 mL to −18 mL). The review also found that luteal phase oral progestogens significantly increased the proportion of women who reported a greater self assessed menstrual blood loss after treatment compared with danazol (2 RCTs: 19/28 [68%] with luteal phase progestogens *v* 8/26 [31%] with danazol; RR 2.2, 95% CI 1.2 to 4.1; NNH 2, 95% CI 1 to 9).[23] **Longer treatment cycle:** We found one systematic review (search date not stated).[23] One RCT (48 women) identified by the review found no significant difference with a longer regimen of oral progestogen (norethisterone, 21 days/cycle) versus a levonorgestrel releasing IUD in menstrual blood loss (94 mL with oral norethisterone *v* 104 mL with levonorgestrel IUD).

Harms: Two systematic reviews (search dates not stated) found that adverse effects (including headache, breast tenderness, premenstrual symptoms, and gastrointestinal disturbances) were reported in a third to a half of the women who received oral progestogens.[16,23] In the RCT that compared longer treatment cycle with oral progestogens with a levonorgestrel releasing IUD, 56% of women did not feel "well" or "very well" on the treatment and 22% elected to continue with treatment after the 3 months of the study.[23]

Comment: None.

OPTION INTRAUTERINE PROGESTOGENS

We found no systematic review or RCTs comparing intrauterine progestogens with placebo. Two systematic reviews and three subsequent RCTs found conflicting evidence about menstrual blood loss, satisfaction rates, and quality of life scores with levonorgestrel releasing intrauterine devices compared with other treatments (endometrial resection, thermal balloon ablation, norethisterone, medical treatment, non-steroidal anti-inflammatory drugs, and hysterectomy).

Benefits: We found no systematic review or RCTs comparing intrauterine progestogens with placebo. Two systematic reviews (search date 1999, 5 RCTs;[24] search date 1999, 5 RCTs[25]) and three subsequent RCTs compared intrauterine progestogens with other treatments.[26–28] The second review identified four of the RCTs in the first review and one additional RCT.[25] **Progesterone releasing intrauterine device (IUD):** The first systematic review found one

RCT that compared four different treatments: a progesterone releasing IUD 65 μg daily, danazol, mefenamic acid, or norethisterone.[24] The review did not compare treatments with each other, but found that all treatments reduced menstrual blood loss compared with baseline values. **Levonorgestrel releasing IUD:** Both reviews found four RCTs that examined the effects of levonorgestrel releasing IUDs 20 μg daily.[24] Two RCTs (60 and 70 women) identified by the reviews compared levonorgestrel releasing IUDs versus transcervical endometrial resection, using the pictorial blood loss assessment chart (see glossary, p 2490).[24,25] The reviews found no significant difference between treatments in mean blood loss (endometrial resection *v* levonorgestrel IUD WMD +12.2 mL, 95% CI −1.9 mL to +26.3 mL) or satisfaction rates (satisfaction rate 94% with endometrial resection *v* 85% with levonorgestrel IUD; P = NS) after 12 months.[24] The third RCT (44 women) identified by the reviews found no significant difference between norethisterone (15 mg daily, day 5 to day 26 of cycle) and levonorgestrel releasing IUDs in reduction of blood loss or rates of satisfaction (median reduction from baseline 6 mL/cycle with norethisterone *v* 20 mL/cycle with levonorgestrel; satisfaction data not stated).[24,25] The fourth RCT (56 women) identified by the reviews found that levonorgestrel releasing IUDs significantly increased the number of women who cancelled their hysterectomy after 6 months of treatment compared with medical treatment and improved all the quality of life scores that were assessed (cancelled hysterectomy: 18/28 [64%] with levonorgestrel releasing IUD *v* 4/28 [14%] with medical treatment; RR 4.5, 95% CI 1.7 to 11.6).[24,25] Details of medical treatment and results of quality of life assessment were not provided. The additional RCT (35 women) identified by the second review compared three groups: a levonorgestrel releasing IUD, flurbiprofen, and tranexamic acid (see comment below).[25] It found that a levonorgestrel releasing IUD significantly reduced mean menstrual flow after 12 months compared with both other treatments (mean menstrual blood flow reduction: 96% with levonorgestrel *v* 21% with flurbiprofen, $P < 0.001$; 96% with levonorgestrel *v* 44% with tranexamic acid, $P < 0.01$). The first subsequent RCT (236 women) compared a levonorgestrel releasing IUD with hysterectomy (see comment below).[26] It found no significant difference in health related quality of life, general health state, anxiety, depression (results presented graphically; significance data not provided), or in haemoglobin concentration (135 g/L with levonorgestrel *v* 132 g/L with hysterectomy; significance data not provided), although both treatments significantly improved these outcomes compared with baseline levels after 12 months. The second subsequent RCT (59 women) found that a levonorgestrel releasing IUD significantly decreased the number of women judged to have been successfully treated after 12 months compared with endometrial resection (treatment success defined as a pictorial blood loss assessment chart score of ≤ 75; 20/30 [67%] with a levonorgestrel releasing IUD *v* 26/29 [90%] with endometrial resection; RR 1.35, 95% CI 1.02 to 1.78; NNT 5, 95% CI 3 to 26).[27] The third subsequent RCT (72 women) compared a levonorgestrel releasing IUD versus thermal balloon ablation (see glossary, p 2490).[28] It found that thermal balloon ablation increased success rate (defined as a

pictorial blood loss assessment chart score of ≤ 75) compared with levonorgestrel releasing IUD, but found no significant difference between treatments in haemoglobin at 1 year (success rate: 97% with thermal balloon ablation *v* 77% with levonorgestrel releasing IUD, neither CI nor P values for comparison were reported; increase in haemoglobin: 3.9 g/dL with thermal balloon ablation *v* 3.7 g/dL with levonorgestrel releasing IUD, neither CI nor P values for comparison were reported).

Harms: There are concerns that progesterone releasing IUDs increase rates of ectopic pregnancy, although the RCTs identified by the reviews did not report this adverse effect.[24,25] The first review found that most adverse effects in women using a levonorgestrel releasing IUD were typical of progestogens (bloating, weight gain, breast tenderness).[24] One RCT included in the review found that levonorgestrel releasing IUD significantly increased the number of women reporting at least one adverse effect compared with transcervical endometrial resection (56% with levonorgestrel releasing IUD *v* 26% with transcervical endometrial resection; RR 2.2, 95% CI 1.2 to 3.0).[29] One further trial found that levonorgestrel releasing IUDs significantly increased the proportion of women who were amenorrhoeic after 3 months of treatment compared with norethisterone (32% with levonorgestrel releasing IUDs *v* 0% with norethisterone).[30] The other main adverse effect reported with levonorgestrel releasing IUDs was irregular, although not usually heavy, menstrual bleeding.[24] RCTs looking at the contraceptive effect of levonorgestrel releasing IUDs in younger women found that during the first few months of use the total number of bleeding days (including menstrual bleeding, intermenstrual bleeding, and spotting) increased in most women.[31] However, most women bled lightly for only 1 day a month and about 15% were amenorrhoeic after 12 months.[32] One RCT (72 women) found that levonorgestrel releasing IUD significantly increased adverse effects compared with thermal balloon ablation (adverse effects: 58.3% with levonorgestrel releasing IUD *v* 22.2% with thermal balloon ablation, $P < 0.05$).[28] Adverse effects with levonorgestrel releasing IUD included spotting (6 women), mastalgia (5 women), weight gain (10 women), mood swings (2 women), bloating (8 women), acne–greasy skin (7 women), nausea (4 women), headache and leg pain (1 woman), and lost IUD (1 woman). Adverse effects with thermal balloon included mastalgia (1 woman), weight gain (4 women), mood swings (1 woman), bloating (1 woman), dysmenorrhoea (2 women), and lower abdominal pain (1 woman). The RCT also found a higher pain score 12 hours after surgery with thermal balloon ablation compared with IUD (no results provided).[28]

Comment: In the additional RCT (35 women) identified by the second review, the first 20 women were given a levonorgestrel releasing IUD and the following 15 women were randomised in a crossover design to receive either flurbiprofen or tranexamic acid.[25] The first subsequent RCT (236 women) found that 24/119 (20%) women who received a levonorgestrel releasing IUD had a hysterectomy, 10/119 (8%) women had the IUD removed, and 3/119 (3%) women were lost to follow up after 12 months.[26] The RCT also found that women had the levonorgestrel releasing IUD removed because of intermenstrual bleeding (94%), heavy bleeding (40%), hormonal symptoms

(17%), or a combination of symptoms. Long term follow up on women with menorrhagia is required to assess continuation rates, satisfaction, and whether surgical treatment is avoided or just postponed. The trials that considered long term bleeding patterns were mainly in women under 40 years of age. It is not yet known whether these results can be extrapolated to older women with menorrhagia.

OPTION GONADORELIN (GONADOTROPHIN RELEASING HORMONE) ANALOGUES

We found no good evidence on the effects of gonadorelin analogues.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs (see comment below).

Comment: A few small non-randomised studies have looked at gonadorelin analogues in menorrhagia. Others have looked at their effects in women with fibroids or on thinning the endometrium before ablation or resection. Adverse effects of gonadorelin analogues are mainly caused by reduced oestrogens. Hormone replacement to counteract hypo-oestrogenism has been tried with limited success to reduce hot flushes.[33] Bone demineralisation occurs in most women after 6 months of treatment but is reversible after treatment is stopped.[34] Contraception whilst using these drugs is not guaranteed.[35]

QUESTION What are the effects of surgical treatments if medical treatments fail?

OPTION DILATATION AND CURETTAGE

We found no good evidence on the effects of dilatation and curettage.

Benefits: We found no systematic review or RCTs.

Harms: Observational evidence suggest that dilatation and curettage may cause adverse effects including uterine perforation and cervical laceration as well as the usual risks of general anaesthesia.[36]

Comment: Dilatation and curettage still plays a part in the investigation of menorrhagia. We found one uncontrolled cohort study (50 women) that measured blood loss before and after dilatation and curettage.[37] It found a reduction in menstrual blood loss immediately after the procedure, but losses returned to previous levels or higher by the second menstrual period.

OPTION HYSTERECTOMY

Systematic reviews have found that hysterectomy reduces menstrual blood loss and the number of women requiring further operations, and increases participant satisfaction compared with endometrial destruction. RCTs found no difference in effectiveness between different types of hysterectomy. One large cohort study reported major or minor complications in about a third of women undergoing hysterectomy.

Benefits: **Versus endometrial destruction:** We found two systematic reviews (search dates 1996[3] and not stated[38]). Both identified the same five RCTs (708 premenopausal women) comparing hysterectomy versus endometrial destruction (transcervical endometrial resection or laser ablation — see glossary, p 2490). The reviews found that hysterectomy significantly reduced menstrual blood loss, and significantly increased the proportion of women with a reduction in menstrual blood loss after 12 months (3 RCTs; 220/220 [100%] with hysterectomy *v* 191/220 [87%] with endometrial destruction; NNT 8, 95% CI 6 to 13). However, the reviews reported that the differences in reduction in blood loss between treatments seemed to narrow with longer follow up, possibly because of re-treatment in the endometrial ablation group or because of menopause. The reviews also found that women were more satisfied with hysterectomy than endometrial ablation after 12 months compared with hysterectomy (RR 0.93, 95% CI 0.89 to 0.99) and after 2 years (RR for being "moderately" or "very" satisfied with endometrial ablation *v* hysterectomy: 0.87, 95% CI 0.81 to 0.94).[3,38] Two RCTs included in the reviews found no significant difference between treatments in satisfaction rates after 3 and 4 years. The reviews found that endometrial destruction significantly increased the number of women requiring repeat surgery compared with hysterectomy (after 12 months, 5 RCTs: 1/320 [0.3%] with hysterectomy *v* 54/386 [14%] with endometrial destruction; RR 44.8, 95% CI 6.2 to 321.8; after 4 years, 1 RCT: 1/95 [1%] with hysterectomy *v* 39/102 [38%] with endometrial destruction; RR 36.3, 95% CI 5.1 to 259.2), but found that endometrial destruction significantly reduced the duration of surgery (–23 minutes), duration of hospital stay (–5 days), and time to return to work (–4.5 weeks). **Different techniques:** We found no systematic review. Five small RCTs (total of 334 women) compared abdominal, vaginal, or laparoscopic hysterectomy.[39–43] They found no evidence of a difference in effectiveness or complication rates. However, operating and recovery times varied.

Harms: Large population based analyses stratified by age have found that mortality after hysterectomy for non-malignant conditions is about 1/2000 in women aged under 50 years.[44] When compared with endometrial destruction, hysterectomy increased the risk of sepsis, blood transfusion, urinary retention, anaemia, pyrexia, vault and wound haematoma, and cautery of hypergranulation before hospital discharge. One large, prospective cohort study of hysterectomy for non-malignant conditions found combined major and minor complication rates (mainly infectious morbidity) of 25% for vaginal hysterectomy and 43% for abdominal hysterectomy.[45] It is possible that the difference seen was attributable to the prevalence and efficacy of prophylactic antibiotic use among the vaginal hysterectomy group. Prophylactic antibiotics are used more routinely in both groups nowadays.

Comment: None.

OPTION ENDOMETRIAL DESTRUCTION (RESECTION OR ABLATION)

Systematic reviews have found that endometrial destruction increases menstrual blood loss and the need for further operations and reduces participant satisfaction compared with hysterectomy. One systematic review found that hysteroscopic methods of endometrial destruction increased amenorrhoea at 12 months compared with non-hysteroscopic methods. We found no consistent evidence of a difference in amenorrhoea or satisfaction rates among different types of hysteroscopic procedure. We found no consistent evidence of a difference in blood loss or satisfaction between transcervical endometrial resection and medical treatment. RCTs found that complications, such as infection, haemorrhage, or uterine perforation occurred in up to 15% of women undergoing endometrial destruction.

Benefits:

Versus hysterectomy: See benefits of hysterectomy, p 2485.

Hysteroscopic resection or ablation versus non-hysteroscopic techniques: We found one systematic review (search date 2001, 8 RCTs, 1595 premenopausal women)[46] and two subsequent RCTs.[47,48] Hysteroscopic methods included in the review were laser ablation, rollerball ablation, transcervical endometrial resection (see glossary, p 2490), and vaporising electrode ablation. Non-hysteroscopic methods included thermal uterine balloon therapy, multielectrode balloon ablation, microwave ablation (see glossary, p 2490), and heated saline. All methods reduced menstrual blood loss compared with baseline assessment. The review found that hysteroscopic ablation significantly increased amenorrhoea at 12 months compared with non-hysteroscopic ablation (amenorrhoea: OR 0.76, 95% CI 0.60 to 0.90). The review found no significant difference between hysteroscopic and non-hysteroscopic methods in satisfaction rate, inability to work, and subsequent requirement for additional surgery or pictorial blood loss assessment chart (see glossary, p 2490) results after 12 months. Among hysteroscopic techniques the review found no significant difference in rates of amenorrhoea between laser ablation and transcervical resection.[49] The review also found no significant difference with vaporising electrode ablation in amenorrhoea rate, satisfaction rate, or pictorial blood loss assessment chart results after 12 months. The first subsequent RCT (120 women, 113 followed up at 5 years) found no significant difference between transcervical endometrial resection and rollerball ablation in reduction in bleeding, hysterectomy rates, or satisfaction at 5 years (median number of days bleeding in 3 months 18 days with resection *v* 16 days with rollerball ablation; hysterectomy 8/59 [14%] with resection *v* 10/61 [16%] with rollerball ablation, $P > 0.05$; would recommend procedure to a friend 46 women with resection *v* 49 women with rollerball ablation, the number of women responding to this question was not reported by treatment group, $P > 0.05$).[47] The second subsequent RCT (82 women) found that transcervical endometrial resection significantly increased recurrent bleeding and reoperation rate at 2 years compared with thermal ablation (68 women included in analysis; recurrent bleeding 24.2% with endometrial resection *v* 8.5% with thermal ablation; reoperation

15.1% with endometrial resection *v* 5.7% with thermal ablation).[48] It also found higher satisfaction rates with thermal ablation at 1 and 2 years (2 years: health excellent or good 79.9% with thermal ablation *v* 60.5% with endometrial resection). **Resection versus medical treatment:** We found one systematic review (search date 1999, 2 RCTs, 60 and 70 women) comparing transcervical endometrial resection versus levonorgestrel releasing intrauterine devices,[24] and one additional RCT (187 women) comparing transcervical endometrial resection versus medical treatment (not including a levonorgestrel releasing intrauterine device).[50] The systematic review found that resection reduced the blood loss from baseline significantly more than levonorgestrel releasing intrauterine devices, but had no significant effect on mean blood loss or satisfaction rates after 12 months (for numerical results see intrauterine progestogens, p 2481). The additional RCT (187 women) found that transcervical endometrial resection versus a variety of medical treatments (oral progestogens, combined oral contraceptive, tranexamic acid, danazol, or hormone replacement therapy plus non-steroidal anti-inflammatory drug) significantly increased total satisfaction at 5 years (not intention to treat analysis, 144 women followed up to 5 years; AR for total satisfaction 61% with resection *v* 39% with medical management; ARR 21%, 95% CI 4% to 37%; see comment below).[50]

Harms: Intraoperative complications include uterine perforation, haemorrhage, and fluid overload from the distension medium. Immediate postoperative complications include infection, haemorrhage, and, rarely, bowel injury. Complication rates in the RCTs included in the systematic review above ranged from 0% to 15%.[46] One large prospective survey of 10 686 women undergoing endometrial destructive procedures in the UK found an immediate complication rate of 4%.[49] Intraoperative emergency procedures were performed in 1%, and two procedure related deaths occurred. Newer non-hysteroscopic methods of endometrial destruction have been evaluated only in small numbers of women and, although complications in the RCTs seem minimal, safety data for routine use are awaited. The first subsequent RCT (120 women) found no significant difference in complication rates at 5 years between transcervical endometrial resection and rollerball ablation (only data for infections were reported 6/59 [10%] infections with resection *v* 9/61 [15%] with coagulation, P not reported).[47] Prophylactic antibiotics were given to 48/74 [65%] having resection compared with 35/61 [57%] having coagulation. The second subsequent RCT (82 women) found that transcervical endometrial resection increased short and long term complications compared with thermal ablation (intraoperative complications 5/42 [12%] with endometrial resection *v* 0/40 [0%] with thermal ablation).[48] Intraoperative complications of endometrial resection included open hysterectomy for uterine perforation (2 women).

Comment: The additional RCT comparing resection with medical treatment (187 women) comparing transcervical endometrial resection with a variety of medical treatments reported that at 5 years, 90% of

women had stopped medical treatment or had other treatments in addition. At 5 years, 77% of women in the medical group received either transcervical endometrial resection or hysterectomy and 27% of women in the transcervical resection group subsequently had repeat surgery.[50] The review found that hysteroscopic ablation significantly increased the duration of procedure compared with non-hysteroscopic ablation and significantly increased the number of times general anaesthesia was required although equipment failure was more likely with non-hysteroscopic methods (duration of procedure: WMD 8.4 minutes, 95% CI 6.8 minutes to 10.1 minutes; general anaesthesia required: OR 6.8, 95% CI 4.5 to 10.4; equipment failure: OR 4.1, 95% CI 1.1 to 15.0).[46] The review found no significant difference in complication rates between hysteroscopic and non-hysteroscopic methods. Among hysteroscopic techniques the review found that laser ablation significantly increased procedural length compared with transcervical resection (WMD 9.15 minutes, 95% CI 7.20 minutes to 11.10 minutes), and significantly increased rates of equipment failure (OR 6.0, 95% CI 1.7 to 20.9) and fluid overload (fluid overload: OR 5.2, 95% CI 1.5 to 18.4).[49] The review found that vaporising electrode ablation reduced duration of surgery compared with transcervical resection (WMD 1.50 minutes, 95% CI 0.35 minutes to 2.65 minutes).

OPTION MYOMECTOMY

We found no good evidence on the effects of myomectomy.

Benefits: We found no systematic review. **Open versus laparoscopic myomectomy:** We found no RCTs or other studies in women with menorrhagia that measured menstrual blood loss. **Hysteroscopic myomectomy:** We found no RCTs.

Harms: Intraoperative complications for hysteroscopic myomectomy are similar to those with endometrial destructive procedures that use a hysteroscope (see harms of endometrial destruction, p 2487). The main complication of open myomectomy is haemorrhage, making a hysterectomy necessary.

Comment: One uncontrolled study (15 women, 10 with additional symptoms) reported objective measures of menstrual blood loss.[51] Mean menstrual blood loss, assessed preoperatively and at 3 and 6 months postoperatively, was significantly reduced (261 mL at baseline, 76 mL at 3 months, and 57 mL at 6 months). The study found a significant reduction in pain scores and menstrual duration, despite the fibroids removed measuring only 1–4 cm. RCTs are needed that use objective assessment of menstrual blood loss. This is especially important in the evaluation of surgical procedures because of the greater difficulty in blinding.

QUESTION **What are the effects of endometrial thinning before endometrial destruction?**

OPTION **ENDOMETRIAL THINNING BEFORE ENDOMETRIAL DESTRUCTION**

One systematic review has found that preoperative gonadorelin (gonadotrophin releasing hormone) analogues reduce moderate or heavy periods and increase amenorrhoea compared with placebo, no preoperative treatment, or preoperative danazol. We found insufficient evidence about effects of preoperative danazol or progestogens compared with placebo or no preoperative treatment.

Benefits: We found one systematic review (search date 2001, 12 RCTs, 1179 women)[52] and one subsequent RCT evaluating medical treatment to thin the endometrium before endometrial destruction for menorrhagia.[53] **Gonadorelin (gonadotrophin releasing hormone) analogues versus placebo/no treatment:** Eight RCTs (618 women) identified by the review compared gonadorelin analogues with placebo or no treatment. The review found that gonadorelin analogues significantly increased the rate of postoperative amenorrhoea at 24 months or longer and significantly reduced the risk of continued moderate or heavy periods after 6–12 months (amenorrhoea, 2 RCTs: RR 1.62, 95% CI 1.04 to 2.52; moderate or heavy periods, 4 RCTs: RR 0.74, 95% CI 0.59 to 0.92). The review found no significant difference in patient satisfaction or the likelihood of undergoing further surgery. **Gonadorelin analogues versus danazol:** Three RCTs (340 women) identified by the review compared gonadorelin analogues (goserelin or decapeptyl) with danazol. The review found that gonadorelin analogues significantly increased postoperative amenorrhoea (RR 1.57, 95% CI 1.06 to 2.33; NNT 5.9).[52] **Danazol versus no treatment:** The review identified two small RCTs and we found one subsequent RCT.[52,53] Both RCTs identified by the review found no significant difference in amenorrhoea between danazol and placebo at 12 and 24 months (1 RCT, 50 women: RR 1.31, 95% CI 0.82 to 2.08; 1 RCT, 20 women: RR 3.00, 95% CI 0.79 to 11.44). The subsequent RCT (132 women) found no significant difference in amenorrhoea between danazol and placebo at 1 year (129 women analysed; amenorrhoea rate: 49% with danazol *v* 52% with placebo, CI and P values not reported).[53] **Progestogens versus no treatment:** Two RCTs included in the review (70 women) compared progestogens with no hormonal medication. They found no significant difference in amenorrhoea at 2 years after endometrial destruction (RR 0.75, 95% CI 0.36 to 1.54).[52] **Progestogens versus other medical treatments:** One RCT included in the review (40 women) compared four groups: progestogens, gonadorelin analogues, danazol, and no treatment. The trial was too small to allow firm conclusions to be drawn.[52]

Harms: The review found no significant difference between goserelin and either placebo or no treatment in intraoperative uterine perforations (2/266 [0.8%] with goserelin *v* 1/275 [0.4%] with no treatment/placebo; RR 2.01, 95% CI 0.19 to 22.67).[52] The review found that

goserelin significantly increased hot flushes, depression, and vaginal dryness and reduced libido compared with danazol. Oily skin, hirsutism, and weight gain were significantly more common with danazol. The review also found that danazol significantly increased withdrawal due to adverse effects compared with goserelin (11/139 [8%] with danazol *v* 1/566 [0.2%] with goserelin; RR 44.80, 95% CI 5.83 to 344.00).

Comment: None of the RCTs included in the review used objective measures of postoperative menstrual blood loss.[52] Rates of withdrawal or loss to follow up were low in all studies. One systematic review found that gonadorelin analogues significantly reduced both the duration of surgery and operative difficulty (duration of surgery, 3 RCTs: WMD –4.8 minutes, 95% CI –6.5 minutes to –3.0 minutes; difficulty during procedure, 2 RCTs: RR 0.32, 95% CI 0.22 to 0.46).[52] The review also found that gonadorelin analogues significantly reduced the duration of surgery compared with danazol. It found no significant difference in operative difficulty (amenorrhoea RR 1.57, 95% CI 1.06 to 2.33; NNT 5.9; duration of surgery, 3 RCTs: WMD –3.9 minutes, 95% CI –6.1 minutes to –1.7 minutes; operative difficulty RR 0.68, 95% CI 0.31 to 1.51).[52] The subsequent RCT (132 women) found that danazol reduced operating time compared with placebo (25.7 minutes with danazol *v* 33.6 minutes with placebo, $P < 0.001$).[53]

GLOSSARY

Laser ablation A hysteroscopic procedure in which endometrium is destroyed under direct vision by a laser beam.

Microwave endometrial ablation A procedure in which a microwave probe is passed through the cervix into the uterine cavity. When activated it is moved slowly from side to side over the whole surface of the uterine cavity in order to destroy the endometrium.

Multielectrode balloon ablation A procedure in which an inflatable device with electrodes on the outside is inserted into the uterine cavity through the cervix. The electrodes make contact with the endometrium and cause necrosis.

Pictorial blood loss assessment chart (PBAC) A semi-quantitative assessment of menstrual blood loss based on women filling in the number and appearances of their sanitary protection and size of blood clots on a pictorial chart. Scores of 100 or more equate to a menstrual blood loss of 80 mL or more.[54]

Rollerball ablation A hysteroscopic procedure in which endometrium is destroyed under direct vision by diathermy applied by a rollerball.

Thermal uterine balloon therapy/thermal ablation A procedure in which a balloon catheter is passed through the cervix into the uterine cavity. The balloon is then filled with fluid, which is heated to about 87 °C, and left for 8 minutes. This causes necrosis of the endometrium.

Transcervical endometrial resection A hysteroscopic procedure in which endometrium is removed under direct vision by using an electrosurgical loop.

QUESTIONS

INTERVENTIONS

See glossary, p 2504

Key Messages

- We found insufficient evidence on the effects of any treatments on quality of life.

Surgical treatments

- **Primary surgery versus no surgery**; **primary surgery plus chemotherapy versus chemotherapy alone** We found no RCTs.

Ovarian cancer

- **Routine interval debulking** One RCT found that routine interval debulking, after primary surgery plus chemotherapy, improved overall survival over about 3.5 years compared with chemotherapy alone. A second RCT found that interval debulking had no effect on survival, but it was probably underpowered to detect a clinically important effect.
- **Routine second look surgery** Two RCTs found no evidence that routine second look surgery improved overall survival compared with watchful waiting in women undergoing chemotherapy after primary surgery for advanced ovarian cancer.

Cytotoxic chemotherapy

- **Adding a single platinum agent to a non-platinum combination regimen** One systematic review (4 RCTs, 1024 women) found that adding a platinum agent to a non-platinum combination regimen reduced mortality compared with the non-platinum regimen alone.
- **Adding a taxane (paclitaxel) to a platinum regimen** One systematic review and one additional RCT have found that adding paclitaxel to platinum based chemotherapy significantly improves progression free survival and overall survival after primary surgery for advanced ovarian cancer.
- **Platinum based chemotherapy (at least as effective as non-platinum regimens)** A systematic review and subsequent RCTs have found that platinum based regimens are at least as effective as non-platinum regimens, and that adding a platinum compound to a non-platinum combination regimen improves survival.
- **Single agent platinum regimens (as effective as combination platinum chemotherapy, but with fewer adverse effects and better than single agent non-platinum regimens)** One systematic review and three subsequent RCTs found that single agent platinum based regimens were at least as effective for progression free or overall survival as combination platinum regimens, and had fewer adverse effects. One RCT found that the platinum agent cisplatin improved progression free survival but not overall survival compared with the non-platinum agent thiotepa.
- **Relative eficiacy of different platinum agents (cisplatin versus carboplatin) added to a taxane (paclitaxel)** One RCT found no significant difference in progression free or overall survival between adding cisplatin and adding carboplatin to paclitaxel, although it may have lacked power to detect clinically important effects.
- **Relative efficiacy of different taxanes (paclitaxel versus docetaxel) added to a platinum agent docetaxel** We found no reliable RCTs comparing the effects of carboplatin plus paclitaxel versus those of carboplatin plus docetaxel.

