Benefits: We found no systematic review. We found one RCT (881 people [83% women] with Rome I [see table 2, p 624] irritable bowel syndrome [IBS]), which compared tegaserod 2 or 6 mg twice daily versus placebo.[34] Participants also had at least two of the following symptoms for at least 25% of the time during the 3 months before recruitment: less than three bowel movements a week, hard or lumpy stools, or straining. People with diarrhoea (loose or watery stools or more than 3 urgent bowel movements a day on 25% of days) were excluded. The RCT found that tegaserod significantly increased global response rate (see comment below) compared with placebo after 12 weeks of treatment (AR 38.8% with lower dose tegaserod *v* 38.4% with higher dose tegaserod *v* 30.2% with placebo; ARI with higher dose tegaserod *v* placebo 8.2%, 95% CI 0.5% to 16.2%; ARI for lower dose tegaserod *v* placebo 8.6%, 95% CI 1.6% to 16.5%).

Harms: In the RCT, tegaserod precipitated diarrhoea more frequently than placebo (AR for diarrhoea: 9.6% with higher dose tegaserod *v* 7.1% with lower dose tegaserod *v* 2.5% with placebo; significance not reported). Withdrawal because of diarrhoea occurred in 2.0% with lower dose tegaserod *v* 2.5% with higher dose tegaserod *v* 0% with placebo; significance not reported).[34] The RCT reported no serious drug related adverse events and there were no cases of ischaemic colitis.

Comment: In the RCT, people completed a self reported global assessment of relief. Global response was defined as "considerable" or "complete" relief on at least 50% of assessments, or when 100% of assessments reported the person was at least "somewhat relieved".[34] Those who took concomitant laxatives or who did not complete 28 days of treatment were considered non-responders.

OPTION 5HT$_3$ RECEPTOR ANTAGONISTS

RCTs have found that alosetron improves symptoms in women with diarrhoea predominant or alternating irritable bowel syndrome compared with placebo. However, it is associated with adverse effects, particularly constipation, and has been restricted in some countries because of concerns that it may be associated with ischaemic colitis. We found no RCTs examining other 5HT$_3$ receptor antagonists.

Benefits: We found no systemtic review. **Alosetron:** We found six RCTs assessing effectiveness of alosetron.[35–40] The first RCT (623 women with non-constipating irritable bowel syndrome [IBS]) compared 12 weeks of alosetron 1 mg twice daily (plus a placebo to maintain blinding) versus mebeverine hydrochloride 135 mg three times daily.[35] It found that alosetron significantly improved clinical response (defined as self reported "adequate" relief of pain and

discomfort for at least 2 weeks a month) compared with mebeverine at 2 and 3 months (at 2 months: AR for response 56% with alosetron *v* 43% with mebeverine; P = 0.001; at 3 months: AR 58% with alosetron *v* 48% with mebeverine; P = 0.009; no further data reported). The second RCT (370 people with Rome I (see table 2, p 624) diarrhoea predominant or alternating diarrhoea–constipation predominant IBS) compared 12 weeks of alosetron 1, 2, 4, or 8 mg twice daily versus placebo.[36] Planned subgroup analysis in men found no significant difference in response defined as self report of "adequate" relief for at least 6 weeks (AR for response 55% with 8 mg alosetron *v* 53% with 4 mg alosetron *v* 63% with 2 mg alosetron *v* 20% with 1 mg alosetron *v* 50% with placebo; all twice daily; P > 0.05 for each treatment group compared with placebo). However, planned subgroup analysis in women found that alosetron (1 or 2 mg) significantly improved clinical response compared with placebo (AR for response 59% with 2 mg alosetron twice daily *v* 33% with placebo; ARI 26.0%, 95% CI 18.5% to 33.5%; AR 60% with 1 mg alosetron twice daily *v* 33% with placebo; ARI 26.0%, 95% CI 20.5% to 31.5%). The third RCT (647 women with diarrhoea predominant or alternating diarrhoea–constipation IBS) compared alosetron 1 mg twice daily versus placebo for 12 weeks with follow up for a further 4 weeks.[37] The primary end point, defined prospectively, was "adequate" relief of IBS pain and discomfort for at least 2 weeks a month. It found that alosetron significantly improved symptoms for all 3 months of treatment compared with placebo (AR for adequate relief 41% with alosetron *v* 29% with placebo; ARI 12.0%, 95% CI 4.7% to 19.2%). The fourth RCT (626 women with Rome I diarrhoea predominant or alternating IBS) compared 12 weeks of alosetron 1 mg twice daily versus placebo.[38] The prospectively defined primary end point was "adequate" relief of IBS pain and discomfort for at least 2 weeks a month. It found that alosetron significantly improved symptoms for all 3 months of treatment compared with placebo (AR for adequate relief 41% with alosetron *v* 26% for placebo; ARI 15.0%, 95% CI 7.8% to 22.5%). The fifth RCT (801 non-constipated women with Rome I IBS; 98% diarrhoea predominant) randomised people to alosetron 1 mg twice daily or placebo in a 2 : 1 ratio.[39] The RCT found that alosetron controlled urgency significantly more than placebo over 12 weeks (proportion of days with satisfactorily controlled urgency 73% with alosetron *v* 57% with placebo; P < 0.001). The sixth RCT (462 people with Rome I IBS; people with severe constipation excluded) compared alosetron (0.1, 0.5, or 2.0 mg twice daily) versus placebo for 12 weeks.[40] It found no significant difference in pain free days between any dose of alosetron and placebo over weeks 9–12 (difference in mean percentage of pain free days with 0.1 mg alosetron twice daily *v* placebo +9.2%, 95% CI –1.5% to +19.8%; 0.5 mg alosetron twice daily *v* placebo +1.1%, 95% CI –9.7% to +12.0%; 2 mg alosetron twice daily *v* placebo +9.1%, 95% CI –1.1% to +19.4%). **Other $5HT_3$ receptor antagonists:** We found no RCTs of sufficient quality.

Harms: Alosetron has been restricted in some countries because of concerns that it may be associated with ischaemic colitis. The first RCT found no significant difference in the risk of adverse events

(69% with alosetron *v* 64% with mebeverine; P = 0.23).[35] Constipation was the most common adverse event (22% with alosetron *v* 3% with mebeverine; P value not reported). One person in the alosetron group developed colitis and another developed gastritis; no one in the mebeverine group developed either colitis or gastritis.[35] Among women, the second RCT found that constipation was more common with alosetron compared with placebo (23% with alosetron 1 mg *v* 28% with alosetron 2 mg *v* 20% with alosetron 4 mg *v* 35% with alosetron 8 mg *v* 3% with placebo; all twice daily; P values not reported).[36] Constipation was the most common reason for stopping alosetron. The third RCT found that constipation was the most common adverse event with alosetron (AR 30% with alosetron *v* 3% with placebo; P value not reported).[37] Withdrawal because of constipation was more common with alosetron than placebo (10.2% with alosetron *v* 0.3% with placebo; P < 0.001). One possible case of ischaemic colitis was reported with alosetron.[37] The fourth RCT found that adverse events and withdrawal because of adverse effects were more common with alosetron than placebo (adverse effects 38% with alosetron *v* 20% with placebo; P < 0.001; withdrawal because of adverse effects 16% with alosetron *v* 7% with placebo; P value not reported).[38] Constipation was the most common adverse event (25% with alosetron *v* 5% with placebo; P value not reported). No other drug related adverse events occurred with a frequency greater than 5% and adverse event profiles were otherwise similar. There were no serious drug related events. The fifth RCT found that adverse events, of which constipation was the most frequent, were more common with alosetron than placebo (any adverse event: 77% with alosetron *v* 66% with placebo; constipation: 39% with alosetron *v* 14% with placebo; withdrawal because of adverse events: 10% with alosetron *v* 6% with placebo; P values not reported).[39] The sixth RCT found that the risk of adverse events was similar among all treatment groups (49–56% with 0.1–2.0 mg alosetron twice daily *v* 51% with placebo).[40] However, constipation was more common with higher doses of alosetron than with placebo (4% with 0.1 mg alosetron *v* 13% with 0.2 mg alosetron *v* 17% with alosetron 2.0 mg *v* 3% with placebo; all twice daily). We found one further RCT (859 people with Rome I diarrhoea predominant or alternating IBS; 3 : 1 randomisation in favour of alosetron), that only assessed the safety and tolerability of alosetron 1 mg twice daily versus placebo for 48 weeks, not the efficacy.[41] Drug related adverse events were those judged by the investigator to be caused by the trial medication, a serious adverse event was defined as one that was life-threatening, disabling or incapacitating, requiring or prolonging hospital admission, or fatal. It found that adverse events, particularly constipation, were more common with alosetron than placebo (AR for all adverse events: 83% with alosetron *v* 76% with placebo; P < 0.05; AR for constipation 32% with alosetron *v* 5% with placebo; P < 0.001). Apart from gastrointestinal events, the nature and incidence of adverse events was similar with alosetron and placebo (AR for any gastrointestinal adverse event 57% with alosetron *v* 36% with placebo; P < 0.001). Fatal, life-threatening, or incapacitating

adverse events were reported in 4% of people with alosetron *v* 5% of people with placebo (P value not reported). Two people taking alosetron died because of cardiac problems during the study, although the deaths were not judged to be drug related.[41]

Comment: None.

OPTION FIBRE SUPPLEMENTATION

Limited evidence from small RCTs suggests that fibre supplementation does not improve symptoms compared with placebo.

Benefits: We found no systematic reviews focusing specifically on fibre supplementation in people with irritable bowel syndrome (IBS). We found eight RCTs comparing fibre supplementation versus placebo in people with IBS. Two trials were of ispaghula husk in doses up to 30 g daily. The first of these (20 people, crossover design) found no significant difference in global improvement between ispaghula husk 30 g daily versus placebo at 4 weeks (OR of 2.25, 95% CI 0.20 to 28.67).[42] The second RCT compared ispaghula versus placebo within a factorial design that also examined effects of an anxiolytic and an antispasmodic drug.[43] Among 24 people randomised to ispaghula alone or placebo, ispaghula significantly improved symptoms compared with placebo over 12 weeks (AR for global improvement 5/12 [42%] with ispaghula *v* 0/12 with placebo [0%]; P = 0.01). The third RCT (80 people) found no significant difference in global symptoms between ispaghula 6 or 30 g daily and placebo (OR for global improvement 1.54, 95% CI 0.53 to 4.47).[44] Five RCTs examined dietary fibre supplements at doses of 4.1–39.0 g daily. One of these RCTs (26 people) found that fibre supplements significantly reduced frequency (P < 0.05) and severity (P < 0.01) of abdominal pain compared with normal diet (global symptom scores not reported).[45] The remaining four RCTs (3 parallel group RCTs of 49, 59, and 57 people and one crossover RCT of 80 people) found no significant difference between fibre supplements and placebo in global assessments of symptoms at 12, 6, 4, and 7 weeks.[46–49]

Harms: The studies did not report on harms.

Comment: None.

Competing interests: The authors have advised several pharmaceutical companies on the development of therapies for irritable bowel syndrome. GR has been reimbursed by Novartis for attending conferences and has received research funding from them. GR has shares in GlaxoSmithKline.

TABLE 1 **Manning criteria.**

Recurrent abdominal pain and two or more of the following:
- Relief of pain with defecation
- More frequent stools at the onset of pain
- Looser stools at the onset of pain
- Visible abdominal distension
- Passage of mucus per rectum
- A sensation of incomplete evacuation

TABLE 2 **Rome I criteria.**

Abdominal pain or discomfort that is one or more of the following:
- Relieved with defecation
- Associated with a change in frequency of stool
- Associated with a change in consistency of stool

Plus two or more of the following for at least 25% of occasions or days:
- Altered stool frequency
- Altered stool form
- Passage of mucus
- Bloating or a feeling of abdominal distension

TABLE 3 **Rome II criteria.**

At least 12 weeks (which need not be consecutive) in the preceding 12 months of abdominal discomfort or pain that has 2 of 3 features:
- Relieved by defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

The following cumulatively support the diagnosis of IBS:
- Abnormal stool frequency (> 3 daily or < 3 weekly)
- Abnormal stool form (lumpy/hard or loose/watery)
- Abnormal stool passage (straining, urgency, feeling of incomplete evacuation)
- Passage of mucus
- Bloating or feeling of abdominal distension

Pancreatic cancer

QUESTIONS

INTERVENTIONS

*RCTs comparing surgery versus no surgery may be considered unethical in people with pancreatic cancer that is considered suitable for complete tumour resection

See glossary, p 632

Key Messages

Surgical treatments in people with resectable pancreatic cancer

- **Pancreaticoduodenectomy (Whipple's procedure)** We found no RCTs comparing pancreaticoduodenectomy (Whipple's procedure) with non-surgical treatment in people with resectable pancreatic cancer, although such studies may be considered unethical. Observational data provide limited evidence that surgery may reduce mortality compared with non-surgical treatment, although results may be confounded by differences in disease stage. Small RCTs found no significant difference in quality of life or survival at 5 years between pancreaticoduodenectomy and pylorus preserving pancreaticoduodenectomy.

- **Pylorus preserving pancreaticoduodenectomy (compared with Whipple's procedure)** Small RCTs found no significant difference between pylorus preserving surgery and classical pancreaticoduodenectomy (Whipple's procedure) for overall quality of life at 1 year or survival at 5 years in people with resectable tumours. However, the studies may have lacked power to exclude clinically important differences for these outcomes.

Adjuvant treatments in people with completely resected pancreatic cancer

- **Systemic fluorouracil based chemotherapy** One RCT has found that adjuvant fluorouracil based chemotherapy improves median survival by about 1 year compared with no adjuvant chemotherapy in people with resected pancreatic cancer. However, this RCT and a second RCT found no significant difference in 5 year survival. The second RCT found that adjuvant fluorouracil based chemotherapy increased ≥ Grade 2 leukopenia, anorexia, and nausea or emesis compared with no chemotherapy. A third RCT did not compare chemotherapy alone with no chemotherapy directly.
- **Systemic gemcitabine based chemotherapy** One systematic review found insufficient evidence about effects of adjuvant gemcitabine compared with no adjuvant chemotherapy in people with resected pancreatic cancer.

DEFINITION

In this chapter, the term "pancreatic cancer" refers to primary adenocarcinoma of the pancreas. Other pancreatic malignancies, such as carcinoid tumour, are not considered. Symptoms of pancreatic cancer include pain, jaundice, nausea, weight loss, loss of appetite, and symptoms of gastrointestinal obstruction and diabetes. Pancreatic cancer is staged from I to IV according to disease spread. Stage I disease is limited to the pancreas, duodenum, bile duct, or peri-pancreatic tissues, with no distant metastases or regional lymph node involvement. Stages II–IV describe disease that has spread more extensively or become metastatic. A pancreatic tumour is considered resectable if there is a possibility that surgery could remove all cancerous tissue completely. Early stage tumours in the tail or body of the pancreas are more likely to be resectable than the more common, later stage cancers in the head of the pancreas. Other factors that influence resectability include proximity of the tumour to major blood vessels and perceived peri-operative risk.

INCIDENCE/ PREVALENCE

Pancreatic cancer is the eighth most common cancer in the UK with an annual incidence in England and Wales of about 12/100 000.[1] It is the fourth most common cause of cancer death in higher income countries, responsible for about 30 000 deaths each year in the USA.[2] Prevalence is similar in men and women, with 5–10% presenting with resectable disease.[3]

AETIOLOGY/ RISK FACTORS

Pancreatic cancer is more likely in people who smoke and have high alcohol intake. Dietary factors, such as lack of fruit and vegetables, are also reported risk factors.[4] One meta-analysis of observational studies found that people with diabetes mellitus of more than 5 years' duration are more likely to develop pancreatic cancer compared with the general population.[5] However, estimates of the magnitude of increased risk vary. Additional risk factors include pancreatitis and, in some cases, a family history.[1]

Pancreatic cancer

PROGNOSIS Prognosis is poor. One year survival is about 12%, with 5 year survival ranging from less than 1% in those with advanced cancer at presentation to 5% in those with early stage cancer at presentation.[1,6]

AIMS OF INTERVENTION In early stage (resectable) pancreatic cancer: to improve survival and quality of life. In advanced pancreatic cancer: treatment aims to improve symptoms and quality of life.

OUTCOMES One and 5 year survival; quality of life; symptoms; and adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal May 2003

QUESTION **What are the effects of surgical treatments in people with pancreatic cancer that is considered suitable for complete tumour resection?**

OPTION PANCREATICODUODENECTOMY (WHIPPLE'S PROCEDURE)

We found no RCTs comparing pancreaticoduodenectomy (Whipple's procedure; see glossary, p 632) versus non-surgical treatment in people with resectable pancreatic cancer, although such studies may be considered unethical. Observational data provide limited evidence that surgery may reduce mortality compared with non-surgical treatment, although results may have been confounded by differences in disease stage. Small RCTs found no significant difference in quality of life or survival at 5 years between pancreaticoduodenectomy and pylorus preserving pancreaticoduodenectomy.

Benefits: **Versus non-surgical treatment:** We found no RCTs in people with resectable (early stage) pancreatic cancer (see comment below). **Versus pylorus preserving pancreaticoduodenectomy:** See benefits of pylorus preserving pancreaticoduodenectomy, p 629.

Harms: We found no RCTs.

Comment: RCTs comparing surgery versus non-surgical treatment would be considered unethical in people with tumours that are considered suitable for resection. One large cohort study (100 313 people with pancreatic cancer) found that people having pancreatectomy lived longer than people not treated surgically (5 year survival, 23% with surgery *v* 5% without surgery).[7] However, results may have been confounded by differences in disease stage between those having surgery and those treated without surgery.

OPTION PYLORUS PRESERVING PANCREATICODUODENECTOMY

Small RCTs found no significant difference between pylorus preserving pancreaticoduodenectomy and standard pancreaticoduodenectomy (Whipple's procedure) for overall quality of life at 1 year, survival at 5 years, or adverse events in people with resectable tumours. However, the studies may have lacked power to exclude clinically important differences for these outcomes.

Benefits:

Versus standard pancreaticoduodenectomy (Whipple's procedure): We found one systematic review (search date 2000, 2 RCTs, 108 people with pancreatic cancer)[9] and two additional RCTs.[10,11] The systematic review compared standard pancreaticoduodenectomy (Whipple's procedure [see glossary, p 632]) versus pylorus preserving pancreaticoduodenectomy.[9] The first small RCT identified by the review (38 people with resectable head of pancreas or peri-ampullary cancer) did not report on cancer recurrence, quality of life, or survival.[8] The second RCT identified by the review (77 people with head of pancreas or peri-ampullary cancer) found no significant difference between techniques after a median follow up of 1.1 years (61 people included in analysis; median survival: 24 months with pylorus preserving surgery *v* 16 months with Whipple's procedure; $P = 0.29$).[12] The first additional RCT (48 people with resectable head of pancreas or peri-ampullary cancer) found no significant difference between pylorus preserving surgery and Whipple's procedure for global quality of life scores at 2–60 weeks (quality of life measured by 100 point EORTC-QLQ-30 score; results presented graphically, score in both groups about 50 preoperatively and 35 at 60 weeks; $P > 0.05$).[10] The second additional RCT (40 people with head of pancreas or peri-ampullary cancer) found no significant difference between procedures for 5 year survival (20% with pylorus preserving surgery *v* 13% with Whipple's procedure). However, the study may have lacked power to exclude a clinically important difference.[11]

Harms:

The first RCT identified by the review found no significant difference in peri-operative blood loss between pylorus preserving surgery and Whipple's procedure (mean blood loss 451 mL with pylorus preserving surgery *v* 687 mL with Whipple's procedure; $P > 0.2$; CI for difference not reported).[8] It also found no significant differences between treatments for peri-operative death (1 person with pylorus preserving surgery *v* 0 with Whipple's procedure), biliary leak (0 in both groups); pancreatitis (1 in both groups), wound infection (1 in both groups), cardiovascular events (0 with pylorus preserving surgery *v* 1 with Whipple's procedure), or upper gastrointestinal bleeding (0 with pylorus preserving surgery *v* 1 with Whipple's procedure). However, the RCT may have lacked power to exclude clinically important differences for these outcomes. Delayed gastric emptying was more common with pylorus preserving surgery (6 people with pylorus preserving surgery *v* 1 with Whipple's procedure).[8] The second RCT identified by the review found no significant differences between the techniques for delayed gastric emptying (32% with pylorus preserving surgery *v* 45% with Whipple's procedure), fistula (2% with pylorus preserving surgery *v* 3% with Whipple's procedure), wound infection (7% with pylorus preserving surgery *v* 8% with Whipple's procedure), or peri-operative mortality (2.7% with pylorus preserving surgery *v* 5% with Whipple's procedure).[12] The first additional RCT also found that complication rates were similar in both groups (wound infection: 3 people with pylorus preserving surgery *v* 4 people with Whipple's procedure; pneumonia: 2 people with pylorus preserving surgery *v* 3 people with Whipple's procedure; peritonitis 1 person in both groups; and sepsis 0 people with pylorus preserving surgery *v* 2 people with

Whipple's procedure).[10] The second additional RCT reported similar complications and frequencies to the other trials. Differences between procedures were not significant for any of these complications except gastric atony (6 people with pylorus preserving surgery *v* 1 person with Whipple's procedure; $P < 0.05$).[11]

Comment: The RCTs may have lacked power to detect clinically important differences between procedures.

QUESTION What are the effects of adjuvant treatments in people with completely resected pancreatic cancer?

OPTION ADJUVANT SYSTEMIC GEMCITABINE BASED CHEMOTHERAPY

One systematic review found insufficient evidence about the effects of adjuvant gemcitabine compared with no adjuvant chemotherapy in people with resected pancreatic cancer.

Benefits: **Versus no adjuvant chemotherapy:** We found one systematic review examining the effects of gemcitabine based chemotherapy in people with resected pancreatic cancer (search date 2000).[1] It identified no RCTs comparing adjuvant gemcitabine versus no adjuvant chemotherapy or placebo (see comment below).

Harms: The systematic review identified two studies that assessed harms of gemcitabine from both controlled and uncontrolled clinical trials.[1] Both studies included people with non-pancreatic tumours. The studies found that gemcitabine was associated with the following grade 3–4 toxicities: anaemia (about 7%), leukopenia (about 9%), neutropenia (about 25%), and thrombocytopenia (5–7%).

Comment: This option excludes adjuvant gemcitabine combined with radiotherapy or immunotherapy, which will be covered in future updates.

OPTION ADJUVANT SYSTEMIC FLUOROURACIL BASED CHEMOTHERAPY

One small multicentre RCT has found that adjuvant fluorouracil based chemotherapy improved median survival from about 1 year to about 2 years compared with no adjuvant chemotherapy in people with resected pancreatic cancer. However, this RCT and a second RCT found no significant difference in 5 year survival between adjuvant chemotherapy with fluorouracil based chemotherapy and no chemotherapy. The RCTs found that chemotherapy was commonly associated with adverse events such as leukopenia, nausea and vomiting, alopecia, and anorexia.

Benefits: **Versus no adjuvant chemotherapy:** We found three RCTs assessing effects of fluorouracil based chemotherapy after successful surgical resection (see glossary, p 632).[13–15] The first RCT (multicentre trial in 61 people: 47 with resected pancreatic cancer and 14 with carcinoma of the papilla of Vater) compared chemotherapy (6 cycles of fluorouracil 500 mg/m^2, doxorubicin 40 mg/m^2, and mitomycin C 6 mg/m^2 once every 3 weeks) versus no adjuvant chemotherapy. It found that chemotherapy significantly improved median survival compared with no adjuvant treatment (intention to

treat analysis: median survival 23 months with chemotherapy *v* 11 months without chemotherapy; P = 0.04). However, there was no difference for 5 year survival (4% with chemotherapy *v* 8% without chemotherapy; P = 0.10; CI not reported). The study may have lacked power to detect clinically important differences in 5 year survival.[13] The second RCT (508 people with pancreaticobiliary cancer including 92 people with pancreatic cancer, 72 people with bile duct cancer, and 41 people with ampulla of Vater cancer who had had successful surgical resection) compared adjuvant chemotherapy (mitomycin C plus 5-fluorouracil) versus no chemotherapy.[14] Chemotherapy consisted of two 5 day courses of intravenous chemotherapy with mitomycin C 6 mg/m^2 and 5-fluorouracil 310 mg/m^2, followed by oral 5-fluorouracil 100 mg/m^2 daily from 5 weeks postoperatively until disease recurrence. People with pancreatic cancer had had different surgical techniques. Subgroup analysis in people with pancreatic cancer found no significant difference in 5 year survival between adjuvant chemotherapy and no adjuvant chemotherapy (median survival: 17.8% with chemotherapy *v* 26.6% with no chemotherapy, P = 0.45). The third RCT (541 people with resected pancreatic cancer) compared four adjuvant strategies: chemotherapy (425 mg/m^2 fluorouracil plus folinic acid 20 mg/m^2), chemoradiotherapy, chemoradiotherapy plus the chemotherapy regimen, and observation only. It did not report results for adjuvant chemotherapy alone compared with no adjuvant chemotherapy (see comment below).[15]

Harms: The first RCT reported that one person died of chemotherapy associated sepsis.[13] Other adverse effects of chemotherapy included non-fatal sepsis (4 people), alopecia (11 people), leukopenia less than 2.5 x 10^9/L white cells (occurred 5 times overall), cardiotoxicity (2 people), and nephrotoxicity (2 people). After 3 months, four people experienced nausea and vomiting with chemotherapy compared with none in the control group. The second RCT (508 people with resected pancreaticobiliary cancer) found that chemotherapy significantly increased leukopenia, anorexia, and nausea or vomiting compared with no chemotherapy (grade ≥ 2 leukopenia: 12.9% with chemotherapy *v* 3% with no chemotherapy; grade ≥ 2 anorexia: 22.4% with chemotherapy *v* 13.9% with no chemotherapy; grade ≥ 2 nausea/vomiting: 12.9% with chemotherapy *v* 6.9% with no chemotherapy, P < 0.05 for each comparison).

Comment: This option excludes adjuvant fluorouracil combined with radiotherapy or immunotherapy, which will be covered in future updates. The first RCT included only people under 75 years old with high performance status (Karnofsky score > 60).[13] Six of 30 people allocated to chemotherapy received no chemotherapy and 17 did not complete all six cycles of treatment. The third RCT found that chemoradiotherapy significantly improved survival compared with no chemoradiotherapy (median survival: 19.7 months with chemoradiotherapy *v* 14.0 months with no chemoradiotherapy; HR 0.66, 95% CI 0.52 to 0.83).[15] It was not possible from this analysis to establish whether effects were due to chemotherapy or concomitant radiotherapy.

Pancreatic cancer

GLOSSARY

Successful surgical resection Surgery is defined as successful if, after resection, no residual disease is observed macroscopically or histologically in the tumour resection margins.

Whipple's procedure Radical pancreaticoduodenectomy involving removal of the pancreas, duodenum, and gastric pylorus.

Substantive changes

Pylorus preserving surgery One systematic review added;[9] conclusions unchanged.

Adjuvant systemic fluorouracil based chemotherapy One RCT added;[14] intervention recategorised from Likely to be beneficial to Trade off between benefits and harms.

*Observational evidence only; RCTs unlikely to be conducted.

See glossary, p 641

Key Messages

- **Complete surgical resection** RCTs of complete surgical resection are unlikely to be conducted. Observational studies and multivariate analysis of RCTs have found a strong association between survival and complete resection of the primary tumour.
- **Subtotal gastrectomy (as effective as total gastrectomy) for resectable distal tumours** RCTs in people with primary tumours in the distal stomach have found no significant difference with total versus subtotal gastrectomy in 5 year survival or postoperative mortality.
- **Adjuvant chemotherapy** Systematic reviews and subsequent RCTs have found conflicting evidence that adjuvant chemotherapy increases survival compared with surgery alone. Two RCTs found that adjuvant chemotherapy increased postoperative complications. The size of any benefit remains uncertain, and many recent adjuvant chemotherapy regimens have not been evaluated fully in RCTs.
- **Radical versus conservative lymphadenectomy** Two large RCTs found no significant difference in 5 year survival rates between radical and conservative lymphadenectomy. However, confounding factors may have affected reliability of results, and we found conflicting data from subgroup analyses of prospective cohort studies.

Stomach cancer

- **Removal of adjacent organs** One RCT found no significant difference between radical gastrectomy plus splenectomy and radical gastrectomy alone in 5 year survival rates or postoperative mortality. The RCT found that radical gastrectomy plus splenectomy significantly increased the number of postoperative infections compared with radical gastrectomy alone. Retrospective analyses of observational studies and RCTs in people with stomach cancer found that removal of additional organs (spleen and distal pancreas) increased morbidity and mortality compared with no organ removal.

DEFINITION Stomach cancer is usually an adenocarcinoma arising in the stomach and includes tumours arising at or just below the gastro-oesophageal junction (type II and III junctional tumours). Tumours are staged according to degree of invasion and spread (see table 1, p 643). Only non-metastatic stomach cancers are considered in this topic.

INCIDENCE/ PREVALENCE The incidence of stomach cancer varies among countries and by sex (incidence per 100 000 population a year in Japanese men is about 80, Japanese women 30, British men 18, British women 10, white American men 11, white American women 7).[1] Incidence has declined dramatically in North America, Australia, and New Zealand since 1930, but the decline in Europe has been slower.[2] In the USA, stomach cancer remains relatively common among particular ethnic groups, especially Japanese–Americans and some Hispanic groups. The incidence of cancer of the proximal stomach and gastro-oesophageal junction is rising rapidly in many European populations and in North America.[3,4] The reasons for this are poorly understood.

AETIOLOGY/ RISK FACTORS Distal stomach cancer is strongly associated with lifelong infection with *Helicobacter pylori* and poor dietary intake of antioxidant vitamins (A, C, and E).[5,6] In Western Europe and North America, distal stomach cancer is associated with relative socioeconomic deprivation. Proximal stomach cancer is strongly associated with smoking (OR about 4),[7] and is probably associated with gastro-oesophageal reflux, obesity, high fat intake, and medium to high socioeconomic status.