DEFINITION Ovarian tumours are classified according to the assumed cell type of origin (surface epithelium, stroma, or germ cells). Most malignant ovarian tumours (85–95%) are derived from the epithelium of the ovarian surface, and thus are termed epithelial.[1] These can be further grouped into histological types (serous, mucinous, endometroid, and clear cell). Epithelial ovarian cancer is staged using the FIGO classification (see table A on web extra). This review concerns only advanced epithelial ovarian cancer, which is regarded as FIGO stages II–IV.

INCIDENCE/ PREVALENCE The worldwide annual incidence of ovarian cancer exceeds 140 000.[2] Rates vary between countries. Differences in reproductive patterns, including age of menarche and menopause, gravidity, breast feeding, and use of the oral contraceptive pill, may contribute to this variation. Rates are highest in Scandinavia, northern America, and the UK; and lowest in Africa, India, China, and Japan.[3] In the UK ovarian cancer is the fourth most common malignancy in women and is the leading cause of death from gynaecological cancers, with a lifetime risk of about 2%.[4] In the UK the incidence was 5174 in 1988[5] and 6880 in 1998.[6] The incidence of ovarian cancer appears to be stabilising in some other countries, and in some affluent countries (Finland, Denmark, New Zealand, and the USA) rates are declining.

AETIOLOGY/ RISK FACTORS Risk factors include increasing age, family history of ovarian cancer, low fertility, use of fertility drugs, and low parity.[7–11] Case control studies found that using the combined oral contraceptive pill for more than 5 years was associated with a 40% reduction in the risk of ovarian cancer.[3,7,12,13]

PROGNOSIS More than 80% of women present with advanced disease, and the overall 5 year survival rates are poor (< 30%).[6] For advanced disease the major independent prognostic factors appear to be stage, and residual tumour mass after surgery.

AIMS OF INTERVENTION To prolong survival and reduce disability; to minimise adverse effects of treatment.

OUTCOMES Mortality; disease free survival; disease related symptoms; quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal June 2003. RCTs with greater than 20% withdrawal or with less than 18 months' follow up were excluded.

QUESTION What are the effects of surgical treatments for ovarian cancer that is advanced at first presentation?

OPTION PRIMARY SURGERY

We found no RCTs in women with advanced ovarian cancer comparing the effects of primary surgery versus those of no surgery, or the effects of primary surgery plus chemotherapy versus those of chemotherapy alone.

Benefits: **Primary surgery alone versus no surgery:** We found one systematic review (search date not reported), which found no RCTs comparing primary debulking (see glossary, p 2504) surgery versus no surgery.[1] We found no subsequent RCT. **Primary surgery plus chemotherapy versus chemotherapy alone:** We found no systematic review and no RCT.

Harms: We found no RCT.

Comment: None.

OPTION ROUTINE SECOND LOOK SURGERY

Two RCTs found no evidence that routine second look surgery improved overall survival compared with watchful waiting in women undergoing chemotherapy after primary surgery for advanced ovarian cancer.

Benefits: **Primary surgery plus chemotherapy with or without second look surgery:** We found two RCTs in women with advanced ovarian cancer.[14,15] The first RCT (102 women in complete remission after primary debulking [see glossary, p 2504] surgery and first line chemotherapy consisting of cisplatin plus cyclophosphamide or doxorubicin plus cyclophosphamide every 3 weeks for 5 cycles) compared second look surgery (see glossary, p 2504), which included visual inspection and biopsy, versus watchful waiting.[14] Complete remission before trial entry was confirmed by clinical and biochemical assessment, computed tomography, and laparoscopy. The RCT found no significant difference between interventions for overall survival after 60 months (AR for survival 65% with second look laparotomy *v* 78% with watchful waiting; CI not reported; P = 0.14). The second RCT (166 women, after primary debulking surgery plus cisplatin every 3 weeks for 5 cycles) compared three groups.[15] One group underwent a second look laparotomy (which included visual inspection, cytology of any free fluid, total hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and multiple biopsies) followed by oral chlorambucil (12 courses of 0.2 mg/kg daily for 14 days). The second group received second look laparotomy plus pelvic irradiation. The third group received chlorambucil without second look surgery. The RCT found no significant difference among groups for overall survival after 46 months (median survival time 21 months, 95% CI 11 months to 31 months with second look laparotomy plus chlorambucil; 15 months, 95% CI 11 months to 19 months with second look laparotomy plus pelvic irradiation; 17 months, 95% CI 8 months to 26 months with chlorambucil without second look surgery).

Harms: The first RCT did not report on harms.[14] The second RCT reported that one woman died of a cerebrovascular accident 10 days after second look laparotomy.[15] Other reported surgical complications were ileus, wound infection, urinary and respiratory tract infection, and anaemia (rates not reported).

Comment: None.

OPTION ROUTINE INTERVAL DEBULKING

One RCT found that routine interval debulking, after primary surgery plus chemotherapy, improved overall survival after about 3.5 years compared with no interval debulking. A second RCT found that interval debulking had no effect on survival, although it was probably underpowered to detect a clinically important effect.

Benefits: We found no systematic review but found two RCTs.[16,17] The first RCT (319 women with non-progressive disease after 3 cycles of cisplatin and cyclophosphamide chemotherapy following primary surgery) compared interval debulking (see glossary, p 2504) plus continued chemotherapy versus continued chemotherapy alone.[16]

All women had a residual tumour diameter of more than 1 cm after primary surgery. It found that interval debulking significantly improved progression free and overall survival after a median of 3.5 years (278 women; median progression free survival 18 months with interval debulking *v* 13 months without, P = 0.01; median overall survival 26 months *v* 20 months, P = 0.01; adjusted HR for death for interval debulking *v* no interval debulking 0.77, 95% CI 0.50 to 0.90).[16] The second RCT (79 women with advanced ovarian cancer with residual tumour of at least 2 cm maximal diameter after primary surgery) compared interval debulking plus continued chemotherapy versus continued chemotherapy alone.[17] Chemotherapy consisted of either cisplatin plus cyclophosphamide or cisplatin plus bleomycin plus doxorubicin followed by escalating cyclophosphamide. Of the women allocated to interval debulking, 11 had non-responsive or progressive disease after three cycles of chemotherapy and were excluded from surgery. Interval debulking (which could include hysterectomy, oophorectomy, and omentectomy) was undertaken at a median of 13 weeks after primary surgery. The RCT found no significant difference between interval debulking and no interval debulking for overall survival after median follow up of 48 months, but it may have lacked power to exclude a clinically important effect (intention to treat analysis: median survival 15 months with interval debulking *v* 12 months without; HR 0.71, 95% CI 0.44 to 1.33).

Harms: The second RCT found that, among 26 women who received interval debulking, 11 received a blood transfusion, two developed intestinal fistulae, and one developed a deep vein thrombosis.[17]

Comment: None.

QUESTION What are the effects of cytotoxic chemotherapy for ovarian cancer that is advanced at first presentation?

OPTION PLATINUM BASED REGIMENS

One systematic review and subsequent RCTs have found that platinum based regimens are at least as effective as non-platinum regimens, and that adding a platinum compound to a non-platinum combination regimen improves survival. The systematic review and three subsequent RCTs found that single agent platinum based regimens were at least as effective for progression free or overall survival as combination platinum regimens, and had fewer adverse effects. One RCT found that a single platinum agent, cisplatin, improved progression free survival but not overall survival compared with a single non-platinum agent, thiotepa. The review found that adding a platinum agent to a non-platinum combination regiment reduced mortality compared with the non-platinum regimen alone. One RCT found no significant difference in progression free or overall survival between adding cisplatin and adding carboplatin to paclitaxel, although it may have lacked power to detect clinically important effects.

Benefits: We found one systematic review (search date 1998, 37 RCTs)[18] and six subsequent RCTs[19–24] in women with advanced ovarian cancer. **Platinum based combination chemotherapy versus**

single agent non-platinum based chemotherapy: The review identified 11 RCTs (1329 women) comparing platinum based combination chemotherapy versus single agent non-platinum chemotherapy.[18] It found no significant difference between treatments for overall survival (9 RCTs, 1704 women; HR 0.93, 95% CI 0.83 to 1.05; P = 0.23; estimated ARR for 2 and 5 year survival with single agent non-platinum versus combination platinum +3%, 95% CI −2% to +7%). **Adding a platinum based compound to a non-platinum single agent regimen:** The systematic review found no significant difference in mortality between a single agent chemotherapy regimen and the same single agent plus a platinum based compound, although results of trials were statistically heterogeneous (5 RCTs, 680 women; HR for death with platinum added to single agent *v* single agent alone 0.93, 95% CI 0.78 to 1.10).[18] **Adding a platinum based compound to a non-platinum combination regimen:** The systematic review found that adding a platinum based compound to a non-platinum combination regimen significantly reduced mortality compared with the same non-platinum regimen alone (4 RCTs, 1024 women; HR 0.85, 95% CI 0.74 to 0.97).[18] The first subsequent RCT (228 women) found similar results.[19] It found that adding cisplatin (50 mg/m^2 every 3–4 weeks) to 12 cycles of doxorubicin plus cyclophosphamide with or without Bacillus Calmette-Guérin significantly improved overall survival compared with same regimen without cisplatin (median survival 17.8 months with cisplatin *v* 9.9 months without cisplatin; P < 0.005). **Platinum based combination regimens versus non-platinum based combination regimens:** The second subsequent RCT (169 women) compared 12 cycles at four weekly intervals of cisplatin (60 mg/m^2/cycle) plus melphalan (1 mg/kg/cycle) versus hexamethylmelamine plus doxorubicin plus cyclophosphamide.[20] It found no significant difference between treatments for overall survival (153 women; median survival 29.6 months with a platinum based regimen *v* 26.4 months with non-platinum based regimen; P value not reported) but the trial may have lacked power to exclude a clinically important difference. The third subsequent RCT (120 women) found no significant difference between hexamethylmelamine plus doxorubicin plus cyclophosphamide versus cisplatin plus doxorubicin plus cyclophosphamide for overall survival after 10 years (median survival 126 months without a platinum based regimen *v* 138 months with a platinum based regimen; P = 0.54).[21] The fourth subsequent RCT (83 women) compared 12 cycles at four weekly intervals of doxorubicin (60 mg/m^2) plus cyclophosphamide (750 mg/m^2) combined with either cisplatin (80 mg/m^2) or vincristine (1.4 mg/m^2).[22] It found that the platinum based regimen increased progression free and overall survival compared with the non-platinum regimen after 5 years (median progression free survival 14 months with platinum based regimen *v* 10 months without the platinum based regimen, P < 0.05; median overall survival 24 months with platinum *v* 15 months without platinum, P < 0.01). The fifth subsequent RCT (186 women) compared hexamethylmelamine plus cyclophosphamide plus methotrexate plus 5-fluorouracil versus a regimen that alternated between cyclophosphamide plus hexamethylmelamine and doxorubicin plus cisplatin.[23] It found that the platinum based

regimen significantly improved progression free and overall survival after about 50 months compared with the non-platinum regimen (median progression free survival 19.5 months with platinum *v* 6.8 months without platinum, $P < 0.0001$; median overall survival 30.7 months with platinum *v* 19.6 months without platinum, $P < 0.002$). A follow up study at 10 years found a survival rate of 9% among women who received non-platinum chemotherapy as first line treatment compared with 23% among those treated with the platinum based regimen (P value not reported).[25] **Single platinum based agent versus single non-platinum agent:** The sixth additional RCT (171 women) compared a single platinum based compound (cisplatin, 75 mg/m^2 every 28 days for 6 cycles) versus a single non-platinum compound (thiotepa, 60 mg loading dose im followed by 10 cycles of 30 mg im every 14 days).[24] It found that cisplatin significantly improved progression free survival after a median follow up of 110 months compared with the non-platinum agent, thiotepa (median progression free survival 10.5 months with cisplatin *v* 6.3 months with thiotepa, $P = 0.025$; HR for thiotepa *v* cisplatin 1.64, 95% CI 1.17 to 2.30). Cisplatin did not significantly improve overall survival compared with thiotepa (median overall survival 20 months with cisplatin *v* 14 months with thiotepa, $P = 0.155$; AR for survival at 8 years 10.6% with cisplatin *v* 7.4% with thiotepa, CI and P value not reported). **Combination platinum based chemotherapy versus single agent platinum based chemotherapy:** We found one systematic review (search date 1998, 9 RCTs, 1095 women with advanced ovarian cancer)[18] and three additional RCTs.[26–28] The review found no significant difference between treatments for risk of death (HR 0.91, 95% CI 0.80 to 1.05).[18] Separate analyses of cisplatin and carboplatin containing regimens yielded similar findings (HR of death for single agent *v* combination cisplatin regimens 0.86, 95% CI 0.73 to 1.02; HR of death for single agent *v* combination carboplatin regimens 1.05, 95% CI 0.82 to 1.35). The first additional RCT (multicentre, 1526 women, 36% of women < 55 years old) compared six cycles of cisplatin (50 mg/m^2) plus cyclophosphamide (500 mg/m^2) plus doxorubicin (50 mg/m^2) versus carboplatin alone (3 times weekly for 6 cycles; dose calculated as follows: [glomerular filtration rate 5] + 25mg).[26] After a median follow up of 35 months, the RCT found no significant difference between treatments for progression free survival or overall survival (HR for progression free survival for combined treatment *v* carboplatin alone 0.92, 95% CI 0.81 to 1.04; HR for overall survival 1.00, 95% CI 0.86 to 1.16). The second additional RCT (611 women aged < 75 years) compared cisplatin alone (50 mg/m^2) weekly for nine cycles versus cisplatin (75 mg/m^2) plus cyclophosphamide (750 mg/m^2) three times weekly for six cycles.[27] It found no difference between groups either for 3 year progression free survival or overall survival (3 year progression free survival 33.8% with cisplatin alone *v* 35.1% with combined treatment, CI and P values not reported; 3 year overall survival 44.1% with cisplatin alone *v* 44.6% with combined treatment, CI not reported, $P = 0.96$). The third RCT (176 women) compared cisplatin alone (75 mg/m^2) for six four weekly courses versus cisplatin (50 mg/m^2) plus cyclophosphamide (500 mg/m^2) every 28 days for six courses.[28] It found no significant difference

between treatments for progression free survival or overall survival after a median of 10 years (median progression free survival 11.9 months with single *v* 10.0 months with combination, P = 0.092; median overall survival 21.5 months with single *v* 19.4 months with combination, P = 0.1299). We found one further RCT that was reported as a conference abstract (see comment below). **Comparison of different platinum agents (cisplatin versus carboplatin) added to a taxane:** We found one RCT (208 women).[29] It compared cisplatin (75 mg/m^2) plus paclitaxel (175 mg/m^2 over 3 hours) versus carboplatin plus the taxane paclitaxel for at least six cycles (dose of carboplatin calculated as follows: [glomerular filtration rate 5] + 25mg). It found no significant difference between treatments for either progression free survival or overall survival after a median of 37 months, although it may have lacked power to detect clinically important effects (median progression free survival 16 months in both groups; HR 1.07, 95% CI 0.78 to 1.48; median overall survival 30 months with paclitaxel plus cisplatin *v* 32 months with paclitaxel plus carboplatin; HR 0.85, 95% CI 0.59 to 1.24).

Harms: The first systematic review did not report adverse effects.[18] One cohort analysis of two RCTs comparing platinum and non-platinum based regimens found that grade 3 nausea and vomiting (see table 1, p 2506), mild renal toxicity, and neurotoxicity were significantly more common with platinum containing regimens than with non-platinum regimens (AR grade 3 nausea and vomiting about 6–10% with platinum based regimens *v* 4% with non-platinum based regimens, P = 0.004; AR any renal toxicity 17–20% with platinum *v* 4% with non-platinum, P value not reported; AR neurotoxicity 1–4% with platinum *v* 0% with non-platinum, P value not reported).[30] **Adding a platinum based compound to a non-platinum combination regimen:** We found one analysis of data from two RCTs (387 women with advanced ovarian cancer) comparing hexamethylmelamine plus cyclophosphamide plus methotrexate plus 5-fluorouracil with or without cisplatin, or with cyclophosphamide plus cisplatin.[31] After a median follow up of 45 months, it found that neurotoxicity was more common and more severe with regimens that included platinum based compounds than with those that did not include platinum (AR for any neurotoxicity 47% with platinum *v* 25% without platinum; AR for grade 2–3 neurotoxicity 25% with platinum *v* 3% without platinum; CI and P values not reported). **Platinum based combination regimens versus non-platinum based combination regimens:** The RCT comparing cisplatin plus melphalan versus hexamethylmelamine plus doxorubicin plus cyclophosphamide found that haematological toxicity was significantly more common with the platinum based regimen (white cells < 3000/m^3, P < 0.0001; platelets < 75 000/m^3, P < 0.0001; anaemia, P = 0.001).[20] The RCT comparing doxorubicin plus cyclophosphamide combined with either vincristine or cisplatin reported that platinum increased haematological toxicity (rates not reported).[22] **Single platinum based agent versus single non-platinum agent:** One additional RCT comparing cisplatin versus thiotepa found that 1/85 (1%) women taking cisplatin stopped because of weakness and dizziness.[24] **Single platinum based agent versus combined**

platinum based chemotherapy: In the RCT comparing carboplatin alone versus cyclophosphamide plus doxorubicin plus cisplatin, 875 women (57%) were assessed for adverse effects.[26] Leucopenia, hair loss, nausea, and vomiting were more common with combination treatment than with carboplatin alone (AR for leucopenia 36% with combination *v* 10% with carboplatin alone; AR for hair loss 70% with combination *v* 4% with carboplatin alone; AR for nausea and vomiting 20% with combination *v* 9% with carboplatin alone). Thrombocytopenia was more common with carboplatin (AR 6% with combination *v* 16% with carboplatin alone). Renal, cardiac, and neurotoxicity were rare in both groups (1–2% in both groups for each category). **Comparison of different platinum agents (cisplatin versus carboplatin) added to a taxane:** The RCT comparing carboplatin plus the taxane paclitaxel, versus cisplatin plus paclitaxel, found no significant difference between treatments for rates of hair loss, fever, mucositis, diarrhoea, allergic reaction, cardiorespiratory complications, skin reactions, muscle or joint pain, constipation, fever, or renal toxicity.[29] However, after six cycles of treatment, grade 4 nausea and vomiting (see table 1, p 2506) was more common with cisplatin plus paclitaxel (AR 17% with cisplatin plus paclitaxel *v* 14% with carboplatin plus paclitaxel; $P < 0.01$). Grade 3–4 thrombocytopenia and grade 4 granulocytopenia (see table 1, p 2506) were more common with carboplatin plus paclitaxel (AR for grade 3–4 thrombocytopenia 6% with carboplatin plus paclitaxel *v* 1% with cisplatin plus paclitaxel, $P < 0.01$; AR for grade 4 granulocytopenia 40% with carboplatin plus paclitaxel *v* 23% with cisplatin plus paclitaxel, $P < 0.01$). Two other RCTs reported as conference abstracts reported on harms (see comment below).

Comment: **Single agent platinum versus combined platinum chemotherapy:** We found one RCT (120 women with advanced ovarian cancer) reported as a conference abstract, which compared six cycles of cisplatin plus cyclophosphamide versus three cycles of epirubicin plus ifosfamide followed by four cycles of cisplatin.[32] It found no significant differences between treatments for relapse free survival or overall survival (relapse free survival at 3 years 24% with cisplatin plus cyclophosphamide *v* 41% with epirubicin plus ifosfamide plus cisplatin, CI and P values not reported; median overall survival 141 weeks with cisplatin plus cyclophosphamide *v* 172 weeks with epirubicin plus ifosfamide plus cisplatin, CI and P values not reported). **Comparison of different platinum agents (cisplatin versus carbaplatin) added to a taxane:** We found two additional RCTs that were reported in three conference abstracts. The first RCT (797 women) compared carboplatin plus paclitaxel versus cisplatin plus paclitaxel, and was reported in two conference abstracts.[33,34] It found no significant difference between treatments for either progression free survival or overall survival after a median follow up of 2 years ($P > 0.05$).[34] A preliminary safety report on 488/797 of the women (61.2%) found that grade 3–4 haematological toxicity (see table 1, p 2506) was more common with the carboplatin regimen, and non-haematological toxicity (other than hair loss) was more common with the cisplatin regimen

(ARs not reported).[33] The second RCT compared carboplatin plus paclitaxel versus paclitaxel plus alternating cisplatin and carboplatin in 164 women and was reported in a single conference abstract.[35] It found no significant differences for disease free survival or overall survival (P = 0.4 for both outcomes).

OPTION TAXANES

One systematic review and one additional RCT have found that adding paclitaxel to platinum based chemotherapy significantly improves progression free survival and overall survival after primary surgery for advanced ovarian cancer compared with platinum based chemotherapy alone. We found no reliable RCTs comparing carboplatin plus docetaxel versus carboplatin plus paclitaxel.

Benefits: **Adding a taxane (paclitaxel) to a platinum regimen:** We found one systematic review[36] and one additional RCT[37] in women with advanced ovarian cancer. The systematic review (search date not reported, 4 RCTs, 3754 women) included one published RCT[38] and three unpublished RCTs, all of which have since been published.[39–41] The first RCT (386 women) compared cisplatin (75 mg/m^2) plus cyclophosphamide versus cisplatin (75 mg/m^2) plus paclitaxel (135 mg/m^2).[38] It found that cisplatin plus paclitaxel improved progression free survival and overall survival when compared with cisplatin plus cyclophosphamide (median progression free survival 18 months with cisplatin plus paclitaxel *v* 13 months with cisplatin plus cyclophosphamide, P < 0.001; median overall survival 38 months with cisplatin plus paclitaxel *v* 24 months with cisplatin plus cyclophosphamide, P < 0.001). The second RCT (680 women) compared cisplatin (75 mg/m^2) plus cyclophosphamide versus cisplatin (75 mg/m^2) plus paclitaxel (175 mg/m^2).[39] It found that cisplatin plus paclitaxel significantly improved progression free survival and overall survival compared with cisplatin plus cyclophosphamide (median progression free survival 17 months with cisplatin plus paclitaxel *v* 12 months with cisplatin plus cyclophosphamide, P = 0.001; median survival 35 months with cisplatin plus paclitaxel *v* 25 months with cisplatin plus cyclophosphamide, P = 0.001). The third RCT (614 women) compared three treatments: cisplatin alone (100 mg/m^2), paclitaxel alone (200 mg/m^2), and paclitaxel (135 mg/m^2) followed by cisplatin (75 mg/m^2).[40] It found no significant difference between cisplatin alone versus cisplatin plus paclitaxel for progression free survival or overall survival after a median follow up of 61 months (progression free survival: median 16 months with cisplatin alone *v* 14 months with cisplatin plus paclitaxel; HR 1.06, 95% CI 0.90 to 1.30; overall survival: median 30 months with cisplatin alone *v* 27 months with cisplatin plus paclitaxel; HR 0.99, 95% CI 0.80 to 1.23). The fourth RCT (2074 women) compared three treatments: paclitaxel (175 mg/m^2) plus carboplatin, carboplatin alone, and cyclophosphamide plus doxorubicin plus cisplatin.[41] It found no significant difference in progression free survival or overall survival between paclitaxel plus carboplatin versus carboplatin alone after 24 months (overall free survival: HR 0.98, 95% CI 0.87 to 1.10; progression free survival: HR 0.93, 95% CI 0.84 to 1.04). The additional RCT (45 women) compared cisplatin (75 mg/m^2) plus paclitaxel

(175 mg/m^2) versus cisplatin (75 mg/m^2) plus cyclophosphamide (750 mg/m^2).[37] It found that cisplatin plus paclitaxel significantly increased the time to relapse and relapse free survival after 25 months compared with cisplatin plus cyclophosphamide (38 women; median time to relapse 17.5 months with cisplatin plus paclitaxel *v* 9.9 months with cisplatin plus cyclophosphamide, CI and P value not reported; P value for difference in relapse free survival = 0.001, mean values and CI not reported). **Comparison of different agents (cisplatin versus carboplatin) added to a taxane:** See benefits of platinum based regimens, p 2497. **Comparison of different taxanes (paclitaxel versus docetaxel) added to a platinum agent:** We found no RCTs with sufficient follow up for inclusion (see comment below).

Harms:

Adding a taxane (paclitaxel) to a platinum regimen: The systematic review found that reporting of adverse effects was not consistent among trials.[36] One RCT found that adding paclitaxel to platinum based regimens did not significantly increase haematological toxicity, fever, or anaemia (any haematological toxicity: RR about 1, 95% CI about 0.8 to 1.3; anaemia: RR 1.10, 95% CI 0.57 to 2.13; fever: RR 16.38 in favour of non-paclitaxel regimen, 95% CI 0.83 to 284).[38] In one RCT, compared with the platinum based regimen alone, infection was more common with paclitaxel plus a platinum compound (RR 3.38, 95% CI 2.15 to 5.32) but less common with cyclophosphamide plus doxorubicin plus a platinum compound (RR 0.59, 95% CI 0.40 to 0.86).[41] Nausea and vomiting was reported in 7–18% of women receiving paclitaxel, and hair loss was reported in 68–77% of women receiving paclitaxel. Cardiac toxicity was not reported in the included RCTs. One RCT (614 women) found that adverse effects were significantly more common with paclitaxel or paclitaxel plus cisplatin (neutropenia, $P < 0.008$; hair loss, $P < 0.001$; fever, $P < 0.001$) than with cisplatin alone.[40] Another RCT found that grades 3 and 4 muscle pain (see table 1, p 2506), neurosensory and neuromotor symptoms, and hair loss were more common with cisplatin plus paclitaxel than with cisplatin plus cyclophosphamide (AR muscle pain 6% with cisplatin plus paclitaxel *v* 0% with cisplatin plus cyclophosphamide; neurosensory symptoms 19.6% with cisplatin plus paclitaxel *v* 1% with cisplatin plus cyclophosphamide; neuromotor symptoms 5% with cisplatin plus paclitaxel *v* 0.6% with cisplatin plus cyclophosphamide; hair loss 51% with cisplatin plus paclitaxel *v* 21% with cisplatin plus cyclophosphamide; CI and P values not reported).[35] Grade 3 and 4 leucopenia (see table 1, p 2506), anaemia, and thrombocytopenia were less common with cisplatin plus paclitaxel than with cisplatin plus cyclophosphamide (AR, CI, and P values not reported). Febrile neutropenia rates were similar between groups (AR 3% for both groups).

Comment:

Comparison of different taxanes (paclitaxel versus docetaxel) added to a platinum regimen: We found one ongoing RCT (1077 women from 83 centres), that will compare effects of six cycles of carboplatin (dose calculated as follows: [glomerular filtration rate 5] + 25 mg) combined with either paclitaxel (175 mg/m^2) or docetaxel (75 mg/m^2).[42]

Ovarian cancer

GLOSSARY

Debulking is removal of a major proportion of the tumour. Initial and primary debulking both refer to surgery performed at first presentation.

Interval debulking is a second operation to remove residual tumour after a specified number of cytotoxic chemotherapy cycles, which is then followed by further chemotherapy.

Routine second look surgery is an operation to assess the response to cytotoxic chemotherapy in women who have already undergone primary surgery.

Substantive changes

Platinum based chemotherapy Long term follow up of existing RCT added;[25] categorisation unchanged.

Taxanes One RCT added;[41] categorisation unchanged.

Premenstrual syndrome

Search date October 2002

Katrina Wyatt

QUESTIONS

INTERVENTIONS

See glossary, p 2523

Key Messages

- **Bromocriptine (breast symptoms only)** RCTs have found limited evidence that bromocriptine relieves breast tenderness compared to placebo, although adverse effects are common.
- **Cognitive behavioural therapy** RCTs found that cognitive behavioural therapy significantly reduced premenstrual symptoms compared to control treatments, but the evidence is insufficient to define the size of an effect.
- **Danazol** RCTs have found that danazol significantly reduces premenstrual symptoms compared to placebo, but has important adverse effects associated with masculinisation when used continuously in the long term.
- **Diuretics** RCTs have found that spironolactone improves symptoms of premenstrual syndrome including breast tenderness and bloating, compared to placebo. Two RCTs have found that metolazone or ammonium chloride versus placebo reduce premenstrual swelling and weight gain.

Premenstrual syndrome

- **Exercise** One RCT has found that aerobic exercise significantly improves premenstrual symptoms compared to placebo. Another RCT has found that high intensity aerobic exercise improves symptoms significantly more than low intensity.
- **Gonadorelin analogues** RCTs have found that gonadorelin analogues (GnRH in previous nomenclatrues) significantly reduce premenstrual symptoms compared to placebo. RCTs have found that gonadorelin plus oestrogen plus progestogen (addback treatment) improves symptom scores less than that gonadorelin analogue alone but more than placebo. One small RCT found a similar reduction in symptom scores with gonadorelin analogue plus tibolone compared to gonadorelin analogue alone. Treatment with gonadorelin analogues for more than 6 months carries a significant risk of osteoporosis, limiting their usefulness for long term treatment.
- **Hysterectomy with or without bilateral oophorectomy** We found no RCTs. Observational studies have found that hysterectomy plus bilateral oophorectomy is curative. Hysterectomy alone may reduce symptoms, but evidence is limited because of the difficulty in providing controls. The risks are those of major surgery. Infertility is an irreversible consequence of bilateral oophorectomy.
- **Non-selective serotonin reuptake inhibitor antidepressants/anxiolytics** RCTs have found that non-selective serotonin reuptake inhibitor antidepressants and anxiolytic drugs significantly improve at least one symptom of premenstrual syndrome compared to placebo, but a proportion of women stop treatment because of adverse effects. We found insufficient evidence from small RCTs about effects of β blockers and lithium.
- **Non-steroidal anti-inflammatory drugs** RCTs found that prostaglandin inhibitors significantly improved a range of premenstrual symptoms but did not reduce premenstrual breast pain, compared to placebo.
- **Oestrogens** Limited evidence from small RCTs suggests that oestradiol improves symptoms compared to placebo, but the magnitude of any effect remains unclear.
- **Oral contraceptives** RCTs found limited evidence that oral contraceptives improved premenstrual symptoms compared to placebo.
- **Progesterone** One systematic review of progesterone has found a small but significant improvement in overall premenstrual symptoms and no increase in the frequency of withdrawals caused by adverse effects, compared to placebo. However, the improvement is unlikely to be clinically important. It remains unclear whether the route or timing of administration of progesterone is important.
- **Progestogens** We found insufficient evidence from one small RCT about the effects of progestogens compared to placebo.
- **Pyridoxine** One systematic review of poor quality RCTs found insufficient evidence about the effects of pyridoxine (vitamin B_6). In the review, an analysis of weak RCTs suggested that pyridoxine significantly reduced symptoms compared to placebo. Additional RCTs with weak methods found conflicting evidence on the effects of pyridoxine.
- **Selective serotonin reuptake inhibitors** One systematic review and subsequent RCTs have found that selective serotonin reuptake inhibitors significantly improve premenstrual symptoms, but cause frequent adverse events compared to placebo.
- **Tibolone** One small RCT found limited evidence that tibolone improved premenstrual symptom score compared to placebo (multivitamins).

- **Chiropractic treatment; dietary supplements; endometrial ablation; evening primrose oil; laparoscopic bilateral oophorectomy; reflexology; relaxation treatment** We found insufficient evidence about the effects of these interventions.

DEFINITION A woman has premenstrual syndrome if she complains of recurrent psychological or somatic symptoms (or both) occurring specifically during the luteal phase of the menstrual cycle, and resolving by the end of menstruation (see table 1, p 2526).[1]

INCIDENCE/ PREVALENCE Premenstrual symptoms occur in 95% of all women of reproductive age; severe, debilitating symptoms (premenstrual syndrome) occur in about 5% of those women.[1]

AETIOLOGY/ RISK FACTORS The aetiology is unknown, but hormonal and other (possibly neuroendocrine) factors probably contribute.[2,3] There may be enhanced sensitivity to progesterone, possibly caused by a deficiency of serotonin.[2]

PROGNOSIS Except after oophorectomy, symptoms usually recur when treatment is stopped.

AIMS OF INTERVENTION To improve or eliminate physical and psychological symptoms; to minimise the impact on normal functioning, interpersonal relationships, and quality of life; to minimise adverse effects of treatment.

OUTCOMES **Symptom severity:** There is no consensus on how this should be assessed. One review of premenstrual syndrome outcomes found 65 different questionnaires or scales, measuring 199 different symptoms or signs.[4]

METHODS The initial search strategy was adapted from the Cochrane Collaboration's Menstrual Disorders and Subfertility Group.[5] *Clinical Evidence* search and appraisal October 2002. We included systematic reviews and subsequent RCTs that (1) diagnosed premenstrual syndrome by validated scales prior to randomisation; (2) used a pre-randomisation placebo cycle to exclude women with a non-specific response; (3) contained sufficient cycles to allow for symptom variability between cycles. Few trials fulfilled these criteria. The wide range of diagnostic scales, outcome criteria, and dosing regimens made comparison between trials difficult. We excluded reviews that systematically searched electronic databases but did not use overt criteria to appraise the results.[6]

QUESTION What are the effects of treatments for women with premenstrual syndrome?

OPTION ANXIOLYTICS/NON-SELECTIVE SEROTONIN REUPTAKE INHIBITOR ANTIDEPRESSANTS

RCTs have found that non-selective serotonin reuptake inhibitor antidepressants and anxiolytic drugs versus placebo significantly improve at least one symptom of premenstrual syndrome, but a proportion of women stop treatment because of adverse effects. We found insufficient evidence from small RCTs about effects of β blockers and lithium.

Premenstrual syndrome

Benefits: We found no systematic review. We found 14 RCTs of antidepressant and anxiolytic drugs for premenstrual syndrome. Most (9/14 [64%]) reported significant improvement of one or more symptoms. **Alprazolam:** Five RCTs (150 women) compared alprazolam (0.25–2.25 mg daily) versus placebo.[7–11] The RCT using the lowest dose (0.25–0.75 mg daily) found no significant reduction in premenstrual symptoms, but four RCTs using a higher dose (≥ 0.75 mg daily) found significant reduction of symptoms. **Buspirone:** Two small RCTs (17 women,[12] 41 women[13]) found significant symptom reduction with buspirone (25 mg daily,[12] 10–20 mg daily[13]) versus placebo. **Non-selective serotonin reuptake inhibitors antidepressants:** Four small RCTs of antidepressants versus placebo (81 women) found variable results: two RCTs of clomipramine (25–75 mg daily) versus placebo found significant reduction of premenstrual symptoms, but RCTs of buproprion[14] and desipramine[15] found no significant reduction. We found no meta-analysis; inconsistent results among RCTs may have arisen by chance. **β blockers:** Three RCTs found variable results. Two small RCTs (27 women) found significant symptom improvement with atenolol versus placebo at lower doses (25 mg daily) but no significant difference with higher doses (100 mg daily).[16,17] The third RCT (30 women) found significant reduction of severe premenstrual headaches with propranolol (20–40 mg daily during luteal phase) versus placebo.[18] **Lithium:** One RCT (19 women) found no significant difference in premenstrual symptoms with lithium carbonate (750–1000 mg daily) versus placebo.[19]

Harms: Adverse effects such as drowsiness, nausea, anxiety, and headache led to problems with adherence to treatment in most of the trials.[7,11,20,21] **Alprazolam:** Drowsiness and sedation were found in about 50% of women, as well as lower rates of headache and nausea. **Antidepressants:** Adverse effects were frequent and more women withdrew when taking antidepressants than when taking placebo (11/81 [14%] with antidepressants *v* 6/81 [7%] with placebo).[14,15,20,22] Common adverse effects reported were dry mouth, fatigue, nausea, and dizziness. **Lithium:** Tremor, weakness, and gastrointestinal disturbances resulted in 4/19 (21%) withdrawals from the RCT. **Other interventions:** The other trials did not report specific adverse effects.

Comment: The evidence is limited, but is consistent with at most a small benefit from antidepressants/anxiolytics in premenstrual syndrome, which is countered by frequent adverse effects.

OPTION BROMOCRIPTINE

RCTs have found limited evidence that bromocriptine versus placebo relieves premenstrual breast tenderness, although adverse effects are common.

Benefits: We found no systematic review. One survey of 14 trials found no evidence that bromocriptine versus placebo improved overall symptom scores in premenstrual syndrome, although it found limited evidence of improvement in premenstrual mastalgia.[23]

Harms: Bromocriptine has a high incidence of adverse effects, including nausea, dizziness, headache, weight increase, and swelling.[24–26] The survey did not include any mention of adverse effects, which on analysis of individual trials are well documented.[23] There have been very rare case reports of stroke and death following bromocriptine treatment to prevent lactation.[27]

Comment: None.

OPTION CHIROPRACTIC MANIPULATION

One systematic review found insufficient evidence about the effects of chiropractic treatment in women with premenstrual syndrome.

Benefits: We found one systematic review (search date 2000, 1 RCT, 45 women).[28] The placebo controlled crossover RCT found a significant decrease in premenstrual syndrome scores with chiropractic treatment (3 sessions premenstrually over 3 cycles) versus placebo. Women who received placebo first did not experience significant additional improvement when they were switched to chiropractic treatment.

Harms: None reported.

Comment: The RCT had a high withdrawal rate (25/45 [56%] completed). Women improved most with whatever treatment they had first (real or sham treatment). The evidence is insufficient to define the effects of chiropractic treatment in women with premenstrual syndrome.

OPTION COGNITIVE BEHAVIOURAL THERAPY

RCTs have found significant reduction of premenstrual symptoms with cognitive behavioural therapy versus control treatments, but the evidence is insufficient to define the size of any effect.

Benefits: **Versus control treatments:** We found no systematic review. Seven RCTs compared a treatment with cognitive behavioural content versus some type of control treatment.[29–35] Four of the RCTs (112 women) found significant reduction of symptoms with cognitive behavioural therapy versus a dummy treatment (relaxation, activity through movement, or information focused treatment) or versus a waiting list group. The abstract of the seventh RCT (41 women 19–40 years old) compared cognitive restructuring intervention (self monitoring, educational, and coping skills training phases), support (general discussion on menstrual symptoms), and assessment only (no treatment). Women were followed for 3 months and treatments were offered during the second month during four weekly sessions that lasted 1 hour. It found that after 3 months all women had improved, experiencing fewer and less severe symptoms and taking less medication (figures not provided in the abstract).[35]

Harms: None reported.

Comment: It is difficult to design appropriate control treatments and to maintain blinding of allocation for cognitive behavioural therapies, but studies using both dummy and waiting list controls have found significant benefits. Several trials noted benefits of cognitive behavioural therapy over the medium to long term. Cognitive behavioural therapy may be appropriate only for a motivated subgroup of women.

OPTION DANAZOL

RCTs have found that danazol versus placebo significantly reduces premenstrual symptoms, but has important adverse effects associated with masculinisation when used continuously in the long term.

Benefits: We found no systematic review but found six RCTs.[36–41] **Continuous danazol:** Four RCTs (3 crossover, 144 women with premenstrual syndrome) found significant symptom reduction with danazol given continuously (over 3 cycles) versus placebo.[36–38,40] Many women withdrew before the trial finished (see harms of danazol below). **Luteal phase danazol:** Two RCTs gave danazol in the luteal phase only.[39,41] One RCT found that danazol versus placebo significantly reduced overall symptoms. The other, larger trial found danazol versus placebo significantly reduced premenstrual breast pain only.[39,41]

Harms: **Continuous danazol:** More people withdrew from the studies when given danazol than when given placebo (e.g. in 1 parallel RCT, withdrawals: 12/30 [40%] with danazol *v* 1/10 [10%] with placebo; RR 4.0, 95% CI 0.6 to 27; NNH 3, 95% CI 1 to 9).[37] The initial severity of the premenstrual symptoms was higher among women who withdrew than among women who remained in the RCTs (see comment below). Observational studies have described masculinisation (deepening of the voice, hirsutism) and weight gain with long term use of danazol (see harms of danazol under breast pain, p 2334). Plasma lipid levels can change, leading to concern that the cardiovascular risk may be increased. Osteoporosis seems not to be a risk. **Luteal phase danazol:** The two RCTs did not find a significantly higher rate of short term adverse effects with danazol than with placebo. Long term adverse effects were not assessed.[39,41]

Comment: It seems clear that danazol is capable of reducing premenstrual symptoms (many women who remained in the RCTs had some types of symptom eradicated by danazol, but fewer did with placebo). However, the magnitude of the danazol effect is less certain because some of the mean improvement in symptom scores can be attributed to the withdrawal of women with worse symptoms. The RCTs did not report intention to treat analyses.

OPTION DIETARY SUPPLEMENTS

One systematic review found insufficient evidence on the effects of calcium and magnesium supplements versus placebo in women with premenstrual syndrome.

Benefits: We found one systematic review (search date 2000).[28] **Magnesium supplements:** The systematic review (3 RCTs, 144 women) found unclear results with magnesium supplements versus placebo for premenstrual syndrome symptoms. One RCT found an improvement in overall premenstrual syndrome symptoms, one found no effect, and the third found significant improvement of bloating. The review did not perform a meta-analysis. **Calcium supplements:** The systematic review (2 RCTs, 557 women) found that calcium supplements (1–1.2 g daily for 3 cycles) versus placebo significantly reduced overall symptoms (including breast tenderness and swelling, headaches, and abdominal cramps).[28]

Harms: None reported.

Comment: **Calcium supplements:** Both RCTs were performed by the same research unit. The smaller RCT had a high withdrawal rate and compliance with treatment was poor. The second, larger RCT did not exclude other treatments of premenstrual symptoms during the trial.[28]

OPTION DIURETICS

RCTs have found that spironolactone versus placebo improves symptoms of premenstrual syndrome including breast tenderness and bloating. Two RCTs have found limited evidence that metolazone or ammonium chloride versus placebo reduce premenstrual swelling and weight gain. One RCT found insufficient evidence about the effects of chlorthalidone versus placebo or lithium on premenstrual symptoms.

Benefits: **Spironolactone:** We found no systematic review but found four RCTs (210 women) that compared spironolactone versus placebo.[42–45] Three RCTs found significant reduction of symptoms with spironolactone (100 mg daily) versus placebo, and one RCT[44] found no significant difference. Two RCTs found that significantly more women had improved irritability[45] and overall symptoms, including breast tenderness and bloating[43] with spironolactone than with placebo (14/17 [82%] with spironolactone *v* 9/16 [56%] with placebo; RR 1.46, 95% CI 0.90 to 2.38; NNT 4, 95% CI 2 to 292;[43] and 20/26 [77%] with spironolactone *v* 11/21 [52%] with placebo; RR 1.47, 95% CI 0.93 to 2.32; NNT 4, 95% CI 2 to 85[45]). **Metolazone:** One RCT (crossover design, 46 women with premenstrual swelling or weight gain, 33 completed) found significant reduction of premenstrual symptoms with luteal phase metolazone (1, 2.5, and 5 mg daily) versus placebo.[46] There was no significant difference in effect among doses. **Chlorthalidone:** One RCT (crossover design, 25 women) found that similar numbers of women felt "much better" over eight menstrual cycles on a global rating scale of premenstrual symptoms with chlorthalidone versus placebo or lithium.[47] However, the RCT did not diagnose premenstrual syndrome prior to randomisation, and it may have been too small to detect a clinically important difference in symptoms.

Ammonium chloride: One RCT (22 women with premenstrual weight gain) found significantly more weight loss on days 20–23 with a diuretic on sale to the general public in the USA (ammonium chloride 325 mg plus caffeine 100 mg 6 times daily for days 18–24) versus placebo.[48]

Harms: **Spironolactone:** Adverse effects were reported in only one RCT: two people reported palpitations while on spironolactone. **Metolazone:** Women on metolazone (5 mg) complained of severe adverse effects (excessive diuresis and weakness).[46] Other adverse effects include nausea, dizziness, palpitations, excess diuresis, and weakness.[48]

Comment: Diuretics are widely used in the belief that many symptoms of premenstrual syndrome are the direct consequence of fluid retention; we found little evidence of water retention in most women with premenstrual syndrome.

OPTION ENDOMETRIAL ABLATION

We found no RCTs about the effects of endometrial ablation in premenstrual syndrome.

Benefits: We found no systematic review or RCTs.

Harms: We found insufficient evidence.

Comment: Studies of women with menorrhagia have claimed that endometrial ablation may relieve symptoms of premenstrual syndrome. However, effects in women with premenstrual syndrome alone remain unclear.

OPTION EVENING PRIMROSE OIL

One systematic review of poor quality RCTs found insufficient evidence about the effects of evening primrose oil.

Benefits: We found one systematic review (search date 1993, 7 RCTs, 329 women).[49] Although some trials found a small beneficial effect, the number of women included in the RCTs was low. Weak methods and different outcome measures prevented meta-analysis. The authors concluded that there was insufficient evidence to define the effects of evening primrose oil in women with premenstrual syndrome.

Harms: Few adverse effects have been reported. There are rare reports of evening primrose oil causing seizures in people with epilepsy.[50]

Comment: Only five of the trials in the review clearly indicated that they were randomised. Evening primrose oil is one of the most popular "self help" remedies for premenstrual syndrome.

OPTION EXERCISE

One RCT has found that aerobic exercise versus placebo significantly improves premenstrual symptoms. Another RCT has found that high intensity aerobic exercise improves symptoms significantly more than low intensity exercise.

Benefits: We found no systematic review, but found two abstracts of RCTs.[51,52] The first RCT (32 women with premenstrual syndrome diagnosed prior to randomisation) found significantly improved symptoms with high intensity aerobic exercise versus low intensity exercise.[51] The second RCT (30 women with premenstrual syndrome) found significant reduction of premenstrual symptoms with both low intensity aerobic exercise (40% maximum effort for 45 mins, 3 times weekly, for 3 cycles) versus placebo weekly and with moderate intensity aerobic exercise (70% maximum effort for 45 mins, 3 times weekly, for 3 cycles) versus placebo.[52]

Harms: Harms were not mentioned in the abstracts of the RCTs.[51,52]

Comment: Both reports[51,52] were available to us only as abstracts. Further details may be available in future *Clinical Evidence* updates.

OPTION GONADORELIN (GNRH) ANALOGUES (BUSERELIN, GOSERELIN, LEUPRORELIN)

RCTs have found that gonadorelin analogues (GnRH) significantly reduce premenstrual symptoms compared to placebo. RCTs have found that gonadorelin plus oestrogen plus progestogen (addback treatment) improves symptom scores less than that gonadorelin analogue alone but more than placebo. One small RCT found similar reduction in symptom scores with gonadorelin analogue plus tibolone compared to gonadorelin analogue plus placebo. Treatment with gonadorelin analogues for more than 6 months carries a significant risk of osteoporosis, limiting their usefulness for long term treatment.

Benefits: We found no systematic review. **Gonadorelin analogues versus placebo:** We found 10 RCTs[53–62] of gonadorelin (GnRH) analogues versus placebo. All 10 trials diagnosed premenstrual syndrome before randomisation. Seven of the RCTs used a crossover design. Nine of the RCTs found a significant reduction in premenstrual symptoms with gonadorelin analogues versus placebo (typically, by 3 months symptom scores fell to about 50% of their initial value with a gonadorelin analogue *v* 10% decline with placebo[61]). **Gonadorelin analogues plus oestrogen and progestogen:** Three of the RCTs (78 women) compared gonadorelin analogues plus oestrogen and progestogen (addback treatment) versus placebo or gonadorelin analogue alone.[57,58,61] Two of the RCTs were small (8 women[57] and 10 women[58]). The largest RCT (60 women, 41 completed the 6 month study) found that gonadorelin plus addback treatment produced a fall in symptom scores that was intermediate between that produced by gonadorelin analogue alone and placebo (irritability symptom score at baseline 2 in all groups; change in score after 6 months: –0.37 with placebo *v* –0.64 with gonadorelin analogue plus addback *v* –1.03 with gonadorelin analogue alone; $P < 0.05$).[61] **Gonadorelin analogue plus tibolone versus gonadorelin analogue alone:** We found one RCT (30 women with severe premenstrual syndrome [see glossary, p 2523]), which found no difference in symptom scores after 8 weeks with gonadorelin analogue plus tibolone versus gonadorelin analogue plus placebo (irritability scores: changed from 7.3 to 3.3 with gonadorelin analogue plus tibolone *v* from 8.4 to 4.0 with gonadorelin analogue alone).[63]

Harms: A large proportion of the women in the RCTs experienced adverse effects. Commonly reported adverse effects include hot flushes, night sweats, nausea, decreased libido, pruritus, bronchospasm, and headache.[53,54,56,60,62] In one typical RCT, over 6 months' withdrawals from the RCT were common (7/20 [35%] with placebo *v* 9/21 [43%] with gonadorelin plus addback treatment *v* 3/19 [16%] with gonadorelin analogue alone).[61]

Comment: A truly double blind RCT of gonadorelin analogues would be hard to conduct because women receiving these agents experience amenorrhoea. Treatment with gonadorelin analogues for more than 6 months carries significant risk of osteoporosis, limiting their usefulness for long term treatment.[64]

OPTION HYSTERECTOMY WITH OR WITHOUT OOPHORECTOMY

We found no RCTs. Observational studies have found that hysterectomy plus bilateral oophorectomy is curative. Hysterectomy alone may reduce symptoms, but evidence is limited because of the difficulty in providing controls. The risks are those of major surgery. Infertility is an irreversible consequence of bilateral oophorectomy.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review or RCT, but potential risks include those associated with major surgery.[65]

Comment: Cohort studies have described a reduction in the symptoms of premenstrual syndrome after hysterectomy.[66,67] However, without a control group, it is impossible to know how much of the observed response is attributable to the hysterectomy itself or to a non-specific placebo response that is seen in most RCTs of premenstrual syndrome. Other cohort studies have found almost complete eradication of the symptoms of premenstrual syndrome after hysterectomy plus bilateral oophorectomy.[68,69] Surgery is rarely used but may be indicated if there are coexisting gynaecological problems.

OPTION LAPAROSCOPIC BILATERAL OOPHORECTOMY

We found no RCTs on the effects of laparoscopic bilateral oophorectomy in women with premenstrual syndrome.

Benefits: We found no systematic review or RCTs.

Harms: We found insufficient evidence.

Comment: After oophorectomy, oestrogen replacement treatment and cyclical progesterone (to prevent endometrial hyperplasia and carcinoma) are often used. Progesterone may restimulate premenstrual syndrome.

OPTION LOW DOSE OESTROGENS

Limited evidence from three small RCTs suggests benefit from oestradiol (oestrogen) compared to placebo, but the magnitude of any effect remains unclear.

Benefits: We found no systematic review but found three RCTs (71 women) of oestrogen versus placebo.[70–72] All trials diagnosed premenstrual syndrome before randomisation. The first RCT (11 women) found no significant difference in symptoms with oral conjugated equine oestrogens (0.6 mg from day 15 until menses) versus placebo over three cycles (9 women had worse symptoms with oestrogen *v* 2 women with placebo).[70] The second RCT (crossover, 40 women, 35 completed) compared oestradiol (200 μg transdermal patches changed every 3 days throughout the cycle) versus placebo for three cycles.[71] Oral norethisterone (5 mg daily) was added from day 19–26 for all women. Women were randomly allocated to a sequence of treatment (active for 3 cycles then placebo for 3 cycles, or the reverse). Both groups improved during the first three cycles. After the crossover, significant further improvement was seen with women switching from placebo to active treatment, but the symptoms of women switching from active treatment to placebo deteriorated to the level they were at the start of the RCT. The third RCT (crossover design, 20 women with migraine just before or during menses, 18 completed) found that oestradiol (oestradiol gel 1.5 mg daily to the skin for 7 days over 3 cycles) versus placebo reduced the number of cycles with menstrual migraine (8/26 [31%] of the oestradiol cycles *v* 26/27 [96%] of placebo cycles; RR 0.32, 95% CI 0.18 to 0.57; NNT 1.5, 95% CI 1.1 to 2.0).[72]

Harms: Adverse effects included mastalgia, nausea, weight gain, headache, and change in cycle length. The patch trial also reported skin irritation and skin pigmentation. Similar numbers of women withdrew on active treatment compared with placebo (3/71 [4%] with active treatment *v* 2/71 [3%] with placebo).[71]

Comment: Oestrogens may improve premenstrual symptoms. To avoid endometrial hyperplasia and adenocarcinoma, a 12 day progestogen course is needed every 28 days. Progestogen may induce premenstrual syndrome symptoms in some women. To avoid this systemic effect, progestogen may be given locally (using a levonorgestrel intrauterine device or progesterone gel). We found no RCTs evaluating this approach. We found one report of an ongoing RCT (80 women) comparing cyclical oestradiol and medroxyprogesterone versus placebo in women with premenstrual syndrome and depressive symptoms.[73]

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

RCTs have found benefit from non-steroidal anti-inflammatory drugs compared to placebo for a range of premenstrual symptoms.

Benefits: We found no systematic review. **Mefenamic acid:** We found five RCTs,[74–78] but only three diagnosed premenstrual syndrome prior to randomisation.[74,75,78] One RCT (37 women) found significantly more women preferred mefenamic acid (1.5 g daily in the luteal phase for 1 cycle) than placebo (23/37 [62%] with mefenamic acid *v* 6/37 [16%] with placebo; RR 3.8, 95% CI 1.8 to 8.3; NNT 3, 95% CI 2 to 4).[74] The frequency of irritability was significantly lower with mefenamic acid than with placebo (11/36 [31%] *v* 24/33 [73%]; RR 0.42, 95% CI 0.25 to 0.72; NNT 3, 95% CI 2 to 4).[74] The other

RCT (crossover design, 19 women) found significantly improved physical and mood symptoms with three cycles of mefenamic acid versus placebo.[75] **Naproxen sodium:** Two RCTs diagnosed premenstrual syndrome before randomisation. One RCT (34 women) found significant reduction of pain symptoms with naproxen sodium (550 mg twice daily for days 21–4 in 3 cycles) versus placebo.[79] The other RCT (crossover design, 42 women randomised, 21 completed) found significant reduction of physical symptoms of premenstrual syndrome with naproxen sodium (500 mg twice daily for 6 cycles) versus placebo.[80]

Harms: Adverse effects included nausea, gastrointestinal disturbances, and rashes.[74–76]

Comment: None.

OPTION ORAL CONTRACEPTIVES

Two RCTs found limited evidence that oral contraceptives versus placebo improved premenstrual symptoms.

Benefits: We found no systematic review but found two RCTs,[81,82] which diagnosed premenstrual syndrome prior to randomisation. The first RCT (82 women) found significant reduction with triphasic oral contraceptive for three cycles versus placebo in premenstrual breast pain and bloating. Oral contraceptives were no better than placebo for mood symptoms. The second RCT (82 women with severe premenstrual syndrome (see glossary, p 2523)) found significant reduction in some premenstrual symptoms (appetite, acne, and food cravings) with an experimental oral contraception (ethinyloestradiol 30 μg plus drospirenone 3 mg over 3 cycles) versus placebo.[82] Other symptom scores were improved with oral contraception, but the differences were not significant.[82]

Harms: Spotting, nausea, cramps, breast pain, and decreased libido were more commonly reported on active treatment compared with placebo. More women withdrew because of adverse effects with active treatment than with placebo (13 *v* 1).[81]

Comment: Some women develop premenstrual syndrome-like symptoms for the first time when taking the oral contraceptive pill. Anecdotal evidence suggests that oral contraceptives may be beneficial in premenstrual syndrome.[83–85] Continuous combined regimens (those without a 1 wk break) should, in theory, suppress ovulation and provide symptom relief, but we found no published trials.

OPTION PROGESTERONE

One systematic review of progesterone versus placebo has found a small but significant improvement in overall premenstrual symptoms and no increase in the frequency of withdrawals caused by adverse effects. However, the improvement is unlikely to be clinically important. It remains unclear whether the route or timing of administration of progesterone is important.

Benefits: We found one systematic review (search date 2000, 10 RCTs, 531 women with previously diagnosed premenstrual syndrome).[86] Six of the RCTs were crossover studies. The review found a small improvement in overall premenstrual symptoms for women taking progesterone versus control treatments over 2–6 months (standardised mean differences –0.028, 95% CI –0.017 to –0.040; no heterogeneity of pooled results). Two RCTs (116 completed) used oral progesterone and seven RCTs (296 completed) used progesterone suppositories. One crossover RCT (25 women) compared oral progesterone versus progesterone pessaries versus placebo, and was analysed as if it was two studies. Six of the 10 RCTs administered the progesterone in the luteal phase of the menstrual cycle.

Harms: Some RCTs reported adverse effects such as abdominal pain, nausea, headache, vaginal pruritus, dizziness, drowsiness, excessive bleeding, and dysmenorrhoea.[86] Withdrawal because of adverse effects was not increased significantly by progesterone (OR 1.66, 95% CI 0.43 to 6.79).