PROGNOSIS Invasive stomach cancer (stages T2–T4) is fatal without surgery. Mean survival without treatment is less than 6 months from diagnosis.[8,9] Intramucosal or submucosal cancer (stage T1) may progress slowly to invasive cancer over several years.[10] In the USA, over 50% of people recently diagnosed with stomach cancer have regional lymph node metastasis or involvement of adjacent organs. The prognosis after macroscopically and microscopically complete resection (R0) is related strongly to disease stage (see glossary, p 641), particularly penetration of the serosa (stage T3) and lymph node involvement. Five year survival rates range from over 90% in intramucosal cancer to about 20% in people with stage T3N2 disease (see table 1, p 643). In Japan, the 5 year survival rate for people with advanced disease is reported to be about 50%, but the explanation for the difference remains unclear. Comparisons between Japanese and Western practice are confounded by factors such as age, fitness, and disease stage, as well as by tumour location, because many Western series include gastro-oesophageal junction adenocarcinoma with a much lower survival after surgery.

AIMS OF INTERVENTION To prevent progression; extend survival; and relieve symptoms, with minimal adverse effects.

OUTCOMES Survival; quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal January 2003. Hand searches of conference proceedings and consultations with experts were used to identify relevant studies. In many instances, we have separated trials and results from different geographical areas, because of differences in baseline risk and demographics, and possible differences in response to treatments. However, the meaning of terms to describe such populations, such as "Western" and "Asian", were not clearly defined in many identified studies.

QUESTION What are the effects of radical versus conservative surgical resection?

OPTION COMPLETE VERSUS INCOMPLETE TUMOUR RESECTION

Observational studies and multivariate analysis of RCTs have found a strong association between survival and complete excision of the primary tumour.

Benefits: We found no systematic review or RCTs directly comparing complete versus incomplete tumour resection or positive versus clear microscopic resection margins (see comment below). Multivariate risk factor analysis of RCTs and retrospective cohort studies found that failure to achieve microscopically clear resection margins was associated with a poor outcome independently of other indicators of tumour spread and behaviour.[11–13]

Harms: We found no systematic review or RCTs.

Comment: Current consensus is that improving long term survival is best achieved by complete resection of the primary tumour with microscopic confirmation of clear resection margins ("curative" gastrectomy). We found two observational studies of surgery versus no surgery.[8,9] They found that people who did not undergo resection (generally those with the most advanced disease and highest comorbidity) had a near zero 5 year survival in all case series, and mean survival without treatment from time of diagnosis was found to be less than 6 months. In view of this evidence it is unlikely that an RCT of surgery versus no surgery or complete versus incomplete tumour removal would be carried out. In people with similar stage weight loss and performance status, macroscopically incomplete tumour resection (palliative gastrectomy) was associated with twice the survival time of non-resection and with better quality of life owing to relief of tumour symptoms.[14]

OPTION TOTAL VERSUS SUBTOTAL GASTRECTOMY FOR RESECTABLE DISTAL TUMOURS

Two RCTs in people with primary tumours in the distal stomach found no significant difference in 5 year survival or postoperative mortality between total and subtotal gastrectomy.

Stomach cancer

Benefits: We found no systematic review, but found two RCTs (787 people) comparing total versus subtotal (see glossary, p 641) gastrectomy.[15–18] Neither RCT used blinded allocation. **Five year survival:** The first RCT (648 people aged < 76 years with a resectable tumour and a macroscopic proximal margin of more than 6 cm) compared total versus subtotal gastrectomy.[15,16] All people involved in the RCT had a regional lymphadenectomy (D2). The RCT found no significant difference in the incidence of microscopic resection margin involvement or in 5 year survival (microscopic resection margin involvement: 15/315 [4.8%] with subtotal gastrectomy *v* 6/303 [2.0%] with total gastrectomy; ARI +2.8%, 95% CI –0.1% to +9.6%; Kaplan–Meier 5 year survival estimates 65% for subtotal *v* 62% for total gastrectomy; HR 0.89, 95% CI 0.68 to 1.17). Multivariate analysis found that after adjustment for covariates, the type of stomach surgery had no significant effect on 5 year survival (HR 1.01, 95% CI 0.76 to 1.33). The second RCT (169 people with potentially curable distal stomach cancer) compared total versus subtotal gastrectomy and found no significant difference in 5 year survival (48% in each group; CI not reported).[17,18] **Nutritional function and quality of life:** These outcomes were better with distal subtotal gastrectomy versus total gastrectomy.[19–22]

Harms: **Postoperative morbidity:** Morbidity included intra-abdominal sepsis, chest infections, wound sepsis, and fistulae. The first RCT found no significant difference between subtotal and total gastrectomy in postoperative morbidity or length of hospital stay (postoperative morbidity: 29/320 [9%] with subtotal gastrectomy *v* 40/304 [13%] with total gastrectomy; RR 0.67, 95% CI 0.44 to 1.08; hospital stay: 13.8 days for subtotal *v* 15.4 days for total gastrectomy).[15,16] The second RCT also found no significant difference in postoperative morbidity (32/93 [34%] for subtotal gastrectomy *v* 25/76 [32%] for total gastrectomy; RR 1.05, 95% CI 0.68 to 1.60).[17,18] **Postoperative mortality:** The first RCT found no significant difference in postoperative mortality (4/320 [1%] with subtotal gastrectomy *v* 7/304 [2%] with total gastrectomy; RR 0.54, 95% CI 0.16 to 1.84). The second RCT also found no significant difference in postoperative mortality (3/93 [3.2%] with subtotal gastrectomy *v* 1/76 [1.3%] with total gastrectomy; RR 2.45, 95% CI 0.26 to 23.01). Nearly all non-randomised studies that we identified reported higher mortality with total gastrectomy versus subtotal gastrectomy, but total gastrectomy tended to be performed in people with more extensive disease.

Comment: Infiltration of the proximal resection margin by microscopic tumour deposits is perceived as a problem in people with poorly differentiated "diffuse" cancer of the distal stomach undergoing distal subtotal gastrectomy. Some surgeons have therefore recommended total gastrectomy "de principe" (see glossary, p 641) for these tumours. The two RCTs have found similar survival after total and subtotal gastrectomy in people with primary tumours in the distal stomach.[15–18] Both RCTs recruited otherwise fit people, which may explain the low postoperative mortality. The lack of any evidence of survival benefit, and the poorer nutritional and quality of life outcomes, argue against total gastrectomy where subtotal distal gastrectomy is technically possible with an adequate margin.

OPTION REMOVAL OF ADJACENT ORGANS

One RCT found no significant difference between radical gastrectomy plus splenectomy and radical gastrectomy alone in 5 year survival rates or postoperative mortality. The RCT found that radical gastrectomy plus splenectomy significantly increased the number of postoperative infections compared with radical gastrectomy alone. Retrospective analyses of observational studies and RCTs in people with stomach cancer found that removal of additional organs (spleen and distal pancreas) increased morbidity and mortality compared with no organ removal.

Benefits: We found no systematic review. We found one RCT (187 people, aged 25–80 years), which compared radical (D2) gastrectomy plus splenectomy versus radical gastrectomy alone.[23] It found no significant difference in 5 year survival rates (42% with gastrectomy plus splenectomy *v* 36% with gastrectomy alone; $P > 0.5$; absolute numbers not provided).

Harms: The RCT (187 people) found that gastrectomy plus splenectomy versus radical gastrectomy alone significantly increased the number of postoperative infections (including fever $> 38\,^{\circ}C$, $P < 0.04$; pulmonary infections, $P < 0.008$; subphrenic abscesses, $P < 0.05$), but found no significant difference in postoperative mortality (4/90 [4%] with gastrectomy plus splenectomy *v* 3/97 [3%] with gastrectomy alone; RR 1.40, 95% CI 0.33 to 6.24).[23] Retrospective analyses of RCTs and cohort studies in which removal of the spleen and distal pancreas had been performed routinely during radical total (see glossary, p 641) gastrectomy (D2) (see table 2, p 644), and at the surgeon's discretion during non-radical total gastrectomy (D1), found that removal of the spleen or distal pancreas was associated with increased perioperative mortality (OR about 2) and no evidence of improved long term survival.[24,25]

Comment: Some advocates of radical surgery have suggested routine removal of the spleen and distal pancreas to ensure complete regional lymph node dissection during total gastrectomy. Current consensus is that removal of adjacent organs is justified only when necessary to ensure complete tumour removal, or when required because of trauma during surgery. An RCT has started in Japan to evaluate the role of splenectomy in total gastrectomy for proximal gastric cancer.[26]

OPTION RADICAL VERSUS CONSERVATIVE LYMPHADENECTOMY

Two large RCTs found no significant difference in 5 year survival rates between radical and conservative lymphadenectomy. However, confounding factors may have affected the reliability of results, and we found conflicting data from subgroup analyses of prospective cohort studies.

Benefits: **Radical (D2, D3) versus conservative lymphadenectomy (D1):** We found no systematic review but found four RCTs comparing radical (regional and local) removal of perigastric lymph nodes (see glossary, p 641) versus conservative (local) removal of lymph

nodes.[27–30] The first RCT (711 people) found no significant difference in 5 year survival rates (45% with conservative lymphadenectomy *v* 47% with radical lymphadenectomy; ARR +2%, 95% CI −5.6% to +9.6%).[27] The second RCT (400 people) also found no significant difference in 5 year survival rates (35% with conservative lymphadenectomy *v* 33% with radical lymphadenectomy; HR 1.1, 95% CI 0.87 to 1.39).[28] The other two smaller RCTs (55 people[29] and 43 people[30]) did not report evaluable 5 year survival rates. Subgroup analysis from the second RCT found a possible advantage for D2 resection in people with stage II and IIIA disease (corresponding to T1N2M0, T2N1M0, T3N0M0, T2N2M0, T3N1M0, and T4N0M0), particularly in those people who did not have additional organ removal.[28] **Para-aortic (D4) versus regional and local (D3, D2) lymphadenectomy:** We found one small pilot study for an RCT (70 people with stomach cancer that had spread to the serosa or adjacent organs, T3 or T4) conducted in Japan, which compared removal of local, regional, and para-aortic lymph nodes with removal of only local and regional lymph nodes (see glossary, p 641).[31] This pilot study was too small to detect clinically important differences in survival.

Harms: The four RCTs comparing radical versus conservative lymphadenectomy found increased perioperative mortality with the more extensive operation.[27–30] The second RCT (400 people) found significantly higher mortality with D2 versus D1 resection (13% with D2 resection *v* 6% with D1 resection; $P < 0.04$).[28] In the first RCT (711 people), the difference in mortality nearly achieved significance (10% with D2 *v* 6% with D1; $P = 0.06$).[27] In both of these large RCTs the excess mortality may have been due to associated pancreatic and splenic removal, rather than the radical lymphadenectomy.[27,28]

Comment: The RCTs were conducted by surgeons with limited prior experience and training in D2 resection, and results may have been affected by both learning curve effects[32] and failure to apply the assigned treatment (contamination and non-compliance).[33] One large prospective cohort study (1654 people with gastric cancer) found no benefit from D2 resection (defined within this study as > 25 lymph nodes removed; 300 people) versus D1 resection (≤ 25 nodes removed; 1096 people) in the entire cohort of people with gastric cancer after 10 years' follow up. Subgroup analysis found that there may be a beneficial effect of D2 versus D1 resection in the subgroup of people with stage II tumours (230 people; RR of long term survival 1.8, 95% CI 1.3 to 2.7).[34] Cohort studies comparing radical versus conservative lymphadenectomy are affected by numerous biases, particularly selection bias, where surgeons reserve D2 surgery for younger or fitter people, or where recent D2 operations are compared with historical D1 controls; definition differences (in the meaning of "limited" and "extended"); and stage migration bias (see glossary, p 641). These biases make the interpretation of observational data difficult.

QUESTION What are the effects of adjuvant chemotherapy?

OPTION ADJUVANT CHEMOTHERAPY

Systematic reviews and subsequent RCTs have found conflicting evidence that adjuvant chemotherapy increases survival compared with surgery alone. Two RCTs found that adjuvant chemotherapy increased postoperative complications. The size of any benefit remains uncertain, and many recent adjuvant chemotherapy regimens have not been evaluated fully in RCTs.

Benefits:

Adjuvant chemotherapy versus surgery alone: We found four systematic reviews[35–38] and two subsequent RCTs,[39,40] which compared adjuvant chemotherapy (see glossary, p 641) versus surgery alone. The first review (search date 1991, 11 RCTs, 2096 people) found that adjuvant chemotherapy versus surgery alone reduced the risk of death by the end of follow up, but the result was not significant (OR 0.88, 95% CI 0.78 to 1.08).[35] This review was criticised for involving trials that included people with known residual tumour after surgery and trials that also included immunotherapy and intraperitoneal delivery of the adjuvant treatment. A subsequent update of the review found that adjuvant chemotherapy versus surgery alone significantly reduced the risk of death by the end of follow up (OR 0.82, 95% CI 0.68 to 0.97).[41] The second review (search date 1999, 13 RCTs, 1990 people in non-Asian countries) excluded trials of people with known residual tumour after surgery or that also included immunotherapy and intraperitoneal treatment.[36] The review found that adjuvant chemotherapy versus surgery alone significantly reduced the risk of death (595/979 [61%] with adjuvant chemotherapy *v* 660/1011 [65%] with surgery alone; RR 0.93, 95% CI 0.87 to 0.99; NNT 22, 95% CI 12 to 353). The third review (search date 2000, 20 RCTs, 3658 people; see comment below) included most of the RCTs from the first two reviews, but also included two subsequent RCTs.[37] It found that adjuvant chemotherapy versus surgery alone significantly reduced the risk of death (HR 0.82, 95% CI 0.75 to 0.89). The fourth systematic review (search date 1998, 60 RCTs plus 92 non-randomised studies; 12 367 people) found that adjuvant chemotherapy versus surgery alone significantly improved survival (21 RCTs, 3692 people; OR 0.84, 95% CI 0.74 to 0.96).[38] Subgroup analysis found that adjuvant chemotherapy versus surgery alone significantly improved survival in people from Asian countries (OR 0.58, 95% CI 0.44 to 0.76), but found no significant difference in people from Western countries (OR 0.96, 95% CI 0.83 to 1.12). The first subsequent RCT (137 people with gastric adenocarcinoma and positive lymph nodes) compared adjuvant chemotherapy versus surgery alone and found that adjuvant chemotherapy significantly increased median survival time (31 months, range 7 to > 60 months with adjuvant chemotherapy *v* 18 months, range 2 to > 60 months with surgery alone; $P < 0.01$; HR for death 1.96, 95% CI 1.32 to 2.92).[39] The second subsequent RCT (274 patients with gastric adenocarcinoma T3, T4 or N1, N2) found no significant difference between adjuvant chemotherapy and surgery alone in 5 year survival (overall survival: 52% with adjuvant chemotherapy *v*

48% with surgery alone; HR 0.93, 95% CI 0.65 to 1.34).[40]
Japanese RCTs: We found 10 Japanese RCTs comparing adjuvant chemotherapy versus surgery alone, most of which were included in the systematic reviews. One recent RCT (579 people after curative gastrectomy for early cancer, stage T1 or T2) compared adjuvant chemotherapy (mitomycin, fluorouracil, uracil, tegafur) versus surgery alone.[42] It found no significant difference in cancer related mortality after a median follow up of 72 months (47/288 [16%] with adjuvant chemotherapy *v* 59/291 [20%] with surgery alone; OR 0.77, 95% CI 0.50 to 1.17). A second recent RCT (435 people with stage II or III cancer) compared surgery plus intraperitoneal chemotherapy (using cisplatin alone) versus surgery plus intraperitoneal chemotherapy (using cisplatin plus tegafur-uracil, an orally administered derivative of 5-fluorouracil) and found no significant difference in 3 year survival rates or disease free survival rates.[43] A third recent RCT (139 people) compared three groups: surgery plus hyperthermic intraperitoneal chemotherapy; surgery plus normothermic intraperitoneal chemotherapy; and surgery alone.[44] It found that surgery plus hyperthermic chemotherapy (mitomycin C plus cisplatin at 42 °C) versus surgery alone significantly increased overall 5 year survival rates ($P = 0.01$; result presented graphically), and that surgery plus hyperthermic chemotherapy versus surgery plus normothermic chemotherapy (mitomycin C plus cisplatin at 37 °C) also significantly increased overall 5 year survival rates ($P = 0.05$; result presented graphically). Subgroup analysis found that these results were consistent for people with advanced disease (T3 or node positive), but in people with less advanced disease (T2 or node negative) found no significant difference in overall 5 year survival rates. Of the seven older RCTs published before 1985, only one found a significant benefit for chemotherapy.[45] This RCT (120 people) compared three groups: adjuvant chemotherapy with mitomycin alone versus adjuvant chemotherapy with mitomycin plus cytarabine plus fluorouracil versus surgery alone. It found that adjuvant chemotherapy with mitomycin plus cytarabine plus fluorouracil versus both other treatments significantly improved survival. The other six RCTs found no significant difference between adjuvant chemotherapy versus surgery alone in survival.

Harms: Two RCTs reported toxicity (mainly nausea and vomiting) in 53% of people.[46,47] Serious toxicity was usually because of cardiac or cumulative haematological problems; treatment related mortality was 1–2%. We found no definitive evidence from completed studies to justify the concern that preoperative chemotherapy increases postoperative morbidity or mortality. Two RCTs found significant increases in some types of postoperative complications after intraperitoneal chemotherapy (pain, intra-abdominal sepsis without anastamotic leak, bleeding, and fistula formation),[48,49] but a more recent RCT in people from Japan found no such increase.[44]

Comment: The four systematic reviews included several trials in common.[35–38] Only published trials were included. All included trials were reported in English. There was no evidence of publication bias. No statistical heterogeneity of effects was found by the first two systematic reviews, but random effects meta-analysis was used, which may give a conservative estimate of the treatment effect.[35,36] The third

systematic review is difficult to interpret.[37] Some of the results, included in the meta-analysis as if they were independent trials, seem to be duplicate versions of the same RCT.[50,51] This systematic review found significant heterogeneity between results of RCTs ($P = 0.028$), but a fixed effects model was used. These factors reduce confidence in the published estimate of effect. The significant effect observed by all four systematic reviews might indicate a small but real effect or alternatively the impact of undetected biases. It is also possible that certain subgroups of people may respond differently to other subgroups. Subgroup analysis in the second systematic review[36] suggested an effect only in RCTs in which at least two thirds of people had node positive disease, but the power was insufficient to draw definite conclusions and the result was not confirmed in the third systematic review.[37] Many more recent adjuvant chemotherapy regimens have not been evaluated fully in RCTs. Japanese adjuvant chemotherapy regimens often contain bacterial or fungal extracts. We found some evidence from one well designed RCT that addition of these substances to combined surgery and chemotherapy was associated with improved 5 year survival;[52] this will be reviewed in a future update. The analysis applied to only 19% of those randomised and may not be generalised to all people with inoperable gastric cancer. One further meta-analysis has been identified, which will be incorporated in this review at a subsequent update.[53] Preoperative superselective intra-arterial chemotherapy may not be available outside of specialist centres.

GLOSSARY

Adjuvant chemotherapy Treatment with cytotoxic drugs given in addition to surgery in an attempt to achieve cure.

Disease stage Surgical and microscopic assessment of the primary tumour. Microscopic spread to distant sites can be detected only by radical surgery, creating a potential bias.

Perigastric lymph nodes Lymph nodes that lie adjacent to the stomach.

Regional lymph nodes Lymph nodes that lie along the blood vessels that supply the stomach.

Stage migration bias Apparent increase in stage specific survival without influencing overall survival caused by recategorisation of the stage after removal of diseased lymph nodes.

Subtotal distal gastrectomy Removal of lower part (usually two thirds or four fifths) of the stomach.

Total gastrectomy Removal of the whole stomach.

Total gastrectomy "de principe" Total gastrectomy where it is not technically necessary to remove a distal tumour; this technique is used to minimise the risk of resection line involvement or later second cancer of the gastric stump.

TABLE 1 **Staging of stomach cancer (see text, p 634).**

Stage	Description
T1	Involvement of mucosa +/– submucosa
T2	Involvement of muscularis propria
T3	Involvement of serosa but no spread to adjacent organs
T4	Involvement of adjacent organs
N0	No lymph node involvement
N1	Local (perigastric) nodes involved
N2	Regional nodes involved
N3	More distant intra-abdominal nodes involved
M0	No metastases
M1	Metastases

Stomach cancer

TABLE 2 **Different types of surgical resection for stomach cancer (see text, p 637).**

Resection	Description
R0	Removal of all detectable tumour, with a margin of healthy tissue confirmed microscopically: synonymous with "curative" resection.
R1	Incomplete removal, with histological evidence of cancer at the resection margin.
R2	Incomplete removal, with macroscopically obvious remnants of the main tumour: synonymous with "palliative" resection.
D1	Removal of all or part of the stomach, together with local (perigastric) nodes.
D2	Removal of all or part of the stomach, together with local and regional nodes, which lie along the branches of the coeliac axis.
D3/D4	More radical lymph node resection, including removal of para-aortic nodes and nodes within the small bowel mesentery.

Chronic suppurative otitis media

Search date March 2003

QUESTIONS

INTERVENTIONS

Key Messages

- We found no RCTs with long term follow up.

Adults

- **Topical antibiotics** We found no RCTs with long term follow up. Two RCTs found limited evidence that topical quinolone antibiotics improved otoscopic appearances compared with placebo in adults with chronic suppurative otitis media. Six RCTs found no clear evidence of clinically important differences among topical antibiotics in adults. One systematic review found that topical antibiotics were more effective than systemic antibiotics for reducing otoscopic features of chronic suppurative otitis media. One RCT found no significant effect of adding topical ceftizoxime to systemic ceftizoxime compared with systemic ceftizoxime alone. One RCT found no significant effect of preoperative topical antibiotics compared with no preoperative treatment in people undergoing tympanoplasty. Short term topical antibiotics have been associated with few adverse events in RCTs. Uncontrolled case studies have reported vestibular ototoxicity after topical non-quinolone antibiotics.
- **Ear cleansing (aural toilet)** We found no RCTs comparing ear cleansing versus no treatment.

Chronic suppurative otitis media

- **Systemic antibiotics** We found insufficient evidence about the effects of systemic antibiotics compared with placebo, no treatment, or topical antiseptics. One systematic review found that systemic antibiotics were less effective than topical antibiotics in reducing otoscopic features of chronic suppurative otitis media. We found no evidence about long term treatment.
- **Topical antibiotics plus topical steroids** One systematic review found insufficient evidence from three RCTs about effects on symptoms of topical antibiotics plus topical steroids versus placebo or topical steroids alone.
- **Topical antiseptics** We found no RCTs comparing topical antiseptics versus placebo or no treatment. One RCT compared topical antiseptics plus ear cleansing under microscopic control versus topical antibiotics alone or versus oral antibiotics. It found no significant difference in the rate of persistent activity on otoscopy. However, the RCT was too small to exclude a clinically important difference.
- **Topical steroids** We found no RCTs comparing topical steroids versus placebo or no treatment.
- **Tympanoplasty with or without mastoidectomy** We found no RCTs comparing tympanoplasty with or without mastoidectomy versus no surgery for chronic suppurative otitis media without cholesteatoma.

Children

- **Ear cleansing** One systematic review found no significant difference in persistent otorrhoea or tympanic perforations with a simple form of ear cleansing versus no ear cleansing. However, a clinically important effect cannot be excluded.
- **Systemic antibiotics** RCTs found insufficient evidence about the effects of systemic antibiotics in children with chronic suppurative otitis media.
- **Topical antibiotics** We found no RCTs comparing topical antibiotics versus placebo.
- **Topical antibiotics plus topical steroids** We found insufficient evidence from small RCTs to compare topical antibiotics plus topical steroids versus cleansing only or topical antiseptics. We found no RCTs comparing topical antibiotics plus topical steroids versus either topical treatment alone.
- **Topical antiseptics** Two RCTs found no significant reduction in otorrhoea with topical antiseptics versus placebo after 2 weeks. One RCT found no significant difference in otorrhoea with topical antiseptics versus topical antibiotic plus steroid. However, the RCTs were too small to exclude a clinically important effect.
- **Topical steroids** We found no RCTs comparing topical steroids versus placebo.
- **Tympanoplasty with or without mastoidectomy** We found no RCTs comparing tympanoplasty with or without mastoidectomy versus no surgery for chronic suppurative otitis media without cholesteatoma.

DEFINITION Chronic suppurative otitis media is persistent inflammation of the middle ear or mastoid cavity. Synonyms include "chronic otitis media (without effusion)", chronic mastoiditis, and chronic tympanomastoiditis. Chronic suppurative otitis media is characterised by recurrent or persistent ear discharge (otorrhoea) over 2–6 weeks through a perforation of the tympanic membrane. Typical findings also include thickened granular middle ear mucosa, mucosal polyps, and cholesteatoma (see glossary, p 658) within the middle ear. Chronic suppurative otitis media is differentiated from chronic otitis media with effusion, in which there is an intact tympanic membrane

with fluid in the middle ear but no active infection. Chronic suppurative otitis media does not include chronic perforations of the eardrum that are dry, or only occasionally discharge, and have no signs of active infection.

INCIDENCE/ PREVALENCE The worldwide prevalence of chronic suppurative otitis media is 65–330 million people. Between 39–200 million (60%) suffer from clinically significant hearing impairment. Otitis media was estimated to have caused 28 000 deaths and loss of over 2 million Disability Adjusted Life Years (see glossary, p 658) in 2000,[1] 94% of which were in developing countries. Most of these deaths were probably due to chronic suppurative otitis media because acute otitis media is a self limiting infection. Estimates of prevalence are shown in table A on web extra.[2–32]

AETIOLOGY/ RISK FACTORS Chronic suppurative otitis media is assumed to be a complication of acute otitis media, but the risk factors for chronic suppurative otitis media are not clear. Frequent upper respiratory tract infections and poor socioeconomic conditions (overcrowded housing,[33] hygiene, and nutrition) may be related to the development of chronic suppurative otitis media.[34,35] Improvement of housing, hygiene, and nutrition in Maori children was associated with a halving of the prevalence of chronic suppurative otitis media between 1978 and 1987.[36] See also acute otitis media, p 314.

PROGNOSIS Most children with chronic suppurative otitis media have mild to moderate hearing impairment (about 26–60 dB increase in hearing thresholds) based on surveys among children in Africa, Brazil,[37] India,[38] and Sierra Leone,[39] and among the general population in Thailand.[40] In many developing countries, chronic suppurative otitis media represents the most frequent cause of moderate hearing loss (40–60 dB).[41] Persistent hearing loss during the first 2 years of life may increase learning disabilities and poor scholastic performance.[42] Spread of infection may lead to life threatening complications such as intracranial infections and acute mastoiditis.[43] The frequency of serious complications fell from 20% in 1938 to 2.5% in 1948 and is currently estimated to be about 0.24% in Thailand and 1.8% in Africa. This is believed to be associated with increased use of antibiotic treatment, tympanoplasty, and mastoidectomy (see glossary, p 658).[44–46] Cholesteatoma is another serious complication that has been found in a variable proportion of people with chronic suppurative otitis media (range 0–60%).[47–50] In the West, the incidence of cholesteatoma is low (in 1993 in Finland the age standardised incidence of cholesteatoma was eight new cases per 100 000 population/year).[51]

AIMS OF INTERVENTION To improve symptoms of otorrhoea; heal perforations; improve hearing; and reduce complications, with minimum adverse effects of treatment.

OUTCOMES **Dichotomous variables:** Proportion of people with otorrhoea measured subjectively or by otoscopy; with tympanic perforation; hearing loss; intra- and extracranial complications; death; or adverse effects. The correlation between subjective cessation of otorrhoea and otoscopic findings was poor in one RCT.[52] Many RCTs used compound outcomes (e.g. otoscopic finding of otorrhoea or otoscopic finding of inflammation in the middle ear). **Continuous**

variables: Duration of otorrhoea free periods; severity of hearing loss. "Otoscopic activity" refers to appearances on otoscopy such as active discharge from the middle ear and inflammation of the middle ear mucosa.

METHODS *Clinical Evidence* search and appraisal March 2003. We found one systematic review (search date 1996, 24 RCTs, 1660 people) of treatments for chronic suppurative otitis media.[53] It did not analyse results for children and adults separately. We have excluded all studies that included both adults (aged ≥ 16) and children (aged ≤ 10),[54–57] or which failed to specify the age of participants.[58,59] The RCTs varied in their definitions of chronic suppurative otitis media and measurements of severity. All RCTs were brief (7 days to 3 weeks). Most had inadequate methods for us to draw reliable conclusions (see main text for descriptions). Participants with cholesteatoma were excluded from most, but not all, trials. All trials excluded people with impending serious complications.

QUESTION What are the effects of treatments for chronic suppurative otitis media in adults?

OPTION EAR CLEANSING (AURAL TOILET)

We found no RCTs of ear cleansing versus no treatment in adults.

Benefits: We found one systematic review (search date 1996), which found no RCTs in adults comparing ear cleansing (see glossary, p 658) versus no treatment.[53]

Harms: We found no RCTs.

Comment: Techniques of ear cleansing vary considerably. In Western countries, microsuction of the external and middle ear under microscopic control by a trained operator is the standard method of ear cleansing. Microscopic examination of the ear with ear cleansing is an important aspect of diagnosis of persistent otorrhoea. RCTs comparing ear cleansing versus no treatment would probably be considered unethical.

OPTION TOPICAL ANTIBIOTICS

We found no RCTs with long term follow up. Two RCTs found limited evidence that topical quinolone antibiotics improved otoscopic appearances compared with placebo in adults with chronic suppurative otitis media. Six RCTs found no clear evidence of clinically important differences among topical antibiotics in adults. One systematic review found that topical antibiotics were more effective than systemic antibiotics for reducing otoscopic features of chronic suppurative otitis media. One RCT found no significant effect of adding topical ceftizoxime to systemic ceftizoxime compared with systemic ceftizoxime alone. One RCT found no significant effect of preoperative topical antibiotics compared with no preoperative treatment in people undergoing tympanoplasty. Short term topical antibiotics have been associated with few adverse events in RCTs. Uncontrolled case studies have reported vestibular ototoxicity after topical non-quinolone antibiotics.

Benefits: **Versus placebo:** We found no systematic review but found two small RCTs in adults.[60,61] Both RCTs found that quinolone topical antibiotics improved otorrhoea compared with placebo, but both RCTs had weak methods. The first RCT (50 adults with chronic suppurative otitis media but no cholesteatoma [see glossary, p 658] in a hospital clinic in Thailand) found that, after 7 days, topical ciprofloxacin in 0.9% sodium chloride (5 drops 0.25 g/L 3 times/day for 7 days) significantly reduced persistent signs on otoscopic examination compared with topical 0.9% sodium chloride (3/19 [16%] had persistent signs with ciprofloxacin *v* 14/16 [88%] with 0.9% sodium chloride solution; RR 0.18, 95% CI 0.06 to 0.52; NNT 2, 95% CI 2 to 3).[60] The RCT lasted only 7 days, had 30% loss to follow up (15/50), and did not clearly describe the methods of randomisation and allocation concealment. The second RCT (51 adults with chronic suppurative otitis media without cholesteatoma in a hospital clinic in Israel; 60 ears) compared 3 weeks' treatment with topical ciprofloxacin versus topical tobramycin versus a dilute antiseptic solution (1% aluminium acetate), which was used as a placebo.[61] It found that ciprofloxacin significantly reduced the proportion of people with unimproved otorrhoea compared with diluted aluminium acetate (4/19 [21%] with ciprofloxacin *v* 10/17 [59%] with diluted aluminium acetate; OR 0.21, 95% CI 0.06 to 0.80; NNT 3, 95% CI 2 to 18). The RCT found that tobramycin did not significantly reduce otorrhoea compared with control (5/18 [28%] with tobramycin *v* 10/17 [59%] with control; OR 0.29, 95% CI 0.08 to 1.09). This RCT randomised people to treatments, but presented results in terms of number of ears. The 1% aluminium acetate may not have been an inert control (see topical antiseptics, p 651). **Versus each other:** We found one systematic review (search date 1996,[53] 4 RCTs, 406 adults) and two subsequent RCTs (see table 1, p 662).[61,66] Three RCTs found no clear difference between the otoscopic response with a topical quinolone (ciprofloxacin) and that with topical non-quinolones (gentamicin, tobramycin, and polymyxin–neomycin–hydrocortisone). The three RCTs comparing different topical non-quinolone antibiotics found no significant difference in the proportion of people who still had a wet ear on otoscopy at the end of treatment (see table 1, p 662).[67–69] **Versus systemic antibiotics:** See benefits of systemic antibiotics, p 652. **Versus topical antiseptics:** See benefits of topical antiseptics, p 651. **Added to systemic antibiotics:** We found one RCT (248 adults), which compared topical ceftizoxime (2 g/day) versus 0.9% sodium chloride solution among people who were given intramuscular ceftizoxime for 7 days.[70] It found no significant difference at the end of treatment between the two groups in terms of improvement of symptoms and otoscopic findings (improvement 96% with topical ceftizoxime *v* 93% with 0.9% sodium chloride; RR and CI not reported). **Added to non-antibiotic treatments:** We found one RCT (101 adults about to undergo tympanoplasty [see glossary, p 658]), which compared preoperative topical ofloxacin instilled for 10 minutes, preoperative topical ofloxacin instilled for 3 minutes, or no preoperative topical

treatment.[71] It found no significant difference among groups for closure of tympanic perforations (28/33 with 10 minuntes ofloxacin; 27/33 with 3 minutes ofloxacin; 31/35 with no treatment). However, the study may have lacked power to detect clinically important differences.

Harms: **Topical antibiotics versus placebo:** One systematic review found that adverse drug reaction rates in RCTs were low and did not vary appreciably among antibiotics.[53] The adverse events included *Candida* infections, dizziness, itching, stinging, and earache. One subsequent small RCT found no reported adverse events with topical ciprofloxacin used for 7 days in 19 ears.[60] Another subsequent RCT (322 people) found no significant difference in adverse event rate with topical ciprofloxacin versus topical polymyxin-B plus neomycin plus hydrocortisone (24/165 [15%] with ciprofloxacin *v* 12/153 [8%] with topical polymyxin-B plus neomycin plus hydrocortisone; RR 1.86, 95% CI 0.96 to 3.6).[66] Vertigo was reported by two people with topical ciprofloxacin and by none using topical polymyxin-B plus neomycin plus hydrocortisone. **Ototoxic effects of topical antibiotics:** We found one systematic review[53] and two subsequent RCTs[55,60] in adults and children, which examined hearing before and after topical antibiotics. The systematic review (search date 1996, 11 RCTs)[53] found negligible or no change in hearing after topical antibiotics. Three RCTs in adults and children[54,55,60] found no case of worsened hearing in those who were given topical ciprofloxacin or topical aminoglycoside. One RCT found deterioration of the audiogram in only one person with topical polymyxin-B plus neomycin plus hydrocortisone after 6–12 days (0/157 with topical ciprofloxacin *v* 1/138 with topical polymyxin-B plus neomycin plus hydrocortisone; OR 0.12, 95% CI 0.002 to 5.99).[66] The clinical importance of this difference is unclear.

Comment: There is consensus that topical antibiotics must be combined with thorough ear cleansing to be effective. We found no evidence about long term effects on complications. The comparative RCTs were small and their quality variable. We found no clear evidence from RCTs of ototoxicity from any topical antibiotic. Evidence about ototoxicity is based only on the assessment of audiograms after short term exposure to the antibiotics, and uncontrolled case studies have reported ototoxicity associated with some topical non-quinolone antibiotics for 7–120 days.[68,69,72] Most of the people in the observational studies had vestibular rather than cochlear symptoms, suggesting that the evidence from audiograms and hearing tests may not exclude ototoxicity. Most topical non-quinolone antibiotics have license restrictions against prolonged use, or use in people with perforation of the ear drum.

OPTION TOPICAL ANTIBIOTICS PLUS TOPICAL STEROIDS

We found no RCTs with long term follow up. Two small RCTs found that topical non-quinolone antibiotics plus topical steroid improved otoscopic appearances compared with placebo. One RCT found that topical non-quinolone antibiotic plus steroid improved otoscopic appearances compared with topical steroid alone. However, we are unable to draw reliable conclusions from this study.

Benefits: **Versus placebo:** We found one systematic review (search date 1996,[53] 2 RCTs,[52,73] 196 people, no pooling of results) of combined topical antibiotics plus steroid for 4–6 weeks compared with placebo. Both RCTs found that topical antibiotics plus steroid significantly reduced persistent otorrhoea compared with control. The first RCT (123 adults with chronic suppurative otitis media, no cholesteatoma, and no open mastoid cavity) found that significantly fewer people had otoscopically active otitis after treatment with gentamicin plus hydrocortisone than with placebo (appearance of active otitis: 33/64 [52%] people with treatment *v* 44/59 [75%] with placebo; OR 0.38, 95% CI 0.18 to 0.78).[52] Similar results were found in 42 other people who had an open mastoid cavity. The second RCT (31 adults) also found that gentamicin plus hydrocortisone reduced active otitis media on otoscopy compared with placebo at the end of 4 weeks of treatment (6/17 [35%] with treatment *v* 11/14 [79%] with placebo; OR 0.18, 95% CI 0.05 to 0.75).[73] **Versus topical steroid:** The systematic review[53] identified one RCT (64 adults),[67] which found that topical gentamicin plus hydrocortisone reduced the proportion of people with persistent activity on otoscopy compared with betametasone after 3 weeks of treatment (6/30 [20%] with gentamicin–hydrocortisone *v* 17/24 [71%] with betametasone; RR 0.28, 95% CI 0.13 to 0.60; NNT 2, 95% CI 2 to 4).

Harms: See harms under topical antibiotics, p 650.

Comment: See comment under topical antibiotics, p 650.

OPTION TOPICAL ANTISEPTICS (ALUMINIUM ACETATE, BORAX, BORIC ACID, HYDROGEN PEROXIDE, IODINE POWDER)

We found no systematic review and no RCTs comparing topical antiseptics versus placebo or no treatment. One RCT in adults found no significant difference with topical antiseptics plus ear cleansing under microscopic control versus topical antibiotics or versus oral antibiotics. The RCT was too small to establish or exclude a clinically important effect from topical antiseptics in adults.

Benefits: **Versus placebo:** We found no systematic review and no RCT. **Versus topical antibiotics:** We found one systematic review (search date 1996,[53] 1 RCT,[74] 51 adults). The included RCT compared three treatments: topical antiseptics, topical antibiotics, and oral antibiotics.[74] It found no significant difference between topical antiseptics (boric acid and iodine powder plus ear cleansing [see glossary, p 658] under microscopic vision) and topical antibiotics (gentamicin or chloramphenicol) in persistent activity on otoscopy (13/20 [65%] with topical antiseptics *v* 15/18 [83%] with topical antibiotics; OR 0.40, 95% CI 0.10 to 1.66).[74] **Versus systemic antibiotics:** See benefits of systemic antibiotics, p 652.

Harms: Adverse effects included dizziness and local pain. The systematic review found negligible or no changes in hearing acuity after topical treatment.[53]

Comment: The available evidence from RCTs in adults is insufficient to establish or exclude a clinically important effect from topical antiseptics.

Chronic suppurative otitis media

OPTION TOPICAL STEROIDS

We found no RCTs in adults comparing topical steroids versus placebo or no treatment.

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: Topical steroids have been used in combination with topical antibiotics (see topical antibiotics, p 649).

OPTION SYSTEMIC ANTIBIOTICS

We found insufficient evidence about the effects of systemic antibiotics versus placebo, no treatment, or topical antiseptics. One systematic review found that systemic antibiotics were less effective than topical antibiotics in reducing otoscopic features of chronic suppurative otitis media. We found no evidence about long term treatment.

Benefits: **Versus placebo in people receiving no other treatment:** We found one systematic review (search date 1996), which found no RCTs investigating the effects of systemic antibiotics in adults receiving no other treatment.[53] **Versus topical antibiotics:** We found one systematic review (search date 1996,[53] 5 RCTs, 271 adults) (see table 2, p 663).[74–78] All RCTs found a better response with topical antibiotics than with systemic antibiotics. The topical antibiotics used were ofloxacin, ciprofloxacin, gentamicin, and chloramphenicol. The systemic antibiotics were oral cefalexin, cloxacillin, amoxicillin, ofloxacin, ciprofloxacin, co-amoxiclav, and intramuscular gentamicin. The systematic review found that, overall, topical antibiotics were more effective than systemic antibiotics at reducing otoscopic features of chronic suppurative otitis media by the end of the trials (34/153 [22%] with topical antibiotics *v* 77/138 [56%] with systemic antibiotics; OR 0.23, 95% CI 0.14 to 0.37). **Versus topical antiseptics:** We found one systematic review (search date 1996, 2 RCTs, 152 people).[53] The first RCT (51 adults) compared three treatments: oral antibiotics (cefalexin, flucloxacillin, cloxacillin, or amoxicillin according to bacterial sensitivity), topical antiseptics (boric acid and iodine powder plus ear cleansing [see glossary, p 658] under microscopic vision), and topical antibiotics (gentamicin or chloramphenicol).[74] It found no significant difference between oral antibiotics and topical antiseptics in the rate of persistent activity on otoscopy (8/13 [62%] with oral antibiotics *v* 13/20 [65%] with topical antiseptics *v* 15/18 [83%] with topical antibiotics; for oral antibiotic *v* topical antiseptic: OR 0.87, 95% CI 0.21 to 3.61). The second RCT (119 people with an age range from 11–79 years) found no significant difference between topical hydrogen peroxide or boric acid for 10–20 days versus various systemic antibiotics (choice based on sensitivity results, administered orally or intravenously) for otoscopically persistent discharge or inflamed mucosa at the end of treatment (33/71 [46%] with systemic antibiotic *v* 29/48 [60%] with topical antiseptic: OR 0.58, 95% CI 0.28 to 1.19). The confidence interval was too large to exclude a clinically important difference. **Systemic antibiotics versus other systemic antibiotics:** We found one

systematic review (search date 1996,[53] 1 RCT, 75 adults) and one subsequent RCT (see comment below).[79] The RCT in the systematic review found no clear evidence of differences between oral ciprofloxacin (500 mg twice daily) and amoxicillin–clavulanate (500 mg 3 times daily) given for 5–10 days in persistent otoscopic activity at 3–4 weeks (16/40 [40%] with ciprofloxacin *v* 22/35 [63%] with amoxicillin–clavulanate; OR 0.41, 95% CI 0.16 to 1.00). The subsequent RCT (190 adults) found no significant difference between oral cefotiam hexetil and amoxicillin–clavulanate given for 10 days in persistent otoscopic abnormality after the end of treatment (37/94 [39%] with cefotiam *v* 33/94 [35%] with amoxicillin–clavulanate; OR 1.20, 95% CI 0.67 to 2.16).[79] **Added to other non-antibiotic treatments:** We found one systematic review (search date 1996,[53] 1 RCT,[80] 26 adults) comparing systemic antibiotics versus placebo in people receiving other forms of treatment. The RCT (26 adults having mastoidectomy/tympanoplasty [see glossary, p 658]) found that intravenous ceftazidime (2 g 12 hours preoperatively and 1–2 g 8 hourly for 5 days postoperatively) reduced the proportion of people with otorrhoea on otoscopy or with positive *Pseudomonas aeruginosa* cultures at 2 months compared with no antibiotic (1/14 [7%] with iv ceftazidime *v* 7/12 [58%] with no antibiotic; OR 0.10, 95% CI 0.02 to 0.51).[80] Although randomisation was thorough, groups are likely to have been unbalanced for baseline severity, with more people in the antibiotic arm having only tympanoplasty. **Added to topical antibiotics:** We found one systematic review (search date 1996,[53] 2 RCTs,[75,80] 100 adults). The first included RCT found no significant difference in otorrhoea at 2 weeks with topical ciprofloxacin with and without oral ciprofloxacin given for 5–10 days (5/20 [25%] with oral ciprofloxacin *v* 3/20 [15%] with no oral ciprofloxacin; OR 1.84, 95% CI 0.40 to 8.49).[75] The second RCT found no significant difference in otorrhoea at the end of treatment with topical gentamicin–hydrocortisone (for 4 weeks) with and without oral metronidazole given for 2 weeks (6/14 [43%] with metronidazole *v* 6/16 [38%] without metronidazole; OR 1.24, 95% CI 0.29 to 5.23).[81] **Oral plus topical non-quinolone antibiotics versus topical quinolone antibiotics alone:** We found one RCT (80 adults, 89 ears),[82] which found that topical ofloxacin (0.3%) reduced the proportion of ears exhibiting persistent signs (ear pain, discharge, or inflammation on otoscopic examination) after 2 weeks compared with oral amoxicillin (amoxycillin) plus topical chloramphenicol (33% of ears with ofloxacin *v* 63% of ears with oral amoxicillin plus topical chloramphenicol; number of ears examined not stated; $P < 0.001$). The RCT randomised people but analysed the number of ears with persistent otorrhoea.

Harms:

The systematic review found that adverse effects of systemic antibiotics include *Candida* infections, headache, nausea, and allergic reactions.[53] One RCT (80 adults) reported ototoxicity (defined as an elevation in bone conduction thresholds, speech reception thresholds of ≥ 5 dB, or both) with amoxicillin–chloramphenicol but not with ciprofloxacin (absolute numbers not stated).[82]

Comment: We found two further, recent RCTs comparing quinolone versus non-quinolone antibiotics; they are being translated and their results will be included in future *Clinical Evidence* updates.[83,84]

OPTION MASTOIDECTOMY AND/OR TYMPANOPLASTY

We found no RCTs comparing tympanoplasty with or without mastoidectomy versus no surgery in people with chronic suppurative otitis media and without cholesteatoma.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: We found many retrospective cohort studies. One of these (41 people with bilateral chronic suppurative otitis media operated on at one unit in Italy) compared hearing in ears that had previous tympanoplasty versus hearing in contralateral ears treated without surgery.[85] The hearing in both operated and non-operated ears progressively deteriorated, but the rate of decline was significantly slower in operated ears. Tympanoplasty can be combined with mastoidectomy (see glossary, p 658) when the possibility of restoring some functional hearing without jeopardising surgical clearance of the disease exists. Observational studies have found that the success of surgery depends on several factors: age, technical skill of the surgeon,[86] availability of remnant eardrum and ossicles,[87] and type of mastoidectomy performed. The success rate for sealing a tympanic perforation with a graft can be 90–95%. Hearing deficit may be corrected in about 50–70% of operated ears.[88–90]

QUESTION What are the effects of treatments for chronic suppurative otitis media in children?

OPTION EAR CLEANSING

One systematic review found insufficient evidence from two RCTs to compare a simple form of ear cleansing versus no ear cleansing in children with chronic suppurative otitis media.

Benefits: **Versus no treatment:** We found one systematic review (search 1996,[53] 2 RCTs,[91,92] 658 children), which found no significant difference in persistent otorrhoea or persistent ear drum perforation between a simple form of ear cleansing (see glossary, p 658) and no ear cleansing over 3–16 weeks (persisting otorrhoea, 2 RCTs; 125/170 [74%] with ear cleansing *v* 91/114 [80%] with no treatment; OR 0.63, 95% CI 0.36 to 1.12; persisting tympanic perforations, 1 RCT;[91] 125/144 [87%] *v* 63/73 [87%]; OR 1.04, 95% CI 0.46 to 2.38).

Harms: The review did not provide any evidence about the adverse effects of ear cleansing.

Comment: Techniques of ear cleansing vary considerably. In some countries, microsuction of the external and middle ear under microscopic control by a trained operator is a standard method of ear cleansing. In other countries, cleansing of the external auditory canal may be

performed by parents, carers, or peers by dry mopping with cotton wool on orange sticks around four times daily. Both RCTs were performed in areas with a high prevalence of chronic suppurative otitis media (Solomon Islands[91] and Kenya[92]). The first RCT followed all the randomised children for 6 weeks but presented results as number of ears with persistent otorrhoea.[91] The second RCT randomised 145 schools but analysed the numbers of children with persistent otorrhoea.[92] It followed children for 16 weeks, but analysed results only for the 72% of the children who completed the RCT. Neither study described allocation concealment methods. In one RCT,[23] the randomisation process was described, but outcome assessors were not blinded to treatment allocation. The results of the meta-analysis in the systematic review[53] need to be approached with care because it combined results from the first RCT for the numbers of ears with persistent signs at 6 weeks with results from the second RCT for the number of children with persistent signs after 16 weeks. There was significant heterogeneity between the two RCTs in the effect of ear cleansing on otorrhoea ($P = 0.02$). Overall, we found no good evidence of benefit from simple ear cleansing, but the evidence is not strong enough to exclude a clinically important benefit.

OPTION TOPICAL ANTIBIOTICS

We found no RCTs about the effects of topical antibiotics in children with chronic suppurative otitis media.

Benefits: We found one systematic review (search date 1996, no RCTs exclusively in children) and no subsequent RCTs.[53]

Harms: We found insufficient evidence.[53]

Comment: We found no RCTs evaluating ototoxicity from any topical antibiotic. Evidence about ototoxicity is based only on the assessment of audiograms after short term exposure to the antibiotics, and uncontrolled case studies have reported ototoxicity associated with use of some topical non-quinolone antibiotics for 7–120 days.[93–95] Most of the people in the observational studies had vestibular rather than cochlear symptoms, suggesting that the evidence from audiograms and hearing tests may not exclude ototoxicity. Most topical non-quinolone antibiotics have license restrictions against prolonged use, or use in people with perforation of the eardrum.

OPTION TOPICAL ANTIBIOTICS PLUS TOPICAL STEROIDS

We found insufficient evidence from small RCTs to compare topical antibiotics plus topical steroids versus cleansing only or topical antiseptics. We found no RCTs comparing topical antibiotics plus topical steroids versus either topical treatment alone.

Benefits: **Versus placebo:** We found one systematic review (search date 1996,[53] 1 RCT,[91] 50 children, 67 ears) comparing combined topical antibiotics plus steroid (topical dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005%) versus ear cleansing (see glossary, p 658) only. The RCT found no significant difference between topical antibiotics plus steroid and ear cleansing

only in the proportion of ears with unchanged otorrhoea on otoscopy after 6 weeks (17/41 [42%] with topical antibiotic plus steroid plus ear cleansing *v* 13/26 [50%] with ear cleansing alone; OR 0.71, 95% CI 0.27 to 1.90). **Versus topical antiseptics:** We found one systematic review (search date 1996,[53] 1 RCT,[91] 55 children, 73 ears), which found no significant difference between topical antiseptic (boric acid 2% in 20% alcohol, 3 drops to each ear, 4 times daily after ear cleansing) and topical antibiotic plus steroid (dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005%) in the proportion of ears with persistent otorrhoea (12/32 [38%] with topical antiseptic *v* 17/41 [41%] with topical antibiotic plus steroid; OR 0.85, 95% CI 0.33 to 2.17). **Versus topical steroid or topical antibiotics alone:** The systematic review found no RCTs.[53]

Harms: The RCTs did not provide any evidence about harms.[53]

Comment: One RCT[23] found no difference in effectiveness between topical antibiotics with steroids and ear cleansing alone. However, this study was small, did not report methods for allocation concealment and blinding, and randomised children but analysed ears. We found no RCTs or systematic reviews about long term effects on complications. See comment under topical antibiotics, p 655.

OPTION TOPICAL ANTISEPTICS (ALUMINIUM ACETATE, BORAX, BORIC ACID, HYDROGEN PEROXIDE, IODINE POWDER)

Two RCTs in children found no significant reduction of otorrhoea with topical antiseptics versus placebo. One RCT in children found no significant difference in otorrhoea between topical antiseptics and topical antibiotic plus steroid. The RCTs were too small to exclude a clinically important effect.

Benefits: **Versus placebo:** We found no systematic review but found two RCTs.[91,96] The first RCT (60 children with otorrhoea in a hospital clinic in South Africa, 67 ears) compared aluminium acetate solutions of varying concentrations (13% *v* 3.25% *v* 1.3%).[96] The most dilute solution was considered to be inactive. Results were obtained for 56 (84%) ears. The RCT found no significant difference in dry ears after 2 weeks (21/26 [81% of ears] with 13% aluminium acetate *v* 15/20 [75%] with a 3.25% aluminium acetate *v* 5/10 [50%] with 1.3% aluminium acetate; P = 0.18). The second RCT (43 children, 58 ears) found no significant difference between topical antiseptic (boric acid 2% in 20% alcohol, 3 drops to each ear, 4/day after ear cleansing [see glossary, p 658]) and ear cleansing alone in the proportion of children with unchanged otoscopic appearance after 6 weeks (12/32 [38%] with topical antiseptic *v* 13/26 [50%] with ear cleansing alone; OR 0.61, 95% CI 0.22 to 1.71).[91] **Versus topical antibiotic plus steroid:** See benefits of topical antibiotics plus topical steroids, p 655. **Versus systemic antibiotics:** See benefits of systemic antibiotics in children, p 657.

Harms: Adverse effects included dizziness and local pain. The systematic review found negligible or no changes in hearing acuity after topical treatment.[53]

Comment: We found small studies, which found no difference in the short term effects of topical antiseptics compared with systemic antibiotics (see systemic antibiotics, p 657). The available evidence is insufficient to establish or exclude a clinically important effect from topical antiseptics.

OPTION TOPICAL STEROIDS

We found no RCTs comparing topical steroids versus placebo or no treatment in children.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION SYSTEMIC ANTIBIOTICS

RCTs found insufficient evidence of the effects of systemic antibiotics in children with otitis media.

Benefits: **Versus placebo in children receiving no other treatment:** We found one systematic review (search date 1996),[53] which found no RCTs investigating the effects of systemic antibiotics in children receiving no other treatment. **Versus topical antibiotics:** We found one systematic review (search date 1996, no RCTs) and no subsequent RCTs.[53] **Versus topical antiseptics:** One systematic review (search date 1996) found no RCTs.[53] **Systemic antibiotics versus other systemic antibiotics:** We found one systematic review (search date 1996,[53] 1 RCT, 36 children) and one subsequent RCT.[97] The systematic review found no significant difference in otoscopic evidence of otorrhoea between intravenous mezlocillin and intravenous ceftazidime at the end of treatment (otoscopic evidence of otorrhoea: 0/17 [0%] with mezlocillin *v* 0/19 [0%] with ceftazidime).[53] The subsequent RCT (30 children) found no significant difference in success rates (complete disappearance of discharge) and days to disappearance between ceftazidime and aztreonam (disappearance of discharge: 84.6% with ceftazidime *v* 67% with aztreonam; P value reported as not significant; days to disappearance of discharge: 7.9 days with ceftazidime *v* 8.4 days with aztreonam).[97] **Added to non-antibiotic treatments:** We found one systematic review (search date 1996,[53] 1 RCT,[98] 33 children). The RCT (33 children having ear cleansing by suctioning and debridement for 1–2 weeks) found that intravenous antibiotic (mezlocillin or ceftazidime for 3–21 days) significantly reduced persistent otorrhoea detected at otoscopy after 6 months compared with no antibiotic (0/21 [0%] with iv antibiotic *v* 11/12 [92%]; OR 0.02, 95% CI 0.004 to 0.08). **Added to topical antibiotics:** We found one systematic review (search date 1996,[53] 1 RCT[91]). The RCT (62 children, 81 ears, all treated with ear cleansing plus drops containing dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005%) found no significant difference between oral clindamycin and no clindamycin (15 mg/kg daily) on the proportion of ears with unchanged otoscopic otorrhoea after 6 weeks (23/40 [58%] with clindamycin *v* 17/41 [41%] without clindamycin; OR 1.88, 95% CI 0.79 to 4.48).[91]

Harms: The systematic review found that (in all age groups) adverse effects of systemic antibiotics included *Candida* infections, headache, nausea, and allergic reactions.[53]

Comment: We found no clear evidence from RCTs that systemic antibiotics differ in their effectiveness. The studies in children found similar results to those in adults.

OPTION MASTOIDECTOMY AND/OR TYMPANOPLASTY

We found no RCTs in children comparing tympanoplasty with or without mastoidectomy versus no surgery for chronic suppurative otitis media without cholesteatoma.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: We found no evidence from RCTs, but found numerous retrospective observational studies. Tympanoplasty is often combined with mastoidectomy whenever the possibility of restoring some functional hearing without jeopardising surgical clearance of the disease exists. Observational studies have found that the success of surgery depends on several factors (age, technical skill of the surgeon,[99] presence of middle ear discharge,[100] type of mastoidectomy performed, and technique of middle ear construction[86]). Success rate for sealing a tympanic perforation with a graft can be 90–95%. Hearing deficit may be corrected in about 50–70% of operated ears.[88–90]

GLOSSARY

Cholesteatoma An accumulation of epithelial debris in the middle ear cavity that can arise congenitally or can be acquired. The tissue is probably derived from skin. It grows slowly but can erode and destroy adjacent structures (ossicles, the mastoid, the inner ear, or the bone leading to the intracranial cavity) potentially leading to persistent pain and otorrhoea, hearing loss, dizziness, facial nerve paralysis, and intracranial infection.

Disability Adjusted Life Year (DALY) A measure of the impact of a condition, designed to include the loss attributable to premature death and the loss caused by a disability of known duration and severity. One DALY is equivalent to the loss of 1 year of healthy life.

Ear cleansing Also known as aural toilet, this consists of mechanical removal of ear discharge and other debris from the ear canal and middle ear by mopping with cotton pledgets, wicking with gauze, flushing with sterile solution, or suctioning. This can be done with an otomicroscope or under direct vision with adequate illumination of the middle ear.

Mastoidectomy A general term used to describe various surgical procedures that are usually used to remove abnormal parts of the mastoid bone and surrounding structures, or to allow access to the middle ear.

Tympanoplasty A general term used to describe various surgical repairs of the eardrum or ossicles of the middle ear to improve hearing in people with conductive deafness.

Menière's disease

Search date June 2003

Adrian James and Marc Thorp

QUESTIONS

INTERVENTIONS

See glossary, p 671

Key Messages

Treatments for acute attacks

- **Anticholinergics; benzodiazepines; betahistine** We found no RCTs on the effects of these interventions.

Interventions to prevent acute attacks and delay progression

- **Betahistine (for vertigo or tinnitus)** Seven RCTs provided insufficient evidence to compare the effects of betahistine versus those of placebo on the frequency and severity of attacks of vertigo, tinnitus, and aural fullness. Two small RCTs in people with definite or possible Menière's disease found no significant difference in tinnitus between betahistine and trimetazidine. One of these RCTs found that trimetazidine reduced the intensity of vertigo compared with betahistine, but the other RCT found no significant difference in vertigo intensity between trimetazidine and betahistine.
- **Diuretics** One small crossover RCT provided insufficient evidence about the effects of triamterene plus hydrochlorothiazide on hearing, vertigo, or tinnitus.
- **Trimetazidine** We found no RCTs comparing trimetazidine versus placebo in Menière's disease. Two small RCTs in people with definite or possible Menière's disease found no significant difference in tinnitus between betahistine and trimetazidine. One of these RCTs found that trimetazidine reduced the intensity of vertigo compared with betahistine, but the other RCT found no significant difference in vertigo intensity between trimetazidine and betahistine.

- **Betahistine (for hearing loss)** Four RCTs in people with possible Menière's disease found no significant difference between betahistine and placebo in change in hearing assessed by pure tone audiograms. Two small RCTs in people with definite or possible Menière's disease found no significant difference in hearing between betahistine and trimetazidine.
- **Lithium** Two small crossover RCTs in people with possible Menière's disease provided insufficient evidence to compare effects of lithium versus those of placebo on vertigo, tinnitus, aural fullness, or hearing, although they found that lithium was associated with tremor, thirst, and polyuria in some people.
- **Dietary modification; psychological support; aminoglycosides; vestibular rehabilitation** We found no RCTs on the effects of these interventions.