Comment: The systematic review[86] did not specify whether results after the crossovers had been included in the analyses. The authors of the systematic review argued that the very small improvement in overall symptoms was statistically significant, but clinically unimportant. The observed change in symptoms was small compared with that produced by selective serotonin reuptake inhibitors (see selective serotonin reuptake inhibitors, p 2521). Subgroup analysis found a small but significant improvement of symptoms with oral progesterone (3 RCTs), and a small but significant deterioration of symptom suppositories or pessaries (8 RCTs). Oral micronised progesterone is not available in many countries.[86] The systematic review tabulated the adverse effects reported with progesterone and placebo, but did not specify how many women were in the five RCTs that reported harms.

OPTION PROGESTOGENS (SYNTHETIC PROGESTERONE-LIKE DRUGS)

We found insufficient evidence about the effects of progestogens versus placebo.

Benefits: We found one systematic review (search date 2000, 3 RCTs, 319 women) of progestogens versus placebo.[86] Two RCTs were crossover studies. One RCT compared medroxyprogesterone versus norethisterone versus placebo and was analysed as if it were two RCTs. The systematic review found a small but significant reduction of premenstrual symptoms with progestogens versus placebo (standardised mean differences –0.036, 95% CI –0.059 to –0.014). However, results may not be reliable (see comments below).

Harms: None of the RCTs reported a detailed analysis of adverse effects.[86] The systematic review found no significant difference with progestogens versus placebo in withdrawals from the RCTs because of adverse events (OR 1.65, 95% CI 0.86 to 3.21).[7] The most common adverse effects associated with progestogens are nausea, breast discomfort, headache, and menstrual irregularity.

Comment: The systematic review[86] did not specify how the results of the crossover studies were analysed (in particular, whether results after the crossover were included). The review stated that it found no heterogeneity of the results from the four RCTs, but published a figure that appears to show disagreement among the studies (3 significantly favouring progestogen and 1 significantly favouring placebo).

OPTION PYRIDOXINE (VITAMIN B_6)

A systematic review of poor quality RCTs found that the evidence was insufficient to define the effects of pyridoxine versus placebo in women with premenstrual syndrome. In the review, an analysis of nine weak RCTs suggested a significant reduction of symptoms with pyridoxine versus placebo. Three additional RCTs with weak methods found conflicting evidence of the benefits of pyridoxine.

Benefits: We found one systematic review[87] and three additional RCTs.[18,88,89] The systematic review (search date 1998, 9 RCTs, 940 women with premenstrual syndrome) found no high quality RCTs comparing pyridoxine (either as a single supplement or as part of a multivitamin supplement) with placebo.[88] The pooled odds ratio for relief of overall premenstrual syndrome symptoms was 2.32 (95% CI 1.95 to 2.54) with pyridoxine (over 2–4 months) versus placebo. There was no dose related response. One additional RCT compared pyridoxine with *Vitex agnus castus*. It found that both treatments improved symptoms.[89] Another RCT with weak methods found no improvement over placebo,[18] whereas the third additional RCT found a significant improvement.[90]

Harms: High doses of pyridoxine (> 200 mg daily) have been associated with a reversible peripheral neuropathy.[88] The review found few reports of adverse events in the RCTs.

Comment: One of the RCTs is being translated.[90] Further details will be added in future *Clinical Evidence* updates.

OPTION REFLEXOLOGY

One systematic review of one RCT found insufficient evidence about the effects of reflexology versus sham reflexology in premenstrual syndrome.

Benefits: We found one systematic review (search date 2000, 1 RCT, 50 women).[28] The RCT found significant reduction of premenopausal symptoms with reflexology (1 weekly session over 2 cycles) versus sham reflexology.

Harms: None mentioned.

Comment: Only 35 women completed the RCT. Reflexology involved manual pressure to specific reflex areas of the body, but the sham treatment comprised uneven tactile stimulation of alternative areas (shoulder, elbow, or nose). The allocated intervention was not concealed to those assessing the outcomes or to participants. The evidence is insufficient to define the effects of reflexology in women with premenstrual syndrome.

OPTION RELAXATION TREATMENT

RCTs found insufficient evidence on the effects of relaxation treatment in premenstrual syndrome.

Benefits: We found one systematic review (search date 2000, 2 RCTs, 101 women).[28] The first RCT found significant reduction of physical symptoms with muscular relaxation treatment versus reading leisure material or charting symptoms. The second RCT compared muscle relaxation versus massage, but did not compare the reduction in symptoms produced by each treatment. Both groups improved compared with baseline symptoms.

Harms: None mentioned.

Comment: Most studies of relaxation techniques have used them as an adjunct to other treatment. The evidence is insufficient to define the effects of relaxation in women with premenstrual syndrome.

OPTION SELECTIVE SEROTONIN REUPTAKE INHIBITORS

One systematic review and subsequent RCTs have found that selective serotonin reuptake inhibitors significantly improve premenstrual symptoms, but cause frequent adverse events compared to placebo.

Benefits: We found one systematic review,[91] one additional report of an RCT in the review,[92] and two subsequent RCTs.[93,94] The systematic review (search date not stated, 15 RCTs, 904 women with premenstrual syndrome) found significant improvement in overall symptoms with selective serotonin reuptake inhibitors (SSRIs) versus placebo (WMD –1.07, 95% CI –1.38 to –0.75).[91] There was no significant difference in symptom improvement between continuous and intermittent dosing. The review did not report absolute proportions of women who had improved symptoms with SSRIs. A large RCT that was included in the review subsequently reported the proportion of women who had improved physical symptoms (observer rated scale of physical symptoms, including breast tenderness, bloating, headache, joint and muscle pain).[92] The first RCT (320 women with severe premenstrual syndrome [see glossary, p 2523] diagnosed before randomisation) found significant reduction of physical premenstrual symptoms with fluoxetine for six cycles versus placebo (substantial reduction of physical premenstrual symptoms: 11/95 [12%] with fluoxetine 20 mg *v* 13/85 [15%] with fluoxetine 60 mg *v* 4/94 [4%] with placebo; ARR fluoxetine *v* placebo 9.1%, 95% CI 1.5% to 16.7%; NNT 11 women treated for 6 cycles for 1 woman to have a substantial reduction in symptoms). No difference in physical premenstrual symptoms was found between the two doses of fluoxetine (20 mg *v* 60 mg daily; OR 0.73, 95% CI 0.31 to 1.71). The subsequent RCT (164 women with severe premenstrual syndrome diagnosed before randomisation) found significant improvement of overall premenstrual symptoms with venlafaxine (50–200 mg daily for 4 cycles) versus placebo (≥ 50% reduction in daily total symptom score: 41/68 [60%] with venlafaxine *v* 26/75 [35%] with placebo; ARR 25%, 95% CI 9% to 42%; NNT 4).[93] The second RCT (multicentre, 260 women with severe premenstrual syndrome and regular menstrual cycles who

were not using hormonal contraception, in 20 different cities of the US, diagnosed prior to randomisation) compared fluoxetine (10 mg daily) and fluoxetine (20 mg) versus placebo. Treatments were started 14 days before the expected date of menses and stopped the first day of bleeding. It found that 20 mg of fluoxetine versus placebo produced significant improvement of overall premenstrual symptoms (breast tenderness, bloating, headache and joint/muscle pain as assessed with the Daily Record of Severity Problems total luteal scores). No detailed figures were provided for comparisons between groups. The RCT found an improvement in symptoms with a dose of 10 mg of fluoxetine.[94]

Harms: Common adverse effects were nausea, drowsiness/fatigue, nervousness, insomnia, headache, and sexual dysfunction (see table 2, p 2526).[91] The frequency of adverse events is similar to that seen with SSRIs in other populations.[92] The systematic review found that withdrawal because of adverse effects was more likely with SSRIs than with placebo (OR 2.4, 95% CI 1.6 to 3.7).[91] Adverse effects were more likely with the higher dose of fluoxetine.[92] The second RCT found no significant differences between groups in adverse effects such as dyspepsia, dysphagia, metrorrhagia, agitation, headache, insomnia, and nausea. However, decreased libido was more frequent reported with fluoxetine (placebo: 0%; 10 mg: 5.8%; 20 mg: 9.3%; $P = 0.007$). In contrast, accidental injury (definition not specified) happened more frequently with placebo (6.8% with placebo; 0% with fluoxetine 10 mg; 1.2% with fluoxetine 20 mg; $P = 0.019$).[94]

Comment: SSRIs used in the RCTs were fluoxetine (7 RCTs), sertraline (5 RCTs), citalopram (1 RCT), fluvoxamine (1 RCT), and paroxetine (1 RCT).[91] Venlafaxine is described as an inhibitor of serotonin and norepinephrine (noradrenaline) uptake. The systematic review found significant heterogeneity of the results ($P < 0.0001$), but the results were robust and did not depend on the type of meta-analysis (fixed effects or random effects). Many of the harms attributed to treatment were frequent, and some (nervousness, headache, insomnia) were similar to the typical symptoms of premenstrual syndrome. However, the net effect of SSRI antidepressants versus placebo was a significant reduction of total symptom scores.[91,93] The second RCT[94] screened 1276 women and randomised 260. Reasons for exclusion included placebo response, physician decision, consent withdrawal, non-compliance to collect data in a digital diary. Of the randomised women, 218/260 (84%) finished the study.[94]

OPTION TIBOLONE

One small RCT found limited evidence of benefit from tibolone versus multivitamins.

Benefits: We found no systematic review but found one small RCT (18 women).[88] It found that tibolone for 3 months versus multivitamins (placebo) significantly improved premenstrual symptom scores (mean improvement in symptom score: –55% with tibolone *v* –10% with placebo; $P < 0.05$).

Harms: No adverse effects were reported.

Comment: The RCT was too small to offer reliable conclusions.

GLOSSARY

Severe premenstrual syndrome The definition of severe premenstrual syndrome varies among RCTs, but in recent studies[92,93] standardised criteria have been used to diagnose one variant of severe premenstrual syndrome (termed the Premenstrual Dysphoric Disorder), based on at least five symptoms, including one of four core psychological symptoms (from a list of 17 physical and psychological symptoms), being severe premenstrually and mild or absent postmenstrually. The 17 symptoms are depression, feeling hopeless or guilty, anxiety/tension, mood swings, irritability/persistent anger, decreased interest, poor concentration, fatigue, food craving or increased appetite, sleep disturbance, feeling out of control or overwhelmed, poor coordination, headache, aches, swelling/bloating/weight gain, cramps, and breast tenderness.

TABLE 1 **Commonly reported symptoms in women with premenstrual syndrome (see text, p 2509).[2]**

Psychological symptoms	Irritability, depression, crying/tearfulness, anxiety, tension, mood swings, lack of concentration, confusion, forgetfulness, unsociableness, restlessness, temper outbursts/anger, sadness/blues, loneliness
Behavioural symptoms	Fatigue, dizziness, sleep/insomnia, decreased efficiency, accident prone, sexual interest changes, increased energy, tiredness
Physical symptoms: pain	Headache/migraine, breast tenderness/soreness/pain/swelling (collectively known as premenstrual mastalgia), back pain, abdominal cramps, general pain
Physical symptoms: bloatedness and swelling	Weight gain, abdominal bloating or swelling, oedema of arms and legs, water retention
Appetite symptoms	Increased appetite, food cravings, nausea

TABLE 2 **Frequency of adverse events with selective serotonin reuptake inhibitors versus placebo in women with premenstrual syndrome (see text, p 2522).[91–93]**

Symptom	Systematic review[91]	RCT[93]
Nausea	66/323 (20%) *v* 13/222 (6%) NNH = 7	34/77 (45%) *v* 10/80 (13%) NNH = 3
Insomnia	56/323 (17%) *v* 17/222 (8%) NNH = 11	26/77 (34%) *v* 13/80 (16%) NNH = 6
Dizziness	32/323 (10%) *v* 46/222 (21%) NNT = 9	25/77 (32%) *v* 4/80 (4%) NNH = 4
Fatigue	46/323 (14%) *v* 24/222 (11%) NS	18/77 (23%) *v* 13/80 (16%) NS
Headache	24/323 (7%) *v* 16/222 (7%) NS	16/77 (21%) *v* 23/80 (29%) NS
Dry mouth	41/323 (13%) *v* 13/222 (6%) NNH = 15	13/77 (17%) *v* 6/80 (8%) NS

Pyelonephritis in non-pregnant women

Search date July 2003

Adriana Wechsler

QUESTIONS

INTERVENTIONS

*Categorisation is not based on placebo controlled RCTs. Such studies are likely to be considered unethical.

Key Messages

- **Intravenous antibiotics in women admitted to hospital with uncomplicated infection** We found no RCTs comparing intravenous antibiotics versus no antibiotics. Consensus holds that intravenous antibiotics are effective, and it is unlikely that a placebo controlled RCT would now be performed. One RCT found no significant difference between intravenous ampicillin plus intravenous gentamicin and intravenous co-trimoxazole plus intravenous gentamicin for relief of symptoms and recurrence of bacteriuria at 28 days. We found insufficient evidence to compare clinical effects of different intravenous regimens.
- **Oral antibiotics for women with uncomplicated infection** We found no RCTs comparing oral antibiotics with no antibiotics. However, consensus holds that these drugs are effective, and it is unlikely that such an RCT would now be performed. One systematic review and one subsequent RCT in women with uncomplicated pyelonephritis (none of whom were admitted to hospital) have found no consistent differences between co-amoxiclav, or quinolones (ciprofloxacin, norfloxacin, levofloxacin, or lomefloxacin) in bacteriological or clinical cure rates. However, observational data suggest that broader spectrum antibiotics, such as quinolones, are more effective than narrow spectrum antibiotics such as amoxicillin and trimethoprim–sulphamethoxazole in areas with high prevalence of resistance to these drugs.
- **Relative effectiveness of different oral and antibiotic regimens, inpatient versus outpatient management, intravenous versus oral antibiotics** We found no RCTs in women with acute uncomplicated pyelonephritis.

Pyelonephritis in non-pregnant women

DEFINITION Acute pyelonephritis, or upper urinary tract infection, is an infection of the kidney characterised by pain when passing urine, fever, flank pain, nausea, and vomiting. White blood cells are almost always present in the urine and occasionally white blood cell casts are also seen on urine microscopy. There is no real consensus on the definitions for grades of severity. However, people with acute pyelonephritis may be divided into those able to take oral antibiotics and without signs of sepsis, who may be managed at home, and those requiring intravenous antibiotics in hospital. There is little difference in the application of treatments between men and non-pregnant women.

INCIDENCE/ PREVALENCE In the USA, there are 250 000 cases of acute pyelonephritis a year.[1] Worldwide prevalence and incidence are unknown.

AETIOLOGY/ RISK FACTORS Pyelonephritis is most commonly caused when bacteria in the bladder ascend the ureters and invade the kidneys. In some cases, this may result in bacteria entering and multiplying in the bloodstream. People with structural or functional urinary tract abnormalities are more prone to pyelonephritis that is refractory to oral therapy or complicated by bacteraemia. Repeated urinary tract infections also predispose them to drug resistant organisms.

PROGNOSIS Complications include urosepsis, renal impairment, and renal abscess. Conditions such as underlying renal disease, diabetes mellitus, and immunosuppression may worsen prognosis, but we found no good long term evidence about rates of sepsis or death among people with such conditions.

AIMS OF INTERVENTION To reduce the duration and severity of symptoms; to prevent or minimise potential complications, with minimum adverse effects.

OUTCOMES Urine culture after treatment; signs and symptoms of infection; rates of complications of infection; and adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal July 2003. We excluded studies that were primarily in men, pregnant women, and people with complicated pyelonephritis, or prone to pyelonephritis because of indwelling catheters, or anatomical or functional bladder abnormalities. Most studies examined both men and women and we have stated how many women were included when available.

QUESTION What are the effects of treatments for acute pyelonephritis?

OPTION ORAL ANTIBIOTICS FOR WOMEN WITH UNCOMPLICATED INFECTION

We found no RCTs comparing oral antibiotics with no antibiotics. However, consensus holds that these drugs are effective, and it is unlikely that such an RCT would now be performed. One systematic review and one subsequent RCT in women with uncomplicated pyelonephritis (some of whom were admitted to hospital) have found no consistent differences between co-amoxiclav, or a quinolone (ciprofloxacin, norfloxacin, levofloxacin, or lomefloxacin) in bacteriological or clinical cure rates.

However, observational data suggest that broader spectrum antibiotics, such as quinolones, are more effective than narrow spectrum antibiotics such as amoxicillin and trimethoprim–sulphamethoxazole in areas with high prevalence of resistance to these drugs.

Benefits: **Versus placebo:** We found no systematic review or RCTs. **Oral antibiotics versus each other:** We found one systematic review (search date 1991, 9 RCTs, 470 men and non-pregnant women) (see table 1, p 2533),[2] and one subsequent RCT[3] comparing different oral antibiotics in acute pyelonephritis. Five RCTs identified by the review were conducted in people outside hospital and four in people admitted to hospital. The studies were conducted in the USA, Europe, and Peru. All RCTs included in the review included more women than men. Most excluded people with complicating factors such as structural abnormalities of the urinary tract, additional diseases, pregnancy, or signs of possible sepsis. All but one of the RCTs in the review found no significant difference between different antibiotics in rates of early cure (negative urine culture within 7–10 days), and six of the RCTs found no significant difference in rates of late cure (negative urine culture 2–4 weeks or more after stopping treatment). However, several of the included RCTs were too small to rule out a clinically important difference between antibiotic regimens. The subsequent RCT (186 people with acute uncomplicated pyelonephritis treated at home) compared oral levofloxacin (250 mg/day for 10 days) versus either oral ciprofloxacin (500 mg twice daily for 10 days) or oral lomefloxacin (400 mg/day for 14 days) and found similar clinical cure rates for all three antibiotics (92% with levofloxacin *v* 88% with ciprofloxacin *v* 80% with lomefloxacin; significance not reported).[3] **Oral versus intravenous antibiotics:** We found no RCTs in women with uncomplicated pyelonephritis.

Harms: The subsequent RCT reported adverse effects in 3/124 (2%) people taking levofloxacin, 6/80 (8%) people taking ciprofloxacin, and 3/55 (5%) people taking lomefloxacin.[3] Gastrointestinal symptoms were common with both ciprofloxacin and levofloxacin, whereas rash was the most common adverse effect with lomefloxacin. One of the 186 people discontinued treatment (lomefloxacin) because of adverse effects.[3]

Comment: The lack of placebo-controlled RCTs may reflect the fact that experimental trials would be considered unethical. **Cure rates:** Calculated cure rates from the systematic review comparing the oral antibiotic regimens are likely to overestimate rates that would be achieved in clinical practice, because many people were excluded from the studies, including those who experienced adverse effects, had growth of resistant bacteria on initial culture, or did not adhere to treatment.[2] **Antibiotic resistance:** Consensus does not recommend ampicillin or amoxicillin (amoxycillin), because of concerns about increasing bacterial resistance. One UK multicentre study (108 people; 87 women) found that *Escherichia coli* was the most prevalent organism (68.5%), followed by *Klebsiella pneumoniae* (6.5%) and *Enterococcus faecalis* (6.5%).[4] It found a high rate of ampicillin resistance (40%). *E coli*, the most common pathogen in pyelonephritis, had low susceptibility to tetracycline, sulphamethoxazole, and trimethoprim, although it had 95% susceptibility to

ciprofloxacin and nitrofurantoin.[4] *K pneumoniae*, however, was highly resistant to nitrofurantoin. Susceptibility patterns were not separated out by type of urinary tract infection, making it hard to interpret these results specifically for pyelonephritis. Recent recommendations by the Infectious Disease Society of America and the European Society of Clinical Microbiology and Infectious Disease warn against the empiric use of trimethoprim–sulfamethoxazole in geographical areas where resistance reaches 10–20%.[5] These recommendations are based on two studies, which found that women with acute pyelonephritis caused by organisms that were resistant to trimethoprim–sulphamethoxazole had significantly lower clinical cure rates with trimethoprim–sulphamethoxazole compared with women in whom the causative organism was not resistant (88–92% clinical cure with non-resistant organisms *v* 35–54%, cure with resistant organisms; $P < 0.01$).[6,7]

OPTION INTRAVENOUS ANTIBIOTICS (AMPICILLIN, CO-TRIMOXAZOLE) IN WOMEN ADMITTED TO HOSPITAL WITH UNCOMPLICATED INFECTION

We found no RCTs comparing intravenous antibiotics versus no antibiotics. Consensus holds that intravenous antibiotics are effective, and it is unlikely that a placebo controlled RCT would now be performed. We found insufficient evidence to compare clinical effects of different intravenous regimens. One RCT found no significant difference between intravenous ampicillin and intravenous co-trimoxazole, both combined with intravenous gentamicin, in terms of relief of symptoms and recurrence of bacteriuria at 28 days.

Benefits:

Versus placebo: We found no systematic review and no RCTs. **Intravenous antibiotics versus each other:** We found no systematic review. We found one RCT (85 women admitted to hospital for acute uncomplicated pyelonephritis; see comment below), which compared intravenous ampicillin (1 g every 6 hours) versus intravenous co-trimoxazole (160 mg/800 mg twice daily), initiated before culture results were known.[8] Both regimens were combined with intravenous gentamicin and followed by oral treatment with either ampicillin or co-trimoxazole. The RCT found that symptoms of infection resolved in all women who completed the trial, but found no significant difference between ampicillin and co-trimoxazole in the recurrence of bacteria in the urine after 28 days (1/20 [5%] with ampicillin *v* 2/27 [7%] with co-trimoxazole; RR 0.70, 95% CI 0.07 to 6.94). We found no other reliable RCTs comparing treatments that included intravenous quinolones, cephalosporins, broad spectrum β lactams, or co-trimoxazole. **Intravenous plus oral antibiotics versus oral antibiotics alone:** We found one RCT (118 women admitted with acute uncomplicated pyelonephritis), which compared a single dose of intravenous tobramycin (2 mg/kg) plus oral ciprofloxacin (500 mg twice daily for 10 days) versus oral ciprofloxacin plus intravenous placebo (0.9% saline solution).[9] Clinical success or failure was assessed, with failure defined as the persistence of fever or pain after 48 hours of treatment and success, the absence of these. The RCT found no significant difference

in rates of clinical success (58/60 [97%] with intravenous tobramycin plus oral ciprofloxacin *v* 54/58 [93%] with oral ciprofloxacin plus placebo; RR 1.04, 95% CI 0.95 to 1.13). **Intravenous versus oral antibiotics:** We found no RCTs in women with uncomplicated pyelonephritis.

Harms: **Intravenous antibiotics versus each other:** The RCT comparing intravenous regimens found no significant difference between treatment adverse effects (10/32 [32%] with ampicillin *v* 13/39 [33%] with co-trimoxazole; RR 0.90, 95% CI 0.48 to 1.85).[9] Common adverse effects with ampicillin include rash, diarrhoea, and vaginitis, and with co-trimoxazole include nausea, vomiting, and vaginitis. **Intravenous plus oral antibiotics versus oral antibiotics alone:** The RCT comparing intravenous tobramycin plus ciprofloxacin versus ciprofloxacin plus placebo reported that "no undesirable side effects were observed".[9] No further details were reported.

Comment: RCTs comparing antibiotics versus placebo would be considered unethical in women with uncomplicated pyelonephritis. The RCT comparing intravenous regimens reported that 47/85 (55%) women completed the trial to the 28 days' follow up assessment; 14/42 (33%) women receiving ampicillin were infected with ampicillin resistant isolates and were withdrawn from the study.[8] There is a consensus view that the choice of empirical antibiotics should take into account the setting, medical history of the patient, Gram stain of the urine, previous infecting organism, and local antibiotic sensitivities. We found two RCTs (258 adults with complicated urinary tract infection or either uncomplicated or complicated pyelonephritis, 58% women and 592 adults, 70% women) comparing intravenous ertapenem with intravenous ceftriaxone.[10,11] Neither RCT found any significant difference between treatments in microbiologic and clinical cure rates, though the first RCT was limited by inclusion of only three quarters of the participants in the final analysis.[11]

OPTION INPATIENT VERSUS OUTPATIENT MANAGEMENT

We found no RCTs comparing inpatient with outpatient management of women with acute uncomplicated pyelonephritis.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: Hospitals might be able to provide closer monitoring and supervision of people with pyelonephritis than can be provided outside hospital. However, we found no RCTs to clarify whether treatment in hospital delivers any benefit in terms of outcomes or whether there is an increased risk of harm from hospital treatment.

Recurrent cystitis in non-pregnant women

Search date April 2003

Adriana Wechsler

QUESTIONS

INTERVENTIONS

Key Messages

- **Continuous antibiotic prophylaxis (trimethoprim, co-trimoxazole, nitrofurantoin, cefaclor, or a quinolone)** RCTs have found that continuous antibiotic prophylaxis for 6–12 months with trimethoprim, co-trimoxazole, nitrofurantoin, cefaclor, or a quinolone reduces rates of recurrent cystitis compared with placebo, and have found no consistent difference in recurrence rates among different continuous regimens. One RCT comparing continuous daily antibiotic prophylaxis versus postcoital antibiotic prophylaxis found no significant difference in rates of positive urine culture after 1 year.
- **Postcoital antibiotic prophylaxis (co-trimoxazole, nitrofurantoin, or a quinolone)** RCTs have found that co-trimoxazole, nitrofurantoin, or a quinolone up to 2 hours after sexual intercourse reduces the rates of cystitis compared with placebo. One RCT comparing continuous daily antibiotic prophylaxis versus postcoital antibiotic prophylaxis found no significant difference in rates of positive urine culture after 1 year.
- **Cranberry juice and cranberry products** One systematic review of two weak RCTs provided insufficient evidence to assess cranberry juice and other cranberry products in women with recurrent cystitis.
- **Prophylaxis with methenamine hippurate** One systematic review of weak RCTs provided insufficient evidence to assess methenamine hippurate (hexamine hippurate) in women with recurrent cystitis.
- **Single dose self administered co-trimoxazole** One small RCT that single dose, self administered co-trimoxazole started at the onset of cystitis symptoms was less effective in reducing recurrence rates over 1 year than continuous co-trimoxazole prophylaxis. However, evidence was too limited to draw firm conclusions.

DEFINITION Cystitis is an infection of the lower urinary tract, which causes pain when passing urine, and causes frequency, urgency, haematuria, or suprapubic pain not associated with passing urine. White blood cells and bacteria are almost always present in the urine. The presence of fever, flank pain, nausea, or vomiting suggests pyelonephritis (upper urinary tract infection) (see pyelonephritis in non-pregnant women, p 2527). Recurrent cystitis may be either a reinfection (after successful eradication of infection) or a relapse after inadequate treatment.

INCIDENCE/ PREVALENCE The incidence of cystitis among premenopausal sexually active women is 0.5–0.7 infections per person year,[1] and 20–40% of women will experience cystitis during their lifetime. Of those, 20% will develop recurrence, almost always (90% of cases) because of reinfection rather than relapse. Rates of infection fall during the winter months.[2]

AETIOLOGY/ RISK FACTORS Cystitis is caused by uropathogenic bacteria in the faecal flora that colonise the vaginal and periurethral openings, and ascend the urethra into the bladder. Prior infection, sexual intercourse, and exposure to vaginal spermicide are risk factors for developing cystitis.[3,4]

PROGNOSIS We found little evidence on the long term effects of untreated cystitis. One study found that progression to pyelonephritis was infrequent, and that most cases of cystitis regressed spontaneously, although symptoms sometimes persisted for several months.[5] Women with a baseline rate of more than two infections a year, over many years, are likely to have ongoing recurrent infections.[6]

AIMS OF INTERVENTION To prevent recurrent cystitis in women predisposed to frequent infections, with minimal adverse effects of treatment.

OUTCOMES Rate of infection based on symptoms and urine culture.

METHODS *Clinical Evidence* search and appraisal January 1998 to April 2003. We reviewed all systematic reviews and RCTs comparing different forms of prophylaxis, or comparing prophylaxis versus placebo in non-pregnant women with a history of recurrent cystitis. We excluded studies in populations consisting mainly of men or pregnant women.

QUESTION **Which interventions prevent further recurrence of cystitis in women experiencing at least two infections per year?**

OPTION **CONTINUOUS ANTIBIOTIC PROPHYLAXIS (TRIMETHOPRIM, CO-TRIMOXAZOLE, NITROFURANTOIN, CEFACLOR, OR A QUINOLONE)**

RCTs have found that continuous antibiotic prophylaxis for 6–12 months with trimethoprim, co-trimoxazole, nitrofurantoin, cefaclor, or a quinolone reduces rates of recurrent cystitis compared with placebo, and have

Recurrent cystitis in non-pregnant women

found no consistent difference in recurrence rates among different continuous regimens. One RCT comparing postcoital versus continuous daily antibiotic prophylaxis found no significant difference in rates of positive urine culture after 1 year.