DEFINITION

Menière's disease is characterised by recurrent episodes of spontaneous rotational vertigo and sensorineural hearing loss with tinnitus, and a feeling of fullness or pressure in the ear. It may be unilateral or bilateral. Acute episodes can occur in clusters of about 6–11 a year, although remission may last several months.[1] The diagnosis is made clinically.[2] It is important to distinguish Menière's disease from other types of vertigo that might occur independently with hearing loss and tinnitus, and respond differently to treatment (e.g. benign positional vertigo, acute labyrinthitis). Strict diagnostic criteria help to identify the condition. In this chapter we applied the classification of the American Academy of Otolaryngology–Head and Neck Surgery to indicate the diagnostic rigour used in RCTs (see table 1, p 672).

INCIDENCE/ PREVALENCE

Menière's disease is most common between 40–60 years of age, although younger people may be affected.[6,7] In Europe, the incidence is about 50–200/100 000 a year. A survey of general practitioner records of 27 365 people in the UK found an incidence of 43 affected people in a 1 year period (157/100 000).[8] Diagnostic criteria were not defined in this survey. A survey of over 8 million people in Sweden found an incidence of 46/100 000 a year with diagnosis strictly based on the triad of vertigo, hearing loss, and tinnitus.[9] From smaller studies, the incidence appears lower in Uganda[10] and higher in Japan (350/100 000, based on a national survey of hospital attendances during a single week).[7]

AETIOLOGY/ RISK FACTORS

Menière's disease is associated with endolymphatic hydrops (raised endolymph pressure in the membranous labyrinth of the inner ear),[11] but a causal relationship remains unproven.[12] Specific disorders associated with hydrops (such as temporal bone fracture, syphilis, hypothyroidism, Cogan's syndrome, and Mondini dysplasia — see glossary, p 671) can produce symptoms similar to those of Menière's disease.

PROGNOSIS

Menière's disease is progressive but fluctuates unpredictably. It is difficult to distinguish natural resolution from the effects of treatment. Significant improvement in vertigo is usually seen in the placebo arm of RCTs.[13,14] Acute attacks of vertigo often increase in frequency during the first few years after presentation and then decrease in frequency in association with sustained deterioration in hearing.[6] In most people, vertiginous episodes eventually cease completely.[15] In one 20 year cohort study in 34 people, 28 (82%)

people had at least moderate hearing loss (mean pure tone hearing loss > 50 dB)[1] and 16 (47%) developed bilateral disease. Symptoms other than hearing loss improve in 60–80% of people irrespective of treatment.[16]

AIMS OF INTERVENTION To prevent attacks of Menière's disease; to reduce the severity of vertigo in acute attacks; to relieve chronic symptoms of hearing loss and tinnitus; to improve quality of life, with minimum adverse effects of treatment.

OUTCOMES Frequency and severity of acute attacks of vertigo; hearing acuity; severity of tinnitus; sensation of aural fullness; functional impairment and quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal June 2003. We excluded studies with loss to follow up of over 20%. We excluded RCTs that did not use American Academy of Otolaryngology–Head and Neck Surgery diagnostic criteria.[3–5]

QUESTION What are the effects of treatments for acute attacks?

OPTION ANTICHOLINERGIC DRUGS

We found no RCTs about the effects of anticholinergics for acute attacks of Menière's disease.

Benefits: We found no systematic review and no RCTs. We found one non-randomised trial (see comment below).[17]

Harms: The non-randomised trial gave no information on adverse effects.[17]

Comment: The non-randomised trial (37 people with definite Menière's disease) compared an anticholinergic (glycopyrrolate 2 mg twice daily as required) versus placebo for 4 weeks.[17] It found that glycopyrrolate significantly reduced the severity of vertigo and its impact on quality of life compared with placebo (Dizziness Handicap Inventory, a validated symptom score,[18] change from baseline to end of trial: 76 to 37 with glycopyrrolate *v* 73 to 75 with placebo; $P < 0.001$). The lack of randomisation means that this result should be interpreted with caution.

OPTION BENZODIAZEPINES

We found no RCTs about the effects of benzodiazepines for acute attacks of Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION BETAHISTINE

We found no RCTs about the effects of betahistine for acute attacks of Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: One observational study conducted in 1940 found that intravenous histamine was associated with a reduced severity of acute attacks of Menière's disease.[19]

QUESTION **What are the effects of interventions to prevent attacks and delay progression?**

OPTION **DIURETICS**

One small crossover RCT provided insufficient evidence about the effects of triamterene plus hydrochlorothiazide on hearing, vertigo, or tinnitus.

Benefits: We found no systematic review but found one crossover RCT (33 people with possible Menière's disease) comparing a diuretic (triamterene 50 mg plus hydrochlorothiazide 25 mg) versus placebo.[20] It found no significant audiological change in hearing over 17 weeks ($P > 0.2$). However, the trial may have lacked power to detect a clinically important difference. The trial provided insufficient data to assess effects on vertigo and tinnitus (see comment below).

Harms: The RCT gave no information on adverse effects.[20]

Comment: In the RCT the frequency of vertigo attacks was reduced and tinnitus was unchanged, but valid statistical analyses cannot be performed because only the means of categorical data were presented.[20]

OPTION **TRIMETAZIDINE**

We found no RCTs comparing trimetazidine versus placebo to prevent attacks of Menière's disease. Two small RCTs in people with definite or possible Menière's disease found no significant difference between trimetazidine and betahistine in hearing or tinnitus. One of these RCTs found that trimetazidine reduced the intensity of vertigo compared with betahistine, but the other RCT found no significant difference in vertigo intensity between trimetazidine and betahistine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus betahistine:** We found two RCTs.[21,22] The first RCT (20 people with definite or probable Menière's disease) compared trimetazidine (20 mg three times daily) versus betahistine (8 mg three times daily) over 3 months.[21] It found no significant difference in hearing, tinnitus, aural fullness, or quality of life (RR for improved quality of life 1.0, 95% CI 0.34 to 2.93). Trimetazidine significantly increased the proportion of people reporting that the duration of vertigo was "substantially better or cured" or reporting that the intensity of vertigo was "substantially better or cured" compared with betahistine (vertigo improved: RR 1.8, 95% CI 1.0 to 3.2; vertigo intensity: RR 1.7, 95% CI 1.0 to 2.8). Trimetazidine also significantly improved the global impression of vertigo scale compared with betahistine, but it is not clear whether this scale has been validated (RR for improvement 2.5, 95% CI 1.17 to 5.3).[21] The second RCT (45 people with possible Menière's disease)

compared trimetazidine (20 mg three times daily) versus betahistine (12 mg three times daily) over 2 months and found no significant difference in hearing or tinnitus.[22] A beneficial effect of trimetazidine on vertigo intensity was reported, but this is not confirmed by analysis of the available data (P = 0.23; 2 sided Fisher's exact test).[22]

Harms: No significant adverse effects were reported in the RCTs.[21,22]

Comment: None.

OPTION BETAHISTINE

Seven RCTs in people with probable or possible Menière's disease provided insufficient evidence to compare effects of betahistine versus those of placebo on frequency and severity of attacks of vertigo, tinnitus, and aural fullness. Four of the RCTs found no significant difference between betahistine and placebo in change in hearing assessed by pure tone audiograms. Two small RCTs in people with definite or possible Menière's disease found no significant difference between trimetazidine and betahistine in hearing or tinnitus. One of these RCTs found that trimetazidine reduced the intensity of vertigo compared with betahistine, but the other RCT found no significant difference in vertigo intensity between trimetazidine and betahistine.

Benefits: **Versus placebo:** We found one systematic review (search date 1999,[23] 6 RCTs,[13,24–28] 162 people) and one subsequent RCT that compared betahistine versus placebo in people with Menière's disease.[29] The review did not include a meta-analysis because of heterogeneity among trials (see comment below).[23] The first RCT identified by the review (30 people with possible Menière's disease) found that betahistine (8 mg three times daily) significantly reduced the severity of vertigo after 6 weeks compared with placebo (P = 0.0001), tinnitus (P = 0.001), and aural fullness (P = 0.02).[24] The second RCT identified by the review (35 people with possible Menière's disease, crossover design) found no significant difference between betahistine (24 mg three times daily in a slow release formulation) and placebo in tinnutus (P = 0.68) or aural fullness (P = 0.63) after 16 weeks.[13] Vertigo was not adequately assessed. The third RCT identified by the review (16/36 people had a possible diagnosis of Menière's disease) found no significant difference between betahistine (18 mg twice daily) and placebo after 2 weeks on the proportion of people reporting improved vertigo or tinnitus (vertigo: RR 1.17, 95% CI 0.86 to 1.58; tinnitus: RR 2.4, 95% CI 0.11 to 51.32).[25] The fourth RCT identified by the review (10 people with possible Menière's disease) found no significant difference between betahistine (8 mg three times daily) and placebo in the proportion of people with improved vertigo, tinnitus, or aural fullness over 6–12 months (improved vertigo: RR 5.0, 95% CI 0.3 to 84).[26] None of the RCTs found any change in hearing as assessed by pure tone audiograms.[13,24–26] The remaining two RCTs identified by the review reported insufficient detail to confirm reliably that the participants had Menière's disease.[27,28] The subsequent RCT (81 people with possible or probable Menière's disease) found that betahistine (8 mg twice daily) significantly reduced the frequency of attacks of vertigo and increased the

proportion of people reporting a reduction in severity of vertigo over 3 months compared with placebo (results presented graphically; decrease in vertigo attacks: about 65% with betahistine *v* about 20% with placebo, $P < 0.05$; reduced intensity score read from graph: about 67% with betahistine *v* about 30% with placebo, $P < 0.03$).[29] However, the results should be interpreted with caution because it was not clear whether other outcomes were assessed but not reported. The RCT did not report the number of people with each outcome, severity of symptoms, or effects on hearing.[29] **Versus trimetazidine:** See benefits of trimetazidine, p 667.

Harms: **Versus placebo:** None of the RCTs identified by the review reported any significant adverse effects.[24–28] The subsequent RCT (81 people) found that betahistine increased headache compared with placebo (5/41 [12.2%] with betahistine *v* 0/40 [0%] with placebo; P value and CI not reported).[29] It found no significant difference between treatments for overall adverse effects (28% with betahistine *v* 22% with placebo; P value and CI not reported).

Comment: The systematic review reported that "we found no trials with a low risk of methodological bias which used the highest level of diagnostic criteria and outcome measures".[23] It stated that the lack of diagnostic certainty made it inappropriate to combine results.[23] Bias from selective reporting of outcome measures cannot be excluded in the subsequent RCT comparing betahistine versus placebo.[29] Crossover studies are difficult to interpret if used to evaluate the effects of treatments on conditions that fluctuate in intensity or if interventions have prolonged effects.[30] Menière's disease is not a stable condition and it is unknown whether any effects of betahistine are prolonged.

OPTION LITHIUM

Two small crossover RCTs in people with possible Menière's disease provided insufficient evidence to compare the effects of lithium versus those of placebo on vertigo, tinnitus, aural fullness, or hearing, although they found that lithium was associated with tremor, thirst, and polyuria in some people.

Benefits: We found no systematic review but found two crossover RCTs (50 people with possible Menière's disease) of lithium versus placebo.[31,32] They reported no difference in vertigo, tinnitus, aural fullness, or hearing, but no analysable results were presented.

Harms: In the RCTs, serum lithium concentration was checked every 2 weeks to reduce the risk of adverse effects.[31,32] Two people withdrew from one RCT because of adverse effects from lithium (tremor, thirst, polyuria).[31]

Comment: The crossover RCT design may be inappropriate because Menière's disease is not stable and it is not clear whether the lithium is free of other effects.[31,32] Dosage was adjusted to maintain serum lithium concentration between 0.7–1.1 mmol/L.

OPTION DIETARY MODIFICATION

We found no RCTs about the effects of dietary modification in preventing attacks of Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: It has been suggested that a low salt diet reduces endolymphatic pressure in endolymphatic hydrops,[33] but we found no RCTs.

OPTION AMINOGLYCOSIDES

We found no RCTs about the effects of aminoglycosides in preventing attacks of Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: Aminoglycosides have been reported to be associated with a risk of severe disruption of balance (including oscillopsia [see glossary, p 671]) and sensorineural hearing loss.[34]

Comment: Aminoglycosides have been used in severe bilateral Menière's disease,[35–37] but we found no evidence from RCTs to support or to refute this.

OPTION PSYCHOLOGICAL SUPPORT

We found no RCTs about psychological support, such as reassurance, to prevent attacks of Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: We found no good evidence about the effect of psychological support on Menière's disease. However, symptomatic improvement is seen with all treatments, including placebo[16,31] or being put on a waiting list for surgery.[38] Improvements noted after these types of psychological support have not been distinguished from improvements attributable to the natural history of Menière's disease.

OPTION VESTIBULAR REHABILITATION

We found no RCTs about the effects of vestibular rehabilitation exercises on Menière's disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: Improvements noted after vestibular rehabilitation (see glossary, p 671) have not been distinguished from spontaneous improvement in Menière's disease.

GLOSSARY

Cogan's syndrome Episodic vertigo of the Menière's type, hearing loss, and interstitial keratitis, without syphilis.[5]

Mondini dysplasia A congenital deformity of the cochlea in which only the basal turns are present.

Oscillopsia A disabling disturbance of the vestibulo-ocular reflex, manifest as oscillating vision typically with head movement.

Vestibular rehabilitation Involves a series of exercises intended to improve the sense of balance through controlled movements of the head and body.[39] It is usually recommended for stable vestibular disorders.[40]

Substantive changes

Betahistine One RCT added;[29] categorisation unchanged.

Middle ear pain and trauma during air travel

Search date July 2003

Simon Janvrin

QUESTIONS

INTERVENTIONS

Key Messages

- **Oral decongestants in adults** One RCT in adult passengers with a history of ear pain during air travel found limited evidence that oral pseudoephedrine decreased symtoms of barotrauma during air travel compared with placebo. One other RCT in adult passengers with a history of ear pain during air travel found limited evidence that oral pseudoephedrine decreased ear pain and hearing loss compared with placebo.
- **Oral decongestants in children** One small RCT in children up to the age of 6 years found no significant difference between oral pseudoephedrine and placebo in ear pain at take off or landing.
- **Topical nasal decongestants** One small RCT in adults with a history of ear pain during air travel found no significant difference between oxymetazoline nasal spray and placebo in symptoms of barotrauma.

Middle ear pain and trauma during air travel

DEFINITION The effects of air travel on the middle ear can include ear drum pain, vertigo, hearing loss, and ear drum perforation.

INCIDENCE/ PREVALENCE The prevalence of symptoms depends on the altitude, type of aircraft, and characteristics of the passengers. One point prevalence study found that 20% of adult and 40% of child passengers had negative pressure in the middle ear after flight, and that 10% of adults and 22% of children had auroscopic evidence of damage to the ear drum.[1] We found no data on the incidence of perforation, which seems to be extremely rare in commercial passengers.

AETIOLOGY/ RISK FACTORS During aircraft descent, the pressure in the middle ear drops relative to that in the ear canal. A narrow, inflamed, or poorly functioning Eustachian tube impedes the necessary influx of air. As the pressure difference between the middle and outer ear increases, the ear drum is pulled inward.

PROGNOSIS In most people symptoms resolve spontaneously. Experience in military aviation shows that most ear drum perforations will heal spontaneously.[2]

AIMS OF INTERVENTION To prevent ear pain and trauma during air travel.

OUTCOMES Incidence and severity of pain and hearing loss; incidence of perforation of ear drum; barotrauma (see glossary, p 675).

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of preventive interventions?

OPTION ORAL DECONGESTANTS

One RCT in adult passengers with a history of ear pain during air travel found limited evidence that oral pseudoephedrine decreased symptoms of barotrauma during air travel compared with placebo. One other RCT in adult passengers with a history of ear pain during air travel found limited evidence that oral pseudoephedrine decreased ear pain and hearing loss compared with placebo. One small RCT in children up to the age of 6 years found no significant difference between oral pseudoephedrine and placebo in ear pain at take off or landing.

Benefits: We found no systematic review. We found three RCTs comparing oral pseudoephedrine versus placebo.[3–5] Two RCTs in adult passengers, with a history of ear pain during air travel, compared oral pseudoephedrine (120 mg given at least 30 minutes before flight) versus placebo.[3,4] Those with acute or chronic ear problems were excluded. Both RCTs assessed outcomes by a post-flight questionnaire returned by mail. The first RCT (150 adults) compared three treatments: oral pseudoephedrine; oxymetazoline nasal spray; or placebo.[3] The RCT found that pseudoephedrine significantly decreased the proportion of people with symptoms of barotrauma (see glossary, p 675) compared with placebo (ear pain, blockage, hearing loss, dizziness/vertigo, tinnitus: 14/41 [34%] with pseudoephedrine *v* 29/41 [71%] with placebo; RR 0.48, 95% CI 0.29 to 0.67).[3] The second RCT (190 adults) found that pseudoephedrine significantly reduced ear pain (25/96 [26%] with pseudoephedrine

v 43/94 [46%] with placebo; P = 0.007) and hearing loss compared with placebo (20/96 [21%] with pseudoephedrine *v* 38/94 [40%] with placebo; P = 0.006).[4] The third RCT (50 children up to the age of 6 years) compared oral pseudoephedrine versus placebo.[5] It found no significant difference in ear pain between children taking pseudoephedrine or placebo at either take off or landing.

Harms: Adverse effects reported by the first RCT included drowsiness (4/41 [10%] with pseudoephedrine *v* 2/41 [5%] with placebo), dry mouth (4/41 [10%] *v* 1/41 [2%]), nasal irritation (1/41 [2%] *v* 0/41 [0%]), stomach upset (1/41 [2%] *v* 0/41 [0%]), and headache (0/41 [0%] *v* 1/41 [2%]).[3] The second RCT reported drowsiness (7/96 [7.3%] with pseudoephedrine *v* 2/94 [2.2%] with placebo) and nausea and dry mouth (4.2% *v* 4.3%).[4] The third RCT found more children taking pseudoephedrine were drowsy on take off compared with placebo (30/50 [60%] with pseudoephedrine *v* 11/41 [27%] with placebo; P = 0.003).[5]

Comment: None.

OPTION TOPICAL NASAL DECONGESTANTS

One small RCT in adults with a history of ear pain during air travel found no significant difference with oxymetazoline nasal spray versus placebo in symptoms of barotrauma.

Benefits: We found no systematic review. We found one RCT in adults with a history of ear pain during air travel, which compared oxymetazoline nasal spray, oral pseudoephedrine, or placebo during air travel.[3] Outcomes were assessed by a post-flight questionnaire returned by mail. The RCT (150 people) found no significant difference in symptoms of barotrauma (see glossary, p 675) between oxymetazoline versus placebo (ear pain, blockage, hearing loss, dizziness/vertigo, tinnitus: 64% of people with oxymetazoline *v* 71% of people with placebo; P = 0.695).[3]

Harms: Adverse effects included nasal irritation (6/42 [14%] with oxymetazoline *v* 0/41 [0%] with placebo), drowsiness (1/42 [2%] *v* 2/41 [5%]), dry mouth (1/42 [2%] *v* 1/41 [2%]), stomach upset (1/42 [2%] *v* 0/41 [0%]), and headache (1/42 [2%] *v* 1/41 [2%]).[3]

Comment: The RCT may have been too small to rule out an effect of topical decongestants.

GLOSSARY

Barotrauma Symptoms caused by changes of atmospheric pressure are called barotrauma. In the ear these include ear drum pain, vertigo, hearing loss, tinnitus and ear drum perforation.

Otitis externa

Search date July 2003

Daniel Hajioff

QUESTIONS

INTERVENTIONS

See glossary, p 683

Key Messages

Treatment of otitis externa

- **Topical aluminium acetate drops (as effective as topical anti-infective agents)** We found no RCTs that compared topical aluminium acetate versus placebo. One RCT in people with acute diffuse otitis externa found no significant difference between aluminium acetate drops and topical polymyxin–neomycin–hydrocortisone drops in clinical rate at 4 weeks.
- **Topical anti-infective agents (antibiotics or antifungals with or without steroids)** One RCT found that methylprednisolone–neomycin drops improved symptoms and signs compared with placebo at 28 days. Two RCTs found no significant difference in cure rate between topical quinolones and other topical anti-infective agents. One RCT found that triamcinolone–neomycin drops improved resolution rates compared with hydrocortisone–neomycin–polymyxin B drops. Two RCTs found limited evidence that neomycin–dexamethasone–acetic acid spray improved clinical cure compared with topical anti-infective drops that did not contain acetic acid. We found no RCTs on the effects of topical anti-infective agents versus oral antibiotics.
- **Topical steroids** One RCT in people with mild or moderate acute or chronic otitis externa found that topical budesonide improved symptoms and signs compared with placebo. We found no RCTs of topical steroids compared with

topical anti-infective agents. One RCT found no significant difference in symptom scores between low potency steroid (topical hydrocortisone) and high potency steroid (topical hydrocortisone butyrate) after 1 week.

- **Oral antibiotics** We found no RCTs of oral antibiotics compared with placebo or topical anti-infective agents.
- **Specialist aural toilet** We found no RCTs that compared specialist aural toilet versus no aural toilet. One RCT found no significant difference between an ear wick with anti-infective drops versus ribbon gauze impregnated with anti-infective ointment in resolution rates after 4 weeks.
- **Oral antibiotics plus topical anti-infective agents (no better than topical anti-infective agents alone)** One RCT found limited evidence of no significant difference between oral co-trimoxazole plus topical anti-infective ointment and topical anti-infective ointment alone in symptom severity, symptom duration, and cure rate.

DEFINITION Otitis externa is inflammation, often with infection, of the external ear canal. This inflammation is usually generalised throughout the ear canal so it is often referred to as "diffuse otitis externa". The present topic excludes localised inflammations such as furuncles. Otitis externa has acute (< 6 weeks), chronic (> 3 months), and necrotising (malignant) forms. Acute otitis externa may present as a single episode, or recur. It causes severe pain with aural discharge and associated hearing loss.[1] If the ear canal is visible, it appears red and inflamed. Chronic otitis externa may result in canal stenosis with associated hearing loss, for which it may be difficult to fit hearing aids. Necrotising otitis externa is defined by destruction of the temporal bone, usually in people with diabetes or in people who are immunocompromised, and can be life-threatening.[2] In this review we look at empirical treatment of acute and chronic otitis externa only.

INCIDENCE/ PREVALENCE Otitis externa is common in all parts of the world. The incidence is not known precisely, but 10% of people are thought to have been affected at some time.[3] The condition affects children but is more common in adults. It accounts for a large proportion of the workload of otolaryngology departments, but milder cases are often managed in primary care.[3]

AETIOLOGY/ RISK FACTORS Otitis externa may be associated with local or generalised eczema of the ear canal. It is more common in swimmers, in humid environments, in people with an absence of ear wax or narrow external ear canals, in hearing aid users, and after mechanical trauma.[4]

PROGNOSIS We found few reliable data. Many cases of otitis externa resolve spontaneously over several weeks or months. Acute episodes have a tendency to recur, although the risk of recurrence is unknown. Experience suggests that chronic inflammation affects a small proportion of people after a single episode of acute otitis externa, and may rarely lead to canal stenosis.[1]

AIMS OF INTERVENTION To improve or abolish symptoms; to prevent recurrence and complications, with minimal adverse effects.

OUTCOMES Severity and duration of signs and symptoms (pain, discharge, hearing loss, redness); rates of resolution or cure (defined as complete resolution of signs and symptoms); prevention of recurrence; ability to use hearing aids; quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal July 2003. We excluded RCTs with a follow up of less than 80%. We also excluded RCTs with a follow up of less than 1 month, so that we could assess rates of sustained resolution and recurrence.

QUESTION What are the effects of empirical treatment?

OPTION ORAL ANTIBIOTICS

We found no RCTs of oral antibiotics compared with placebo or compared with topical anti-infective agents. One RCT found limited evidence of no significant difference between oral co-trimoxazole plus topical anti-infective ointment and topical anti-infective ointment alone in symptom severity, symptom duration, and cure rate.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus topical anti-infective agents:** We found no RCTs. **Plus topical anti-infective agents:** One double blind RCT (105 people with any severity of acute diffuse otitis externa on otoscopy) compared 5 days of oral co-trimoxazole versus placebo in a primary care setting.[5] Both groups also received repeated applications of ointment containing triamcinolone, neomycin, and gramicidin, and had suction of the external canal if discharge was present. The RCT found no significant difference between groups in symptom and sign severity scores, duration of symptoms, or cure rate (improvement in mean symptom and sign severity score on scale ranging from 1 [no symptoms] to 5 [severe symptoms]: 0.72 with added oral co-trimoxazole *v* 0.69 with added placebo; $P > 0.4$ mean duration of symptoms: 3.1 days with added oral co-trimoxazole *v* 3.1 days with placebo, $P > 0.5$; cure rates: 18/47 [38%] with added oral co-trimoxazole *v* 21/53 [40%] with placebo; $P > 0.8$).[5]

Harms: The RCT did not report on harms.[5]

Comment: None.

OPTION TOPICAL ANTI-INFECTIVE AGENTS (ANTIBIOTICS AND ANTIFUNGALS)

One RCT found that methylprednisolone–neomycin drops improved symptoms and signs compared with placebo at 28 days. Two RCTs found no significant difference in cure rate between topical quinolones and other topical anti-infective agents. One RCT found that triamcinolone–neomycin drops improved resolution rates compared with hydrocortisone–neomycin–polymyxin B drops. Two RCTs found limited evidence that neomycin–dexamethasone–acetic acid spray improved clinical cure compared with topical anti-infective drops that did not contain acetic acid. We found no RCTs on the effects of topical anti-infective agents versus oral antibiotics. One RCT found limited

evidence of no significant difference between topical anti-infective ointment plus oral co-trimoxzaole and topical anti-infective ointment alone in symptom severity, symptom duration, and cure rate.

Benefits: We found no systematic review. **Versus placebo:** One double blind RCT (40 people in secondary care with mild, moderate, or severe, acute or chronic diffuse otitis externa) compared methylprednisolone–neomycin drops versus placebo drops for 10 days.[6] All people in the RCT had "cleansing" of their external ear canals (details not reported). The RCT found that methylprednisolone–neomycin drops significantly improved symptoms compared with placebo at 28 days ("good" response: 11/20 [55%] with methylprednisolone–neomycin drops *v* 2/20 [10%] with placebo; $P < 0.001$) **Versus oral antibiotics:** We found no RCTs. **Plus oral antibiotics:** See benefits of oral antibiotics, p 679. **Versus each other:** We found four RCTs.[7–10] Three RCTs compared preparations containing a quinolone versus other agents.[7–9] The first, a double blind RCT (842 people with mild to severe acute diffuse otitis externa on otoscopy), compared ciprofloxacin drops with or without hydrocortisone versus polymyxin–neomycin–hydrocortisone drops in a primary care setting for 1 week.[7] People in both groups received suction or mopping of discharge if present. The RCT found no significant difference between ciprofloxacin alone, ciprofloxacin–hydrocortisone and polymyxin–neomycin–hydrocortisone at 14–28 days' follow up (improvement or resolution: 222/239 [93%] with ciprofloxacin *v* 212/236 [90%] with ciprofloxacin–hydrocortisone *v* 198/228 [87%] with polymyxin–neomycin–hydrocortisone; P values not reported).[7] The second RCT (single blind, 601 people with any severity of acute diffuse otitis externa on otoscopy) compared ofloxacin drops versus neomycin–hydrocortisone–polymyxin B drops in a primary care setting for 10 days.[8] At 1 month, it found no significant difference between groups for clinical or microbiological cure (clinical cure: 215/242 [89%] with ofloxacin *v* 206/232 [89%] with neomycin–hydrocortisone–polymyxin B drops, $P = 0.86$; microbiological cure: 85/93 [91%] with ofloxacin *v* 97/103 [94%] with neomycin–hydrocortisone–polymyxin B drops, $P = 0.77$; no further data reported). A third RCT is being translated and will be included in future updates of *Clinical Evidence*.[9] The fourth RCT (double blind, 55 people with moderate to severe acute or chronic diffuse otitis externa on otoscopy, in a secondary care setting) compared drops containing hydrocortisone–neomycin sulphate and polymyxin B versus drops containing triamcinolone–neomycin undecenoate for 1 month or until resolution of all symptoms and signs.[10] All people received microsuction of their ears if discharge was present. The RCT found that triamcinolone–neomycin drops significantly improved resolution rates compared with hydrocortisone–neomycin–polymyxin B drops at 1 month (resolution: 27/34 [79%] with triamcinolone–neomycin *v* 10/21 [47%] with hydrocortisone–neomycin–polymyxin B; $P < 0.01$).[10] **Antibiotic–steroid–acetic acid spray versus antibiotic–steroid drops:** We found two RCTs.[11,12] One single blind RCT (60 people with any severity of acute or chronic diffuse otitis externa on otoscopy) compared neomycin–dexamethasone–acetic acid spray versus framycetin–gramicidin–dexamethasone drops in a primary care setting for 10 days.[11] At 1 month, the neomycin–dexamethasone–acetic acid spray significantly improved

symptoms and signs compared with the framycetin–gramicidin–dexamethasone drops (symptom free: 26/32 [81.3%] with neomycin–dexamethasone–acetic acid spray *v* 6/26 [23.1%] with framycetin–gramicidin–dexamethasone drops, $P < 0.0001$; free of clinical signs: 17/32 [53.1%] with neomycin–dexamethasone–acetic acid spray *v* 10/28 [37.0%] with framycetin–gramicidin–dexamethasone drops, $P < 0.05$). A second non-blind RCT (187 people with any severity of acute or chronic diffuse otitis externa on otoscopy) compared neomycin–dexamethasone–acetic acid spray versus neomycin–hydrocortisone–polymyxin B drops in a primary care setting for 10 days.[12] It found no significant difference between groups in the proportion of people with improved global symptom scores at 10 days and at 1 month (at 10 days: 86/91 [94.5%] improved with neomycin–dexamethasone–acetic acid spray *v* 79/85 [92.9%] with neomycin–hydrocortisone–polymyxin B drops, $P > 0.5$; at 1 month: 54/86 [62.8%] improved with neomycin–dexamethasone–acetic acid spray *v* 48/81 [59.3%] with neomycin–hydrocortisone–polymyxin B drops, $P > 0.5$).[12] However, compared with neomycin–hydrocortisone–polymyxin B drops, neomycin–dexamethasone–acetic acid spray significantly increased the proportion of people considered to have "good" improvement in signs at 10 days (48/91 [52.7%] with neomycin–dexamethasone–acetic acid spray *v* 31/85 [36.5%] with neomycin–hydrocortisone–polymyxin B drops, $P < 0.05$). **Versus topical steroids:** We found no RCTs. **Versus topical aluminium acetate:** See benefits of topical aluminium acetate, p 682.

Harms: One RCT found no significant difference between ofloxacin drops and neomycin–hydrocortisone–polymyxin B drops in rates of local pruritus, dizziness, or vertigo (local pruritus: 25/158 [15.8%] with ofloxacin *v* 18/156 [11.5%] with neomycin–hydrocortisone–polymyxin B, $P = 0.33$; dizziness or vertigo: 4/158 [2.5%] with ofloxacin *v* 2/156 [1.3%] with neomycin–hydrocortisone–polymyxin B, P value not reported).[8] One RCT reported that 6/32 (18.8%) people using neomycin–dexamethasone–acetic acid spray and 3/26 [11.5%] people using framycetin–gramicidin–dexamethasone drops reported local stinging or burning in the first few days of treatment (significance not reported), which did not affect adherence.[11] The other RCTs did not report on harms.[7,9,10,12]

Comment: None.

OPTION TOPICAL STEROIDS

One RCT in people with mild or moderate acute or chronic otitis externa found that topical budesonide improved symptoms and signs compared with placebo. We found no RCTs of topical steroids compared with topical anti-infective agents. One RCT found no significant difference in symptom scores between low potency steroid (topical hydrocortisone) and high potency steroid (topical hydrocortisone butyrate) after 1 week.

Benefits: We found no systematic review. **Versus placebo:** We found one double blind RCT (60 people with mild or moderate acute or chronic diffuse otitis externa on otoscopy).[13] People with complete occlusion of the external ear canal were excluded. The RCT compared

budesonide drops with placebo drops in a secondary care setting for 7 days.[13] Ear discharge was treated by suction in both groups. The RCT found that budesonide drops significantly improved symptoms and signs compared with placebo after 10 days (change from baseline in a global clinical score ranging from 0 [no symptoms/signs] to 3 [severe symptoms/signs]: −2.29 with budesonide *v* +0.23 with placebo; P = 0.001). **Versus topical anti-infective agents:** We found no RCTs. **Low versus high potency steroids:** One double blind RCT (55 people with any severity of acute or chronic diffuse otitis externa on otoscopy) compared low potency steroid drops (1% hydrocortisone) versus high potency steroid drops (hydrocortisone-17-α-butyrate) in a secondary care setting.[14] It found no significant difference between treatments in symptom scores after 1 week of treatment (score ranging from 0 [no symptoms] to 3 [severe symptoms]: 0.84 with low potency steroid drops *v* 0.80 with high potency steroid drops; P > 0.2).[14]

Harms: **Versus placebo:** The RCT found no significant difference in the frequency of local or systemic adverse events between groups (30% with budesonide *v* 27% with placebo).[13] **Low versus high potency steroids:** The RCT did not report on harms.[14]

Comment: None.

OPTION TOPICAL ALUMINIUM ACETATE

We found no RCTs that compared topical aluminium acetate versus placebo. One RCT in people with acute diffuse otitis externa found no significant difference between aluminium acetate drops and topical polymyxin–neomycin–hydrocortisone drops in time to clinical cure or clinical cure rate at 4 weeks.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus topical anti-infective agents:** One RCT (126 people with any severity of acute diffuse otitis externa on otoscopy) compared aluminium acetate drops versus polymyxin–neomycin–hydrocortisone drops in a primary care setting for 14 days.[15] People in both groups had discharge removed if present (no further details of technique provided). The RCT found no significant difference between groups in clinical cure rate or mean time to clinical resolution at 4 weeks (clinical cure rate: 59/65 [91%] with aluminium acetate *v* 49/61 [80%] with polymyxin–neomycin–hydrocortisone, P > 0.2; mean time to clinical resolution: 9.4 days with aluminium acetate *v* 11.1 days with polymyxin–neomycin–hydrocortisone, P > 0.2).

Harms: The RCT did not report on harms.[15]

Comment: None.

OPTION SPECIALIST AURAL TOILET

We found no RCTs that compared specialist aural toilet versus no aural toilet. One RCT found no significant difference between an ear wick plus anti-infective drops versus ribbon gauze impregnated with anti-infective ointment in resolution rates after 4 weeks.

Benefits: We found no systematic review. **Versus no aural toilet:** See glossary, p 683. We found no RCTs. **Comparison of different types of aural toilet:** One RCT in a secondary care setting (94 people with moderate to severe acute diffuse otitis externa on otoscopy) compared an ear wick plus anti-infective drops (framycetin–gramicidin–dexamethasone or flumetasone) removed after 3 days versus ribbon gauze impregnated with anti-infective ointment (framycetin–gramicidin or triamcinolone–gramicidin–neomycin–nystatin) removed after 3 days.[16] It found no significant difference between groups in resolution rates at 4 weeks (resolution defined as absence of symptoms and signs: 33/47 [70%] with ribbon gauze *v* 30/47 [64%] with ear wick; P = 0.58).

Harms: No adverse effects were reported.[16]

Comment: The results of studies may not be generalisable to settings where professionals have not been trained to provide specialist aural toilet.

GLOSSARY

Aural toilet Aural toilet is usually performed in a secondary (specialist) setting and includes dry mopping of the ear canal or suction. These can be performed using a head light or microscope, which allows cleaning of the more medial areas of the ear canal.

Otitis media with effusion

Search date July 2003

Ian Williamson

QUESTIONS

INTERVENTIONS

Key Messages

Prevention

- **Modifying risk factors to prevent otitis media with effusion** We found no RCTs on the effects of interventions aimed at modifying risk factors, such as passive smoking and bottle feeding in preventing otitis media with effusion.

Treatment

- **Autoinflation (with purpose-manufactured nasal balloon)** One systematic review has found that autoinflation with a purpose-manufactured nasal balloon significantly improves effusion compared with no treatment. Some children may find autoinflation difficult. We found no evidence on other methods of autoinflation.
- **Grommets plus adenoidectomy/adenotonsillectomy** We found one systematic review, which found that grommets and adenoidectomy alone or in combination were equally effective and reduced mean hearing impairment by less than 12 decibels. The clinical significance of this hearing improvement was variable. One RCT from the review, which subsequently reported outcomes after 5 years, found that grommets plus adenoidectomy/adenotonsillectomy was more effective than adenoidectomy/adenotonsillectomy or grommets

alone; all of these surgical interventions were more effective than no treatment in reducing duration of otitis media with effusion. Two subsequent RCTs found different effects on language development with grommets compared with watchful waiting. A fourth subsequent RCT found that early insertion of grommets reduced behavioural problems at 9 months compared with watchful waiting.

- **Corticosteroids (intranasal)** One small RCT found no significant difference between intranasal corticosteroids alone compared with placebo for resolution of effusion. A second small RCT found limited evidence that intranasal corticosteroids plus antibiotics improved symptoms compared with antibiotics alone.
- **Antimicrobial drugs** One systematic review found limited evidence that antibiotics compared with placebo or no treatment improved short term outcomes. However, a second systematic review of higher quality and incorporating six RCTs from the first review found no significant difference between antibiotics and placebo. A third systematic review found limited evidence from four RCTs that antibiotics plus oral corticosteroids improved resolution rates compared with antibiotics alone. Another small RCT in the same review found limited evidence that intranasal corticosteroids plus antibiotics improved symptoms compared with antibiotics alone. Adverse effects with antibiotics (mainly nausea, vomiting, and diarrhoea) were reported in 2–32% of children.
- **Mucolytics** One systematic review found no significant difference between 1–3 month courses of carbocisteine or carbocistine lysine and placebo or no treatment in resolution of effusion. Three small RCTs of bromhexine versus placebo found inconclusive results.
- **Antihistamines plus oral decongestants** One systematic review found no significant difference between antihistamines plus oral decongestants compared with placebo in clearance of effusion after 4 weeks.
- **Corticosteroids (oral)** One systematic review found no significant difference between oral corticosteroids and placebo in clearance of effusion after 2 weeks. It found limited evidence that oral corticosteroids plus antibiotics improved resolution rates compared with antibiotics alone. Oral corticosteroids may cause behavioural changes, increased appetite, and weight gain.
- **Adenoidectomy alone; adenotonsillectomy alone; autoinflation (with other devices); grommets alone; tonsillectomy** We found insufficient evidence on the effects of these interventions.

DEFINITION Otitis media with effusion (OME), or "glue ear", is serous or mucoid but not mucopurulent fluid in the middle ear. Children usually present with hearing loss and speech problems. In contrast to those with acute otitis media (see chapter, p 314), children with OME do not suffer from acute ear pain, fever, or malaise. Hearing loss is usually mild and often identified when parents express concern regarding their child's behaviour, performance at school, or language development.

INCIDENCE/ PREVALENCE One study in the UK found that, at any time, 5% of children aged 5 years had persistent (at least 3 months) bilateral hearing loss associated with OME.[1] The prevalence declines considerably beyond 6 years of age.[2] About 50–80% of children aged 4 years have been affected by OME some time in the past.[2,3] OME is the most common reason for referral for surgery in children in the UK.

Middle ear effusions also occur infrequently in adults after upper respiratory tract infection or after air travel, and may persist for weeks or months after an episode of acute otitis media.[4]

AETIOLOGY/ RISK FACTORS Contributory factors include upper respiratory tract infection and narrow upper respiratory airways.[5,6] Case control studies have identified risk factors, including age 6 years or younger at first onset, day care centre attendance, large number of siblings, low socioeconomic group, frequent upper respiratory tract infection, bottle feeding, and household smoking.[2,5] These factors may be associated with about twice the risk of developing OME.[6]

PROGNOSIS In 5% of preschool children, OME (identified by tympanometric screening) persists for at least 1 year.[7,8] The disease is ultimately self limiting in most cases.[1,4,9] However, one large cohort study (534 children) found that middle ear disease increased reported hearing difficulty at 5 years of age (OR 1.44, 95% CI 1.18 to 1.76) and was associated with delayed language development in children up to 10 years of age.[10]

AIMS OF INTERVENTION To improve hearing and wellbeing; to avoid poor behavioural, speech, and educational development; to prevent recurrent earache and otitis media, with minimal adverse effects.

OUTCOMES Resolution of effusion (both speed and completeness) assessed by otoscopy, tympanometry, or global clinical assessment; hearing impairment, assessed by audiometry or tympanometry (although the positive predictive value of these tests has been reported as low as 49%);[11] developmental and behavioural tests; language and speech development; adverse effects of treatment. Patient centred outcomes in children with OME (e.g. disability or quality of life) need further development and evaluation.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of preventive interventions?

OPTION MODIFYING RISK FACTORS

We found no RCTs on the effects of risk factors interventions aimed at modifying, such as passive smoking and bottle feeding, in preventing otitis media with effusion.

Benefits: We found no systematic review or RCTs of interventions aimed at modifying risk factors for otitis media with effusion (see comment below).

Harms: We found no RCTs.

Comment: There is good epidemiological evidence that the risk of otitis media with effusion is increased by passive smoking,[2] bottle feeding,[5] low socioeconomic group, and exposure to a large number of other children.[11] Feasible preventive interventions may include strategies to reduce household smoking and encourage breast feeding.

QUESTION What are the effects of pharmacological, mechanical, and surgical treatments?

OPTION ANTIMICROBIAL DRUGS

One systematic review found limited evidence that antibiotics improved short term outcomes compared with placebo or no treatment. However, a second systematic review of higher quality and incorporating six RCTs from the first review, found no significant difference between antibiotics and placebo. A third systematic review found limited evidence from four RCTs that antibiotics plus oral corticosteroids improved resolution rates compared with antibiotics alone, and another small RCT in the same review found limited evidence that intranasal corticosteroids plus antibiotics improved symptoms compared with antibiotics alone. Adverse effects with antibiotics (mainly nausea, vomiting, and diarrhoea) were reported in 2–32% of children.

Benefits:

Versus placebo: We found two systematic reviews.[11,12] The first systematic review (search date 1992, 10 RCTs, 1041 children with otitis media with effusion, age range not reported) reported RCTs which were heterogeneous in study design. Eight RCTs compared antimicrobial drugs (amoxicillin [amoxycillin] with or without clavulanic acid, cefaclor, erythromycin, sulfisoxazole, sulfamethoxazole [sulphamethoxazole], or trimethoprim) versus placebo or no treatment. One RCT compared antimicrobial drugs (erythromycin plus sulfisoxazole, cefaclor, and amoxicillin [amoxycillin]) versus each other and placebo and one RCT compared an antibiotic (cotrimoxazole) versus antihistamine plus decongestant plus antitussic.[11] Treatment duration varied from 2–5 weeks. Follow up was from 10–60 days. At up to 1 month, antimicrobial treatment significantly increased resolution of effusion (assessed by pneumatic otoscopy, tympanometry, and audiometry) compared with placebo or no treatment (pooled ARR for non-resolution with antibiotics *v* placebo or no treatment: 14%, 95% CI 4% to 24%). The second systematic review (search date 1997, 8 RCTs [including 6 of the RCTs from the first review], 1292 children with otitis media with effusion, age range not reported) compared antibiotics versus placebo and found no significant difference in cure rate over 2–5 weeks (cure rate: 179/813 [22%] with antibiotics *v* 85/479 [18%] with placebo; ARI of cure: +4.3%, 95% CI −0.1% to +8.6%).[12] **Antibiotics plus corticosteroids:** See benefits of corticosteroids, p 688.

Harms:

The systematic reviews did not report rates of adverse events in children on placebo or no treatment.[11,12] Adverse events were frequent with antibiotics. For amoxicillin, diarrhoea was reported in 20–30% and rashes in 3–5% of children. For co-amoxiclav, diarrhoea was reported in 9%, nausea and vomiting in 4%, and skin rashes and urticaria in 3% of children.[11,13] For antibiotics overall, nausea and vomiting, diarrhoea, or both were reported in 2–32% of children, and cutaneous reactions in fewer than 5%.[13] Adherence to long courses of antibiotics was poor. Prescribing antibiotics for minor illness encouraged further consultations[14] and antibiotic resistance.[15]

Otitis media with effusion

Comment: The second systematic review[12] contained a methodological criticism of the first review[11] and pointed out that pooling data from studies with and without placebo controls introduced a significant bias towards antibiotic efficacy.

OPTION CORTICOSTEROIDS

One systematic review found no significant difference between oral corticosteroids and placebo in clearance of effusion after 2 weeks. It found limited evidence that oral corticosteroids plus antibiotics improved resolution rates compared with antibiotics alone. One small RCT found no significant difference between intranasal corticosteroids alone compared with placebo for resolution of effusion. A second small RCT found limited evidence that intranasal corticosteroids plus antibiotics improved symptoms compared with antibiotics alone.

Benefits: We found one systematic review (search date 2002, 10 RCTs, 718 children in secondary care and selected (air force base) settings).[16] **Oral corticosteroids versus placebo:** The systematic review identified three RCTs (108 children) comparing oral corticosteroids (either prednisone or dexamethasone) with placebo. Presence of effusion was assessed clinically by pneumatic otoscopy, tympanometry, and audiometry after 7–14 days of treatment. The review found no significant difference in mean improvement at 2 weeks after treatment (AR of clearance compared with placebo +21%, 95% CI –3% to +44%). Longer term effects were not sufficiently recorded for inclusion. **Oral corticosteroids plus antibiotic:** The systematic review identified four RCTs (274 children) comparing antibiotic (cefixime, amoxycillin, or sulfisoxazole) plus oral corticosteroids (betamethasone or prednisone) versus antibiotic alone.[16] Time to measurement of results varied from 1 week to 6 months. The review found a significant difference in clearance rates with combined treatment compared with antibiotic alone (ARR for non-clearance *v* antibiotic alone at 2 weeks 32%, 95% CI 20% to 50%, $P < 0.01$). Longer term effects were not sufficiently recorded for inclusion. **Intranasal corticosteroids versus placebo:** The systematic review identified one RCT (45 children), which found no significant difference between intranasal dexamethasone and placebo in persistence of effusion at 3 weeks (OR 2.12, 95% CI 0.65 to 6.90).[17] **Intranasal corticosteroids plus antibiotics:** The systematic review identified one RCT (59 children aged 3–11 years), which found that intranasal corticosteroids plus antibiotics significantly reduced effusions at 4 weeks ($P < 0.05$), 8 weeks ($P < 0.05$), and 12 weeks ($P < 0.01$) compared with antibiotics plus placebo.[18]

Harms: The six RCTs in the review reporting on adverse events found no severe or lasting adverse effects of corticosteroids.[16] The other RCTs mentioned mild possible adverse effects of cortcosteroids, such as vomiting, diarrhoea, dermatitis, transient nasal stinging, and epistaxis.

Comment: The trials in the review were small and showed significant heterogeneity.[16] Use of secondary care populations weakens the applicability of results to primary care.

OPTION ANTIHISTAMINES PLUS DECONGESTANTS

One systematic review found no significant difference between antihistamines plus decongestants compared with placebo in clearance of effusion in children with otitis media with effusion after 4 weeks.

Benefits: We found one systematic review (search date 1992, 4 large RCTs, 1202 infants and older children, age range not stated).[11] The review found no significant difference between 4 weeks of treatment with antihistamine plus decongestants compared with placebo in effusion clearance rate, as assessed by history, otoscopy, and tympanometry (mean difference –0.009, 95% CI –0.036 to +0.054).

Harms: Adverse effects of antihistamines include hyperactivity, insomnia, drowsiness, behavioural change, blood pressure variability, and seizures.[11] One RCT in healthy volunteers found that decongestant nose drops given for 3 weeks or more led to iatrogenic rhinitis.[19]

Comment: The RCTs in the review included clinically heterogeneous groups (e.g. infants and older children) and selected individuals from ambulatory care or waiting lists.[11] However, the review suggested that the evidence could be generalised to a child of any age.

OPTION MUCOLYTICS

One systematic review found no significant difference between 1–3 month courses of carbocisteine or carbocistine lysine and placebo or no treatment in resolution of effusion. Three small RCTs of bromhexine versus placebo found inconclusive results.

Benefits: We found one systematic review (search date 1993, 6 RCTs, 428 children aged 3–11 years and 2 adults) comparing 15–90 days' treatment with carbocisteine, carbocisteine lysine, or both, compared with placebo or no treatment.[20] The review found that mucolytics were associated more frequently with complete resolution but the difference with the control group was not significant (178 children; 80/81 [99%] with treatment *v* 54/98 [55%] with placebo; OR 2.25, 95% CI 0.97 to 5.22). Three small RCTs (155 children and 195 ears) comparing another mucolytic (bromhexine) with placebo found inconclusive results.[21–23]

Harms: The review gave no information on adverse effects.[20]

Comment: The RCTs in the review were heterogeneous in their clinical outcomes and treatment duration.[20] However, the RCTs combined in the meta-analysis were homogeneous regarding dosage and outcome.

OPTION AUTOINFLATION

One systematic review has found that autoinflation with a purpose-manufactured nasal balloon significantly improves effusion compared with no treatment. Some children may find autoinflation difficult. We found no evidence on other methods of autoinflation.

Otitis media with effusion

Benefits: We found one systematic review (search date not reported, 6 RCTs, 435 children, age range not stated) comparing autoinflation versus no treatment (see comment below).[24] Three RCTs (386 children) found that children using purpose-manufactured nasal balloons were more likely than controls to improve within 1 week to 3 months using tympanometric and audiometric criteria (OR 3.53, 95% CI 2.03 to 6.14).[24] We found no systematic reviews and no RCTs on other methods of autoinflation (such as inflating a carnival blower through the nostril or forcible exhalation through the nostrils, with closed mouth, into an anaesthetic mask with a flow meter attachment).

Harms: The review found no reports of serious adverse effects.[24]

Comment: The quality of the review's evidence is limited by several weaknesses. Most trials seemed not to use intention to treat analysis, and beneficial effects were noted only when adherence was 70% or greater.[24] Outcome assessments were not blinded, and follow up was short. The RCTs also varied in their outcome measures: being effusion free, improved tympanogram, or improvement in hearing. The Eustachian tubes can be inflated by several methods, including blowing up a balloon through a plastic tube inserted into the nostril. In one RCT, 12% of children aged 3–10 years were unable to use the balloon.[25]

OPTION SURGERY

We found one systematic review, which found that grommets and adenoidectomy alone or in combination were equally effective and reduced mean hearing impairment by less than 12 decibels. The clinical significance of this hearing improvement was variable. One RCT from the review, which subsequently reported outcomes after 5 years, found that grommets plus adenoidectomy/adenotonsillectomy was more effective than adenoidectomy/adenotonsillectomy or grommets alone, and all of these surgical interventions were more effective than no treatment in reducing duration of otitis media with effusion. Two subsequent RCTs found different effects on language development with grommets compared with watchful waiting. A fourth subsequent RCT found that early insertion of grommets reduced behavioural problems at 9 months compared with watchful waiting. We found no good evidence on the effects of tonsillectomy alone or any evidence of additional benefit of adenotonsillectomy over adenoidectomy alone.

Benefits: **Grommets versus adenoidectomy:** We found one systematic review (search date 1992, 19 RCTs)[9] and one subsequent report after 5 years of an RCT included in the review,[26] and three subsequent RCTs.[27–29] The review concluded that grommets and adenoidectomy alone or in combination were equally effective and reduced mean hearing impairment by less than 12 decibels. The clinical significance of this hearing improvement was variable.[9] Nine RCTs reported the data per child (1508 children) and 10 reported data per ear (1452 children). None were placebo controlled, although some used children who had received grommets in one ear only and in these cases the operated and non-operated ears

were compared against each other (see comment below). Outcomes were mean change in audiometry, tympanometry, and clinical and otoscopic evidence of otitis media with effusion. One of the RCTs within the review subsequently reported outcomes after 5 years.[26] The RCT (228 children aged 2–9 years) compared adenotonsillectomy or adenoidectomy (analysed together) versus neither procedure. All children had a grommet inserted into one randomly chosen ear. Outcomes were mean audiometric change, and tympanometric and otoscopic clearance assessed over 6 months to 10 years after treatment and reported per ear. The three subsequent RCTs assessed treatment with grommets alone by comparing the use of grommets with watchful waiting,[27] early versus delayed insertion of grommets,[28] and early insertion of bilateral grommets versus watchful waiting.[29] **Grommets alone (also referred to as ventilation tubes or tympanostomy tubes):** The 5 year follow up of an RCT within the review found that median duration of glue ear was reduced from 7.8 years without treatment to 4.9 years with grommets.[26] The first and second subsequent RCTs studied children under the age of 3 years and the main outcomes reported were speech and language development rather than hearing or persistence of effusion.[27,28] The first subsequent RCT (187 children aged 16–24 months) found that treatment with grommets improved verbal comprehension and expressive language compared with watchful waiting (significance not reported).[27] The second subsequent RCT (429 children aged ≤3 years with persistent effusion and mild to moderate hearing loss) compared early versus delayed insertion of grommets.[28] It found no significant effect on language development measured on a range of scales. The third subsequent RCT (182 children, mean age 2.9 years) found that early insertion of bilateral grommets significantly reduced behavioural problems at 9 months compared with watchful waiting using the Richman behaviour check list (see glossary, p 692) (percentage ≥10 on Richman score: 25/84 [30%] of children with bilateral grommets *v* 31/66 [47%] of children with watchful waiting; RR 0.63, 95% CI 0.30 to 0.96).[29] **Adenoidectomy alone:** The review reported a mean of less than 12 decibels short term improvement in hearing after adenoidectomy (CI not reported).[9] The 5 year follow up of the included RCT found that median duration of otitis media with effusion (OME) was reduced from 7.8 years without treatment to 4 years with adenoidectomy alone.[26] **Grommets plus adenoidectomy:** The review found that adenoidectomy gave little additional benefit over grommets alone in terms of mean short term hearing gain, which varied from 1.1–2.6 decibels.[9] The 5 year follow up of an RCT within the review found improved tympanometric and otoscopic clearance when combining adenoidectomy/adenotonsillectomy with grommets versus grommets alone or no treatment. Median duration of OME assessed tympanometrically was reduced from 7.8 years without treatment to 2.8 years with adenoidectomy/adenotonsillectomy plus grommets.[26] **Tonsillectomy:** The review found no RCTs of good quality for tonsillectomy alone in OME.[9] **Adenotonsillectomy:** One RCT in the review found that adding tonsillectomy gave no benefit over adenoidectomy alone in the treatment of children with OME.[9]

Otitis media with effusion

Harms: We found one systematic review (search date 1999), which found that transient otorrhoea was a common complication of grommet insertion (7 studies, 1522 children: incidence 16%, 95% CI 14% to 18%) and even more so later (23 studies, 5491 people: incidence 26%, 95% CI 25% to 27%).[30] Recurrent ear discharge was also common (7 studies, 1144 children: incidence 7.4%, 95% CI 6.0% to 9.0%) and often became chronic (3 studies, 451 children: incidence 3.8%, 95% CI 2.0% to 6.0%). **Grommets alone:** A systematic review of observational and experimental studies (search date 1998) of the complications after grommet insertion found a reported prevalence of tympanosclerosis in 39–65% of treated ears as opposed to 0–10% of untreated ears.[31] Partial atrophy was noted in 16–73% of treated ears and in 5–31% of those untreated. Atelectasis ranged from 10–37% of treated ears as opposed to 1–20% of those untreated, and attic retraction was noted in 10–52% of treated ears and 29–40% of those untreated. The average hearing loss associated with these abnormalities was less than 5 decibels. The rate of otorrhoea after swimming in children with grommets is low, particularly in non-divers, and protection to the ear confers no proven benefit.[32] **Adenotonsillectomy:** Deaths have been reported in 1/16 700–1/25 000 children for adenotonsillectomy (no figures provided for adenoidectomy alone) and postoperative haemorrhage occurred in 0.5%.[33]

Comment: Myringotomy is usually performed together with grommet insertion but is not effective on its own.[9] The validity of using operated and non-operated grommet insertion as intervention and control as described in the systematic review is uncertain and the more recent studies have randomised children rather than ears.[9] The second subsequent RCT reported that the groups were not equivalent at baseline, with an initially higher level of educational development in children in the watchful waiting group.[27] The third subsequent RCT had low withdrawal rates (17/90 [18%] with watchful waiting *v* 9/92 [9%] with early surgery) but no intention to treat analysis.[29] About half of children who have grommets inserted will have reinsertion within 5 years.[34] Resolution after surgery takes longer in younger children and in those whose parents smoke, irrespective of treatment.[29]

GLOSSARY

Richman behaviour check list A 12 item derivation of the Behaviour Screening questionnaire.

Substantive changes

Antimicrobial drugs Change of categorisation from trade off between benefits and harms to unlikely to be beneficial on re-analysis of the data.

Grommets with adenoidectomy/adenotonsillectomy Change of categorisation from unknown effectiveness to likely to be beneficial on re-evaluation of the evidence.

QUESTIONS

INTERVENTIONS

Key Messages

Quality of life

- **Oral fexofenadine** Of all the oral antihistamines, only fexofenadine has been shown in RCTs to improve quality of life as well as rhinitis symptoms compared with placebo.
- **Oral leukotriene receptor antagonists** One systematic review provided good evidence that montelukast improved quality of life compared with placebo.
- **Oral leukotriene receptor antagonists plus oral antihistamines** One systematic review has found that montelukast plus loratadine improves quality of life compared with placebo. However, it found no evidence that combined treatment was any more effective than loratadine or montelukast alone.

- **Intranasal antihistamines; intranasal ipratropium bromide; oral decongestants; oral decongestants plus oral antihistamines; other oral antihistamines** We found no RCTs evaluating the effects of these interventions on quality of life.

Rhinitis symptoms

- **Oral antihistamines** Numerous RCTs have found that oral antihistamines (acrivastine, azatadine, brompheniramine, cetirizine, ebastine, loratadine, desloratadine, or mizolastine) improve rhinitis symptoms compared with placebo. Drowsiness, sedation, and somnolence were the most commonly reported adverse effects.
- **Oral pseudoephedrine plus oral antihistamines** RCTs have found that pseudoephedrine plus oral antihistamines (fexofenadine, acrivastine, cetirizine, terfenadine, triprolidine, loratadine, or azatadine) improve overall symptoms of seasonal allergic rhinitis compared with pseudoephedrine or oral antihistamine or placebo alone. The most common adverse effects reported with combination treatment were headache and insomnia.
- **Intranasal levocabastine** RCTs found that intranasal levocabastine improved symptoms of seasonal allergic rhinitis compared with placebo.
- **Oral leukotriene receptor antagonists** One systematic review provided good evidence that montelukast improved nasal symptoms compared with placebo. One RCT provided inconclusive evidence about effects of pranlukast compared with placebo.
- **Oral leukotriene receptor antagonists plus oral antihistamines** One systematic review has found that montelukast plus loratadine improves nasal symptoms compared with placebo. However, it found no evidence that combined treatment was any more effective than loratadine or montelukast alone.
- **Oral astemizole** RCTs have found that astemizole improves rhinitis symptoms compared with placebo but astemizole has been associated with prolongation of the QTc interval, and may induce ventricular arrhythmias.
- **Oral terfenadine** RCTs have found conflicting results about the effectiveness of terfenadine compared with placebo on rhinitis symptoms. Terfenadine is associated with risk of fatal cardiac toxicity if used in conjunction with macrolide antibiotics, oral antifungal agents, or grapefruit juice.
- **Intranasal azelastine** RCTs have found conflicting results about effectiveness of intranasal azelastine compared with placebo on symptoms of seasonal allergic rhinitis. Two small RCTs found no significant difference in nasal symptoms between intranasal antihistamines (azelastine, levocabastine) and oral antihistamines (cetirizine, terfenadine).
- **Intranasal ipratropium bromide** We found no systematic review or published RCTs.