Benefits: We found no systematic review. We found eight RCTs (in women with at least 2 episodes of cystitis per year) comparing different regimens for continuous antibiotic prophylaxis lasting 6–12 months (see table 1, p 2541).[7–14] **Versus placebo or no treatment:** Four of the RCTs (225 women) found that active treatment (co-trimoxazole, nitrofurantoin, or a quinolone) significantly reduced rates of cystitis compared with placebo or no treatment.[7–9] **Versus each other:** One RCT (72 women) found that women taking oral nitrofurantoin (100 mg at night) compared with oral trimethoprim (100 mg at night) had significantly fewer episodes of cystitis after 12 months ($P < 0.05$; absolute numbers not reported).[10] Four other RCTs compared different antibiotic regimens versus each other and found no significant difference in numbers of infections among treatments over 6–12 months.[7,11–13] **Versus postcoital prophylaxis:** One RCT (135 women) compared daily oral ciprofloxacin (125 mg) versus postcoital (within 2 hours of sexual intercourse) oral ciprofloxacin (125 mg) (see benefits of postcoital prophylaxis, p 2537). It found no significant difference in the number of positive urine cultures after 1 year (27/239 [11%] positive urine cultures with daily prophylaxis *v* 32/254 [13%] with postcoital prophylaxis; RR 0.9, 95% CI 0.55 to 1.45).[8]

Harms: Rates of adverse effects in the RCTs ranged from 7–40% for trimethoprim, 0–40% for nitrofurantoin, 5% for cefaclor, 7–21% for norfloxacin, and 13% for ciprofloxacin.[7–9,11–13] The most common adverse effects for all agents were gastrointestinal symptoms, rash, and yeast vaginitis. One cohort study (see comment below) reported no significant adverse effects in women taking trimethoprim, co-trimoxazole, or nitrofurantoin, even when treatment continued for as long as 5 years. The development of bacterial resistance from continuous antibiotic prophylaxis was rare. However, the number of co-trimoxazole resistant infections increased during the latter part of the study.[2]

Comment: Many of the RCTs were not placebo controlled or blinded, and had small study populations. However, most of the reported rates of infection in the RCTs comparing different antibiotic regimens versus each other were much less than 0.6 per person year, suggesting that they were all effective in reducing the rate of infection in people with a history of recurrent cystitis.[7,10–13] These studies were not powered to exclude a clinically important difference between treatments, and adjustments were not made for confounding factors such as frequency of sexual intercourse. We found one cohort study (51 non-pregnant women with a baseline rate of more than 2 urinary tract infections a year over many years), which compared continuous treatment with three different antibiotics (trimethoprim, co-trimoxazole, or nitrofurantoin) for more than 12 months.[2] It found that all were effective in preventing both cystitis and pyelonephritis for over 112 person years.

OPTION POSTCOITAL ANTIBIOTIC PROPHYLAXIS

RCTs have found that co-trimoxazole, nitrofurantoin, or a quinolone up to 2 hours after sexual intercourse reduces the rates of cystitis compared with placebo. One RCT comparing postcoital versus continuous daily antibiotic prophylaxis found no significant difference in rates of cystitis after 1 year.

Benefits: We found no systematic review. **Versus placebo or no treatment:** We found four RCTs (in women with at least 2 episodes of cystitis per year) comparing postcoital (within 2 hours of sexual intercourse) antibiotic regimens versus placebo or no treatment evaluated over 6–14 months.[8,15–17] All four RCTs found that active treatment (co-trimoxazole, nitrofurantoin, or a quinolone) significantly reduced rates of cystitis (see table 2, p 2542). **Versus continuous daily prophylaxis:** See benefits of continuous antibiotic prophylaxis, p 2536.

Harms: Rates of adverse effects were as follows: co-trimoxazole 18%, ciprofloxacin 6%, and nitrofurantoin less than 1%.[8,15–17] The most common adverse effects for all agents were gastrointestinal symptoms, rash, and yeast vaginitis.

Comment: Only one of the studies was placebo controlled and blinded.[15] Adjustments were not made for confounding factors such as frequency of sexual intercourse.

OPTION SINGLE DOSE SELF ADMINISTERED CO-TRIMOXAZOLE

One small RCT found that single dose, self administered co-trimoxazole started at the onset of cystitis symptoms was less effective in reducing recurrence rates over 1 year than continuous co-trimoxazole prophylaxis. However, evidence was too limited to draw firm conclusions.

Benefits: We found no systematic review but found one RCT (38 non-pregnant women with 2 or more culture documented urinary tract infections in the previous 12 months; see comment below).[18] The RCT compared continuous oral co-trimoxazole prophylaxis (40 mg/200 mg) versus single dose, self administered co-trimoxazole (40 mg/200 mg) to be taken at the onset of cystitis symptoms. It found that single dose co-trimoxazole was significantly less effective in reducing the number of episodes of cystitis compared with continuous co-trimaxazole (2.2 infections per person year with treatment at onset of symptoms *v* 0.22 infections per person year with continuous prophylaxis; $P < 0.001$; see comment below).

Harms: The RCT reported a total of eight adverse reactions; five in women taking continuous antibiotic prophylaxis compared with three in women taking single dose treatment (CI not reported).[18] Adverse reactions included mild nausea, abdominal pain, rash, mouth ulcers, and yeast vulvovaginitis.

Comment: The RCT reported that 10/38 (26%) women did not complete the full study protocol, and it is not clear whether analysis of results was by intention to treat.[18] It found that the women were almost always able to diagnose their own episodes of cystitis from symptoms (positive predictive value 92%). The higher rate of cystitis in women using single dose prophylaxis is to be expected because treatment was only administered after the onset of symptoms.

OPTION CRANBERRY JUICE AND CRANBERRY PRODUCTS

One systematic review of two weak RCTs provided insufficient evidence to assess cranberry juice and other cranberry products in women with recurrent cystitis.

Benefits: We found one systematic review (search date 2001, 2 RCTs, 211 women) comparing cranberry juice or other cranberry products versus placebo in the prevention of urinary tract infections (see comment below).[19] The first RCT (19 women with recurrent cystitis) included in the review compared cranberry capsules versus placebo (see comment below). The review reported 21 infections among 10 women who completed the study; six of these infections occurred in women taking cranberry capsules (the number of infections/women in the different groups was not reported; significance testing not possible). The second RCT (192 elderly women) compared cranberry juice versus placebo and found that cranberry juice significantly reduced the rate of infection (defined as ≥100 000 organisms/mL of urine plus white blood cells in the urine; OR 0.42, P = 0.004; see comment below).

Harms: The review gave no information on adverse effects.[19]

Comment: The RCTs identified by the review were small, with high withdrawal rates (47% in the first RCT and 20% in the second RCT), and the lack of intention to treat analyses in either trial may mean that they overestimated the effectiveness of cranberry juice and products.[19] High withdrawal rates suggest that long term adherence may be difficult to achieve.

OPTION PROPHYLAXIS WITH METHENAMINE HIPPURATE

One systematic review of weak RCTs provided insufficient evidence to assess methenamine hippurate (hexamine hippurate) in women with recurrent cystitis.

Benefits: We found one systematic review (search date 2000, 3 RCTs, 372 women) comparing methenamine hippurate versus placebo or antibiotics.[20] The review concluded that there was insufficient evidence about effects of methenamine hippurate (see comment below).

Harms: We found no reliable RCTs.

Comment: The review found three RCTs comparing methenamine hippurate versus placebo or versus antibiotics in women with recurrent urinary tract infection.[20] All had important problems with their methods, principally that each participant could contribute more than once to assessment of recurrence rate.[21–23] Two of the included RCTs were

small (30 and 52 women with recurrent lower urinary tract infection).[21,22] Both found that methenamine hippurate reduced recurrence compared with placebo (monthly recurrence rate 0.03–0.08 episodes per month with methenamine hippurate *v* 0.25–0.34 episodes per month with placebo; CI not reported).[21,22] The largest of the RCTs (290 people [92% women] with recurrent urinary tract infection) also included women with chronic pyelonephritis. It found that methenamine hippurate reduced recurrence of cystitis compared with placebo after 1 year (recurrence was observed on 34% of tests in women receiving methenamine hippurate *v* 63.2% with placebo; CI not reported).[23]

QUESTIONS

INTERVENTIONS

See glossary, p 2556

Key Messages

Non-surgical interventions

- **Pelvic floor electrical stimulation** RCTs have found that pelvic floor electrical stimulation reduces symptoms compared with no treatment or sham pelvic floor electrical stimulation. One systematic review found no significant difference in rates of cure or improvement at 12 months between pelvic floor electrical stimulation and pelvic floor muscle exercises. It found that pelvic floor

electrical stimulation was associated with a small number of cases of vaginal irritation and difficulties in maintaining motivation for treatment. RCTs found no significant difference in self reported cure or improvement rates or urinary leakage between pelvic floor electrical stimulation and vaginal cones, but they may have lacked power to detect a clinically important difference.

- **Pelvic floor muscle exercises** One systematic review has found that pelvic floor muscle exercises increase rates of cure or improvement and reduce the number of leakages over 3–6 months compared with no treatment or placebo. It found no significant difference in cure or improvement rates at 12 months between pelvic floor muscle exercises and pelvic muscle electrical stimulation. It found that pelvic floor muscle exercises reduced the number of leakage episodes at 6 months compared with vaginal cones. There was no significant difference in rates of cure or improvement at 12 months.
- **Vaginal cones** One systematic review found that vaginal cones increased self reported cure or improvement rates compared with control over 6–12 months. It found no significant difference in leakage episodes. RCTs found no significant difference in self reported cure or improvement rates over 12 months between vaginal cones and pelvic floor muscle exercises. It found that vaginal cones were less effective than pelvic floor muscle exercises in reducing the number of leakage episodes over 6 months. RCTs also found no significant difference between vaginal cones and pelvic floor electrical stimulation in self reported cure or improvement rates, or urinary leakage over 4 weeks to 12 months, but they may have lacked power to detect a clinically important difference. The most common adverse effect associated with vaginal cones was difficulty maintaining motivation for use but a small number of more serious events such as vaginitis and abdominal pain were reported.
- **Oestrogen supplements** RCTs provided insufficient evidence to assess oestrogen supplements in women with stress incontinence.

Surgical interventions

- **Laparoscopic colposuspension** We found no RCTs comparing laparoscopic colposuspension versus no treatment, non-surgical treatment, anterior vaginal repair, suburethral slings, or needle colposuspension. One systematic review found that laparoscopic colposuspension was less effective than open retropubic colposuspension in improving objective cure rates at 1 year. It found no significant difference in objective cure rates at 5 years, or in subjective cure rates at 1 or 5 years.
- **Open retropubic colposuspension** We found no RCTs comparing open retropubic colposuspension versus no treatment or sham treatment. One systematic review found that open retropubic colposuspension increased cure rates at 1–5 years compared with non-surgical treatment, anterior vaginal repair, or needle colposuspension but was associated with more adverse effects than non-surgical treatment or needle colposuspension. It found that open retropubic colposuspension increased objective cure rates at 12 months compared with laparoscopic colposuspension. It found no significant difference in objective cure rates at 5 years, or in subjective cure rates at 1 or 5 years. It also found no significant difference in cure rates at 1 year between open retropubic colposuspension and suburethral slings. The review found that open retropubic colposuspension was associated with fewer perioperative complications than anterior vaginal repair or suburethral slings but more than needle colposuspension.

- **Needle colposuspension** We found no RCTs comparing needle colposuspension versus no treatment, non-surgical treatment, or laparoscopic colposuspension. One systematic review found no significant difference in cure or improvement rates between needle colposuspension and anterior vaginal repair or suburethral slings, but found that needle colposuspension was associated with fewer perioperative complications than suburethral slings. Another systematic review found that open retropubic colposuspension improved cure rates compared with needle colposuspension at 5 years but that needle colposuspension was associated with fewer perioperative complications.
- **Suburethral slings** We found no RCTs comparing suburethral slings versus no treatment, non-surgical treatment, anterior vaginal repair, or laparoscopic colposuspension. One systematic review found no significant difference in cure or improvement rates at 1 year between suburethral slings and open retropubic colposuspension but found that slings may increase the risk of bladder perforation. One small RCT identified by the review found no significant difference in cure rates at 1 year between suburethral slings and needle colposuspension, but it may have been underpowered to detect a clinically important difference. The RCT found that suburethral slings increased perioperative complications compared with needle colposuspension.
- **Anterior vaginal repair** We found no RCTs comparing anterior vaginal repair (anterior colporrhaphy) versus no treatment, suburethral slings, or laparoscopic colposuspension. One RCT provided insufficient evidence to compare anterior vaginal repair versus non-surgical treatment. One systematic review found that anterior vaginal repair was less effective than open retropubic colposuspension in increasing cure rates at 12 months or 5 years. It found no significant difference in overall operative complications between the two procedures. It found no significant difference in cure rates at 12 months between anterior vaginal repair and needle colposuspension.

DEFINITION Stress incontinence is the involuntary loss of urine on laughing, coughing, sneezing, or straining, which causes a social or hygiene problem. It predominantly affects women. Typically, there is no anticipatory feeling of needing to pass urine. Physiologically, stress incontinence is defined as intravesical pressure that exceeds urethral pressure in the absence of a detrusor contraction.

INCIDENCE/ PREVALENCE Stress incontinence is a common problem. Prevalence has been estimated at 17–45% of adult women in the setting of a high income country.[1] During 2000/2001, about 10 000 operations on the outlet of the female bladder were carried out in England.[2] About 4000 were open abdominal operations, about 3000 were vaginal, about 1500 were endoscopic, and the rest were categorised as "other".

AETIOLOGY/ RISK FACTORS Aetiological factors include pregnancy and vaginal delivery, obesity, and cigarette smoking.[3–5] We found no reliable data measuring the risks associated with these factors.

PROGNOSIS We found no reliable data about the natural history of stress incontinence. Untreated stress incontinence is believed to be a persistent, lifelong condition.

AIMS OF INTERVENTION To improve quality of life and social function, to reduce embarrassment and to reduce frequency and volume of involuntary urine leakage, with minimal adverse effects.

OUTCOMES **Primary outcomes:** quality of life, social functioning, subjective reduction in urine loss, and adverse effects of treatment. **Secondary outcomes:** reduced urine leakage on urodynamic testing, and pad tests (see glossary, p 2556) for objective demonstration of leakage. **Excluded proxy/surrogate outcomes:** pelvic floor strength, tension, contractility, physiological measures, and perineometry. Ideally, studies would include a follow up length of 5–10 years, but most studies reported outcomes of less than 1 year. We have not excluded studies based on length of follow up.

METHODS *Clinical Evidence* search and appraisal April 2003. We excluded studies comparing different techniques within a single procedure (e.g. high intensity *v* low intensity pelvic floor muscle training, or Burch colposuspension *v* Marshall-Marchetti-Krantz urethropexy). We excluded RCTs that reported only within group comparisons. We have included only RCTs that stated that more than half of the participants had stress incontinence.

QUESTION **What are the effects of non-surgical treatments for women with stress incontinence?** New

OPTION PELVIC FLOOR MUSCLE EXERCISES

One systematic review has found that pelvic floor muscle exercises increase rates of cure or improvement and reduce the number of leakages over 3–6 months compared with no treatment or placebo. It found no significant difference in cure rates and improvement at 12 months between pelvic floor muscle exercises and pelvic muscle electrical stimulation. It found that pelvic floor muscle exercises reduced the number of leakage episodes at 6 months compared with vaginal cones. There was no significant difference in cure rates or improvement at 12 months.

Benefits: We found one systematic review (search date 2000).[6] **Versus no treatment:** The review identified seven RCTs (816 women) comparing pelvic floor muscle exercises (PFME) (see glossary, p 2556) versus no treatment.[6] It found that PFME significantly improved self reported cure rates and self reported cure or improvement rates over 3–6 months compared with no treatment (cure rates: 2 RCTs; 18/108 [17%] with PFME *v* 2/108 [2%] with no treatment, RR 7.25, 95% CI 1.99 to 26.49; cure or improvement rates: 2 RCTs; 62/78 [79%] with PFME *v* 3/86 [3%] with no treatment, RR 23.04, 95% CI 7.56 to 70.22). It also found that PFME significantly reduced the number of daily leakage episodes over 3–6 months (3 RCTs; $P < 0.00001$; pooled absolute numbers not reported, WMD reported graphically). **Versus placebo:** The review identified three RCTs (284 women) comparing PFME versus placebo (sham PFME, sham pelvic floor electrical stimulation [PFES; see glossary, p 2556], or placebo tablet).[6] It found that PFME significantly improved self reported cure rates and self reported cure or improvement rates over 3–6 months compared with placebo (cure rates: 2 RCTs; 28/85 [33%] with PFME *v* 8/82 [10%] with placebo, RR 3.12, 95% CI 1.56 to 6.23; cure or improvement rates: 3 RCTs; 85/107 [79%] with PFME *v* 54/107 [50%] with

placebo, RR 1.53, 95% CI 1.26 to 1.87). It also found that PFME significantly reduced the number of daily leakage episodes over 3–6 months (1 RCT; mean episodes 0.4 with PFME *v* 1.17 with placebo; $P < 0.0007$). **Versus pelvic floor electrical stimulation:** The review identified six RCTs (382 women) comparing PFME versus PFES.[6] It found no significant difference in cure rates and self reported cure or improvement rates between PFME and PFES at up to 12 months (cure rates: 4 RCTs; 11/63 [17%] with PFME *v* 4/69 [6%] with PFES, RR 2.94, 95% CI 0.99 to 8.67; cure or improvement rates: 4 RCTs; 47/63 [75%] with PFME *v* 41/69 [60%] with PFES, RR 1.24, 95% CI 0.97 to 1.57). It also found no significant difference in the number of daily leakage episodes over 6 months between PFME and PFES (1 RCT, 57 women, mean episodes 0.27 with PFME *v* 0.56 with PFES; $P = 0.06$). The RCT may have been underpowered to detect a clinically important difference. **Versus vaginal cones:** The review identified seven RCTs (661 women) comparing PFME versus vaginal cones.[7] It found no significant difference in cure rates and self reported cure or improvement rates between PFME and vaginal cones over 12 months (failure to cure: 3 RCTs; 41/63 [65%] with PFME *v* 46/66 [70%] with vaginal cones, RR 0.93, 95% CI 0.72 to 1.16; failure to cure or improve: 4 RCTs; 30/90 [33%] with PFME *v* 35/92 [38%] with vaginal cones, RR 0.87, 95% CI 0.58 to 1.28). It found that PFME significantly reduced the number of daily leakage episodes at 6 months compared with vaginal cones (2 RCTs; $P = 0.008$; pooled absolute numbers not reported, WMD reported graphically).

Harms:

Versus no treatment: One RCT identified by the review reported that one woman doing PFME felt pain when contracting pelvic muscles, three women had an uncomfortable feeling, and two had difficulty in complying with treatment.[6] **Versus placebo:** One RCT identified by the review found that PFME were associated with significantly less dry mouth than placebo tablets (absolute numbers not reported; $P = 0.03$).[6] **Versus pelvic floor electrical stimulation:** One RCT identified by the review found that two women receiving PFES had vaginal irritation, two urinary tract infection, and two had tingling in the thigh.[6] It found no adverse effects associated with PFME. A second RCT identified by the review also found that two women receiving PFES reported vaginal "smarting" and eight women had difficulties using the stimulator and maintaining motivation for use. **Versus vaginal cones:** Three RCTs identified by the review gave information on adverse events, all of which were in women using vaginal cones.[6] In one RCT, 14 women had difficulties using the cones and maintaining motivation for use, two women had vaginitis, one women had abdominal pain, and one woman had bleeding. The second RCT found that cones produced an unpleasant feeling in five women, three women said cones were time consuming, two women said cones were difficult to insert when anxious or in a hurry, two women said cones interfered with menstruation, and two women suffered from muscle fatigue.

Comment: None.

OPTION PELVIC FLOOR ELECTRICAL STIMULATION

RCTs have found that pelvic floor electrical stimulation reduces stress incontinence symptoms compared with no treatment or sham pelvic floor electrical stimulation. One systematic review found no significant difference in cure or improvement rates at 12 months between pelvic muscle electrical stimulation and pelvic floor muscle exercises, but found that pelvic floor electrical stimulation was associated with a small number of cases of vaginal irritation and difficulties in maintaining motivation for treatment. RCTs found no significant difference between pelvic floor electrical stimulation and vaginal cones in self reported cure, improvement rates, or urinary leakage over 4 weeks to 12 months, but they may have lacked power to detect a clinically important difference.

Benefits:

Versus no treatment or sham treatment: We found one systematic review (search date 1998, 1 RCT),[8] three additional,[9–11] and two subsequent RCTs.[12,13] The RCT identified by the review (52 women) found that pelvic floor electrical stimulation (PFES) (see glossary, p 2556) significantly reduced the number of weekly incontinence episodes compared with sham PFES (mean reduction of 4.1 episodes/week with PFES *v* mean increase of 6.9 episodes/week with sham PFES; P = 0.009).[8] The first additional RCT (121 women; 60 [49.5%] with stress incontinence, 28 [23.2%] with urge incontinence [see glossary, p 2556], and 33 [27.3%] with mixed incontinence) found that PFES significantly increased the proportion of women with self reported improvement in symptoms after 6 weeks compared with sham PFES (35% with PFES *v* 17% with sham PFES; P = 0.03; results not intention to treat; see comment below).[9] The second additional RCT (33 men and women with stress incontinence; see comment below) found that PFES significantly increased the proportion of people with self reported improvement in symptoms and reduced urine loss (measured with the 1 hour pad test [see glossary, p 2556] over 4 weeks compared with sham PFES; proportion with subjective improvement: 60% with PFES *v* 8% with sham PFES, P = 0.005; proportion with reduced urine loss: AR not reported, P = 0.008).[10] The third additional RCT (43 women) found that more people receiving PFES reported improvement or cure compared with no treatment (27% with PFES *v* 0% with no treatment; P value not reported).[11] The first subsequent RCT (60 women) found that PFES significantly reduced frequency and severity of incontinence after 6 weeks compared with no treatment (each symptom scored using the Bristol Urinary Symptoms Questionnaire scoring, 1 [not a problem] to 5 [very serious problem]; mean reduction in frequency score 0.97 with PFES *v* 0 with no treatment; P < 0.01; mean reduction in severity score: 1.2 with PFES *v* 0 with no treatment; P < 0.01).[12] The second subsequent RCT (27 women) found that PFES significantly reduced scores on the Urogenital Distress Inventory Questionnaire after 8 weeks (score 0–100, greater score indicating worse distress) compared with sham PFES (31% reduction in score with PFES *v* 9% increase in score with sham PFES; P = 0.01).[13] **Versus pelvic floor muscle exercises:** See benefits of pelvic floor muscle exercises, p 2546. **Versus vaginal cones:** We found one systematic review (search date 2001, 4 RCTs, 274 women).[7] It found no

significant difference between PFES and vaginal cones (see glossary, p 2556) in self reported cure rates, self reported cure or improvement rates, daily leakage episodes, or grams of daily leakage after treatment over 4 weeks to 12 months (failure to cure: 50/55 [91%] with PFES *v* 47/51 [92%] with vaginal cones, RR 0.99, 95% CI 0.88 to 1.12; failure to improve or cure: 18/61 [30%] with PFES *v* 24/60 [40%] with vaginal cones, RR 0.74, 95% CI 0.45 to 1.22; daily leakage episodes: 1 RCT; 0.57 with PFES *v* 1.17 with vaginal cones; P = 0.1; grams of daily leakage after 6 months, 1 RCT; 0.8 with PFES *v* 0.6 with vaginal cones; P = 0.6). The review may have lacked the power to detect a clinically important difference in outcomes.

Harms: **Versus no treatment or sham treatment:** The RCTs gave no information on harms.[8–13] **Versus pelvic floor muscle exercises:** See harms of pelvic floor muscle exercises, p 2547. **Versus vaginal cones:** Two women in one of the RCTs included in the review reported vaginitis with vaginal cones, one reported bleeding, and 14 reported difficulty with use.[14]

Comment: **Versus no treatment or sham treatment:** The first additional RCT enrolled 148 women but only 121 completed the study.[9] The RCT did not perform an intention to treat analysis. It found no significant difference in withdrawal rates between PFES and sham treatment (14% with PFES *v* 21% with sham treatment; P = 0.27). The second additional RCT included men so the findings of this RCT may not be fully generalisable to women with stress incontinence.[10]

OPTION VAGINAL CONES

One systematic review found that vaginal cones improved self reported cure and improvement rates compared with control over 6–12 months. It found no significant difference in leakage episodes. RCTs found no significant difference in self reported cure or improvement rates over 12 months between vaginal cones and pelvic floor muscle exercises. It found that vaginal cones were less effective than pelvic floor muscle exercises in reducing the number of leakage episodes over 6 months. RCTs also found no significant difference between vaginal cones and pelvic floor electrical stimulation in self reported cure, improvement rates, or urinary leakage over 4 weeks to 12 months, but they may have lacked power to detect a clinically important difference. The most common adverse effect associated with vaginal cones was difficulty maintaining motivation for use but a small number of more serious events such as vaginitis and abdominal pain were reported.

Benefits: **Versus control:** We found one systematic review (search date 2001, 2 RCTs, 252 women) comparing vaginal cones (see glossary, p 2556) versus control (no treatment or advice to use a continence guard).[7] It found that vaginal cones significantly improved the self reported cure and self reported improvement or cure rates over 6–12 months compared with control (failure to cure: 2 RCTs; 32/48 [67%] with vaginal cones *v* 98/121 [81%] with control, RR 0.74, 95% CI 0.59 to 0.93; failure to improve or cure: 1 RCT; 10/27 [37%] with vaginal cones *v* 29/30 [97%] with no treatment, RR 0.38, 95% CI 0.23 to 0.63). It found no significant difference in

the number of daily leakage episodes over 6–12 months between vaginal cones and no active management (mean daily leakage episodes: 1.17 with vaginal cones *v* 1.07 with control; P = 0.8). **Versus pelvic floor muscle exercises:** See benefits of pelvic floor muscle exercises versus vaginal cones, p 2546. **Versus pelvic floor electrical stimulation:** See benefits of pelvic floor electrical stimulation versus vaignal cones, p 2548.

Harms: **Versus control:** The systematic review gave little information on adverse effects.[7] It gave some reasons for withdrawal from RCTs in women using vaginal cones, including motivation problems, unpleasantness, aesthetic dislike, discomfort, bleeding, and vaginal prolapse. **Versus pelvic floor muscle exercises:** See harms of pelvic floor muscle exercises versus vaginal cones, p 2547. **Versus pelvic floor electrical stimulation:** See harms of pelvic floor electrical stimulation versus vaginal cones, p 2549.

Comment: None.

OPTION OESTROGEN SUPPLEMENTS

RCTs provided insufficient evidence to assess oestrogen supplements in women with stress incontinence.

Benefits: **Versus placebo:** We found one systematic review[15] and one subsequent RCT.[16] The systematic review (search date 1992, 3 RCTs, 58 women) compared oral or vaginal oestrogens versus placebo.[15] It found that oestrogen supplementation significantly improved self reported symptoms after 1–3 months compared with placebo (P = 0.04). The subsequent RCT (62 women) found no significant difference in quality of life or urinary symptoms between oral oestradiol valerate 2 mg once daily and placebo (no further data reported).[16]

Harms: The review and subsequent RCT gave no information on adverse effects.[15,16] The harms of long term oestrogen supplements include venous thromboembolic disease, endometrial cancer, and breast cancer (see harms of oestrogens under menopausal symptoms, p 2459).

Comment: None.

QUESTION What are the effects of surgical treatments for women with stress incontinence? New

OPTION ANTERIOR VAGINAL REPAIR (ANTERIOR COLPORRHAPHY)

We found no RCTs comparing anterior vaginal repair versus no treatment, suburethral slings, or laparoscopic colposuspension. One RCT provided insufficient evidence to compare anterior vaginal repair versus non-surgical treatment. One systematic review found that anterior vaginal repair was less effective than open retropubic colposuspension in increasing cure rates at 12 months or at 5 years, and found no significant difference in overall operative complications between the two procedures. It found no significant difference in cure rates at 12 months between anterior vaginal repair and needle colposuspension.