DEFINITION Seasonal allergic rhinitis is a symptom complex that may affect several organ systems. Symptoms will typically consist of seasonal sneezing, nasal itching, nasal blockage, and watery nasal discharge.[1] Eye symptoms (red eyes, itchy eyes, and tearing) are common. Other symptoms may include peak seasonal coughing, wheezing, and shortness of breath, oral allergy syndrome (manifesting as an itchy swollen oropharynx on eating stoned fruits), and systemic symptoms such as tiredness, fever, a pressure sensation

in the head, and itchiness. Confirming the presence of pollen hypersensitivity using objective allergy tests such as skin prick tests, detection of serum specific IgE, and nasal provocation challenge testing may improve diagnostic accuracy.

INCIDENCE/ PREVALENCE Seasonal allergic rhinitis is found throughout the world. Epidemiological evidence suggests that there is considerable geographical variation in its prevalence. Prevalence is highest in socioeconomically developed countries, where the condition may affect as much as 25% of the population.[2–4] Prevalence and severity are increasing. It is thought that improved living standards and reduced risk of childhood infections may lead to immune deviation of T helper cells in early life, which may increase susceptibility to seasonal allergic rhinitis (the so called "hygiene hypothesis").[5,6] Although people of all ages may be affected, the peak age of onset is adolescence.[7]

AETIOLOGY/ RISK FACTORS The symptoms of seasonal allergic rhinitis are caused by an IgE mediated type 1 hypersensitivity reaction to grass, tree, or weed pollen. Allergy to other seasonal aeroallergens such as fungal spores may also provoke symptoms. Typically, symptoms become worse during the relevant pollen season and in the open, when pollen exposure is increased. Risk factors include a personal or family history of atopy or other allergic disorders, male sex, birth order (increased risk being seen in first born), and small family size.[8,9]

PROGNOSIS Seasonal allergic rhinitis may impair quality of life, interfering with work, sleep, and recreational activities.[10] Other allergic problems such as asthma and eczema frequently coexist, adding to the impact of rhinitis.[11]

AIMS OF INTERVENTION Treatments for seasonal allergic rhinitis aim to minimise or eliminate symptoms, optimise quality of life, and reduce the risk of developing coexistent disease.

OUTCOMES We extracted data on the following outcomes: quality of life, days off school/work, rhinitis symptom scores (as described in studies), medication usage and medication usage scores (as defined in studies), and adverse effects. Although most of these outcome measures have face validity, few have been formally validated. Few studies used validated quality of life measures.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION What are the effects of treatments for symptoms of seasonal allergic rhinitis?

OPTION ORAL ANTIHISTAMINES

Only fexofenadine has been shown in RCTs to improve quality of life as well as rhinitis symptoms, although astemizole has been associated with prolongation of the QTc interval, and may induce ventricular arrhythmias. RCTs have found conflicting results about the effectiveness of terfenadine compared with placebo on rhinitis symptoms. Terfenadine is associated with the risk of fatal cardiac toxicity if used with macrolide antibiotics, oral antifungal agents, or grapefruit juice. Numerous RCTs have found that other oral antihistamines (acrivastine, azatadine,

brompheniramine, cetirizine, desloratidine, ebastine, loratadine, and mizolastine) improve rhinitis symptoms compared with placebo. Drowsiness, sedation, and somnolence were the most commonly reported adverse effects of oral antihistamines.

Benefits: We found no systematic review. We found numerous RCTs comparing oral antihistamines versus placebo or other antihistamines, but only three RCTs evaluated quality of life as an outcome measure.[12–14] Most of the RCTs used symptom scores to evaluate the effectiveness of oral antihistamines on rhinitis symptoms (see tables A, B, and C on web extra). **Acrivastine:** Three RCTs found that acrivastine 16–32 mg daily significantly reduced rhinitis symptoms compared with placebo.[15–17] **Astemizole:** Eight RCTs found that astemizole (10 mg once daily or 10 or 25 mg once weekly) reduced overall symptoms compared with placebo.[18–25] One RCT did not specify either the dose of treatment or the frequency of its administration.[25] **Azatadine:** One small RCT (crossover, 38 people aged > 12 years with both asthma and rhinitis) found no significant difference in rhinitis symptoms between adding azatadine (1 mg twice daily) or placebo to the existing treatment regimen (not specified).[26] **Brompheniramine:** Two large RCTs comparing brompheniramine 8–24 mg daily versus terfenadine 60–120 mg daily or placebo found that brompheniramine significantly improved rhinitis symptoms compared with placebo.[27,28] **Cetirizine:** Eight RCTs found that cetirizine 10 mg daily significantly improved rhinitis symptoms compared with placebo.[29–36] One additional RCT (470 people) found that levocetirizine (2.5, 5, and 10 mg once daily for 2 weeks) significantly reduced sneezing, rhinorrhoea, nasal pruritus, and ocular pruritus compared with placebo over the 2 weeks (difference in mean total 4 symptom score compared with placebo: 0.91 with 2.5 mg; 1.11 with 5 mg; 1.61 with 10 mg; $P < 0.001$).[37] **Ebastine:** We found three RCTs comparing ebastine 10–40 mg daily versus placebo[38–40] and one RCT comparing ebastine 10 or 20 mg daily versus loratadine 10 mg daily versus placebo.[39] All four RCTs found that ebastine significantly improved rhinitis symptoms compared with placebo.[38–41] **Fexofenadine:** We found nine RCTs.[12–14,41–46] Three of these RCTs reported on quality of life. The first RCT (multicentre, 845 people aged 12–65 years with history of seasonal allergic rhinitis and positive skin test to an unspecified allergen) compared fexofenadine 120 or 180 mg daily versus placebo over 2 weeks.[12] Outcomes were assessed using Rhinoconjunctivitis Quality of Life Questionnaire (see glossary, p 705) score; work, classroom, and daily activity impairment (Work Productivity and Activity Impairment instrument [see glossary, p 706]) and general health (SF-36 Health Survey [see glossary, p 705]). The RCT found that fexofenadine significantly improved quality of life ($P \leq 0.006$) and reduced work and daily activity impairment ($P \leq 0.004$) compared with placebo. The RCT found no significant difference in classroom impairment between fexofenadine and placebo. The second RCT (multicentre, 1948 people aged 11–68 years with 2 year history of seasonal allergic rhinitis and positive skin test to grass and tree allergens) also found that fexofenadine 120 mg daily significantly improved quality of life ($P \leq 0.05$) and reduced work impairment ($P \leq 0.05$) compared with placebo.[13] The third RCT (multicentre, 688 people aged 12–75 years with a 2 year

history of seasonal allergic rhinitis and a positive skin test for grass, tree pollen, or both) compared fexofenadine 120 mg daily with loratadine 10 mg daily or placebo over 2 weeks.[14] The RCT found that fexofenadine significantly improved quality of life ($P < 0.005$) and 24 hour reflective symptom scores ($P < 0.0001$) compared with placebo.[14] The remaining six RCTs did not report on quality of life. All the RCTs found that fexofenadine 80–240 mg daily significantly improved rhinitis symptoms compared with placebo.[41–46] **Loratadine:** Ten RCTs comparing loratadine versus placebo or other antihistamines (clemastine, mequitazine, terfenadine) found that loratadine reduced rhinitis symptom scores more than placebo.[47–56] One further RCT (337 people aged ≥ 12 years or with 2 year history of seasonal allergic rhinitis) found that, over 2 weeks, desloratadine 5 mg daily reduced total rhinitis symptom score more than placebo ($P < 0.01$).[57] **Desloratadine:** We found one systematic review (search date 2002, 4 RCTs of people with seasonal allergic rhinitis)[58] and one additional RCT comparing desloratadine versus placebo or other antihistamines.[59] The systematic review found that desloratadine significantly reduced the total symptom score, total nasal symptoms, total non-nasal symptoms, and self assessed congestion scores compared with placebo ($P \leq 0.05$ for all comparisons).[58] One additional RCT (337 people aged ≥ 12 years or with 2 year history of seasonal allergic rhinitis) found that over 2 weeks desloratadine 5 mg daily was significantly faster at reducing total rhinitis symptom score compared with placebo ($P < 0.01$).[54] **Mizolastine:** Two RCTs found that mizolastine 10 or 15 mg daily significantly reduced physician rated overall symptom scores compared with placebo ($P < 0.005$). They found no significant difference between mizolastine 5 mg daily and placebo.[59,60] **Terfenadine:** We found 15 RCTs comparing terfenadine versus placebo or other antihistamines.[30,33,38,50–52,60–68] Eight of the RCTs found that terfenadine significantly reduced overall subject rated symptom scores compared with placebo.[50–52,60–64] The seven other RCTs found no significant difference in subject rated overall rhinitis symptom scores between terfenadine and placebo.[30,33,38,65–68] **Other antihistamines:** We found no RCTs. **Oral versus intranasal antihistamines:** See benefits of intranasal antihistamines, p 699.

Harms: Most of the RCTs reported drowsiness, sedation, or somnolence as a common adverse effect (see tables A, B, and C on web extra). **Astemizole:** Astemizole has been associated with prolongation of the QTc interval, and thus has the potential to induce ventricular arrhythmias.[69] **Fexofenadine:** Two RCTs did not report specifically on any adverse effects.[12,13] One RCT found no significant difference in adverse effects between fexofenadine and placebo or loratadine.[14] **Desloratadine:** One RCT found no significant difference in adverse effects between desloratadine and placebo.[54] **Terfenadine:** Terfenadine is associated with risk of fatal cardiac toxicity if used in conjunction with macrolide antibiotics, oral antifungal agents, or grapefruit juice.[70] **Other antihistamines:** We found one cohort study (postmarketing surveillance of fexofenadine, acrivastine, cetirizine, and loratadine involving 43 363 people; the main outcome measure was sedation or drowsiness).[71] It found significantly higher incidence of sedation for acrivastine (OR 2.79, 95% CI 1.69 to 4.58; $P < 0.0001$) and cetirizine (OR 3.53, 95%

CI 2.07 to 5.42; P < 0.0001) compared with loratadine. However, it found no difference between fexofenadine and loratadine (OR 0.63, 95% CI 0.36 to 1.11; P = 0.1). No increase in risk of accident or injury was found with any of the four antihistamines.[71]

Comment: None.

OPTION INTRANASAL ANTIHISTAMINES

We found no systematic review or RCTs evaluating the effects of intranasal antihistamines on quality of life. One meta-analysis of 11 RCTs (10 unpublished) has found that intranasal levocabastine improves symptoms of seasonal allergic rhinitis compared with placebo. Four RCTs found conflicting results on effectiveness of intranasal azelastine compared with placebo on symptoms of seasonal allergic rhinitis. Two small RCTs found no significant difference in nasal symptoms between intranasal antihistamines (azelastine, levocabastine) and oral antihistamines (cetirizine, terfenadine).

Benefits: We found no systematic review or RCTs evaluating the effect of intranasal antihistamines on quality of life. **Levocabastine versus placebo:** We found one meta-analysis (11 RCTs, only 1 published study, total of 693 people, no significant heterogeneity found across individual studies) comparing the global effectiveness of intranasal levocabastine with placebo.[72] Global effectiveness was defined as response or no response of rhinitis symptoms to treatment, assessed by study investigators. The meta-analysis found that the global effectiveness of levocabastine was significantly better than placebo (pooled OR 2.30, 95% CI 1.70 to 3.11; P < 0.001). One of two additional levocabastine RCTs not included in the meta-analysis found that levocabastine significantly reduced subject rated rhinitis symptoms compared with placebo over a 4 week period (P < 0.05).[73] The second levocabastine trial was small (16 people).[74] It found no significant difference in symptoms between the active and placebo treated groups. **Azelastine versus placebo:** We found four RCTs comparing effects of azelastine with placebo on rhinitis symptoms.[75–78] The first RCT (160 people aged 18–65 years with a history of seasonal allergic rhinitis of at least 3 years) compared intranasal azelastine 1.12 mg daily with intranasal beclomethasone 0.4 mg daily or placebo for 2 weeks.[75] Six symptoms (sneezing, nasal itching, rhinorrhoea, nasal stuffiness, eye itching, and watery eyes) were scored daily by the participants. The RCT found that azelastine significantly reduced subject rated rhinitis symptom scores compared with placebo (P < 0.05; summary data not reported). The second RCT (multicentre, 262 people aged > 12 years with a history of seasonal allergic rhinitis for at least 2 years and positive skin test for unspecified seasonal allergens) compared intranasal azelastine 0.52–1.04 mg daily with oral chlorpheniramine 24 mg daily versus placebo for 4 weeks.[76] Efficacy was measured as changes from baseline in total and major symptom complex severity scores. Symptoms included runny nose or sniffles; itchy nose; watery eyes; itchy eyes, ears, throat or palate; cough; postnasal drip; stuffiness; nose blows; and sneezes. The RCT found no significant difference between azelastine and placebo in total subject rated symptom scores 4 weeks after randomisation. The

third RCT (30 people aged 18–53 years with 2 year history of seasonal allergic rhinitis and positive skin test to grass or Parietaria) found no significant difference between intranasal azelastine 0.28–0.56 mg daily and placebo in symptoms scores (summary data and P value not reported).[77] The fourth RCT (99 people, aged 19–61 years with a history of seasonal allergic rhinitis of at least 1 year) found that azelastine decreased symptoms compared with placebo at 7 days, although statistical significance depended on how "response" was defined (decrease in total ocular and nasal scores by ≥ 50%, with fewer than 3 cetirizine rescue tablets in the first 7 days: 43% with azelastine *v* 30% with placebo; P = 0.18; decrease of total ocular and nasal scores by ≥ 50% at day 7, with no cetirizine rescue tablets: 49% with azelastine *v* 28% with placebo; P = 0.04).[78] **Intranasal versus oral antihistamines:** We found two small double blind RCTs comparing intranasal antihistamines versus oral antihistamines.[79,80] Both RCTs found no significant difference in nasal symptoms between intranasal antihistamines (azelastine, levocabastine) and oral antihistamines (cetirizine, terfenadine).

Harms: No serious adverse effects were reported in these trials. Frequency of adverse effects was similar in treatment and placebo arms. The most common adverse effects were sinusitis and headache.

Comment: **Intranasal versus oral antihistamines:** The two RCTs comparing intranasal versus oral antihistamines may have been underpowered to detect any significant difference between these two classes of treatment.[79,80]

OPTION ORAL DECONGESTANTS

We found no systematic review or RCTs evaluating the effect of oral decongestants on quality of life. RCTs have found that pseudoephedrine plus oral antihistamines (fexofenadine, acrivastine, cetirizine, terfenadine, triprolidine, loratadine, desloratadine, or azatadine) improve overall symptoms of seasonal allergic rhinitis compared with pseudoephedrine, oral antihistamine, or placebo. The most common adverse effects reported with combination treatment were headache and insomnia.

Benefits: We found no systematic review or RCTs evaluating the effect of oral decongestants on quality of life. We found no RCTs only comparing oral decongestants with placebo. We found 10 RCTs comparing the effects of oral decongestants plus oral antihistamines with either decongestant alone, antihistamine alone, or placebo on rhinitis symptoms.[77–86] **Pseudoephedrine plus fexofenadine:** The first RCT (651 people aged 12–65 years with positive skin prick to ragweed extract and clinical response to antihistamines) compared sustained release pseudoephedrine (120 mg twice daily) plus fexofenadine (60 mg twice daily) with pseudoephedrine (120 mg twice daily) or fexofenadine (60 mg twice daily) for 2 weeks.[77] The RCT found that pseudoephedrine plus fexofenadine reduced symptom scores for sneezing (P < 0.0001); itchy nose and palate, throat, or

both (P = 0.002); and itchy, watery, red eyes (P = 0.0006) compared with pseudoephedrine alone. Pseudoephedrine plus fexofenadine reduced nasal congestion scores compared with fexofenadine alone (P = 0.0005).[77] **Pseudoephedrine plus acrivastine:** The second RCT (multicentre, double blind, 702 people aged ≥ 12 years with a history of seasonal allergic rhinitis symptoms during the ragweed pollen season of at least 2 years and a positive skin test for ragweed antigen) compared pseudoephedrine 60 mg daily plus acrivastine 8 mg daily versus pseudoephedrine 60 mg daily or acrivastine 8 mg daily or placebo for 2 weeks.[78] The RCT found that pseudoephedrine plus acrivastine reduced the mean nasal congestion scores (P < 0.001) compared with acrivastine and improved the mean diary symptom scores from baseline when compared with acrivastine alone, pseudoephedrine alone, or placebo (P < 0.01). **Pseudoephedrine plus cetirizine:** The third RCT (687 people aged 12–65 years with history of pollen associated allergic rhinitis and positive skin test to unspecified seasonal allergens) compared sustained release pseudoephedrine (120 mg twice daily) plus cetirizine (5 mg twice daily) versus pseudoephedrine alone or cetirizine alone.[79] The main outcome measure was based on five symptoms (blocked nose, sneezing, runny nose, itchy nose, and itchy eyes) assessed by participants over the 2 week treatment period. The RCT found that pseudoephedrine plus cetirizine improved symptoms of sneezing, runny nose, itchy nose, and itchy eyes (P < 0.001 for all outcomes). However, it had no effect on blocked nose compared with pseudoephedrine or cetirizine alone. **Pseudoephedrine plus terfenadine:** The fourth RCT (41 people, pollen sensitivity status not reported) found that sustained release pseudoephedrine (120 mg twice daily) plus terfenadine (60 mg twice daily) improved overall symptoms (P < 0.05) when assessed by both the physician and the participant compared with terfenadine alone (60 mg twice daily).[80] **Pseudoephedrine plus triprolidine:** The fifth RCT (crossover, 40 people aged 22–47 years with clinical history of seasonal allergic rhinitis and positive skin test to mixed grasses, flowers, moulds, trees, house dust extract, and house dust mite) compared pseudoephedrine (60 mg 3 times daily) plus triprolidine (2.5 mg 3 times daily) with pseudoephedrine alone, triprolidine alone, or placebo for 10 weeks. Efficacy was measured with participant assessed symptom score. The RCT found that pseudoephedrine plus triprolidine gave the lowest sneezing, runny nose, and eye irritation score but pseudoephedrine alone gave the lowest blocked nose score.[81] **Pseudoephedrine plus loratadine or desloratadine:** The sixth RCT (multicentre, 847 people aged 12–60 years with history of moderate or severe seasonal allergic rhinitis and positive skin test to ragweed and other prevalent seasonal allergens) compared pseudoephedrine 240 mg daily plus loratadine 10 mg daily versus pseudoephedrine alone, loratadine alone, or placebo for 2 weeks. The RCT found that pseudoephedrine plus loratadine or loratadine alone reduced total symptom scores (P ≤ 0.01) compared with pseudoephedrine or placebo.[82] The seventh RCT (multicentre, 435 people aged 12–60 years with history of moderate to severe symptoms of seasonal allergic rhinitis and positive skin test to unspecified allergens) compared modified release pseudoephedrine (120 mg twice daily) plus loratadine

(5 mg twice daily) versus pseudoephedrine alone, loratadine alone, or placebo. The RCT found that pseudoephedrine plus loratadine improved mean total symptom scores compared with pseudoephedrine alone or placebo ($P < 0.05$).[83] The eighth RCT (1018 people) compared three treatments; desloratadine 5 mg plus pseudoephedrine 240 mg once daily, desloratadine alone, and pseudoephedrine alone.[84] It found that desloratadine plus pseudoephedrine significantly decreased mean morning and evening self assessed nasal congestion scores ($P < 0.01$) and morning nasal congestion scores ($P < 0.01$) at 15 days compared with desloratadine alone or pseudoephedrine alone. It found no significant difference between single treatments in mean nasal congestion scores.[84] **Pseudoephedrine plus azatadine:** The ninth RCT (65 people aged 14–72 years with severe seasonal allergic rhinitis assessed with by symptom scoring method) compared pseudoephedrine 60 mg twice daily plus azatadine 1 mg twice daily with pseudoephedrine alone or placebo for 2 weeks. The RCT found that pseudoephedrine plus azatadine improved signs and symptoms of seasonal allergic rhinitis compared with placebo (74% people with pseudoephedrine plus azatadine *v* 29% people with placebo).[85] The 10th RCT (80 people randomised, 65 analysed) compared azatadine maleate 1 mg plus pseudoephedrine sulphate 60 mg twice daily versus placebo.[86] It found that pseudoephedrine plus azatadine increased the proportion of people with "excellent" self and physician rated improvement (> 75% improvement from baseline) compared with placebo at 2 weeks, but the statistical significance was not reported (self rated excellent improvement: 77% with azatadine plus pseudoephedrine *v* 23% with placebo; physician rated excellent improvement: 74% with azatadine plus pseudoephedrine *v* 19% with placebo). **Other decongestants:** We found no RCTs.

Harms:

Pseudoephedrine plus fexofenadine: The first RCT found no significant difference in the incidence of adverse effects between pseudoephedrine plus fexofenadine and pseudoephedrine alone.[77] It found that pseudoephedrine plus fexofenadine significantly increased adverse effects compared with fexofenadine alone ($P < 0.001$). Headache and insomnia were the most commonly reported adverse effects. **Pseudoephedrine plus acrivastine:** The second RCT found that pseudoephedrine plus acrivastine increased adverse effects (dry mouth, somnolence, nervousness, insomnia) compared with placebo.[78] **Pseudoephedrine plus cetirizine:** The third RCT found no significant difference in the incidence of adverse effects between pseudoephedrine plus cetirizine compared with pseudoephedrine alone or cetirizine alone.[79] **Pseudoephedrine plus terfenadine:** The fourth RCT did not compare the incidence of adverse effects between pseudoephedrine plus terfenadine and terfenadine alone.[80] Terfenadine has been associated with serious adverse events (see harms of oral antihistamines, p 698). **Pseudoephedrine plus triprolidine:** The fifth RCT reported drowsiness with pseudoephedrine plus triprolidine and triprolidine alone.[81] Dry mouth was reported with pseudoephedrine plus triprolidine and pseudoephedrine alone. **Pseudoephedrine plus loratadine:** The sixth RCT found higher incidence of adverse effects (headache, dry mouth) with pseudoephedrine plus loratadine and

pseudoephedrine alone compared with placebo ($P \leq 0.05$).[82] The seventh RCT found no significant difference in adverse effects between pseudoephedrine plus loratadine and pseudoephedrine alone.[83] It found a significantly higher incidence of adverse effects (insomnia, dry mouth) with the pseudoephedrine plus loratadine compared with either loratadine alone or placebo ($P = 0.01$).[83] **Pseudoephedrine plus desloratidine:** The eighth RCT found a higher rate of insomnia with pseudoephedrine alone than desloratadine alone or desloratadine plus pseudoephedrine (7.9% with pseudoephedrine alone *v* 0.6% with loratadine alone *v* 4.8% with pseudoephedrine plus loratadine, P value not reported).[84] However, rates of discontinuing treatment because of adverse events were similar with pseudoephedrine plus desloratadine and pseudoephedrine alone. **Pseudoephedrine plus azatadine:** The ninth RCT did not compare the incidence of adverse effects between pseudoephedrine plus azatadine and placebo.[85] The 10th RCT reported that three people had adverse effects (1 person with nervousness and 1 person with raised blood pressure with azatadine plus pseudoephedrine, and 1 person with palpitations and nervousness with placebo).[86]

Comment: None.

OPTION INTRANASAL IPRATROPIUM BROMIDE

We found no systematic review or fully published RCTs.

Benefits: We found no systematic review or fully published RCTs comparing intranasal ipratropium bromide with placebo for seasonal allergic rhinitis (see comment below).

Harms: We found no systematic review or RCTs.

Comment: We found one RCT reported as an abstract only.[87] The RCT (429 people) compared intranasal ipratropium bromide (84 mg/nostril given 4 times daily) with placebo for 3 weeks during the ragweed season. It found that ipratropium bromide significantly reduced the severity ($P = 0.002$) and duration ($P = 0.008$) of rhinorrhoea during the 3 weeks of treatment compared with placebo. This benefit was maintained during periods of high pollen count. The RCT found no significant difference between ipratropium bromide and placebo for symptoms of nasal congestion, sneezing, or postnasal drip.

OPTION ORAL LEUKOTRIENE RECEPTOR ANTAGONISTS

One systematic review provides good evidence that an oral leukotriene receptor antagonist, montelukast, improves nasal symptoms and quality of life compared with placebo. Three RCTs identified by a systematic review have found that montelukast plus loratadine improves nasal symptoms and quality of life compared with placebo, although they found no evidence that combined treatment was any more effective than loratadine or montelukast alone. One RCT found inconclusive evidence about effects of pranlukast compared with placebo on symptoms.

Benefits: **Montelukast alone:** We found one systematic review (search date 2003, 5 RCTs) that did not pool results.[88] The first RCT in the review (1302 people aged 15–81 years) compared three treatments:

montelukast 10 mg daily, loratadine 10 mg daily, and placebo.[55] It found that montelukast significantly improved daytime nasal symptoms and quality of life compared with placebo (symptoms rated from 0 [none] to 3 [bothersome most of the time/very bothersome some of the time]; mean difference compared with placebo: –0.13, 95% CI –0.21 to –0.06; quality of life assessed by improvement in Rhinoconjunctivitis Quality of Life Questionnaire score [see glossary, p 705]: –0.89 with montelukast *v* –0.65 with placebo; P = 0.003). The RCT did not directly compare montelukast versus loratadine. The second RCT in the review (907 people aged 15–82 years with seasonal allergic rhinitis for ≥ 2 years and positive skin test), carried out in the autumn, compared montelukast 10 mg daily, loratadine 10 mg daily, montelukast plus loratadine, and placebo.[56] Montelukast significantly improved daytime nasal symptom scores and quality of life compared with placebo (mean difference from baseline versus placebo: –0.23, 95% CI –0.35 to –0.11; P < 0.001; difference in Rhinoconjunctivitis Quality of Life Questionnaire score: –1.09, 95% CI –1.26 to –0.92; P < 0.02). The third RCT in the review (1214 non-smoking people) compared the same three treatments (montelukast 10 mg, loratadine 10 mg, and placebo) and used the same outcome measures.[89] It found that montelukast significantly improved daytime nasal symptoms, night time symptoms, and rhinoconjunctivitis quality of life over 2 weeks (mean difference, daytime nasal symptoms: –0.09, 95% CI –0.16 to –0.03; night time symptoms [difficulty getting to sleep, night time wakenings, and nasal congestion on wakening] all scored from 0 to 3: –0.08, 95% CI –0.13 to –0.02; Rhinoconjunctivitis Quality of Life Questionnaire score:–0.24, 95% CI –0.38 to –0.11) The fourth RCT in the review (460 people aged 15–75 years) compared four treatments: montelukast 10 mg daily, montelukast 20 mg daily; montelukast 10 mg daily plus loratadine 10 mg daily; loratadine 10 mg daily; and placebo.[90] It found no significant difference in daytime nasal symptoms score between montelukast alone and placebo at 2 weeks (difference in daytime symptom score using the same outcome measures: –0.11 with 10 mg; –0.04 with 20 mg, P value not reported in review). The fifth RCT in the review (62 people) compared four treatments: montelukast 10 mg daily; montelukast 10 mg daily plus loratadine 10 mg daily; fluticasone nasal spray; and placebo.[91] It found that montelukast alone significantly reduced daytime nasal symptoms compared with placebo at 6–8 weeks (improvement in symptoms [absolute score on 0 to 4 scale]: 1.1; P = 0.03). **Montelukast plus oral antihistamines:** We found one systematic review (search date 2003; 3 RCTs).[88] The identified RCTs compared montelukast 10 mg daily plus loratadine 10 mg daily versus montelukast 10 or 20 mg daily, loratadine 10 mg daily, or placebo. The review did not pool results. The first RCT in the review (460 people aged 15–75 years) found that montelukast plus loratadine significantly improved daytime nasal symptoms and quality of life at 2 weeks compared with placebo (daytime nasal symptoms: P < 0.05; improvement in Rhinoconjunctivitis Quality of Life Score: 0.36; P < 0.05). The second RCT in the review (907 people aged 15–82 years with seasonal allergic rhinitis for ≥ 2 years and positive skin test) was carried out in the autumn.[56] It found that montelukast plus loratadine significantly

improved nasal symptom scores at 2 weeks compared with placebo but not compared with montelukast alone or loratadine alone (*v* placebo, combination: –0.32, 95% CI –0.42 to –0.21; P < 0.001; montelukast alone: –1.09, 95% CI –1.26 to –0.92; *v* loratadine alone: –0.26, 95% CI –0.37 to –0.16). It found that montelukast plus loratadine significantly improved quality of life compared with placebo. However, it found no significant difference in quality of life between montelukast plus loratadine and either montelukast alone or loratadine alone (improvement in Rhinoconjunctivitis Quality of Life Questionnaire score, montelukast plus loratadine *v* placebo: 1.16, 95% CI 1.03 to 1.29; P < 0.001). The third RCT in the review (62 people) compared four treatments: montelukast 10 mg daily plus loratadine 10 mg daily; montelukast 10 mg daily; fluticasone nasal spray; and placebo.[91] It found that montelukast plus loratadine significantly reduced daytime nasal symptoms compared with placebo at 6–8 weeks (P < 0.001). **Other oral leukotriene receptor antagonists:** We found one systematic review (search date not reported),[92] which identified one RCT.[93] The RCT (484 people) compared four treatments: pranlukast 300 or 600 mg daily; loratadine 10 mg daily and placebo.[93] It found that pranlukast 300 mg significantly reduced symptoms at 4 weeks compared with placebo. However, it found no significant difference between pranlukast 600 mg and placebo at 4 weeks (pranlukast 300 mg *v* placebo; P value not reported; pranlukast 600 mg *v* placebo; results and P value not reported).