Benefits: We found one systematic review (search date 2002) of anterior vaginal repair.[17] **Versus no treatment or sham treatment:** The review identified no RCTs.[17] **Versus non-surgical treatment:** The review identified one RCT (50 women) that compared anterior vaginal repair versus pelvic floor muscle exercises (see glossary, p 2556). Only 16 women were suitable for anterior vaginal repair (7 received anterior repair and 9 received pelvic floor muscle exercises) so no reliable conclusions could be drawn.[17] **Versus suburethral slings:** See glossary, p 2556. The review identified no RCTs.[15] **Versus open retropubic colposuspension:** See glossary, p 2556. The review identified eight RCTs (929 women).[17] It found that anterior vaginal repair was significantly less effective than open retropubic colposuspension in increasing cure rates at 12 months or 5 years (failure to cure at 12 months: 82/279 [29%] with anterior repair *v* 50/346 [14%] with open retropubic colposuspension, RR 1.89, 95% CI 1.39 to 2.59; failure to cure at 5 years: 49/128 [38%] with anterior repair *v* 31/145 [21%] with open retropubic colposuspension, RR 2.02, 95% CI 1.36 to 3.01). **Versus laparoscopic colposuspension:** See glossary, p 2556. The review identified no RCTs.[17] **Versus needle colposuspension:** See glossary, p 2556. The review identified two RCTs (469 women).[17] It found no significant difference between anterior vaginal repair and needle colposuspension in cure rates at 1 year (failure to cure: 33/134 [25%] with anterior vaginal repair *v* 31/132 [23%] with needle colposuspension, RR 1.05, 95% CI 0.69 to 1.59).

Harms: **Versus no treatment or sham treatment:** We found no RCTs. **Versus non-surgical treatment:** The RCT identified by the review gave no information on harms.[17] **Versus suburethral slings:** We found no RCTs. **Versus open retropubic colposuspension:** One RCT identified by the review reported more positive urine cultures after anterior vaginal repair than after open retropubic colposuspension. Another RCT identified by the review found one bladder perforation in the open retropubic colposuspension group. A third RCT identified by the review reported more intraoperative complications in women receiving open retropubic colposuspension, but more postoperative pyrexia and bleeding in women receiving anterior vaginal repair. It found no significant difference in overall operative complications between anterior vaginal repair and open retropubic colposuspension (14/73 [19%] *v* 12/91 [13%]; RR 1.57, 95% CI 0.84 to 2.95).[17] **Versus laparoscopic colposuspension:** We found no RCTs. **Versus needle colposuspension:** The systematic review gave no information on adverse effects.[17] An earlier systematic review (search date 1995) found one non-randomised study assessing complications after surgery.[18] The review reported that anterior vaginal repair caused fewer major complications than needle suspension (no further data reported).[18]

Comment: None.

OPTION SUBURETHRAL SLINGS

We found no RCTs comparing suburethral slings versus no treatment, non-surgical treatment, anterior vaginal repair, or laparoscopic colposuspension. One systematic review found no significant difference

in cure or improvement rates at 1 year between suburethral slings and open retropubic colposuspension. It found that slings may increase the risk of bladder perforation. One small RCT identified by the review found no significant difference in cure rates at 1 year between suburethral slings and needle colposuspension, but it may have been underpowered to detect a clinically important difference. The RCT found that suburethral slings increased perioperative complications compared with needle colposuspension.

Benefits:

Versus no treatment, sham treatment, or non-surgical treatment: We found one systematic review (search date 2002), which identified no RCTs.[19] **Versus anterior vaginal repair:** We found one systematic review (search date 2002), which identified no RCTs.[17] **Versus open retropubic colposuspension:** See glossary, p 2556. We found one systematic review (search date 2002, 9 RCTs, 697 women) which found no significant difference in cure or improvement rates at 1 year between suburethral slings (see glossary, p 2556) and open retropubic colposuspension (failed to cure within first year: 4 RCTs; 56/202 [28%] with suburethral slings *v* 41/170 [24%] with colposuspension, RR 1.10, 95% CI 0.78 to 1.53; failed to cure after first year: 3 RCTs; 10/89 [11%] with suburethral slings *v* 12/88 [14%] with colposuspension, RR 0.82, 95% CI 0.37 to 1.80; failed to improve over first year: 1 RCT; 3/36 [8%] with suburethral sling *v* 3/35 [9%] with colposuspension, RR 0.97, 95% CI 0.21 to 4.50).[19] **Versus laparoscopic colposuspension:** See glossary, p 2556. We found one systematic review (search date 2002) which found no RCTs.[19] **Versus needle colposuspension:** See glossary, p 2556. We found one systematic review (search date 2002, 1 RCT, 20 women) which found no significant difference in cure rate at 1 year between suburethral slings and needle colposuspension (failed to cure: 1/10 [10%] with suburethral slings *v* 3/10 [30%] with needle colposuspension, RR 0.33, 95% CI 0.04 to 2.69), but the RCT may have lacked power to detect a clinically important difference.[19]

Harms:

Versus no treatment, sham treatment, or non-surgical treatment: We found no RCTs. **Versus anterior vaginal repair:** We found no RCTs. An earlier systematic review (search date 1995) identified one retrospective study assessing complications after surgery.[18] It found that significantly more women had perioperative complications, including residual urine, urinary retention, and uterine prolapse with suburethral slings than with anterior vaginal repair (see glossary, p 2556) ($P < 0.01$).[18] **Versus open retropubic colposuspension:** The systematic review found no significant difference in minor or major perioperative complications between suburethral slings and open retropubic colposuspension (5 RCTs; 75/284 [26%] with suburethral slings *v* 71/261 [27%] with open retropubic colposuspension, RR 0.92, 95% CI 0.72 to 1.19).[19] However, the largest RCT (344 women) identified by the review found that suburethral slings increased bladder perforations compared with open retropubic colposuspension (12 with suburethral slings *v* 3 with open colposuspension; CI not reported). **Versus laparoscopic colposuspension:** We found no RCTs. **Versus**

needle colposuspension: The systematic review found that suburethral slings significantly increased perioperative complications, including pyrexia, blood loss, wound infection, and pulmonary embolus, compared with needle colposuspension (1 RCT; 9/10 [90%] with suburethral sling *v* 2/10 [20%] with needle colposuspension, RR 4.50, 95% CI 1.28 to 15.81).[19]

Comment: None.

OPTION OPEN RETROPUBIC COLPOSUSPENSION

We found no RCTs comparing open retropubic colposuspension versus no treatment or sham treatment. One systematic review found that open retropubic colposuspension increased cure rates at 1–5 years compared with non-surgical treatment, anterior vaginal repair, or needle colposuspension. It was associated with more adverse effects than non-surgical treatment or needle colposuspension. It found that open retropubic colposuspension improved objective cure rates at 1 year compared with laparoscopic colposuspension. It found no significant difference in objective cure rates at 5 years, or in subjective cure rates at 1 or 5 years. It also found no significant difference in cure rates at 1 year between open retropubic colposuspension and suburethral slings. The review found that open retropubic colposuspension was associated with fewer perioperative complications than anterior vaginal repair or suburethral slings but more than needle colposuspension.

Benefits: **Versus no treatment or sham treatment:** We found one systematic review (search date 2002) which identified no RCTs.[20] **Versus non-surgical treatment:** We found one systematic review (search date 2002, 2 RCTs, 120 women) comparing open retropubic colposuspension (see glossary, p 2556) versus non-surgical treatments (pelvic floor muscle exercises alone or pelvic floor muscle exercises plus pelvic floor electrical stimulation [see glossary, p 2556]).[20] It found that open retropubic colposuspension significantly improved self reported and objective cure rates at 1 year compared with non-surgical treatment (self reported failure to cure: 1 RCT; 3/16 [19%] with open retropubic colposuspension *v* 10/13 [77%] with conservative treatments, RR 0.24, 95% CI 0.08 to 0.71; objective failure to cure: 1 RCT; 6/24 [25%] with open retropubic colposuspension *v* 42/44 [95%] with conservative treatments, RR 0.26, 95% CI 0.13 to 0.53). **Versus anterior vaginal repair:** See glossary, p 2556. See benefits of anterior vaginal repair versus open retropubic colposuspension, p 2551. **Versus suburethral slings:** See glossary, p 2556. See benefits of suburethral sling versus open retropubic colposuspension, p 2552. **Versus laparoscopic colposuspension:** See glossary, p 2556. We found one systematic review (search date 2002, 7 RCTs, 599 women).[20] It found no significant difference between open retropubic colposuspension and laparoscopic colposuspension in self reported cure rates at 1 or 5 years (failure to cure at 1 year: 4 RCTs; 13/207 [6%] with open retropubic colposuspension *v* 13/196 [6%] with laparoscopic colposuspension, RR 0.97, 95% CI 0.47 to 2.03; failure to cure at 5 years: 1 RCT; 6/40 [15%] with open retropubic colposuspension *v* 4/33 [12%] with laparoscopic colposuspension, RR 1.24, 95% CI 0.38 to 4.02). It found that open retropubic

colposuspension significantly increased objective cure rates at 1 year but found no significant difference in objective cure rates at 5 years (failure to cure at 1 year: 5 RCTs; 30/241 [12%] with open retropubic colposuspension *v* 45/224 [20%] with laparoscopic colposuspension, RR 0.63, 95% CI 0.42 to 0.95; failure to cure at 5 years: 2 RCTs; 10/68 [15%] with open retropubic colposuspension *v* 6/57 [11%] with laparoscopic colposuspension, RR 1.39, 95% 0.54 to 3.60). **Versus needle colposuspension:** See glossary, p 2556. We found one systematic review (search date 2002, 7 RCTs, 570 women).[20] It found that open retropubic colposuspension significantly improved self reported and objective cure rates at 5 years compared with needle colposuspension (self reported failure to cure: 6 RCTs; 38/278 [14%] with open retropubic colposuspension *v* 66/291 [23%] with needle suspension, RR 0.56, 95% CI 0.39 to 0.81; objective failure to cure: 5 RCTs; 32/248 [13%] with open retropubic colposuspension *v* 57/271 [21%] with needle suspension, RR 0.59, 95% CI 0.40 to 0.88).[20]

Harms:

Versus anterior vaginal repair: See harms of anterior vaginal repair versus open retropubic colposuspension, p 2551. **Versus non-surgical treatment:** The review identified one RCT which gave information on adverse effects.[20] It found that open retropubic colposuspension was associated with more adverse events than non-surgical treatments (pelvic floor muscle exercises alone or pelvic floor muscle exercises plus pelvic floor electrical stimulation). They were retropubic pain (1/16 [6.25%] with open retropubic colposuspension *v* 0/24 [0%] with non-surgical treatment; CI not reported), detrusor overactivity (1/16 [6.25%] with open retropubic colposuspension *v* 0/24 [0%] with non-surgical treatment; significance not reported), and persistent dyspareunia with loss of libido (1/16 [6.25%] with open retropubic colposuspension *v* 0/24 [0%] with non-surgical treatment; CI not reported). **Versus suburethral slings:** See harms of suburethral sling versus open retropubic colposuspension, p 2552. **Versus laparoscopic colposuspension:** We found one systematic review (search date 2002, 7 RCTs, 599 women).[20] It found no significant difference in perioperative complications between open retropubic colposuspension and laparoscopic colposuspension (14/120 [12%] with open retropubic colposuspension *v* 10/107 [9%] with laparoscopic colposuspension, RR 1.28, 95% CI 0.60 to 2.75). The review gave no information on the nature or severity of perioperative complications. **Versus needle colposuspension:** We found one systematic review (search date 2002, 7 RCTs, 570 women).[20] It found that open retropubic colposuspension significantly increased the risk of surgical complications compared with needle colposuspension (3 RCTs: 23/77 [30%] with open retropubic colposuspension *v* 36/75 [48%] with needle colposuspension, RR 0.66, 95% CI 0.46 to 0.94). The review gave no information on the nature or severity of surgical complications.[20]

Comment:

The studies included in the systematic review comparing colposuspension versus needle colposuspension had weak methods.[20]

OPTION LAPAROSCOPIC COLPOSUSPENSION

We found no RCTs comparing laparoscopic colposuspension versus no treatment, non-surgical treatment, anterior vaginal repair, suburethral slings, or needle colposuspension. One systematic review found that laparoscopic colposuspension was less effective than open retropubic colposuspension in improving objective cure rates at 1 year. It found no significant difference in objective cure rates at 5 years, or in subjective cure rates at 1 or 5 years.

Benefits: **Versus no treatment, sham surgery, or non-surgical treatment:** We found one systematic review (search date 2001) which identified no RCTs.[21] **Versus anterior vaginal repair:** See glossary, p 2556. See benefits of anterior vaginal repair versus laparoscopic colposuspension, p 2551. **Versus suburethral slings:** See glossary, p 2556. See benefits of suburethral sling versus laparoscopic colposuspension, p 2552. **Versus open retropubic colposuspension:** See glossary, p 2556. See benefits of open retropubic colposuspension versus laparoscopic colposuspension, p 2553. **Versus needle colposuspension:** See glossary, p 2556. We found no RCTs.

Harms: **Versus no treatment, sham surgery, or non-surgical treatments:** We found no RCTs. **Versus anterior vaginal repair:** See harms of anterior vaginal repair versus laparoscopic colposuspension, p 2551. **Versus suburethral slings:** See harms of suburethral sling versus laparoscopic colposuspension, p 2552. **Versus open retropubic colposuspension:** See harms of open retropubic colposuspension versus laparoscopic colposuspension, p 2554.

Comment: None.

OPTION NEEDLE COLPOSUSPENSION

We found no RCTs comparing needle colposuspension versus no treatment, non-surgical treatment, or laparoscopic colposuspension. One systematic review found no significant difference in cure or improvement rates between needle colposuspension and anterior vaginal repair or suburethral slings. It found that needle colposuspension was associated with fewer perioperative complications than suburethral slings. Another systematic review found that open retropubic colposuspension improved cure rates compared with needle colposuspension at 5 years. However, needle colposuspension was associated with fewer perioperative complications.

Benefits: **Versus no treatment, sham treatment, or non-surgical treatment:** We found one systematic review (search date 2001), which found no RCTs.[22] **Versus anterior vaginal repair:** See glossary, p 2556. See benefits of anterior vaginal repair versus needle colposuspension, p 2551. **Versus suburethral slings:** See glossary, p 2556. See benefits of suburethral sling versus needle colposuspension, p 2552. **Versus open retropubic**

colposuspension: See glossary, p 2556. See benefits of open retropubic colposuspension versus needle colposuspension, p 2553. **Versus laparoscopic colposuspension:** See glossary, p 2556. See benefits of laparoscopic colposuspension versus needle colposuspension, p 2555.

Harms: **Versus no treatment, sham treatment, or non-surgical treatment:** We found no RCTs. **Versus anterior vaginal repair:** See harms of anterior vaginal repair versus needle colposuspension, p 2551. **Versus suburethral slings:** See harms of suburethral sling versus needle colposuspension, p 2552. **Versus open retropubic colposuspension:** See harms of open retropubic colposuspension versus needle colposuspension, p 2554. **Versus laparoscopic colposuspension:** See harms of laparoscopic colposuspension versus needle colposuspension, p 2555.

Comment: None.

GLOSSARY

Anterior vaginal repair (anterior colporrhaphy) The vaginal mucosa below the urethra is dissected, ending just in front of the cervix. Sutures are placed in the periurethral tissue and the pubocervical fascia to support and elevate the bladder neck. Excess vaginal tissue is removed and then the dissected area is closed.

Laparoscopic colposuspension An endoscope is inserted into or through the abdominal wall to view abdominal and pelvic organs. Sutures are inserted into the paravaginal tissues on either side of the bladder neck and then attached to the ileopectineal ligaments on the same side.

Needle colposuspension To support the bladder neck, a needle threads sutures from the vagina to the anterior abdominal fascia through the paraurethral tissue of the bladder neck.

Open retropubic colposuspension Open retropubic colposuspension involves lifting the tissues near the bladder neck and proximal urethra in the area of the pelvis behind the anterior pubic bones through an incision over the lower abdomen.

Pad test After the placement of a pre-weighed sanitary pad, the woman is asked to exercise. The pad is then re-weighed to determine the amount of urine loss.

Pelvic floor electrical stimulation Recurrent electrical pulse is delivered by vaginal probe to stimulate pelvic floor muscle contractions.

Pelvic floor muscle exercises Repetitive contraction exercises designed to strengthen the pelvic floor muscles based on the rationale that a strong, fast pelvic floor muscle contraction will clamp the urethra, thus increasing the intraurethral pressure, preventing leakage during abrupt increases in intra-abdominal pressure.

Suburethral sling Strips of material are tunnelled under the urethra, attached either to the rectus muscle or the ileopectineal ligaments resulting in a tightening of the sling and increased bladder support every time the woman contracts her rectus muscles.

Urge incontinence Urge incontinence is typically caused by a spontaneous or inappropriately provoked involuntary bladder contraction (detrusor instability). Urge incontinence, unlike stress incontinence, is associated with a feeling of needing to void. It is rarer than stress incontinence.

Vaginal cones A women inserts a weighted cone into the vagina. When she can successfully retain that cone while standing, moving around, and coughing, she will move onto the next heaviest cone and so on.

Key Messages

Prevention

- **Education** We found no RCTs of the effect of education programmes on the incidence of mammalian bites. One RCT in school children found that an educational programme increased precautionary behaviour around dogs compared with no education.
- **Education in specific occupational groups** We found no RCTs of education to prevent bites in specific occupational groups.

Prevention of complications

- **Antibiotic prophylaxis** The effects of antibiotic prophylaxis in preventing complications of mammalian bites remain unclear. Limited evidence from one systematic review found that, when all causes and sites of mammalian bite were combined, there was no evidence of a difference in infection rate between antibiotics and placebo. Meta-analysis according to the site of the wound found that antibiotics reduced infections of the hand only. One small RCT in the review found that in people with human bites, antibiotics reduced the rate of infection compared with placebo.

- **Debridement, irrigation, and decontamination** We found no reliable studies assessing debridement, irrigation, decontamination measures, or serum infiltration in the wound. However, there is consensus that such measures are likely to be beneficial.
- **Primary wound closure** One poor quality RCT comparing primary wound closure with no closure in people with dog bites found no significant difference in the incidence of infection, but the RCT was too small to exclude clinically important effects.
- **Tetanus immunisation after mammalian bites** We found no evidence on the effects of tetanus toxoid or tetanus immunoglobulin in preventing tetanus after human or animal bites.

Treatment

- **Antibiotics for treatment of infected mammalian bites** We found no RCTs of antibiotics compared with placebo for infected mammalian bites. However, there is consensus that antibiotics are likely to be beneficial.
- **Comparative effectiveness of different antibiotics for treatment of infected mammalian bites** One RCT in people with infected and uninfected animal and human bites found no significant difference in failure rate (which was undefined) with penicillin, with or without dicloxacillin, compared with amoxicillin/clavulanic acid.

DEFINITION Bite wounds are mainly caused by humans, dogs, or cats. They include superficial abrasions (30–43%), lacerations (31–45%), and puncture wounds (see glossary, p 2563) (13–34%).[1]

INCIDENCE/ PREVALENCE In areas where rabies is poorly controlled among domestic animals, dogs account for 90% of reported mammalian bites compared with less than 5% in areas where rabies is well controlled. In the USA, an estimated 3.5–4.7 million dog bites occur each year.[2] About 1 in 5 people bitten by a dog seek medical attention, and 1% of those require admission to hospital.[3,4] Between a third and half of all mammalian bites occur in children.[5]

AETIOLOGY/ RISK FACTORS In over 70% of cases, people are bitten by their own pets or by an animal known to them. Males are more likely to be bitten than females, and are more likely to be bitten by dogs, whereas females are more likely to be bitten by cats.[2] One study found that children under 5 years old were significantly more likely than older children to provoke animals before being bitten.[6] One study of infected dog and cat bites found that the most commonly isolated bacteria was *Pasteurella*, followed by *Streptococci*, *Staphylococci*, *Moraxella*, *Corynebacterium*, and *Neisseria*.[7] Mixed aerobic and anaerobic infection was more common than anaerobic infection alone.

PROGNOSIS In the USA, dog bites cause about 20 deaths a year.[8] In children, dog bites frequently involve the face, potentially resulting in severe lacerations and scarring.[9] Rabies, a life threatening viral encephalitis, may be contracted as a consequence of being bitten or scratched by a rabid animal. More than 99% of human rabies occurs in developing countries where canine rabies is endemic.[10]

AIMS OF INTERVENTION To prevent mammalian bites; to prevent or achieve rapid resolution of complications after mammalian bites, with minimal adverse effects.

Bites (mammalian)

OUTCOMES **Prevention:** Incidence of mammalian bites. **Prophylaxis:** Rate of infection after mammalian bites, incidence of tetanus. **Treatment:** Cure rate of infection owing to mammalian bites.

METHODS *Clinical Evidence* search and appraisal March 2003, including a search for observational studies. In addition, the authors searched Web of Science (Science Citation Index to October 2001).

QUESTION What are the effects of interventions to prevent mammalian bites?

OPTION EDUCATION

We found no RCTs of the effect of education programmes on the incidence of mammalian bites. One RCT found that an educational programme compared with no education in school children increased precautionary behaviour around dogs. We found no RCTs of education to prevent bites in specific occupational groups.

Benefits: We found no systematic review. **In the general population:** We found no RCTs on the effect of education programmes on the incidence of mammalian bites. One RCT (346 school children aged 7–8 years in 8 primary schools in Sydney, Australia) cluster randomised schools to either an educational programme or no education.[11] The educational programme consisted of one 30 minute lesson demonstrating behavioural techniques around dogs, such as how to recognise friendly, angry, or frightened dogs; how to approach dogs and owners when wanting to pat a dog; and how to use a precautionary and protective body posture when approached or knocked over by a dog. After 10 days, children were videotaped for 10 minutes while playing in school grounds where a dog was leashed. The trial found that children in schools receiving education were significantly less likely to pat the dog without hesitation and try to excite it (118/149 [79%] *v* 18/197 [9%]; RR 0.16, 95% CI 0.064 to 0.20). **In specific occupational groups:** We found no RCTs.

Harms: The RCT did not report on adverse effects.[11]

Comment: The RCT was brief and reported only the proxy outcome of behaviour modification. The effect of such a programme on the incidence of dog bites in the long term is unclear.

QUESTION What are the effects of measures to prevent complications from mammalian bites?

OPTION IMMUNISATION AGAINST TETANUS

We found no evidence on the effects of tetanus toxoid or tetanus immunoglobulin in preventing tetanus after human or animal bites.

Benefits: We found no systematic review. **Tetanus toxoid:** We found no RCTs or cohort studies. **Tetanus immunoglobulin:** We found no RCTs or cohort studies.

Harms: We found no evidence.

Comment: General measures to prevent tetanus, such as cleaning the wound, removing debris, excision (except on the face), irrigation, and excision and removal of skin flaps around puncture wounds (see glossary, p 2563), may be beneficial. However, we found no evidence to confirm or refute this. We found no RCTs on the effects of passive immunisation using tetanus immunoglobulin.

OPTION ANTIBIOTIC PROPHYLAXIS

The effects of antibiotic prophylaxis in preventing complications of mammalian bites remain unclear. Limited evidence from one systematic review found that, when all causes and sites of mammalian bite were combined, there was no evidence of a difference in infection rate between antibiotic prophylaxis and placebo. Meta-analysis according to the site of the wound found that antibiotic prophylaxis reduced infections of the hand only. One small RCT in the review found that in people with human bites, antibiotic prophylaxis reduced the rate of infection compared with placebo.

Benefits: We found one systematic review (search date 2001, 7 RCTs and 1 quasi-randomised controlled trial, 522 people bitten by dogs, cats, or humans in the preceding 24 hours) comparing prophylactic antibiotics versus placebo or no treatment.[12] There was significant heterogeneity between trials. The review found no significant difference in infection rate with antibiotic prophylaxis compared with placebo after dog, cat, or human bites (OR 0.49, 95% CI 0.15 to 1.58; timescale not reported). When the results were analysed for each wound site (hands, trunk, arms, or head/neck), antibiotic prophylaxis significantly reduced infections of the hand only (3 RCTs: 2% with antibiotic prophylaxis *v* 28% with control; OR 0.10, 95% CI 0.01 to 0.86; NNT 4, 95% CI 2 to 50). **Animal bites:** The review identified six RCTs of dog bites (463 people) and found no significant difference in infection rate with antibiotic prophylaxis compared with control (10/225 [4%] with antibiotic prophylaxis *v* 13/238 [5%] with control; OR 0.74, 95% CI 0.30 to 1.85). The review identified one small RCT of cat bites (12 people), which found no significant difference in infection rate with antibiotic prophylaxis compared with control (4/6 [67%] with antibiotic prophylaxis *v* 0/5 [0%] with control; $P < 0.06$).[12] **Human bites:** The review included one RCT of human bites (48 people with uncomplicated bites on the hand in the preceding 24 hours) comparing oral cephalosporin versus intravenous cephalosporin plus penicillin versus placebo. All participants received debridement, irrigation, and sterile dressing and remained in hospital for 5 days. It found that antibiotic prophylaxis by either route significantly reduced the proportion of people with wound infection compared with placebo (0/33 [0%] with oral or iv antibiotic prophylaxis *v* 7/15 [47%] with placebo; $P < 0.05$; timescale not reported).[12]

Harms: The review did not report on adverse effects.[12]

Comment: Most of the RCTs were small and gave insufficient information about allocation concealment and randomisation. Some studies were not double blind, and four studies had withdrawal rates greater than

Bites (mammalian)

10%.[12] The effects of antibiotic prophylaxis in preventing complications of mammalian bites remain unclear. Only a few studies analysed the effect of antibiotic prophylaxis on specific wound types (lacerations, puncture [see glossary, p 2563], or avulsions).[12]

OPTION PRIMARY WOUND CLOSURE

One poor quality RCT comparing primary wound closure with no closure in people with dog bites found no significant difference in the incidence of infection, but the RCT was too small to exclude clinically important effects.

Benefits: We found no systematic review. We found one RCT comparing primary wound closure versus no closure (96 people bitten by dogs in the preceding 24 hours).[13] All wounds were debrided and irrigated, and tetanus immunisation was updated, but no antibiotic prophylaxis was given. In uncomplicated lacerations (see glossary, p 2563), closure was performed by an experienced nurse; in complicated lacerations closure was performed by a specialist physician. The RCT found no difference in the incidence of infection with closed compared with open wounds (7/92 [8%] with closed *v* 6/77 [8%] with open; RR 0.98, 95% CI 0.33 to 2.62; timescale not reported). There were significantly more infections of the hand compared with the rest of the body (69% *v* 31% of body), but there was no difference between closure and non-closure groups in the rate of hand infection (5/9 [56%] with closure *v* 4/9 [44%] with non-closure).

Harms: The RCT did not report on adverse effects.[13]

Comment: Although the RCT found no increased risk of infection with primary wound closure, further RCTs are required to confirm this conclusion, and also to evaluate if wound closure of bites from a rabid animal may increase the risk of rabies.

OPTION DEBRIDEMENT, IRRIGATION, AND DECONTAMINATION

We found no reliable studies assessing debridement, irrigation, decontamination measures, or serum infiltration in the wound. However, there is consensus that such measures are likely to be beneficial.

Benefits: We found no systematic review, RCTs, or good cohort studies.

Harms: We found no evidence.

Comment: It would be regarded as unethical to conduct an RCT comparing debridement, irrigation, and decontamination versus no treatment. There is consensus that such measures are likely to be beneficial.

QUESTION **What are the effects of treatments for infected mammalian bites?**

OPTION **ANTIBIOTICS**

We found no RCTs comparing antibiotics versus placebo for infected mammalian bites; however, there is consensus that they are likely to be beneficial. One RCT in people with infected and uninfected animal and human bites found no significant difference in failure rate (which was undefined) with penicillin, with or without dicloxacillin, compared with amoxicillin/clavulanic acid.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus other antibiotics:** We found one RCT (61 people bitten in the preceding 10 days; 48 by animals, 13 by humans) comparing penicillin with or without dicloxacillin versus amoxicillin (amoxycillin)/clavulanic acid.[10] Treatment was given for 5 days in people bitten less than 8 hours previously or in those without clinical infection (34 people), and for 10 days in people bitten more than 8 hours previously or with clinical infection (27 people). All wounds received usual care and were left closed or open at the discretion of the attending physician. The RCT found no significant difference in failure rate (which was undefined) with penicillin/dicloxacillin compared with amoxicillin/clavulanic acid (1/31 [3%] with penicillin/dicloxacillin *v* 3/30 [10%] with amoxicillin/clavulanic acid; RR 0.32, 95% CI 0.03 to 2.54; time-scale not reported).

Harms: Adverse effects were significantly more common in people using amoxicillin/clavulanic acid compared with penicillin/dicloxacillin (3/30 [10%] penicillin/dicloxacillin *v* 13/31 [42%] with amoxicillin/clavulanic acid; RR 4.2, 95% CI 1.5 to 7.4; NNH 3, 95% CI 2 to 19). Diarrhoea was the most common adverse event (1/30 [3%] with penicillin/dicloxacillin *v* 9/31 [29%] with amoxicillin/clavulanic acid; RR 8.71, 95% CI 1.34 to 23.3; NNH 4, 95% CI 1 to 79).[10]

Comment: Interpretation of the results of the RCT is difficult as the main outcome measure of "failure rate" was not defined. Also, failure rates were not separated according to whether people had infected or uninfected wounds at inclusion.[10] We found no RCTs comparing antibiotics versus placebo for infected mammalian bites; however, there is consensus that they are likely to be beneficial.

GLOSSARY

Abrasion The scraping or rubbing away of a small area of skin or mucous membrane.

Laceration Occurs when the skin, soft tissues, or both are torn by the crushing and shearing forces produced on impact; characterised by ragged, irregular margins, surrounding contusion, marginal abrasion, and tissue bridging in the wound depths.

Puncture A wound caused by perforation of the skin with a sharp point.

QUESTIONS

INTERVENTIONS

Key Messages

Prevention

- **Foam alternatives (compared with standard foam mattresses)** One systematic review has found that foam alternatives to the standard hospital foam mattress reduces the incidence of pressure sores over 10–14 days in people at high risk. We found no evidence of a "best" foam alternative.
- **Pressure relieving overlays on operating tables** One systematic review has found that the use of pressure relieving overlays on operating tables reduces the incidence of pressure sores.
- **Low air loss beds in intensive care (compared with standard beds)** One RCT in people in intensive care found that low air loss beds reduced the risk of new pressure sores compared with standard intensive care beds.

Pressure sores

- **Medical sheepskin overlays** One RCT found that medical sheepskin overlays reduced the incidence of pressure sores compared with standard treatment in people aged 60 years or more who underwent orthopaedic surgery.
- **Alternating pressure surfaces; different seat cushions; electric profiling beds; low air loss hydrotherapy beds; low tech constant low pressure supports; repositioning (regular "turning"); topical lotions and dressings** We found insufficient evidence about the effects of these interventions in preventing pressure sores.
- **Air filled vinyl boots with foot cradle** One small RCT found that air filled vinyl boots with foot cradles were associated with more rapid development of pressure sores compared with hospital pillows.

Treatment

- **Air fluidised supports (compared with standard care)** We found limited evidence from three RCTs that air fluidised supports healed more established sores than standard care.
- **Alternating pressure surfaces; debridement; electrotherapy; hydrocolloid dressings (compared with gauze soaked in saline or hypochlorite); low air loss beds; low level laser therapy; low tech constant low pressure supports; nutritional supplements; other dressings; seat cushions; surgery; therapeutic ultrasound; topical negative pressure; topical phenytoin** We found insufficient evidence on the effects of these interventions in healing pressure sores.

DEFINITION Pressure sores (also known as pressure ulcers, bed sores, and decubitus ulcers) may present as persistently hyperaemic, blistered, broken, or necrotic skin and may extend to underlying structures, including muscle and bone. Whether blanching or non-blanching erythema constitute pressure sores is controversial.

INCIDENCE/ PREVALENCE The most comprehensive data on prevalence and incidence come from hospital populations. Studies have found a prevalence of 6–10% in National Health Service hospitals in the UK,[1] and 8% in a teaching hospital in the USA.[2]

AETIOLOGY/ RISK FACTORS Pressure sores are caused by unrelieved pressure, shear, or friction; they are most common below the waist and at bony prominences, such as the sacrum, heels, and hips. They occur in all healthcare settings. Increased age, reduced mobility, and impaired nutrition emerge consistently as risk factors;[3] however, the relative importance of these and other factors is uncertain.

PROGNOSIS The presence of pressure sores has been associated with a twofold to fourfold increased risk of death in elderly people and people in intensive care.[4,5] However, pressure sores are a marker for underlying disease severity and other comorbidities rather than an independent predictor of mortality.[4]

AIMS OF INTERVENTION To prevent pressure sore formation; heal existing pressure sores; and improve quality of life.

OUTCOMES Incidence and severity of pressure sores; rate of change of area and volume; and time to heal. Interface pressure recorded at various anatomical sites is a surrogate outcome that is sometimes used in studies of preventive interventions but has not yet been linked to clinical outcomes.

METHODS *Clinical Evidence* search and appraisal May 2003 after a search of the Specialist Trials Register of the Cochrane Wounds Group (compiled by searching 19 electronic databases, including Medline, Cinahl, BIDS, and Embase, and hand searching of journals and conference proceedings). We reviewed all RCTs that used objective clinical outcome measures. For many trials, we could not be sure that the size of pressure sores was distributed evenly between groups at baseline. Unequal distribution of wound size at baseline would impact on all measures of wound healing. Ideally, studies of treatment should stratify randomisation by initial wound area and be of sufficient size to ensure even distribution of baseline wound size. Many of the studies by manufacturers were in healthy people who are not representative of clinical subjects, and these studies have been excluded.

QUESTION What are the effects of preventive interventions?

OPTION PRESSURE RELIEVING SURFACES

One systematic review found that foam alternatives to the standard hospital foam mattress reduced the incidence of pressure sores over 10–14 days in people at high risk. We found no evidence of a "best" foam alternative. We found insufficient evidence on the effects of electric profiling beds, different seat cushions, and constant low pressure supports. The relative merits of alternating and constant low pressure, and of the different alternating pressure surfaces are unclear. One RCT in people in intensive care found that low air loss beds reduced the risk of new pressure sores compared with standard beds. The systematic review found that the use of pressure relieving overlays on operating tables significantly reduced the incidence of pressure sores. One small RCT found that air filled vinyl boots with foot cradles were associated with more rapid development of pressure sores compared with hospital pillows.

Benefits: We found one systematic review (search date 2000).[6] **Foam alternatives versus standard hospital mattress:** The systematic review[6] identified four RCTs (850 people), and we found one subsequent RCT (101 people);[7] all five RCTs were undertaken primarily in elderly people in orthopaedic hospital wards. A meta-analysis of the five RCTs (Cullum N, Nelson EA, Nixon J, personal communication, 2002) found that foam alternatives to the standard hospital mattress significantly reduced the incidence of sores over 10–14 days (RR 0.31, 95% CI 0.22 to 0.46; NNT 5, 95% CI 4 to 7).[6,7] **Different foam alternatives:** The systematic review identified five RCTs (795 people) that compared different foam alternatives.[6] One RCT (40 people) found that a foam and fibre replacement that comprised five sections reduced the risk of a patient developing a pressure sore compared with a 4 inch (10 cm) thick dimpled foam (RR 0.42, 95% CI 0.18 to 0.90; NNT for 10–21 days' treatment 3, 95% CI 2 to 25). The other RCTs were too small to detect a difference between the foam alternatives. **Electric profiling beds:** We found one RCT (70 people in medical or surgical hospital wards), which compared an electrically operated profiling bed that comprised four sections plus a pressure relieving foam

mattress versus a standard hospital bed with pressure relieving mattress (foam or alternating pressure). It found no significant difference in the incidence of pressure sores up to 10 days (no one who received either intervention developed a sore).[8] The RCT may have been underpowered to detect a clinically important difference. **Different seat cushions:** The systematic review identified two RCTs.[6] The first RCT (53 people) compared slab foam versus bespoke contoured foam cushions, and the other RCT (141 people) compared a gel and foam wheelchair cushion versus a foam cushion. The RCTs found no significant difference in the incidence of pressure sores with different types of cushions after 5 months' use of a slab foam cushion and 3 months of the gel and foam cushion, but they may have been too small to detect a clinically important difference. **Low tech constant low pressure supports:** See glossary, p 2573. The systematic review identified seven RCTs (1451 people), which were too small or flawed to draw reliable conclusions.[6] **Alternating pressure surfaces:** The systematic review identified nine RCTs (1242 people) that compared alternating pressure surfaces (see glossary, p 2573) versus standard foam or constant low pressure supports.[6] Most RCTs were too small to rule out a clinically important difference in the prevention of pressure sores. One RCT (327 people) found that an alternating pressure surface significantly reduced the incidence of pressure sores compared with a standard foam mattress (RR 0.32, 95% CI 0.14 to 0.72; NNT for 10 days' treatment 11, 95% CI 6 to 34). Another RCT (230 people) found that a range of alternating pressure surfaces significantly reduced the incidence of pressure sores compared with a range of constant low pressure supports after an average of 16 days. The other RCTs found no significant difference between alternating pressure devices and constant low pressure supports over periods ranging from 8 days to 3 months. **Low air loss beds:** The systematic review identified one RCT (98 people).[6] It found that low air loss beds (see glossary, p 2573) in intensive care significantly reduced the risk of new pressure sores compared with standard intensive care beds (duration of trial not stated; RR 0.24, 95% CI 0.11 to 0.51; NNT 3, 95% CI 2 to 5). **Low air loss hydrotherapy beds:** The systematic review identified one RCT (98 people with incontinence admitted to acute and long stay hospital wards).[6] Low air loss hydrotherapy beds (see glossary, p 2573) significantly increased the risk of developing a pressure sore compared with a range of support surfaces after 60 days (RR 3.6, 95% CI 6.7 to 11.3). **Pressure relieving overlays on the operating table:** The systematic review identified three RCTs.[6] The first RCT (446 people who had undergone elective major general, gynaecological, or vascular surgery) found that a pressure relieving viscoelastic polymer pad significantly reduced the incidence of postoperative pressure sores compared with a standard table after 8 days (RR 0.52, 95% CI 0.32 to 0.83; NNT for intraoperative use 11, 95% CI 6 to 36). Meta-analysis of results from the two other RCTs (368 people; Cullum N, Nelson EA, Nixon J, personal communication, 2001) found that an alternating pressure surface (used during and for 7 days after surgery) significantly reduced the incidence of pressure sores over 7 days compared with a gel pad (used during surgery) plus a standard mattress (used for 7 days after surgery)

(RR 0.20, 95% CI 0.06 to 0.65; NNT for seven days' treatment 16, 95% 9 to 48). Whether the reduced incidence of pressure sores was because of intraoperative or postoperative pressure relief, or both, is unclear.[6] **Air filled vinyl boot with foot cradle:** The systematic review identified one small RCT (52 people), which found that hospital pillows significantly reduced the rate of developing pressure sores compared with a vinyl boot (air filled with a built in foot cradle) (mean time to skin breakdown 10 days *v* 13 days; $P < 0.036$ log rank test).[6]

Harms: The systematic review noted that hypothermia was found in a few people who used low air loss hydrotherapy beds.[6]

Comment: Most RCTs were small and of poor quality, and few performed the same comparison. Alternative foam mattresses comprised foam of varying densities, often within the same mattress, and sometimes were sculptured.

OPTION OTHER PREVENTIVE INTERVENTIONS

Systematic reviews found insufficient evidence about the effects of repositioning (regular "turning"), topical lotions, or dressings. We found limited evidence from one RCT that medical sheepskin overlays reduced the incidence of pressure sores compared with standard treatment in people aged 60 years or more who underwent orthopaedic surgery.

Benefits: **Repositioning (regular "turning"):** We found one systematic review (search date 1995, three small RCTs, 56 people [see comment below]), which found no significant difference in the incidence of pressure sores between regular manual repositioning and control treatment.[9] We found no RCTs that evaluated placement of people in different positions. **Topical lotions and dressings:** We found one systematic review (search date 2000) that identified two RCTs of topical lotions.[10] One RCT (319 people) that compared hexachlorophene (hexachlorophane) lotion versus cetrimide lotion found no significant difference in the incidence of new pressure sores over 3 weeks (OR 0.97, 95% CI 0.46 to 1.65; no raw data reported). These results must be interpreted with caution, because they were based on a completer analysis of 167 people. The other RCT (120 people) compared hexachlorophene lotion versus an inert lotion and found no significant difference in the proportion of people with changes in skin condition over 3 weeks. **Medical sheepskin overlays:** We found one systematic review (search date 2000, one small, poor quality RCT, 36 people)[6] and one subsequent RCT[11] of sheepskin overlays compared with standard treatment. The systematic review found no conclusive evidence.[6] The subsequent RCT (297 people aged ≥ 60 years who underwent orthopaedic surgery) found that medical sheepskin overlays plus standard pressure area care significantly reduced the incidence of pressure sores over an unspecified period compared with standard care alone (RR 0.30, 95% CI 0.17 to 0.51; NNT 5, 95% CI 4 to 9).[11]

Harms: We found no direct or indirect evidence of harm arising from repositioning, topical lotions or dressings, or medical sheepskin overlays.

Pressure sores

Comment: The RCTs identified by the reviews were small, of poor quality, and few comparisons had been undertaken more than once.[9,10] In one of the RCTs of regular repositioning identified by the review,[9] 23 people were randomised to repositioning but only 10 people actually were repositioned regularly.

QUESTION What are the effects of treatments?

OPTION PRESSURE RELIEVING SURFACES

We found limited evidence from three RCTs that air fluidised supports healed more established sores than standard care. We found insufficient evidence on the effects of constant low pressure supports, alternating pressure surfaces, low air loss beds, or seat cushions.

Benefits: We found one systematic review (search date 2000).[6] **Air fluidised supports:** The systematic review identified four RCTs (214 people) that compared air fluidised supports (see glossary, p 2572) versus standard care.[6] Two RCTs (105 people in hospital) found that air fluidised supports healed more established sores than standard care (alternating pressure mattresses, regular changes of position, sheepskin, gel pads, or limb protectors) after 15 days. The third RCT (97 people being cared for at home) found no significant difference after 36 weeks, although this RCT had a high withdrawal rate. The fourth RCT (12 people who had undergone plastic surgery to repair pressure sores) found no significant difference in rates of pressure sore healing between air fluidised supports and dry flotation after 2 weeks. **Low tech constant low pressure supports:** See glossary, p 2573. The systematic review identified one RCT (120 elderly people with pressure sores in a nursing home) and found no significant difference in rates of pressure sore healing between a layered foam replacement mattress and a water mattress after 4 weeks. **Alternating pressure surfaces:** The systematic review identified three RCTs.[6] Two RCTs (182 older people with pressure sores in hospital) found no significant differences in rates of pressure sore healing with different alternating pressure mattresses (see glossary, p 2573) after 4 and 18 weeks. The third RCT (32 older people in hospital and nursing homes) found no significant difference in pressure sore healing between an alternating pressure mattress and standard care after 2 weeks. **Low air loss beds:** The systematic review identified two RCTs (133 people), which found no significant difference in healing of pressure sores between low air loss beds (see glossary, p 2573) and convoluted foam.[6] We found no RCTs that compared low air loss beds versus alternating pressure or air fluidised supports. **Seat cushions:** The systematic review identified one RCT (25 people) that compared seat cushions with dry flotation versus alternating pressure and found no significant difference in healing rates (mean healing time: 44 days with dry flotation *v* 59 days with alternating pressure).[6]

Harms: The systematic review[6] noted that, in one of the RCTs identified,[12] hypothermia was found in a few people who used low air loss hydrotherapy beds.

Comment: People are unable to move in and out of bed independently when they use air fluidised beds, and this limits the type of people for whom they are suitable.

OPTION OTHER TREATMENTS

We found inconclusive evidence about the effects of hydrocolloid dressings, other types of dressings, debridement, topical phenytoin, surgery, nutritional supplements, electrotherapy, therapeutic ultrasound, low level laser therapy, or topical negative pressure on healing rates of pressure sores.

Benefits: **Hydrocolloid dressings (compared with gauze soaked in saline or hypochlorite):** We found one systematic review (search date 1997, five RCTs; 396 wounds)[13] and one subsequent RCT (32 people)[14] of dressings or topical agents for pressure sores. Most RCTs were small, of poor quality, and inconclusive. A meta-analysis within the review found a significant benefit (wounds healed up to 75 days: 102/205 [50%] with hydrocolloid dressing *v* 59/191 [31%] with traditional dressings; OR 2.57, 95% CI 1.58 to 4.18),[6] as did the subsequent RCT (relative volume of wound at 12 weeks relative to 100% at baseline: 26% with hydrogel *v* 64% with saline; $P < 0.02$). However, a subsequent meta-analysis (Cullum N, Nelson EA, Nixon J, personal communication, 2001) that used a more conservative statistical technique found no significant difference in healing of pressure sores (RR 1.63, 95% CI 0.97 to 2.75).[14–19] **Other dressings:** We found one systematic review (search date 1997), which found nine RCTs (713 people) that compared hydrocolloid versus other dressings and seven RCTs (463 people) that compared other types of dressing.[13] We found five subsequent RCTs.[20–24] The RCTs had weak methods and were too small to draw reliable conclusions. **Debridement:** We found one systematic review (search date 1998)[25] and five subsequent RCTs.[26–30] The systematic review found no RCTs that compared debridement versus no debridement.[25] It identified 32 RCTs that compared different debriding agents, but the studies were small, included a range of wounds, and few comparisons were undertaken in more than one RCT. The review concluded that there was insufficient evidence to promote the use of any particular debriding agent over another.[25] The first subsequent RCT (23 people with 30 ulcers) compared dextranomer paste (see glossary, p 2573) versus saline soaked gauze and found no significant difference in the proportion of sores ready for skin grafting within 15 days (5/15 [33%] with dextranomer paste *v* 4/15 [27%] with saline; ARI +7%, 95% CI –26% to +38%).[26] The second subsequent RCT (43 people) compared collagenase versus hydrocolloid dressings and found no significant difference in healing (3 people in each group healed, no denominator reported).[27] The third subsequent RCT (24 women) compared collagenase versus hydrocolloid for full thickness heel sores and found that sores treated with collagenase healed significantly more quickly, but no data that showed baseline equivalence for wound size were given.[28] The fourth subsequent RCT (21 people), which compared papain plus urea versus collagenase, found no significant difference in healing rates over 4 weeks.[29] The fifth subsequent RCT (135 people) found no significant difference

between collagenase and fibrinolysin plus deoxyribonuclease for healing at 4 weeks (decrease ≥ 25% in necrotic wound area: 37/60 [62%] with collagenase *v* 35/61 [57%] with fibrinolysin plus deoxyribonuclease; P = 0.115 across five classifications of wound change).[30] **Topical phenytoin:** We found one RCT (48 patients) that compared topical phenytoin suspension (100 mg capsule in 5 mL saline) with hydrocolloid dressings or antibiotic ointment as a treatment for partial thickness pressure sores.[31] Topical phenytoin significantly increased the healing rate compared with hydrocolloid dressings or antibiotic ointment (mean time to healing 35.3 ± 14.3 days with phenytoin *v* 51.8 ± 19.6 days with hydrocolloid *v* 53.8 ± 8.5 days with antibiotic; P < 0.005 for both comparisons), but no data that showed baseline equivalence for wound size were presented.[31] **Surgery:** We found no RCTs of surgical treatments for pressure sores. **Nutritional supplements:** We found two RCTs that looked at supplementation with ascorbic acid for healing of pressure sores.[32,33] One small RCT (20 people undergoing surgery for pressure sores) found that ascorbic acid supplementation (500 mg twice daily) improved healing rates compared with placebo after 1 month.[32] A larger RCT (88 people) found no significant difference in healing rates between ascorbic acid 500 mg twice daily and 10 mg twice daily over 12 weeks.[33] We found no RCTs of the effects of parenteral nutrition or hyperalimentation on wound healing. **Electrotherapy:** We found one systematic review (search date 2000; 3 RCTs).[6] Two of the RCTs (91 pressure sores) were suitable for meta analysis, which found that electrotherapy (see glossary, p 2573) significantly increased healing compared with sham therapy after about 3–5 weeks (RR 7.92, 95% CI 2.4 to 26.3). The third RCT included in the review found similar results after 4 weeks (percentage area of pressure sore healed: 49.8% with electrotherapy *v* 23.4% with sham; P = 0.042).[34] These RCTs were small, however, and had important weaknesses in their methods. Results therefore should be interpreted with caution. **Therapeutic ultrasound:** We found one systematic review (search date 1999, three RCTs, 140 people).[35] None of the three RCTs found any evidence of improved pressure sore healing with ultrasound therapy (see glossary, p 2573) compared with no ultrasound therapy. **Low level laser therapy:** We found one systematic review (search date 1998, 1 RCT, 18 people) of low level laser therapy (see glossary, p 2573) in pressure sores; it found no evidence of benefit.[36] **Topical negative pressure:** We found one systematic review (search date 2000, two small RCTs, one of which included 34 people with pressure sores).[37] The review found no clear evidence of improved healing of pressure sores with topical negative pressure (see glossary, p 2573) compared with no topical negative pressure.

Harms: We found no reports on harms with these treatments.

Comment: Overall, the evidence that relates to these treatments is poor.

GLOSSARY

Air fluidised supports Membranes that cover a layer of particles that are fluidised by having air forced through them. The airflow can be turned off, which makes the surface solid again, to allow the person to be moved. People find it difficult to get

in and out of these beds independently; therefore, they are usually reserved for people who spend most of the day in bed.

Alternating pressure surfaces Mattresses or overlays made of one or two layers of parallel air sacs. Alternate sacs are inflated and deflated, which provides alternating pressure and release for each area of skin.

Dextranomer paste Anhydrous, porous beads 0.1–0.3 mm in diameter. These beads are hydrophilic and absorb and adsorb exudate, wound debris, and bacteria, depending on particle size.

Electrotherapy The application of electrical fields by placing electrodes near a wound. Treatments include pulsed electromagnetic therapy, low intensity direct current, negative polarity and positive polarity electrotherapy, and alternating polarity electrotherapy.

Low air loss beds Mattresses that comprise inflatable upright sacs of semi-permeable fabric. Inflation of the sacs increases the area of contact between the individual and the support surface and reduces the pressure on the skin. People find it difficult to get in and out of these beds independently; therefore, they are usually reserved for people who spend most of the day in bed.

Low air loss hydrotherapy beds A mattress that comprises cushions covered by a permeable, fast drying filter sheet, through which air is circulated. The bed also contains a urine collecting device.

Low level laser therapy Also known as low intensity or low power therapy. It is thought to work by inducing a photochemical response to laser light, which results in biochemical alterations in cells and physiological changes.

Low or high tech constant low pressure supports Mattresses, overlays, and cushions made of high density or contoured foam or filled with fibre, gel, water, beads, or air. They increase the area of contact between the person and the support surface and thus reduce the pressure at the interface. See also air fluidised supports, low air loss beds, and low air loss hydrotherapy beds.

Therapeutic ultrasound The application of ultrasound to a wound with a transducer and water based gel. The power of ultrasound waves used in wound healing is low to avoid heating the tissues.

Topical negative pressure Negative pressure (suction) applied to a wound through an open cell dressing (for example, foam or felt).

Substantive changes

Other treatments Two RCTs added;[24,30] conclusions unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 2588

Key Messages

Treatment

- **Compression** One systematic review has found that compression heals more venous leg ulcers than no compression. We found insufficient evidence from RCTs to compare the effects of different types of multilayer compression, or multilayer high compression versus short stretch bandages. One systematic review found that multilayer compression increased ulcer healing compared with single layer bandages.
- **Pentoxifylline** One systematic review and two subsequent RCTs have found that oral pentoxifylline increases the proportion of ulcers healed over 6–12 months compared with placebo.

- **Cultured allogenic bilayer skin replacement** One RCT found that cultured allogenic bilayer skin replacement increased the proportion of ulcers healed after 6 months compared with a non-adherent dressing.
- **Flavonoids** Two RCTs found that flavonoids increased ulcer healing compared with placebo or standard care.
- **Peri-ulcer injection of granulocyte–macrophage colony stimulating factor (GM-CSF)** One RCT found that peri-ulcer injection of GM-CSF increased the proportion of ulcers healed after 13 weeks' treatment compared with placebo.
- **Sulodexide** Two RCTs found that sulodexide plus compression increased the proportion of ulcers healed after 60–90 days' treatment compared with compression alone.
- **Systemic mesoglycan** One RCT found that systemic mesoglycan plus compression increased the proportion of ulcers healed after 24 weeks' treatment compared with compression alone.
- **Antimicrobial agents; aspirin; debriding agents; foam, film, or alginate (semi-occlusive) dressings versus simple dressings in the presence of compression; intermittent pneumatic compression; low level laser treatment; oral rutosides; oral zinc; skin grafting; thromboxane α_2 antagonists; topical calcitonin gene related peptide plus vasoactive intestinal polypeptide; topical keratinocyte growth factor 2; topical mesoglycan; topical negative pressure; ultrasound; vein surgery** We found insufficient evidence about the effects of these interventions on ulcer healing.
- **Hydrocolloid dressings versus simple low adherent dressings in the presence of compression** One systematic review found that, in the presence of compression, hydrocolloid dressings did not heal more venous leg ulcers than simple, low adherent dressings.
- **Topically applied autologous platelet lysate** One RCT found no significant difference in time to healing of ulcers after 9 months between topically applied autologous platelet lysate and placebo.

Preventing recurrence

- **Compression** We found limited evidence that compression reduced recurrence, and that non-compliance with compression is a risk factor for recurrence.
- **Rutoside; stanozolol; vein surgery** We found insufficient evidence about the effects of these interventions on ulcer recurrence.

DEFINITION Definitions of leg ulcers vary, but the following is widely used: loss of skin on the leg or foot that takes more than 6 weeks to heal. Some definitions exclude ulcers confined to the foot, whereas others include ulcers on the whole of the lower limb. This review deals with ulcers of venous origin in people without concurrent diabetes mellitus, arterial insufficiency, or rheumatoid arthritis.

INCIDENCE/ PREVALENCE Between 1.5 and 3/1000 people have active leg ulcers. Prevalence increases with age to about 20/1000 in people aged over 80 years.[1]

AETIOLOGY/ RISK FACTORS Leg ulceration is strongly associated with venous disease. However, about a fifth of people with leg ulceration have arterial disease, either alone or in combination with venous problems, which may

Venous leg ulcers

require specialist referral.[1] Venous ulcers (also known as varicose or stasis ulcers) are caused by venous reflux or obstruction, both of which lead to poor venous return and venous hypertension.

PROGNOSIS People with leg ulcers have a poorer quality of life than age matched controls because of pain, odour, and reduced mobility.[2] In the UK, audits have found wide variation in the types of care (hospital inpatient care, hospital clinics, outpatient clinics, home visits), in the treatments used (topical agents, dressings, bandages, stockings), in healing rates, and in recurrence rates (26–69% in 1 year).[3,4]

AIMS OF INTERVENTION To promote healing; to reduce recurrence; to improve quality of life, with minimal adverse effects.

OUTCOMES Ulcer area; number of ulcers healed; number of ulcer free limbs; recurrence rates; number of new ulcer episodes; number of ulcer free weeks or months; number of people who are ulcer free; frequency of dressing/bandage changes; quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal March 2003.

QUESTION What are the effects of treatments?

OPTION COMPRESSION

One systematic review has found that compression heals more venous leg ulcers than no compression. We found insufficient evidence from RCTs to compare the effects of different types of multilayer compression, or multilayer high compression versus short stretch bandages. One systematic review found that multilayer compression increased ulcer healing compared with single layer bandages.

Benefits: **Compression versus no compression:** We found one systematic review (search date 2000, 6 RCTs, 260 people) comparing compression versus no compression.[5] It found that compression (e.g. elastomeric multilayer high compression bandages, short stretch bandages, double layer bandages, compression hosiery, or Unna's boot — see glossary, p 2589) healed more venous leg ulcers than no compression (e.g. dressing alone). The RCTs were heterogeneous, using different forms of compression in different settings and populations. The results were not pooled. The results of individual RCTs consistently favoured compression. **Elastomeric versus non-elastomeric multilayer compression:** The systematic review[5] identified three RCTs (273 people), and we found one subsequent RCT (112 people)[6] comparing elastomeric multilayer high compression bandages versus non-elastomeric multilayer compression. Meta-analysis of all four RCTs (Nelson EA, Cullum N, Jones J, personal communication, 2002) found no significant difference in the proportion of people whose ulcers healed with 12–26 weeks of high compression compared with non-high compression bandages (RR 1.30, 95% CI 0.94 to 1.82). **Multilayer high compression versus short stretch bandages:** The systematic review[5] identified four small RCTs (search date 2000, 167 people), and we identified one subsequent RCT (112 people).[7] The

systematic review found no significant difference in healing rates between multiplayer high compression and short stretch bandages (RR 1.10, 95% CI 0.78 to 1.55).[5] Meta-analysis of all five RCTs (Nelson EA, Cullum N, Jones J, personal communication, 2003; 279 people) found no significant difference in healing rates between multilayer high compression and short stretch bandages (RR 1.0, 95% CI 0.81 to 1.24). The lack of power in these small studies means that a clinically important difference cannot be excluded. **Multilayer high compression versus single layer bandage:** The systematic review identified four RCTs (280 people) comparing multilayer high compression versus a single layer of bandage.[5] It found a significant increase in the proportion of people whose reference ulcer had healed with multilayer compression compared with single layer bandages (82/139 [59%] *v* 59/141 [42%]; RR 1.41, 95% CI 1.12 to 1.77; NNT for variable periods of treatment 6, 95% CI 4 to 18) (see table 1, p 2591). **Multilayer high compression versus each other:** The systematic review identified three RCTs (285 people) comparing different elastic layered bandage regimens versus four layer bandage regimens, and we found two subsequent RCTs (294 people).[5,8,9] Meta-analysis of all five RCTs (Nelson et al, personal communication, 2003) found no significant difference in healing rates between the systems (RR for healing 0.98, 95% CI 0.89 to 1.09).