Harms: Neither of the two systematic reviews assessed harms.[88,92] RCTs found no significant difference in adverse effects among montelukast plus loratadine, montelukast alone, loratadine alone, and placebo.[55,56,90] One RCT found no significant difference in adverse effects between montelukast plus loratadine, montelukast alone, loratadine alone, and placebo.[94]

Comment: **Other oral leukotriene receptor antagonists:** It is unclear why the RCT found that the lower dose of pranlukast significantly reduced symptoms compared with placebo, while the larger dose did not. These results should be interpreted with caution.[93]

GLOSSARY

Rhinoconjunctivitis Quality of Life Questionnaire is widely used in clinical trials to evaluate problems associated with rhinoconjunctivitis such as nose and eye symptoms by adults. It has 28 questions in seven domains (activity limitations, sleep problems, non-nasal/eye symptoms, practical problems, nose symptoms, eye symptoms, and emotional function) and is in both self administered and interviewer administered formats. People are asked to recall their experiences during the previous week and to give their responses on a seven point scale.[95]

SF-36 Health Survey includes one multi-item scale that assesses eight health concepts: limitations in physical activities because of health problems; limitations in social activities because of physical or emotional problems; limitations in usual role activities because of physical health problems; bodily pain; general mental health (psychological distress and wellbeing); limitations in usual role activities because of emotional problems; vitality (energy and fatigue); and general health perceptions. The survey was constructed for self administration by people aged 14 years or older, and for administration by a trained interviewer in person or by telephone.[96]

Seasonal allergic rhinitis

Work Productivity and Activity Impairment instrument is a questionnaire designed to measure work and activity impairment in adults during the previous 7 days. It is constructed for self administration or for use by interviewer in person or by telephone. The number of items varies between six and nine, depending on the version used.

Substantive changes

Antihistamines One systematic review[88] and seven RCTs added;[35–37,40,46] categorisation unchanged but benefits data enhanced.

Oral decongestants Two RCTs added;[84,86] categorisation unchanged but benefits enhanced.

Oral leukotrienes Two systematic reviews added;[88,92] categorisation unchanged, but benefits data enhanced.

Intranasal levocabastine Recategorised from beneficial to likely to be beneficial after reanalysis of the evidence.

QUESTIONS

INTERVENTIONS

See glossary, p 716

Key Messages

In people with clinically diagnosed acute sinusitis

- **Antibiotics** Two RCTs found no evidence that amoxicillin reduced or cured symptoms compared with placebo in people with clinically diagnosed acute sinusitis, who had not had radiological or bacteriological confirmation of disease. One RCT has found that diarrhoea was more common with amoxicillin than with placebo. We found no RCTs examining effects of other antibiotics (amoxicillin–clavulanate, co-trimoxazole, cephalosporins, azithromycin, and erythromycin) compared with placebo or each other.
- **Antihistamines; decongestants; steroids (topical)** We found no RCTs examining clinical effects of topical or systemic decongestants, topical steroids, or antihistamines in people with clinically diagnosed acute sinusitis.

In people with radiologically or bacteriologically confirmed acute sinusitis

- **Cephalosporins and macrolides** One systematic review in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution between amoxicillin or amoxicillin–clavulanate and cephalosporins or macrolides. However, cephalosporins and macrolides caused fewer adverse effects than amoxicillin and amoxicillin–clavulanate. One RCT found no significant difference in clinical improvement or clinical cure between cefaclor (a cephalosporin) and azithromycin (a macrolide).
- **Amoxicillin and amoxicillin–clavulanate** One systematic review identified two RCTs in people with radiologically or bacteriologically confirmed acute maxillary sinusitis, which found that amoxicillin improved early clinical cure rate compared with placebo, but was associated with more frequent adverse effects, mainly gastrointestinal. One systematic review in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution between amoxicillin or amoxicillin–clavulanate and cephalosporins or macrolides. However, amoxicillin and amoxicillin–clavulanate caused more adverse effects.
- **Different dosages of antibiotics** One RCT in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution rates or adverse events between two and three daily doses of cefaclor (a cephalosporin).
- **Antihistamines; decongestants; steroids (topical)** We found no RCTs examining effects of antihistamines, decongestants, or topical steroids in people with radiologically or bacteriologically confirmed acute sinusitis.
- **Long course antibiotic regimens** RCTs in people with confirmed acute sinusitis found no significant difference in clinical resolution rates between a 10 day course and 3–5 day courses of either co-trimoxazole or cefuroxime (a cephalosporin) up to 3 weeks after treatment. One RCT found that adverse effects, which were mainly gastrointestinal, were more frequent with longer course cefuroxime than with shorter course cefuroxime.

DEFINITION Acute sinusitis is defined pathologically, by transient inflammation of the mucosal lining of the paranasal sinuses lasting less than 4 weeks. Clinically, it is characterised by nasal congestion, rhinorrhoea (see glossary, p 716), facial pain, hyposmia (see glossary, p 716), sneezing, and, if more severe, additional malaise and fever. The diagnosis is usually made clinically (on the basis of history and examination, but without radiological or bacteriological investigation). Clinically diagnosed acute sinusitis is less likely to be due to bacterial infection than is acute sinusitis confirmed by radiological or bacteriological investigation.[1] In this chapter, we have excluded studies in children, in people with symptoms for more than 4 weeks (chronic sinusitis), and in people with symptoms after facial trauma. We have made it clear in each section whether we are dealing with clinically diagnosed acute sinusitis or acute sinusitis that has been confirmed by bacteriological or radiological investigation, because the effects of treatment may be different in these groups.

INCIDENCE/ PREVALENCE Each year in Europe, 1–5% of adults are diagnosed with acute sinusitis by their general practitioner.[2] Extrapolated to the British population, this is estimated to cause 6 million restricted working days a year.[3,4] Most people with acute sinusitis are assessed and treated in a primary care setting. The prevalence varies according to whether diagnosis is made on clinical grounds or on the basis of radiological or bacteriological investigation.

AETIOLOGY/ RISK FACTORS One systematic review (search date 1998) reported that about 50% of people with a clinical diagnosis of acute sinusitis have bacterial sinus infection.[1] The usual pathogens in acute bacterial sinusitis are *Streptococcus pneumoniae* and *Haemophilus influenzae*, with occasional infection with *Moraxella catarrhalis*. Preceding viral upper respiratory tract infection is often the trigger for acute bacterial sinusitis,[5] with about 0.5% of common colds becoming complicated by the development of acute sinusitis.[6]

PROGNOSIS One meta-analysis of RCTs found that up to two thirds of people with acute sinusitis had spontaneous resolution of symptoms without active treatment.[7] One non-systematic review reported that people with acute sinusitis are at risk of chronic sinusitis and irreversible damage to the normal mucociliary mucosal surface.[8] One further non-systematic review reported rare life-threatening complications such as orbital cellulitis (see glossary, p 716) and meningitis after acute sinusitis.[9] However, we found no reliable data to measure these risks.

AIMS OF INTERVENTION To relieve symptoms as quickly as possible, with minimal adverse effects.

OUTCOMES Symptom scores; time to self reported symptom resolution; time to clinical resolution (defined by examiner). In the identified studies, clinical improvement and clinical cure were often used as outcome measures. "Clinical improvement" was defined as improvement in clinical state as rated by the assessor or by the participant. "Clinical cure" was defined as resolution of symptoms as rated by assessor or participant.

METHODS *Clinical Evidence* search and appraisal September 2003 for the following interventions: topical or systemic decongestants; topical or systemic steroids; topical or systemic antihistamines; amoxicillin; amoxicillin–clavulanate; co-trimoxazole; cephalosporins; erythromycin; and azithromycin.

QUESTION **What are the effects of treatments in people with clinically diagnosed acute sinusitis?**

OPTION **ANTIBIOTICS**

Two RCTs found no evidence that amoxicillin reduced or cured symptoms compared with placebo in people with clinically diagnosed acute sinusitis, who had not had radiological or bacteriological confirmation of disease. One RCT has found that diarrhoea was more common with amoxicillin than with placebo. We found no RCTs examining effects of other antibiotics (amoxicillin–clavulanate, co-trimoxazole, cephalosporins, azithromycin, and erythromycin) compared with placebo or each other.

Benefits: **Amoxicillin versus placebo:** We found two RCTs in people with an exclusively clinical diagnosis of acute sinusitis, without reliance on radiological or bacteriological investigations.[10,11] The first RCT (416 people in a primary care setting) compared amoxicillin (500 mg 3 times daily) versus placebo for 10 days. It found no significant difference between amoxicillin and placebo in treatment success at the end of treatment (treatment success defined by absent or mild

symptoms: 35% with amoxicillin *v* 29% with placebo; RR 1.14, 95% CI 0.92 to 1.42). The second RCT (150 people with clinically diagnosed acute maxillary sinusitis in a primary care setting) compared three antibiotics (amoxicillin, doxycycline, and penicillin) versus placebo.[11] It found that amoxicillin increased recovery rates compared with placebo at 2 weeks but the statistical significance was not reported (recovery assessed by telephone: 18/23 [78%] with amoxicillin *v* 39/59 [66%] with placebo). **Amoxicillin–clavulanate, co-trimoxazole, cephalosporins, azithromycin, or erythromycin versus placebo:** We found no RCTs. **Versus each other:** We found no RCTs.

Harms: **Amoxicillin versus placebo:** The first RCT found that diarrhoea was significantly more common with amoxicillin compared with placebo (29% with amoxicillin *v* 19% with placebo; RR 1.28, CI 1.05 to 1.57).[10] The second RCT did not report adverse effects separately for amoxicillin compared with placebo.[11] **Amoxicillin–clavulanate, co-trimoxazole, cephalosporins, azithromycin, or erythromycin versus placebo:** We found no RCTs. **Versus each other:** We found no RCTs.

Comment: The RCTs may have lacked adequate follow up to detect clinically important differences between amoxicillin and placebo.

OPTION DECONGESTANTS, TOPICAL STEROIDS, AND ANTIHISTAMINES

We found no RCTs examining clinical effects of topical or systemic decongestants, topical steroids, or antihistamines in people with clinically diagnosed acute sinusitis.

Benefits: **Decongestants; topical steroids; antihistamines:** We found no RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION What are the effects of antibiotics in people with radiologically or bacteriologically confirmed acute sinusitis?

OPTION AMOXICILLIN AND AMOXICILLIN–CLAVULANATE

One systematic review identified two RCTs in people with radiologically or bacteriologically confirmed acute maxillary sinusitis, which found that amoxicillin improved early clinical cure rate compared with placebo, but was associated with more frequent adverse effects, mainly gastrointestinal. One systematic review in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution between amoxicillin or amoxicillin–clavulanate and cephalosporins or macrolides. However, amoxicillin and amoxicillin–clavulanate caused more adverse effects.

Benefits: **Amoxicillin versus placebo:** We found two systematic reviews (search date 1998, number of relevant RCTs not reported, 761 adults with acute uncomplicated sinusitis;[1] and search date 1998,

2 RCTs, 344 adults with acute sinusitis[12]). The review with the most recent search date did not report separately on effects of amoxicillin compared with placebo.[1] The earlier review found that 7–10 days of amoxicillin significantly increased complete symptom resolution compared with placebo (2 RCTs; OR 2.24, 95% CI 1.40 to 3.56).[12] **Amoxicillin–clavulanate versus placebo:** The review with the most recent search date did not report separately on the effects of amoxicillin–clavulanate compared with placebo.[1] The earlier review found no RCTs.[12] We found no subsequent RCTs. **Versus cephalosporin and macrolides:** See benefits of cephalosporins and macrolides, p 714.

Harms: **Amoxicillin versus placebo:** Both RCTs included in the earlier review[12] found that antibiotics significantly increased adverse effects (mainly gastrointestinal) compared with placebo (first RCT:[13] diarrhoea 47% with amoxicillin *v* 11% with placebo, P = 0.001; second RCT:[14] all adverse effects 28% with amoxicillin *v* 9% with placebo, P < 0.001). **Amoxicillin–clavulanate versus placebo:** We found no RCTs.

Comment: One of the RCTs that compared amoxicillin with placebo was a three arm trial, which also examined effects of penicillin. We have not reported results in the penicillin group.

OPTION CEPHALOSPORINS AND MACROLIDES

One systematic review in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution between amoxicillin or amoxicillin–clavulanate and cephalosporins or macrolides. However, cephalosporins and macrolides caused fewer adverse effects than amoxicillin and amoxicillin–clavulanate. One RCT found no significant difference in clinical improvement or clinical cure between cefaclor (a cephalosporin) and azithromycin (a macrolide).

Benefits: **Versus placebo:** We found two systematic reviews (search dates 1998[1] and 1998[12]). The review with the most recent search date did not report separately on the effects of cephalosporins and macrolides compared with placebo.[1] The earlier review found no RCTs comparing these antibiotics with placebo.[12] We found no subsequent RCTS. **Versus amoxicillin:** The earlier systematic review found 10 RCTs (1590 adults), which compared penicillin antibiotics (including amoxicillin) versus cephalosporins, macrolides (clarithromycin, spiramycin, azithromycin, roxithromycin, pristamycin, and erythromycin), or minocycline in people with radiologically or bacteriologically confirmed acute maxillary sinusitis.[12] It found no significant difference in clinical resolution rate between newer non-penicillins and the other antibiotics (OR 0.85, 95% CI 0.70 to 1.08). **Versus amoxicillin–clavulanate:** The systematic review found 10 RCTs (3957 adults), which compared amoxicillin–clavulanate versus macrolides or cephalosporins.[12] It found no significant difference in clinical resolution rate between amoxicillin–clavulanate and the other antibiotics (OR 0.90, 95% CI 0.76 to 1.08). **Macrolides versus cephalosporins:** The systematic review[12] identified one RCT (496 people).[15] It found no

significant difference between azithromycin (500 mg once daily for 3 days) and cefaclor (250 mg 3 times daily for 10 days) in clinical improvement or resolution of symptoms after 11–15 days (clinical improvement or clinical resolution: 228/245 [93%] with azithromycin *v* 233/241 [97%] with cefaclor; P value not reported).

Harms: **Versus placebo:** We found no RCTs. **Versus amoxicillin:** The systematic review found that the risk of stopping treatment because of adverse effects was lower with cephalosporins and macrolides (clarithromycin, spiramycin, azithromycin, roxithromycin, pristamycin, and erythromycin) than with penicillins (OR 0.54, 95% CI 0.29 to 1.00).[12] **Versus amoxicillin–clavulanate:** The systematic review found that the risk of stopping treatment because of adverse effects was lower with cephalosporins and macrolides than with amoxicillin–clavulanate (OR 0.37, 95% CI 0.26 to 0.52).[12] **Macrolides versus cephalosporins:** One RCT comparing azithromycin versus cefaclor found no significant difference in adverse effects between treatments (11% with azithromycin *v* 10% with cefaclor, P = 0.82).[15] The most common adverse effects gastrointestinal symptoms (9.4% with azithromycin *v* 5.7% with cefaclor).

Comment: None.

OPTION LONG COURSE ANTIBIOTIC REGIMENS

RCTs in people with confirmed acute sinusitis found no significant difference in clinical resolution rates between a 10 day course and 3–5 day courses of either co-trimoxazole or cefuroxime (a cephalosporin) up to 3 weeks after treatment. One RCT found that adverse effects, which were mainly gastrointestinal, were more frequent with longer course cefuroxime than with shorter course cefuroxime.

Benefits: **Amoxicillin, amoxicillin–clavulanate, azithromycin, and erythromycin:** We found no RCTs comparing longer versus shorter courses of the same antibiotic. **Co-trimoxazole:** One RCT (80 people with confirmed sinusitis) found no significant difference in clinical resolution or improvement between a 10 day and a 3 day course of co-trimoxazole at 14 days follow up (AR for resolution or improvement about 76% in each group; CI not reported; P = 0.45).[16] **Cephalosporins:** One RCT (401 people with confirmed sinusitis) found no significant difference in clinical resolution rates between a 10 day and a 5 day course of cefuroxime 11–18 days after treatment (73% with 10 day course *v* 74% with 5 day course; ARR with shorter course +1%, 90% CI −7.5% to +8.5%).[2]

Harms: **Co-trimoxazole:** The RCT found no significant difference in adverse events between a 10 day and a 3 day course of co-trimoxazole (CI not reported; P = 0.2).[16] **Cephalosporins:** The RCT found that a larger proportion of people on the 10 day course of cefuroxime reported minor adverse effects, mainly gastrointestinal, compared with the 5 day course of cefuroxime (11.8% with 10 day course *v* 5.8% with 5 day course; significance not reported).[2]

Comment: None.

OPTION DIFFERENT DOSAGES OF ANTIBIOTICS

One RCT in people with radiologically or bacteriologically confirmed acute sinusitis found no significant difference in clinical resolution rates or adverse events between two and three daily doses of cefaclor.

Benefits: **Amoxicillin, amoxicillin–clavulanate, azithromycin, erythromycin, and co-trimoxazole:** We found no RCTs comparing different daily dosing regimens of the same antibiotic. **Cephalosporins:** One RCT (298 people with confirmed acute sinusitis) compared different daily dose regimens of the same cephalosporin.[17] It found no significant difference in clinical resolution rates between cefaclor 500 mg three times daily and cefaclor 750 mg twice daily at 14 days follow up (clinical resolution rate 95.7% with 500 mg three times daily *v* 97.3% with 750 mg twice daily; CI not reported; P = 0.333).

Harms: The RCT found no significant difference in adverse event rates between cefaclor 500 mg three times daily and cefaclor 750 mg twice daily (adverse event rate 24.7% with 750 mg twice daily *v* 32% with 500 mg 3 times daily; CI not reported; P = 0.162).[17]

Comment: None.

OPTION DECONGESTANTS, TOPICAL STEROIDS, AND ANTIHISTAMINES

We found no RCTs examining the effects of antihistamines, decongestants, or topical steroids in people with radiologically or bacteriologically confirmed acute sinusitis.

Benefits: **Decongestants; topical steroids; antihistamines:** We found no RCTs.

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Hyposmia Reduced, not absent, sense of smell.
Orbital cellulitis Inflammation of the soft tissues in and around the eye socket.
Rhinorrhoea Discharge from the nasal cavity.

QUESTIONS

INTERVENTIONS

See glossary, p 727

Key Messages

- **Tricyclic antidepressants** One systematic review in people with depression and chronic tinnitus found that tricyclic antidepressants (nortriptyline) improved tinnitus related disability, audiometric tinnitus loudness matching, and symptoms of depression at 6 weeks, but found no significant difference in self reported tinnitus severity compared with placebo. One small RCT in people with tinnitus without depression found that a greater proportion of people rated themselves as improved with tricyclic antidepressants (amitriptyline) compared with placebo at 6 weeks.
- **Benzodiazepines (alprazolam)** One systematic review found limited evidence that alprazolam, a benzodiazepine, improved self reported tinnitus severity after 12 weeks. Benzodiazepines can have side effects that may outweigh potential benefits.
- **Psychotherapy** One systematic review found insufficient evidence about cognitive behavioural treatment, relaxation therapy, education, or biofeedback compared with other or no treatment in people with chronic tinnitus.
- **Carbamazepine** One systematic review found no significant difference between carbamazepine and placebo in tinnitus severity at 30 days. Treatment with carbamazepine was associated with an increased risk of dizziness, nausea, and headaches.
- **Ginkgo biloba** One systematic review and one subsequent RCT found no significant difference between ginkgo biloba and placebo in tinnitus symptoms.
- **Tocainide** One systematic review found no significant difference between tocainide and placebo in improving symptoms, but found evidence that tocainide increased adverse effects after 30 days' treatment.

- **Acupuncture; baclofen; cinnarizine; electromagnetic stimulation; hyperbaric oxygen; hypnosis; lamotrigine; low power laser; nicotinamide; tinnitus masking devices; zinc** We found insufficient evidence about the effects of these interventions.

DEFINITION Tinnitus is defined as the perception of sound, which does not arise from the external environment, from within the body (e.g. vascular sounds), or from auditory hallucinations related to mental illness. This review is concerned with tinnitus, where tinnitus is the only, or the predominant, symptom in an affected person.

INCIDENCE/ PREVALENCE Up to 18% of the general population in industrialised countries are mildly affected by chronic tinnitus, and 0.5% report tinnitus having a severe effect on their ability to lead a normal life.[1]

AETIOLOGY/ RISK FACTORS Tinnitus may occur as an isolated idiopathic symptom or in association with any type of hearing loss. Tinnitus may be a particular feature of off presbyacusis (see glossary, p 727), noise induced hearing loss, Menière's disease (see glossary, p 727) (see Menière's disease, p 664), or the presence of an acoustic neuroma. In people with toxicity from aspirin or quinine, tinnitus can occur while hearing thresholds remain normal. Tinnitus is also associated with depression, although it may be unclear whether the tinnitus is a manifestation of the depressive illness or a factor contributing to its development.[2]

PROGNOSIS Tinnitus may have an insidious onset, with a long delay before clinical presentation. It may persist for many years or decades, particularly when associated with a sensorineural hearing loss. In Menière's disease, both the presence and intensity of tinnitus can fluctuate. Tinnitus may cause disruption of sleep patterns, an inability to concentrate, and depression.[3]

AIMS OF INTERVENTION To reduce the loudness and intrusiveness of the tinnitus and to reduce its impact on daily life, with minimum adverse effects from treatment.

OUTCOMES The number of people with resolution of tinnitus; tinnitus loudness (assessed by a visual analogue scale, symptom scores, or by audiometric matching); impact of tinnitus measured by estimates of interference with activities of daily life or with emotional state.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION What are the effects of treatments for chronic tinnitus?

OPTION TRICYCLIC ANTIDEPRESSANTS

One systematic review in people with depression and chronic tinnitus found that tricyclic antidepressants (nortriptyline) improved tinnitus related disability, audiometric tinnitus loudness matching, and symptoms of depression at 6 weeks, but found no significant difference in self reported tinnitus severity compared with placebo. One small RCT in people with tinnitus without depression found that a greater proportion of people rated themselves as improved with tricyclic antidepressants (amitriptyline) compared with placebo at 6 weeks.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 1 RCT, 92 people with tinnitus and depression or depressive symptoms but no bipolar disorder or other mental health diagnosis)[4] and one subsequent RCT.[5] The systematic review found that nortriptyline (titrated to maintain therapeutic blood levels for depression) significantly improved measures of depression, a tinnitus related disability score, and audiometric tinnitus loudness matching compared with placebo at 6 weeks.[4] However, the RCT, found no significant difference in the proportion of people reporting overall improvement in tinnitus severity after 6 weeks (16 to 11 dB tinnitus loudness matching with nortriptyline *v* 19 to 18 dB with placebo; P = 0.006; 43% of people reported improved tinnitus severity with nortriptyline *v* 30% with placebo; P = 0.2; raw data not reported).[6] The subsequent RCT (37 people with no history of depression) found that a greater proportion of people rated themselves as "improved" with amitriptyline (50 mg/night for 1 week followed by 100 mg/night for 5 weeks) compared with placebo after 6 weeks but found no significant difference between treatments in the frequency of occurrence of tinnitus (19/20 [95%] "improved" on amitriptyline *v* 2/17 [12%] with placebo; OR 8.1, 95% CI 5.6 to 10.6; no values were reported for tinnitus frequency).[5]

Harms: The subsequent RCT found mild sedation and dryness of the mouth lasting for 1–2 weeks but reported no major adverse effects.[5] Other studies have established that adverse effects of nortriptyline include dry mouth, blurred vision, and constipation (see harms of tricyclic antidepressants under depressive disorders, p 1278).

Comment: The subsequent RCT may have lacked power to detect clinically important effects on the frequency of occurrence of tinnitus.[5]

OPTION BENZODIAZEPINES

One systematic review found limited evidence that alprazolam, a benzodiazepine, improved self reported tinnitus severity after 12 weeks. Benzodiazepines can have side effects that may outweigh potential benefits.

Benefits: We found one systematic review (search date 1995, 1 RCT, 40 people).[7] It found that alprazolam (initially 0.5 mg/night) significantly improved reported tinnitus severity compared with placebo after 12 weeks (13/17 [76%] improved with alprazolam *v* 1/19 [5%] with placebo; RR 14.5, 95% CI 2.1 to 53.0), but interpretation of these results is difficult (see comment below).[8]

Harms: The RCT reported that two (10%) people receiving alprazolam withdrew from the trial because of excessive tiredness.[8] Long term use of benzodiazepines can lead to dependence (see harms of benzodiazepines under generalised anxiety disorder, p 1302).

Comment: The RCT used dose adjustment of alprazolam but no dose adjustment of placebo, potentially biasing the results because of a difference in the attention given to people in the two groups.[8] Another systematic review (search date 1998) found three other studies that used weaker methods; none of the studies provided evidence that benzodiazepines improved symptoms of tinnitus compared with placebo.[4]

OPTION ANTIEPILEPTICS (CARBAMAZEPINE AND LAMOTRIGINE)

One systematic review found no significant difference between carbamazepine and placebo for tinnitus severity at 30 days. Treatment with carbamazepine was associated with an increased risk of dizziness, nausea, and headaches. One small crossover RCT found no significant difference in tinnitus loudness or annoyance between lamotrigine and placebo. However, the RCT may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review (search date 1995, 1 RCT, 48 people)[7] and one subsequent RCT.[9] The RCT identified by the review found no significant difference with carbamazepine (150 mg 3 times daily for 30 days) on reported tinnitus severity compared with placebo after 30 days' treatment (2/24 [8%] improved with carbamazepine *v* 3/24 [13%] with placebo; RR 0.67, 95% CI 0.12 to 3.60).[10] The subsequent RCT (31 people) was a crossover trial comparing lamotrigine and placebo.[9] However, it did not report results before the crossover (see comment below).[9]

Harms: The RCT identified by the review found that carbamazepine significantly increased the number of people reporting adverse effects compared with placebo (including dizziness, nausea, and headaches; 25/34 [63%] with carbamazepine *v* 1/24 [4%] with placebo; RR 17.6, 95% CI 2.6 to 121.0; NNH 1, 95% CI 1 to 2).[10] The subsequent RCT did not report harms.[9]

Comment: A more recent systematic review (search date 1998) found four additional RCTs comparing antiepileptic treatment versus placebo.[4] All were appraised in the earlier review,[7] but were excluded from the review on methodological grounds. The subsequent RCT found no significant difference with lamotrigine (25 mg/day for 2 weeks, 50 mg/day for 2 weeks, and then 100 mg/day for 4 weeks) compared with placebo in tinnitus loudness or annoyance measured on a visual analogue scale (11/31 [35%] people improved with lamotrigine *v* 6/31 [19%] people with placebo; RR 1.80, 95% CI 0.78 to 4.34).[9]

OPTION NICOTINAMIDE

One systematic review found no significant difference between nicotinamide and placebo for tinnitus severity at 30 days. However, the included RCT may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review (search date 1998, 1 RCT, 48 people).[4] It found no significant difference between nicotinamide (70 mg 3 times daily for 30 days) and placebo on subjective improvement after 30 days' treatment (2/24 [8%] with nicotinamide *v* 3/24 [13%] with placebo; RR 0.7, 95% CI 0.1 to 3.6).[11]

Harms: The systematic review found no significant difference between nicotinamide and placebo in the proportion of people reporting headache (4/24 [16%] with nicotinamide *v* 1/24 [4%] with placebo; RR 4.0, 95% CI 0.5 to 33.2) or dizziness (2/24 [8%] *v* 0/24 [0%]; ARI +0.08, 95% CI –0.06 to +0.20).[4]

Comment: The RCT may have lacked power to detect a clinically important effect.[11]

OPTION CINNARIZINE

One systematic review found no significant difference between cinnarizine and placebo for tinnitus severity. However, the RCT may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review (search date 1998, 1 RCT, 30 people).[4] It found no significant difference between cinnarizine (25 mg 3 times daily for 10 weeks) and placebo on reported subjective improvement (1/10 [10%] people improved with cinnarizine *v* 1/20 [5%] people with placebo; RR 2.00, 95% CI 0.14 to 29.00; see comment below).[12]

Harms: The RCT did not report harms.[12]

Comment: The RCT did not specify the follow up period and may have lacked power to detect a clinically important effect.[12]

OPTION ZINC

One systematic review found no significant difference between zinc and placebo for tinnitus severity at 8 weeks. However, the included RCT may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review (search date 1998, 1 RCT, 50 people).[4] It found no significant difference between zinc (100 mg 3 times daily for 8 weeks) and placebo on reported tinnitus severity after 8 weeks' treatment (2/23 [9%] people improved with zinc *v* 2/25 [8%] people with placebo; RR 1.10, 95% CI 0.16 to 7.00).[13]

Harms: The systematic review did not report harms.[13]

Comment: The included RCT may have lacked power to detect a clinically important effect.

OPTION BACLOFEN

One systematic review found no significant difference between baclofen and placebo for tinnitus severity. However, the trial may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review (search date 1998, 1 RCT, 63 people).[4] It found no significant difference between baclofen (10 mg twice daily increasing to 30 mg twice daily for 3 weeks) and placebo on reported subjective improvement (3/31 [10%] improved with baclofen *v* 1/32 [3%] with placebo; RR 3.10, 95% CI 0.34 to 28.00; see comment below).[14]

Harms: The RCT included in the systematic review did not report harms.[14]

Comment: The RCT did not specify the follow up period and may have lacked power to detect a clinically important effect.[14]

OPTION TOCAINIDE

One systematic review found no significant difference between tocainide and placebo in improving symptoms, but found evidence that tocainide increased adverse effects after 30 days' treatment.

Benefits: We found one systematic review (search date 1995, 2 RCTs, 88 people).[7] The first RCT (40 people) identified by the review used a crossover design and did not give details of the washout period or the results before the crossover (see comment below).[15] The second RCT (48 people) identified by the review found no significant difference between tocainide (300 mg 3 times daily for 30 days) and placebo on the proportion of people with improved symptoms after 30 days' treatment (1/24 [4%] with tocainide *v* 3/24 [13%] with placebo; RR 0.33, 95% CI 0.04 to 3.00).[16]

Harms: The second RCT identified by the review found that tocainide significantly increased adverse effects compared with placebo (11/24 [45.8%] with tocainide *v* 2/24 [8.3%] with placebo; RR 5.5, 95% CI 1.4 to 22.2; NNH 2, 95% CI 1 to 8).[16] The main adverse effects reported were rash (6/24 [25%] with tocainide *v* 1/24 [4%] with placebo), dizziness (3/24 [12%] with tocainide *v* 0/24 [0%] with placebo), and tremor (2/24 [8%] with tocainide *v* 0/24 [0%] with placebo).

Comment: The first RCT found no significant difference between oral tocainide (400 mg/day rising to 2.4 g/day for 4 weeks) and placebo in symptom scores (10/40 [25%] improved with tocainide *v* 4/40 [10%] with placebo; RR 2.5, 95% CI 0.85 to 7.3).