Harms: High levels of compression applied to limbs with insufficient arterial supply, or inexpert application of bandages, can lead to tissue damage and, at worst, amputation.[10] Complication rates were rarely reported in RCTs. One observational study (194 people) found that four layer compression bandaging for several months was associated with toe ulceration in 12 (6%) people.[11]

Comment: People thought to be suitable for high compression bandages are those with clinical signs of venous disease (ulcer in the gaiter region, from the upper margin of the malleolus to the bulge of the gastrocnemius; staining of the skin around an ulcer; or eczema), no concurrent diabetes mellitus or rheumatoid arthritis, and adequate arterial supply to the foot as determined by ankle/brachial pressure index. The precise ankle/brachial pressure index below which compression is contraindicated is often quoted as 0.8; however, many RCTs used the higher cut off of 0.9.[5] Effectiveness is likely to be influenced by the ability of those applying the bandage to generate safe levels of compression. Bandages may be applied by the person with the leg ulcer, their carer, nurse, or doctor. We found no comparisons of healing rates between specialist and non-specialist application of compression. Training improves bandaging technique among nurses.[12] Bandages containing elastomeric fibres can be applied weekly as they maintain their tension over time. Bandages made of wool or cotton, or both, such as short stretch bandages, may need to be reapplied more frequently as they do not maintain their tension.

Venous leg ulcers

OPTION INTERMITTENT PNEUMATIC COMPRESSION

We found insufficient evidence from one small RCT about the effects of intermittent pneumatic compression compared with compression bandages. One RCT found that intermittent pneumatic compression plus compression bandaging improved ulcer healing at 3 months compared with compression bandaging alone, but two other RCTs found no significant difference in healing at 6 months.

Benefits: **Intermittent pneumatic compression versus compression bandaging:** We found two systematic reviews (search dates 2001, 1 RCT, 16 people).[13,14] The RCT found no significant difference in the proportion of people with healed ulcers over 2–3 months between intermittent pneumatic compression (see glossary, p 2588) and compression (0/10 *v* 0/6), but the RCT was probably too small to exclude a clinically important difference. **Intermittent pneumatic compression plus compression bandaging versus compression bandaging alone:** We found two systematic reviews (search dates 2001).[13,14] The more comprehensive review identified three small RCTs (115 people).[13] It did not perform a meta-analysis because of clinical and methodological heterogeneity among the trials. The first RCT (45 people) found that intermittent pneumatic compression plus graduated compression stockings significantly increased the proportion of people with healed ulcers at 3 months compared with graduated compression stockings alone (10/21 [48%] *v* 1/24 [4%]; RR 11.4, 95% CI 1.6 to 82). The second RCT (53 people) found no significant difference between intermittent pneumatic compression plus elastic stockings and Unna's boot (see glossary, p 2589) in the proportion of people healed at 6 months (20/28 [71%] *v* 15/20 [75%]; RR 0.95, 95% CI 0.67 to 1.34). The third RCT (22 people) found no significant difference in healing at 6 months between intermittent pneumatic compression plus Unna's boot and Unna's boot alone (12/12 [100%] *v* 8/10 [80%]; RR 1.25, 95% CI 0.92 to 1.70).[13]

Harms: The RCTs identified by the review gave no information on adverse effects.[13]

Comment: Availability may vary widely in different healthcare settings. Treatment can be delivered in the home, in outpatient clinics, or in the hospital ward. RCTs have evaluated the use of intermittent pneumatic pressure for 1 hour twice weekly and 3–4 hours daily. Treatment requires resting for 1–4 hours daily, which may reduce quality of life. One RCT (45 people) identified by a systematic review found that a few people were not able to use the pump for 4 hours every day.[14]

OPTION DRESSINGS AND TOPICAL AGENTS

One systematic review found insufficient evidence on the effects of semi-occlusive dressings (foam, film, or alginate) compared with simple dressings, in the presence of compression. The review found that, in the presence of compression, hydrocolloid dressings did not heal more venous leg ulcers than simple, low adherent dressings. The review found insufficient evidence from small, heterogeneous RCTs about the effects

of topical agents, such as growth factors, compared with inert comparators. One RCT found that cultured allogenic bilayer skin replacement increased complete ulcer healing at 6 months compared with simple dressings. One small RCT found no significant difference in the proportion of people with healed ulcers after 12 weeks iontophoretic treatment with calcitonin gene related peptide plus vasoactive intestinal polypeptide versus placebo. One RCT found no significant difference after 9 months in time to healing between topical autologous platelet lysate and placebo. We found insufficient evidence from one small RCT to compare topical mesoglycan versus placebo. One RCT found no significant difference in ulcer healing between topical keratinocyte growth factor 2 and placebo after 12 weeks. One systematic review found insufficient evidence on the effects of topical negative pressure. One systematic review found insufficient evidence on the effects of antimicrobial agents compared with placebo or standard care. One systematic review found insufficient evidence on the effects of debriding agents compared with traditional dressings.

Benefits:

Foam, film, or alginate (semi-occlusive) dressings compared with simple dressings, in the presence of compression: We found one systematic review (search date 1997, 5 RCTs) comparing semi-occlusive dressings (foam, film, alginates) versus simple dressings (such as paraffin-tulle or knitted viscose dressings).[15] Two comparisons of foam dressings versus simple dressings; two of film dressings versus simple dressings; and one comparing an alginate versus a simple dressing found no evidence of benefit. However, the RCTs were too small (10–132 people, median 60) to detect anything but a very large difference in effectiveness. **Hydrocolloid (occlusive) dressings compared with simple low adherent dressings, in the presence of compression:** We found one systematic review (search date 1997), which identified nine RCTs comparing hydrocolloid dressings versus simple dressings in the presence of compression.[15] A pooled analysis of seven RCTs (714 people) found no evidence of benefit. **Comparisons between occlusive or semi-occlusive dressings:** The same systematic review identified 12 small RCTs comparing different occlusive or semi-occlusive dressings.[15] It found no significant difference in healing rates between dressings, or insufficient data were provided to calculate their significance. We found one subsequent RCT comparing hydrocolloid versus hydrocellular dressings, which found no significant difference in healing rates.[16] **Topical agents (e.g. growth factors) versus inert comparators:** The same systematic review identified 16 RCTs comparing topical agents (such as growth factors, cell suspensions, oxygen free-radical scavengers) versus either placebo or standard care in the treatment of venous leg ulcers.[15] It found insufficient evidence to recommend any topical agent. The studies were small (9–233 people, median 45) and heterogeneous; therefore, results could not be pooled. We found five subsequent RCTs, which are described below.[17–21] **Cultured allogenic bilayer skin replacement versus non-adherent dressing:** The first subsequent RCT (293 people) found that a cultured allogenic bilayer skin replacement (see glossary, p 2588), containing both epidermal and dermal components, significantly increased the proportion of ulcers healed completely in 6 months compared with a non-adherent dressing (92/146 [63%] *v* 63/129

[49%]; RR 1.29, 95% CI 1.04 to 1.60; NNT for 6 months' treatment 7, 95% CI 4 to 41) (see table 1, p 2591).[17] **Topical calcitonin gene related peptide plus vasoactive intestinal polypeptide versus placebo:** The second subsequent RCT (66 people) compared calcitonin (salcatonin) gene related peptide plus vasoactive intestinal polypeptide administered by iontophoresis (see glossary, p 2588) with placebo iontophoresis.[18] It found no significant difference in the proportion of people with healed ulcers after 12 weeks' treatment (11/33 [37%] *v* 6/33 [28%]; RR 1.83, 95% CI 0.77 to 4.38), but may have been too small to exclude a clinically important difference.[18] **Topical mesoglycan:** The third subsequent RCT (40 people) of topically applied mesoglycan, a profibrinolytic agent, found no evidence of benefit.[19] **Topically applied autologous platelet lysate:** The fourth subsequent RCT (86 people) found no difference after 9 months in time to healing between topical autologous platelet lysate and placebo.[20] **Topical recombinant human keratinocyte growth factor 2:** The fifth subsequent RCT (94 people) compared topically applied recombinant human keratinocyte growth factor 2 (repifermin 20 or 60 $\mu g/cm^2$) versus placebo (beneath compression).[21] The RCT found no significant difference in rates of complete ulcer healing ulcers between human keratinocyte growth factor 2 and placebo after 12 weeks (32% with 20 μg dose *v* 38% with 60 μg dose *v* 29% with placebo, for all doses of human keratinocyte growth factor 2 *v* placebo $P = 0.57$). **Topical negative pressure:** We found one systematic review (search date 2000, 2 small RCTs, 34 people).[22] One of the RCTs included some people with venous leg ulcers. It found no clear evidence of benefit of topical negative pressure (see glossary, p 2589), but the RCTs may have been too small to exclude a clinically important difference in outcomes. **Antimicrobial agents versus placebo or standard care:** We found one systematic review (search date 1997, 14 RCTs) comparing antimicrobial agents versus either placebo agents or standard care.[23] The RCTs were small (25–153 people, median 56), of poor quality, and no firm conclusions could be drawn. **Debriding agents:** We found one systematic review (search date 1997) comparing debriding agents versus traditional agents.[24] The review did not perform a meta-analysis specifically in people with venous leg ulcers.[24] Six RCTs (277 people) identified by the review compared dextranomer polysaccharide bead dressings with traditional dressings, but only two RCTs reported complete ulcer healing. Data pooling of these RCTs (137 ulcers) found no significant difference in the proportion of ulcers completely healed over 3 weeks (RR 2.15, 95% CI 0.34 to 13.3), but the size of the trials meant that a clinically important difference cannot be excluded (Nelson EA, Cullum N, Jones J, personal communication, 2002). Seven RCTs (451 people) identified by the review compared cadexomer iodine with traditional dressings, but only three RCTs reported complete ulcer healing. Data pooling of these RCTs (181 ulcers) found that cadexomer iodine healed significantly more ulcers than traditional dressings (31/60 *v* 15/75; RR 2.03, 95% CI 1.21 to 3.43), but the ulcers were smaller in people treated with cadexomer iodine, and results must be treated with caution as four RCTs could not be included in the data pooling. Two RCTs identified by the review compared

enzymatic preparations with traditional dressings (52 ulcers) and found no evidence of a difference in ulcer healing rates.[24] Four RCTs identified by the review compared debriding agents versus each other, two compared cadexomer iodine versus dextranomer (69 people), one compared cadexomer iodine versus hydrogel (95 people), and one compared dextranomer versus hyaluronic acid (50 people). The RCTs found no significant difference in ulcer healing with different debriding agents, but may have been too small to detect a clinically important difference.[24]

Harms: It is unlikely that low adherent primary wound dressings cause harm, although dressings containing iodine may affect thyroid function if used over large surface areas for extended periods.[25] Many people (50–85%) with venous leg ulcers have contact sensitivity to preservatives, perfumes, or dyes.[26] **Topical recombinant human keratinocyte growth factor 2:** One RCT (94 people) found no significant difference in adverse effects (leg pain, pruritus, skin ulcer, rash abrasion, reopening of venous ulcer) between repifermin and placebo.[21] However, this study may have lacked power to detect a clinically important difference between groups.

Comment: Simple primary dressings maintain a moist environment beneath compression bandages by preventing loss of moisture from the wound.[27]

OPTION ULTRASOUND

One systematic review found insufficient evidence about the effects of therapeutic ultrasound in the treatment of venous leg ulcers.

Benefits: We found one systematic review (search date 1999, 7 RCTs, 470 people) comparing therapeutic ultrasound (see glossary, p 2589) with no ultrasound or sham ultrasound for venous leg ulcers.[28] Ultrasound improved ulcer healing in all studies, but a significant difference was found in only four of the seven RCTs, and heterogeneity precluded pooling the seven RCTs.

Harms: Mild and severe erythema, local pain, and small areas of bleeding were reported in trials included in the review.[29,30]

Comment: None.

OPTION SYSTEMIC DRUG TREATMENTS

One systematic review and two subsequent RCTs have found that oral pentoxifylline increases ulcer healing over 6–12 months in people receiving compression compared with placebo. Two RCTs found that flavonoids increased the proportion of ulcers healing compared with placebo or standard care. One RCT found that injections of granulocyte macrophage-colony stimulating factor increased complete healing compared with placebo. Two RCTs found that sulodexide plus compression increased the proportion of ulcers healed after 60–90 days' treatment compared with compression alone. One RCT found that systemic mesoglycan plus compression increased the proportion of

ulcers healed after 24 weeks treatment compared with compression alone. RCTs found insufficient evidence on the effects of oral thromboxane α_2 antagonists, aspirin, oral rutosides, or oral zinc supplements.

Benefits:

Pentoxifylline: We found one systematic review (search date 2001, 9 RCTs, 572 people)[31] and two subsequent RCTs.[32,33] The systematic review compared pentoxifylline (oxpentifylline) (1200 mg or 2400 mg daily) versus placebo or versus other treatments, with or without compression.[31] It found that, in the presence of compression, pentoxifylline significantly increased the proportion of people with healed ulcers over 8–24 weeks compared with placebo (5 RCTs: 155/243 [64%] *v* 96/204 [47%]; RR 1.30, 95% CI 1.10 to 1.54; NNT for 6 months' treatment 6, 95% CI 4 to 14) (see table 1, p 2591). One RCT identified by the review found no evidence of benefit for pentoxifylline compared with defibrotide in people receiving compression.[31] The two subsequent RCTs compared pentoxifylline (400 mg three times daily) and placebo in people receiving compression.[32,33] The first RCT (172 people, 160 analysed) found that pentoxifylline for 6 months significantly increased rates of complete healing compared with placebo (55/82 [67%] with pentoxifylline *v* 24/78 [30.7%] with placebo; $P < 0.02$).[31] The second subsequent RCT (85 people, 80 analysed) found that pentoxifylline for 12 months significantly increased rates of complete healing compared with placebo (complete healing: 36/41 [88%] with pentoxifylline *v* 17/39 [44%] with placebo; $P < 0.02$).[33] **Flavonoids:** We found two RCTS, which compared micronised purified flavonoid fraction 1 g/day plus standard care with standard management alone.[34,35] When pooled in a random effects model (Nelson EA, Cullum N, Jones J, personal communication, 2001), flavonoids healed significantly more ulcers than placebo (100/206 [48%] with flavonoids *v* 53/189 [28%] with placebo; RR 1.80, 95% CI 1.20 to 2.70).[34,35] **Peri-ulcer injection of granulocyte macrophage–colony stimulating factor versus placebo:** One RCT (60 people) found that a 4 week course of injections around the ulcer of granulocyte–macrophage colony stimulating factor (400 μg) significantly increased the proportion of people whose ulcers had completely healed after 13 weeks' treatment compared with placebo (23/39 [59%] *v* 4/21 [19%]; RR 3.21, 95% CI 1.23 to 8.34; NNT for 13 weeks' treatment 2, 95% CI 1 to 7) (see table 1, p 2591).[36] **Sulodexide:** We found two RCTs (330 people).[37,38] They found that sulodexide (daily im injection for 20 or 30 days and then orally for 70 or 30 days) plus compression treatment significantly increased the proportion of ulcers healed after 60–90 days' treatment compared with compression alone (33% with compression alone *v* 54% with sulodexide plus compression; RR for healing 1.65, 95% CI 1.27 to 2.15; NNT 4, 95% CI 3 to 9) (Nelson EA, Cullum N, Jones J, personal communication 2003) (see table 1, p 2591).[37,38] **Systemic mesoglycan:** We found one RCT (183 people) comparing systemic mesoglycan (daily im injection for 21 days and then orally for 21 weeks) plus compression versus placebo plus compression.[39] It found that systemic mesoglycan significantly increased the proportion of people with healed ulcers after 24 weeks' treatment compared with placebo (82/92 [89%] *v* 69/91 [76%]; RR 1.17, 95% CI 1.03 to 1.35).

Thromboxane α_2 antagonists: We found one RCT (165 people) of an oral thromboxane α_2 antagonist versus placebo. It found no significant difference in the proportion of ulcers healed (54% *v* 55%).[40] **Oral zinc:** We found one systematic review (search date 1997, 5 RCTs, 151 people) comparing daily doses of 440–660 mg oral zinc sulphate versus placebo. The review found no evidence of benefit for oral zinc.[41] **Aspirin:** We found one small RCT of aspirin (300 mg daily, enteric coated) versus placebo. It found aspirin increased ulcer healing rates compared with placebo (38% *v* 0%), but the RCT had several methodological weaknesses so the result should be treated with caution.[42] **Rutosides:** We found one report of two RCTs.[43] The RCTs (total of 119 people) compared two different doses of oral hydroxyethyl rutosides (500 mg and 1000 mg twice daily) with placebo.[43] The RCTs found no significant difference between either dose of rutosides and placebo in rates of complete ulcer healing at 12 weeks (1 RCT, 55 people, 48 analysed: 12/23 [52%] with 1 g/day rutoside *v* 7/25 [28%] with placebo, P = 0.087; results for the other RCT were not reported). The RCTs may have been too small to detect a clinically important difference.

Harms: **Pentoxifylline:** The systematic review of pentoxifylline found that pentoxifylline increased adverse effects compared with placebo, although the difference was not significant (RR 1.25, 95% CI 0.87 to 1.80).[30] Nearly half of the adverse effects were gastrointestinal (dyspepsia, vomiting, or diarrhoea). Adverse effects of flavonoids, such as gastrointestinal disturbance, were reported in 10% of people. **Rutosides:** One report of two RCTs (119 people) found no significant difference in adverse effects between rutosides and placebo (no details were presented).[43] However, they may have lacked power to detect a clinically important difference between the groups.

Comment: Sulodexide is not widely available, and daily injections may be unacceptable to some people.

OPTION VEIN SURGERY

One RCT found insufficient evidence of the effects of vein surgery on ulcer healing.

Benefits: We found no systematic review. We found one RCT (47 people) comparing vein surgery (perforator ligation) versus no surgery or surgery plus skin grafting.[44] It found no difference in the proportion of ulcers healed after 1 year, or in the rate of ulcer healing. The RCT may have been too small to rule out a beneficial effect.

Harms: Vein surgery carries the usual risks of surgery and anaesthesia.

Comment: Several operative approaches are commonly used, including perforator ligation, saphenous vein stripping, and a combination of both procedures.

OPTION SKIN GRAFTING

One systematic review found insufficient evidence of the effects of skin grafting on ulcer healing.

Venous leg ulcers

Benefits: We found one systematic review (search date 1999, 6 RCTs, 197 people) of skin grafts (autografts or allografts) for venous leg ulcers.[45] In five RCTs, people also received compression bandaging; two RCTs (98 people) evaluated split thickness autografts; three RCTs (92 people) evaluated cultured keratinocyte allografts; and one RCT (7 people, 13 ulcers) compared tissue engineered skin (artificial skin) with split thickness skin grafts. We found insufficient evidence to determine whether skin grafting increased the healing of venous ulcers.[45]

Harms: Taking a skin graft leaves a wound that itself requires management and may cause pain. We found no evidence of harm from tissue engineered skin.

Comment: None.

OPTION LOW LEVEL LASER TREATMENT

Systematic reviews and two subsequent small RCTs found insufficient evidence of the effects of low level laser treatment on ulcer healing.

Benefits: We found two systematic reviews and two subsequent RCTs.[46–49] The first review (search date 1998) identified four RCTs (139 people).[46] Two RCTs compared low level laser treatment (see glossary, p 2589) versus sham treatment and found no significant difference in healing rates over 12 weeks (17/44 [39%] *v* 14/44 [32%]; RR 1.21, 95% CI 0.73 to 2.03). One three-arm RCT (30 people) identified by the review compared laser treatment versus laser treatment plus infrared light or versus non-coherent, unpolarised red light. It found that significantly more ulcers healed completely after 9 months' treatment in the group receiving a combination of laser and infrared light compared with non-coherent, unpolarised red light (12/15 [80%] *v* 5/15 [33%]; RR 2.4, 95% CI 1.12 to 5.13). The fourth RCT identified by the review compared laser and ultraviolet light and found no significant difference in healing over 4 weeks.[46] The second review (search date 1999, 5 RCTs)[47] identified but did not fully describe the four RCTs identified by the first review. The review did not perform a meta-analysis. The additional RCT identified by the review (9 people, 12 venous leg ulcers) compared low level laser treatment with sham treatment and found limited evidence that ulcer area reduction was greater with laser over 10 weeks (25% of ulcer area remained unhealed in people receiving laser *v* 85% in people receiving sham treatment).[47] The RCT did not assess complete ulcer healing. The first subsequent small RCT (15 people) compared laser therapy plus phototherapy once weekly for 4 weeks versus sham therapy.[48] It found no significant difference between laser and sham in ulcer area at 12 weeks. The second small subsequent RCT (65 people) compared laser, sham laser, and no treatment (although it is unclear if the "no additional treatment" was established by randomisation).[49] It found no significant difference between treatments in the change in area of ulceration (reduction in area: 4.25 cm^2 (27%) with laser *v* 5.21 cm^2 (39%) with sham laser *v* 2.98 cm^2 (18%) with no treatment; P value not reported).

Harms: Eye protection is required when using some types of laser as the high energy beam may lead to damage of the retina.

Comment: The laser power, wavelength, frequency, duration, and follow up of treatment were different for all of the studies. The subsequent RCTs may have lacked power to detect clinically important differences between laser and sham treatment.

QUESTION What are the effects of interventions to prevent recurrence?

OPTION COMPRESSION

We found limited evidence that compression reduced recurrence, but non-compliance with compression is a risk factor for recurrence.

Benefits: **Versus no compression:** We found one systematic review of compression hosiery versus no compression (search date 2000, no identified RCTs),[50] and one subsequent RCT.[51] The RCT (153 people) found that wearing compression stockings significantly reduced recurrence at 6 months compared with not wearing compression stockings (21% *v* 46%; RR 0.46, 95% CI 0.28 to 0.76; NNT for 6 months' treatment 2, 95% CI 2 to 5).[51] **Versus other forms of compression:** We found one systematic review (search date 2000, 2 RCTs).[50] One RCT (166 people) compared two brands of UK Class 2 stockings (see comment below) and found no significant difference in recurrence. The larger RCT (300 people) compared Class 2 and Class 3 stockings (see comment below). With intention to treat analysis, the RCT found no significant reduction in recurrence after 5 years with high compression hosiery (UK Class 3) compared with moderate compression hosiery (UK Class 2). This analysis may underestimate the effectiveness of the Class 3 hosiery because a significant proportion of people changed from Class 3 to Class 2. Both RCTs found that non-compliance with compression hosiery was associated with recurrence.

Harms: The application of high compression to limbs with reduced arterial supply may result in ischaemic tissue damage and, at worst, amputation.[31]

Comment: Compression hosiery is classified according to the magnitude of pressure exerted at the ankle; the UK classification states that Class 2 hosiery is capable of applying 18–24 mm Hg pressure and Class 3 is capable of applying 25–35 mm Hg pressure at the ankle. Other countries use different classification systems. Hosiery reduces venous reflux by locally increasing venous pressure in the legs relative to the rest of the body. This effect only takes place while hosiery is worn. The association between non-compliance with compression and recurrence of venous ulceration provides some indirect evidence of the benefit of compression in prevention. People are advised to wear compression hosiery for life and may be at risk of pressure necrosis from their compression hosiery if they subsequently develop arterial disease. Regular reassessment of the arterial supply is considered good practice, but we found no evidence about the optimal frequency of assessment. Other measures designed to reduce leg oedema, such as resting with the leg elevated, may be useful.

Venous leg ulcers

OPTION SYSTEMIC DRUG TREATMENT

One systematic review found insufficient evidence on the effects of rutoside or stanozolol on ulcer recurrence.

Benefits: We found one systematic review (search date 1997, 2 RCTs, 198 people) comparing stanozolol or rutoside with placebo in the prevention of leg ulcer recurrence.[52] **Rutoside:** The first RCT (139 people) identified by the review found no significant difference between rutoside and placebo in recurrence at 18 months (32% *v* 34%; P = 0.93; no raw data available to calculate CI). **Stanozolol:** The second RCT (60 people) identified by the review found no significant difference between stanozolol and placebo for 6 months in recurrence at the end of the study (length of follow up not specified; recurrence in 7/25 [28%] legs with stanozolol *v* 4/23 [17%]; RR 1.61, 95% CI 0.54 to 4.79).[52]

Harms: Stanozolol is an anabolic steroid; adverse effects include acne, hirsutism, amenorrhoea, oedema, headache, dyspepsia, rash, hair loss, depression, jaundice, and changes in liver enzymes. Tolerance of rutoside was reported to be good; adverse effects include headache, flushing, rashes, and mild gastrointestinal disturbances.[53]

Comment: None.

OPTION VEIN SURGERY

One RCT identified by a systematic review found insufficient evidence on the effects of vein surgery on ulcer recurrence.

Benefits: We found one systematic review (search date 1997, 1 RCT, 30 people).[52] The identified RCT, which was poorly controlled, compared surgery plus compression hosiery versus compression hosiery alone for prevention of recurrence. It found a reduced rate of recurrence when surgery was carried out in addition to the use of compression hosiery (5% *v* 24%; RR 0.21, 95% CI 0.03 to 0.80).

Harms: Vein surgery has the usual risks of surgery and anaesthesia.

Comment: The results of the RCT should be interpreted with caution because it was small and poorly controlled.[52] The RCT randomised legs rather than people.

GLOSSARY

Cultured allogenic bilayer skin replacement Also called human skin equivalent. This is made of a lower (dermal) layer of bovine collagen containing living human dermal fibroblasts and an upper (epidermal) layer of living human keratinocytes.

Elastomeric multilayer high compression bandages Usually a layer of padding material followed by one to three additional layers of elastomeric bandages.

Intermittent pneumatic compression External compression applied by inflatable leggings or boots either over, or instead of, compression hosiery or bandages. A pump successively inflates and deflates the boots to promote the return of blood from the tissues. Newer systems have separate compartments in the boots so that the foot is inflated before the ankle, which is inflated before the calf.

Iontophoresis The delivery of an ionic substance by application of an electrical current.

Low level laser treatment Application of treatment energy (< 10 J/cm^2) using lasers of 50 mW or less.

Short stretch bandages Minimally extensible bandages usually made of cotton with few or no elastomeric fibres. They are applied at near full extension to form a semi-rigid bandage.

Therapeutic ultrasound Application of ultrasound to a wound, using a transducer and a water based gel. Prolonged application can lead to heating of the tissues but, when used in wound healing, the power used is low and the transducer is constantly moved by the therapist so that the tissue is not significantly heated.

Topical negative pressure Negative pressure (suction) applied to a wound through an open cell dressing (e.g. foam, felt).

Unna's boot An inner layer of zinc oxide impregnated bandage, which hardens as it dries to form a semi-rigid layer against which the calf muscle can contract. It is usually covered in an elastomeric bandage.

Competing interests: EAN has been reimbursed for attending symposia by Smith and Nephew, Huntleigh Healthcare Ltd, Convatec, and Johnson & Johnson. EAN and NC are applicants on a RCT of compression bandages for which Beiersdorf UK Ltd provided RCT related education. JJ has been reimbursed for attending symposia by 3M.

TABLE 1 **NNTs for healing of leg ulcers (see text, p 2578).**

Intervention	NNT (95% CI)
Elastomeric multilayer compression *v* non-elastomeric multilayer compression bandages	5 (3 to 12)[5]
Multilayer high compression *v* single layer compression bandages	6 (4 to 18)[5]
Pentoxifylline 400 mg three times a day *v* placebo (concurrent use of compression)	6 (4 to 14)[31]
Peri-ulcer injection of GM–CSF (400 μg) *v* placebo	2 (1 to 17)[36]
Cultured allogenic bilayer skin equivalent *v* non-adherent dressing	7 (4 to 41)[17]
Sulodexide plus compression *v* compression alone	4 (3 to 9)[37,38]

GM–CSF, granulocyte–macrophage colony stimulating factor.