OPTION ACUPUNCTURE

One systematic review found insufficient evidence about the effects of acupuncture.

Benefits: We found one systematic review (search date 1998, 6 studies, 185 people).[17] The review included one quasi-randomised RCT,[18] two open RCTs,[12,19] two crossover RCTs,[20,21] and one blinded RCT.[22] All studies were small and brief. The blinded RCT (54 people) found no significant difference between acupuncture (25 sessions over 2 months) and sham acupuncture (superficial penetration at random non-acupuncture points) in tinnitus loudness on a pooled visual analogue score (4% improvement with acupuncture *v* 1% deterioration with placebo).[22] The first crossover RCT identified by the review (14 people) found that acupuncture compared with sham acupuncture significantly increased the number of people who reported a reduction in tinnitus loudness after one session of treatment (5/14 [36%] with acupuncture *v* 0/14 [0%] with sham acupuncture; $P = 0.05$).[20] The second crossover RCT (20 people) found no significant difference between acupuncture and placebo on a pooled visual analogue score of subjective tinnitus severity after 3 weeks ($P = 0.22$).[21]

Harms: The review did not report on adverse effects.[17]

Comment: None.

OPTION PSYCHOTHERAPY

One systematic review found insufficient evidence about effects of cognitive behavioural treatment, relaxation therapy, education, or biofeedback, compared with other or no treatment in people with chronic tinnitus.

Benefits: We found one systematic review (search date 1998, 8 RCTs, 269 people) of different psychotherapeutic approaches (cognitive behavioural treatment, relaxation therapy, education/information, biofeedback).[23] The review had important methodological problems that compromise its validity (see comments below). It found significant reductions in subjective loudness and tinnitus annoyance for a combination of different psychotherapeutic approaches at 3 months or more post-treatment versus pre-treatment (SMD for subjective loudness 0.68, 95% CI 0.62 to 0.74; SMD for tinnitus annoyance 0.83, 95% CI 0.82 to 0.84).

Harms: The review did not report harms.[23]

Comment: Despite many studies on psychotherapeutic measures to treat tinnitus, the evidence for benefit remains limited. Many of the RCTs suffer from weak methods, high withdrawal rates, and pooled or surrogate outcome measures. The systematic review pooled study results across arms of trials, losing the benefits of randomisation and increasing the risk of bias. Pre-treatment to post-treatment effect sizes do not allow comparison of psychotherapy with no treatment or any other treatment.[23] The review did not report which interventions were used as control in the RCTs.

OPTION ELECTROMAGNETIC STIMULATION/EAR CANAL MAGNETS

Three small RCTs found insufficient evidence on perceived improvement in tinnitus symptoms with electromagnetic stimulation compared with placebo. One RCT found no significant difference between simple ear canal magnets and placebo on tinnitus symptoms after 4 weeks.

Benefits: **Electromagnetic stimulation:** We found no systematic review, but found three small RCTs (136 people) comparing electromagnetic stimulation with placebo.[24–26] The first RCT (58 people) found that electromagnetic stimulation significantly increased the number of people who had improved tinnitus compared with placebo (14/31 [45%] with electromagnetic stimulation *v* 2/23 [9%] with placebo; RR 5.2, 95% CI 1.3 to 20.6; see comment below).[25] The second RCT (48 people) found no significant difference between electromagnetic stimulation and placebo in tinnitus sensation levels after 1 week (6/24 [25%] with electromagnetic stimulation *v* 6/24 [25%] with placebo; RR 1.00, 95% CI 0.39 to 2.59).[24] The third RCT (20 people; see comment below) used a crossover design and did not report results before the crossover.[26] **Magnets:** We found no systematic review but found one RCT (49 people).[27] The RCT found no significant difference between a simple ear canal magnet (neodymium, iron, and boron) and placebo (same material but unmagnetised) on tinnitus symptoms after 4 weeks' treatment (7/26 [27%] with magnet *v* 4/23 [17%] with placebo; RR 1.50, 95% CI 0.53 to 4.50).

Harms: The RCTs reported no adverse effects associated with electromagnetic stimulation.[24–26]

Comment: The first RCT, which did not specify the length of follow up, reported that 4/58 (7%) people withdrew from the trial and that the analysis was not by intention to treat.[25] The crossover RCT found no significant difference with electrical suppression compared with a placebo device in reduction in tinnitus severity (2/20 [10%] active device *v* 4/20 [20%] with placebo device; P = NS).[26]

OPTION HYPNOSIS

One RCT found no significant difference between hypnosis and counselling for symptom severity at 3 months.

Benefits: We found one systematic review (search date 1995)[7] and one additional RCT.[28] The review found no RCTs that met its inclusion criteria. The additional RCT (92 people who were preselected to be suggestible to hypnosis) found no significant difference between three sessions teaching self hypnosis and control (a single counselling session) on symptom severity scores after 3 months (24/44 [55%] improved with hypnosis *v* 23/42 [55%] with counselling; RR 1.00, 95% CI 0.68 to 1.46). The RCT also found no significant difference in the number of people reporting worsened tinnitus (11/44 [25%] with hypnosis *v* 14/42 [32%] with counselling; RR 0.8, 95% CI 0.4 to 1.5).

Harms: No adverse effects were reported.[7,28]

Comment: None.

OPTION LOW POWER LASER

One RCT found no significant difference between low power laser and placebo for symptom severity at 1 month.

Benefits: We found no systematic review but found one RCT.[29] The RCT (49 people) found no significant difference between laser (50 mW directed towards the mastoid bone) and placebo in the number of people reporting improved tinnitus symptoms after 1 month (2/25 [8%] with laser *v* 7/24 [29%] with placebo; RR 0.27, 95% CI 0.06 to 1.20).[29]

Harms: No adverse effects were reported.[29]

Comment: None.

OPTION TINNITUS MASKING DEVICES

One systematic review found limited evidence that masking devices improved unspecified tinnitus symptoms compared with no intervention.

Benefits: **Masking devices versus no treatment:** We found one systematic review (search date 1998, 2 RCTs).[4] One RCT was of insufficient quality to include in this review.[30] The other RCT (21 patients)

showed no significant difference in tinnitus intensity symptoms between a masking device (see glossary, p 727) and placebo at 12 weeks (7/21 [33%] improved with the masking device; 5/21 [24%] improved with the placebo; RR 1.40, 95% CI 0.55 to 3.55).[31]

Harms: The RCT found that 2/21 (10%) people reported worsened tinnitus with a masking device.[31]

Comment: The excluded RCT had a high drop-out rate (67%) and was unblinded.[30]

OPTION GINKGO BILOBA

One systematic review and one subsequent RCT found no significant difference between ginkgo biloba and placebo in tinnitus symptoms.

Benefits: We found one systematic review (search date 1998, 5 RCTs)[32] and one subsequent RCT.[33] The systematic review included three RCTs of insufficient quality for inclusion in this review (see comment). Of the remaining two trials identified by the review, the first RCT (crossover RCT, 20 people) found no significant difference between ginkgo biloba extract (29.2 mg/day for 2 weeks) and placebo in tinnitus symptoms (see comment below).[34] The second RCT (99 people) compared ginkgo biloba extract (120 mg/day for 12 weeks) and placebo.[35] It found an improvement in measured tinnitus loudness from 42 dB to 39 dB with ginkgo biloba extract compared with no improvement in the control group (significance not stated; additional numerical data not reported). The subsequent RCT (1121 people) compared ginkgo biloba (50 mg 3 times daily for 12 weeks) and placebo.[33] It found no significant difference in the proportion of people reporting subjective improvement after 12 weeks' treatment (34/360 [9.4%] with ginkgo biloba *v* 35/360 [9.7%] with placebo; ARI +0.3%, 95% CI −4.7% to +4.2%).[33]

Harms: The subsequent RCT reported gastrointestinal upset (3%), dizziness (1%), and mouth dryness (1%) in both treatment and control groups.[33]

Comment: Of the 3 RCTs we have excluded from the systematic review, two had poor methodology (pseudo-randomisation and unblinded assessors). The third had an inappropriate control arm. Of the trials we included, the crossover RCT identified by the review did not specify the length of follow up.[34]

OPTION HYPERBARIC OXYGEN

We found no systematic review or RCTs on the effects of hyperbaric oxygen for people with tinnitus.

Benefits: We found no systematic review or RCTs.

Harms: We found no evidence of harms.

Comment: None.

GLOSSARY

Masking device A small device similar to a behind-the-ear hearing aid, which produces a broad frequency noise. It is thought to hide the noise of the tinnitus.
Menière's disease A condition characterised by episodic vertigo, tinnitus, and sensorineural hearing loss.
Presbyacusis Age related hearing loss.

Substantive changes

Tricyclic antidepressants Evidence re-evaluated; categorisation changed to Trade off between benefits and harms.

QUESTIONS

INTERVENTIONS

Trade off between benefits and harms

Unknown effectiveness

To be covered in future updates

Intermittent antibiotics

Long term antibiotics

Key Messages

- **Tonsillectomy versus antibiotics in children** Two systematic reviews found insufficient evidence to compare surgical versus medical treatment. One subsequent RCT in less severely affected children found that surgery significantly reduced the frequency of tonsillitis compared with medical treatment over 3 years. The modest benefit may be outweighed by morbidity associated with the operation in populations with a low incidence of tonsillitis.
- **Tonsillectomy versus antibiotics in adults** We found no RCTs evaluating tonsillectomy in adults.

DEFINITION

Tonsillitis is infection of the parenchyma of the palatine tonsils. The definition of severe recurrent tonsillitis is arbitrary, but recent criteria have defined tonsillitis as five or more episodes of true tonsillitis a year, symptoms for at least a year, and episodes that are disabling and prevent normal functioning.[1] The definition does not include tonsillitis occurring as a manifestation of the viral illness infectious mononucleosis, which usually occurs as a single episode. However, acute tonsillitis in this situation may be followed by recurrent tonsillitis in some patients. Infection of the palatine tonsils may occur in isolation or as part of the clinical picture of a generalised pharyngitis. The clinical distinction between tonsillitis and pharyngitis is unclear in the literature and the condition is often referred to simply as "acute sore throat". A sore throat lasting for 24–48 hours as part of the prodrome of minor upper respiratory tract infection is excluded from this definition. The diagnosis of acute tonsillitis is primarily clinical, with the main interest of the clinician being in whether the illness is viral or bacterial, this information being of relevance if the prescription of antibiotics is being considered. Several authors have attempted to distinguish viral from bacterial sore throat on clinical grounds but the results of these studies are conflicting, suggesting a lack of reliable diagnostic criteria. Investigations to assist with this distinction include throat swabs and serological tests, including the rapid antigen test and the antistreptolysin O (ASO) titre. Of these, throat swabs and the ASO titre are of less practical value because of the time lag before results are obtainable. Throat swabs are also potentially misleading, as their sensitivity and specificity is low. There is a high asymptomatic carrier rate of up to 40% for potentially pathogenic bacteria such as group A β haemolytic streptococcus, and the results of surface swab bacteriology may be irrelevant to the deeper flora which may be responsible for the clinical infection. Rapid antigen testing is convenient and popular in North America but also has doubtful sensitivity (61–95%), at least when measured against throat swab results, although specificity is higher (88–100%).[1] The monospot test, Epstein-Barr virus serology, and occasional other viral serology may be of assistance in the diagnosis of infectious mononucleosis

INCIDENCE/ PREVALENCE

Recurrent sore throat has an incidence in general practice in the UK of 100 per 1000 population a year.[2] Acute tonsillitis is more common in childhood.

AETIOLOGY/ RISK FACTORS

Common bacterial pathogens include β haemolytic and other streptococci. Bacteria are cultured successfully only from a minority of people with tonsillitis. The role of viruses is uncertain in most cases of acute tonsillitis. In the tonsillitis associated with infectious mononucleosis, the most common infective agent is the Epstein-Barr virus (present in 50% of children and 90% of adults with the condition). Cytomegalovirus infection may also result in the clinical picture of infectious mononucleosis, and the differential diagnosis also includes toxoplasmosis, HIV, hepatitis A, and rubella.[3]

PROGNOSIS

We found no good data on the natural history of tonsillitis or recurrent sore throat in children or adults. Participants in RCTs who were randomised to medical treatment (courses of antibiotics as required) have shown a tendency towards improvement over

time.[4,5] Recurrent severe tonsillitis results in significant morbidity, including time lost from school or work. The most common complication of acute tonsillitis is peritonsillar abscess, but we found no good evidence on the incidence of this condition. Rheumatic fever and acute glomerulonephritis are recognised complications of acute tonsillitis associated with group A β haemolytic streptococci. These diseases are rare in developed countries, but do occasionally occur sporadically. They are still a common problem in certain populations, notably Australian Aboriginals, and may be effectively prevented in closed communities by the use of penicillin. A systematic review found that there is no evidence that aggressive antibiotic treatment of acute sore throat in the developed world is useful in the prevention of these diseases.[6]

AIMS OF INTERVENTION To abolish tonsillitis; to reduce the frequency and severity of recurrent throat infections; to improve general wellbeing, behaviour, and educational achievement, with minimal adverse effects.

OUTCOMES Number and severity of episodes of tonsillitis or sore throat; requirement for antibiotics and analgesics; time off work or school; behaviour, school performance, general wellbeing; morbidity and mortality of surgery; and adverse effects of drugs.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of tonsillectomy in children and adults with severe tonsillitis?

OPTION TONSILLECTOMY VERSUS ANTIBIOTICS

Two systematic reviews found insufficient evidence to compare surgical versus medical treatment. One subsequent RCT in less severely affected children found that surgery reduced the frequency of tonsillitis compared with medical treatment over 3 years. The modest benefit may be outweighed by recognised complications of tonsillectomy in populations with a low incidence of tonsillitis. We found no RCTs evaluating tonsillectomy versus antibiotics in adults.

Benefits: We found two systematic reviews (search dates 1997[7] and 1998[8]) and one subsequent RCT.[9] **Children:** Both reviews identified the same two RCTs as being the only ones that met quality inclusion criteria.[4,5] The smaller RCT involved 91 children who fulfilled criteria for "severe tonsillitis" (7 episodes in the preceding year, 5 episodes/year in the preceding 2 years, or 3 episodes/year in the preceding 3 years).[4] It compared three treatments: tonsillectomy alone (27 children); adenotonsillectomy (16 children); or intermittent courses of antibiotics as needed (48 children). Sixteen children were withdrawn from the non-surgical group by their parents and underwent surgery, and children who developed infections after surgery received antibiotics as necessary for each episode of infection. Secondary outcome measures, such as time off school, were also considered. The RCT found that children undergoing tonsillectomy experienced significantly fewer throat infections than those on antibiotics, amounting to an average of three fewer throat infections in the first 2 years, but by the third year the difference was no longer significant, (year 1, 1.24 *v* 3.09 episodes per person, P = 0.001;

year 2, 1.61 *v* 2.66, P = 0.001; year 3, 1.77 *v* 2.20, P > 0.05). The larger RCT (246 "less severely affected" children) is published only in abstract form.[5] Some children in this study also underwent adenoidectomy. The limited data available provide no evidence of a difference between surgical and medical treatment. The first systematic review concluded that the risk of adverse effects was such that the use of tonsillectomy was not supportable from the available evidence.[7] The second review concluded that it was not possible to determine the effectiveness of tonsillectomy from these RCTs because of the significant baseline differences between the people assigned to surgical and non-surgical treatment and the impossibility of eliminating any effect from that achieved by adenoidectomy additionally carried out on some of the included children.[8] One subsequent RCT (328 children with a history of milder recurrent episodes of throat infection) evaluated the effects of tonsillectomy in two different populations by stratifying children according to their history and age. Children with no apparent indication for adenoidectomy (recurrent or persistent otitis media or obstructing adenoids) were randomised to tonsillectomy, adenotonsillectomy, or medical treatment (3 way trial, 177 children). Children with any apparent indication for adenoidectomy were randomised to adenotonsillectomy or medical treatment (2 way trial, 151 children). In both RCTs outcomes were significantly better with surgery compared with medical treatment (children without indication for adenoidectomy [3 way trial]: mean number of moderate or severe episodes/year during 3 years' follow up: 0.09 with tonsillectomy [P = 0.002] *v* 0.08 with adenotonsillectomy [P = 0.003] *v* 0.33 with medical treatment; in children with indication for adenotonsillectomy [2 way trial]: 0.07 with adenotonsillectomy *v* 0.28 with medical treatment [P < 0.001]).[9] **Adults:** The reviews found no RCTs that evaluated tonsillectomy in adults with recurrent tonsillitis or sore throats. We found no RCTs addressing long term effects of tonsillectomy.

Harms:

Tonsillectomy: The risks of tonsillectomy include those associated with general anaesthesia and those specific to the procedure (bleeding, pain, otalgia, and, rarely, nasopharyngeal stenosis). The subsequent RCT[9] found that 16/203 (8%) of the children who underwent surgery suffered complications. One suffered anaesthetic induction trismus and possible incipient malignant hyperthermia; three children had intraoperative haemorrhage with one of them needing reintervention under anaesthesia; and one child required a posterior nasopharyngeal pack and admission to intensive care. Seven children (3.4%) developed postoperative haemorrhage and five of these were readmitted to hospital, one requiring transfusion. The mean duration of postoperative sore throat was 6.3 days (range 0–21 days).[9] The overall complication rate in the smaller RCT (91 children)[4] was 14% (all were "readily managed or self limiting") compared with 2–8% in one Scottish tonsillectomy audit.[10] Haemorrhage, either primary (in the immediate postoperative period) or secondary, occurred in 4% of children studied in the larger RCT[5] and fewer than 1% of children in the Scottish tonsillectomy audit.[10] **Antibiotics:** In the smaller RCT (91 children), erythematous rashes occurred in 4% of children in the non-surgical group while taking penicillin.[4] Other adverse effects of antibiotics

include allergic reactions and the promotion of resistant bacteria. One RCT found that, for people with milder episodes of sore throat, the prescribing of antibiotics compared with no initial prescription increased the proportion of people who returned to see their physician in the short term because of sore throat (716 people with sore throat and an abnormal physical sign; return rate 38% with initial antibiotics *v* 27% without; adjusted HR for return 1.39, 95% CI 1.03 to 1.89).[11] The subsequent RCT found that rates of erythematous rash were similar in children from the surgical and control groups (4/190 [2%] in surgery groups *v* 3/138 [2%] in control groups).[9] We found no evidence of adverse effects on the immune system following tonsillectomy.

Comment: In the subsequent RCT, 79% of the children allocated to tonsillectomy and 78.8% of those assigned to adenotonsillectomy had surgery within 90 days of the randomisation.[9] In the control groups, 12/60 (20%) children in the three way RCT and 19/78 (24%) in the two way RCT eventually underwent surgery. Although a significant reduction was found in the mean number of episodes of throat illnesses with surgical interventions, rates of illness in the control groups were low.[9] The authors of the RCT concluded that the benefits of surgery may outweigh the risks in populations with a low incidence of illness, such as the population of children included in the study.[9] **Background:** Tonsillectomy is one of the most frequently performed surgical procedures in the UK, particularly in children, and accounts for about 20% of all operations performed by otolaryngologists.[10] Adenoidectomy is now performed with tonsillectomy only when there is a specific indication to remove the adenoids as well as the tonsils. **Quality of the evidence:** In the smaller RCT[4] there were significant baseline differences between groups before treatment, and the authors pooled the results of tonsillectomy and adenotonsillectomy, making it impossible to assess the effectiveness of tonsillectomy alone. The systematic reviews came to broadly the same conclusions but the weighting of the evidence was different. The earlier review did not quantify the evidence for the adverse effects mentioned, although it concluded that because of adverse effects tonsillectomy was not supported.[7] The principal author of the original trial[4] defends its conclusions in the Comments and Criticisms section in the current issue of the Cochrane Review.[8] He argues that the baseline differences between cases in the control and treatment groups that were not accounted for in the randomisation are irrelevant to the outcome. Furthermore, he contends that the effect of adenoidectomy in some members of the treatment group could not have accounted for the difference in outcome in that group. The subsequent RCT on less severely affected children[9] was designed and run at the same time as the other RCTs discussed,[4,5] but the authors did study tonsillectomy separately from adenoidectomy, and the conclusions are more robust. **Gaps in the evidence:** We found no RCT that found improved general wellbeing, development, or behaviour, despite suggestions that these are influenced by tonsillectomy.[10] **New techniques:** Various newer techniques for tonsillectomy have been described and are in use, including ultrasonic dissection, cold

ablation, laser tonsillectomy, and diathermy tonsillectomy. These are currently being assessed, and possible benefits and harms have not yet been fully evaluated. Adjuvant treatment may reduce adverse effects, and various modalities are being studied.[12]

QUESTIONS

INTERVENTIONS

*Although many practitioners consider these to be standard treatments, we found no RCTs of these interventions

See glossary, p 738

Key Messages

- **Ear syringing** There is consensus that ear syringing is effective but we found no RCTs comparing ear syringing versus no treatment or versus other treatment. Reported complications of ear syringing include otitis externa, perforation of the ear drum, damage to the skin of the external canal, tinnitus, pain, and vertigo.
- **Manual removal (other than ear syringing)** We found no RCTs about other mechanical methods of removing ear wax.
- **Wax softeners** One small RCT in people with impacted wax found that active treatment (with a proprietary softening agent, sodium bicarbonate, or sterile water) reduced the risk of persisting impaction after 5 days compared with no treatment, but found no significant difference among active treatments. Three RCTs found no consistent evidence that any one type of wax softener was superior to the others. RCTs found insufficient evidence to assess the effects of wax softeners prior to syringing.

Wax in ear

DEFINITION Ear wax is normal and becomes a problem only if it produces deafness, pain, or other aural symptoms. Ear wax may also need to be removed if it prevents inspection of the ear drum. The term "impacted" (see glossary, p 738) is used in different ways, and can merely imply the coexistence of wax obscuring the ear drum with symptoms in that ear.[1,2]

INCIDENCE/ PREVALENCE We found four surveys of the prevalence of impacted wax (see table 1, p 739).[3–6] The prevalence was higher in men than in women, in the elderly than in the young, and in people with intellectual impairment.[7] One survey found that 289 Scottish general practitioners each saw an average of nine people a month requesting removal of ear wax.[1]

AETIOLOGY/ RISK FACTORS Factors that prevent the normal extrusion of wax from the ear canal (e.g. wearing a hearing aid, using cotton buds) increase the chance of ear wax accumulating.

PROGNOSIS Most ear wax emerges from the external canal spontaneously. Without impaction or adherence to the drum, there is likely to be minimal, if any, hearing loss.

AIMS OF INTERVENTION To relieve symptoms or to allow examination by completely removing impacted wax or obstructing wax; and to soften impacted wax to ease mechanical removal.

OUTCOMES Proportion of people (or ears) with relief of hearing loss or discomfort; total removal of wax; proportion of people requiring further intervention to improve symptoms; ease of mechanical removal measured, for example, by the volume of water used to accomplish successful syringing.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of methods to remove ear wax?

OPTION WAX SOFTENERS

One small RCT in people with impacted wax found that active treatment (with a proprietary softening agent, sodium bicarbonate, or sterile water) reduced the risk of persisting impaction after 5 days compared with no treatment, but found no significant difference among active treatments. Three RCTs found no consistent evidence that any one type of wax softener was superior to the others. RCTs found insufficient evidence to assess the effects of wax softeners prior to syringing.

Benefits: We found no systematic review. **Versus placebo or no treatment:** We found one RCT (113 people with impacted wax [see glossary, p 738] in one or both ears) (see table 2, p 740).[2] Ears were randomly allocated to treatment by the nursing staff with sterile water, sodium bicarbonate, a proprietary softening agent (arachis oil/chlorobutanol/*p*-dichlorobenzene), or no treatment. Participants and nurses were blinded to the active treatment allocation. The people were recruited from a hospital for the elderly. People already using ear drops and people with other pathology of the ear canal or ear drum were excluded. Of those recruited, 13 left hospital and three died before completing the RCT. Analysis of the remaining 97

people (155 ears) found that the proportion of ears with persisting impaction was significantly reduced by any active form of treatment after 5 days compared with no treatment (AR: 26/38 [68%] ears with no treatment *v* 55/117 [47%] ears with any active treatment; RR 1.46, 95% CI 1.09 to 1.94; NNT 5, 95% CI 3 to 17).[2] It found no significant difference in wax clearance among active treatments (P value not reported).[2] **Versus other wax softeners:** We found six trials comparing wax softeners (see table 2, p 740).[2,8–12] Only three were RCTs,[2,11,12] the other trials did not state the allocation strategy or were quasi-randomised trials. The trials were conducted in a variety of settings. They varied in size from 35 people to 286 ears. The most common outcomes were a subjective assessment of the amount of wax remaining, the need for syringing, the perceived ease of syringing, or the result of syringing. The trials found no consistent evidence that any one type of wax softener was clinically superior to any other. **Prior to syringing:** We found four RCTs[13–16] and one quasi-randomised trial[17] comparing various wax softeners given prior to ear syringing. All had design deficiencies that could lead to bias. Two of the RCTs found differences in effectiveness among wax softeners, and the other RCTs two found no overall difference (see table 3, p 742). The quasi-randomised trial found no difference between water instilled for 15 minutes and oil instilled nightly for 3 days.[17]

Harms: Seven RCTs did not report complications or adverse effects. Two trials found single cases of irritation, itching, or buzzing.[8,9] One RCT found that the frequency of adverse effects was similar in people using arachis oil/chlorobutanol/*p*-dichlorobenzene versus a proprietary agent (Otocerol® — the composition of which was not stated — see table 2, p 740).[11]

Comment: We found no good evidence about the optimal duration of treatment. Most trials did not use rigorous methods of randomisation, and did not include control for degree of occlusion at randomisation. Many trials were sponsored by companies that manufactured only one of the products being tested, but the possibility of publication bias has not been assessed. The inclusion criteria for the RCTs were not always clear: many stated that the participants had impacted wax without defining how this was defined. The RCT that included a no treatment group found that 32% of ears with impacted wax showed spontaneous resolution after 5 days.[2]

OPTION MECHANICAL METHODS

We found no RCTs about mechanical methods of removing ear wax. There is consensus that ear syringing is effective but we found no RCTs comparing ear syringing versus no treatment or versus other treatment. Reported complications of ear syringing include otitis externa, perforation of the ear drum, damage to the skin of the external canal, tinnitus, pain, and vertigo.

Benefits: We found no systematic review and no RCTs comparing mechanical methods intended to remove ear wax versus no treatment or alternative treatment.

Harms: One survey found that 38% of 274 general practitioners reported complications in people receiving syringing, including otitis externa, perforation of the ear drum, damage to the skin of the external canal, tinnitus, pain, and vertigo.[1] We found no study of the incidence of these complications, or the effect of training and experience. People may experience dizziness during syringing or when wax is removed by suction.

Comment: There is consensus that syringing is effective and that training can reduce complications, but we found no reliable evidence. Mechanical techniques other than syringing include manual removal under direct vision, with or without a microscope, using suction, probes, or forceps. These methods require specific training and access to appropriate equipment.

GLOSSARY

Impacted wax Wax that has been compressed in the ear canal, completely obstructing the lumen. In practice, many RCTs define impaction as the presence of symptoms associated with obstructing wax.

Obstructing wax Wax that obscures direct vision of the ear drum.

QUESTIONS

INTERVENTIONS

See glossary, p 751

Key Messages

Preventive interventions

- **Screening and referral to foot care clinics** One RCT found that a diabetes screening and protection programme (involving referral to a foot clinic if high risk features were present) reduced the risk of major amputation compared with usual care after 2 years.
- **Education** One systematic review found insufficient evidence about the effects of patient education for preventing foot ulcers, serious foot lesions, or amputation.
- **Therapeutic footwear** In people with diabetes and previous diabetic foot ulcer, one RCT found no significant difference in rates of foot ulceration between therapeutic footwear and usual footwear.

Foot ulcers and amputations in diabetes

Treatments

- **Pressure off-loading with non-removable cast** RCTs found that pressure off-loading with total contact casting or non-removable fibreglass casts improved healing of non-infected diabetic foot ulcers compared with traditional dressing changes, removable cast walkers or half shoes, or specialised cloth shoes.
- **Human skin equivalent** One RCT found that human skin equivalent increased ulcer healing rates compared with saline moistened gauze in people with chronic neuropathic non-infected foot ulcers.
- **Systemic hyperbaric oxygen (for infected ulcers)** One RCT identified by a systematic review found that systemic hyperbaric oxygen plus usual care reduced amputation rates at 10 weeks compared with usual care alone in people with severely infected diabetic foot ulcers, but one small RCT found no significant difference between treatments in major amputation rates. The second RCT but may have been too small to detect a clinically important difference.
- **Topical growth factors** One systematic review found that topical growth factors increased healing rates compared with placebo in people with non-infected diabetic foot ulcers.
- **Cultured human dermis** One systematic review found insufficient evidence of the effects of cultured human dermis on ulcer healing in people with non-infected diabetic foot ulcers.
- **Pressure off-loading with felted foam or pressure relief half shoe** One RCT found no significant difference in time to ulcer healing between a pressure off-loading felted foam dressing and a pressure relief half shoe.
- **Systemic hyperbaric oxygen (for non-infected non-ischaemic ulcers)** One small RCT found no significant difference between hyperbaric oxygen plus usual care and usual care alone in ulcer healing at 4 weeks in people with non-infected, neuropathic, non-ischaemic ulcers.

DEFINITION Diabetic foot ulceration is full thickness penetration of the dermis of the foot in a person with diabetes. Ulcer severity is often classified using the Wagner system. Grade 1 ulcers are superficial ulcers involving the full skin thickness but no underlying tissues. Grade 2 ulcers are deeper, penetrating down to ligaments and muscle, but not involving bone or abscess formation. Grade 3 ulcers are deep ulcers with cellulitis or abscess formation, often complicated with osteomyelitis. Ulcers with localised gangrene are classified as grade 4 and those with extensive gangrene involving the entire foot are classified as grade 5.

INCIDENCE/ PREVALENCE Studies conducted in Australia, Finland, the UK, and the USA have reported the annual incidence of foot ulcers among people with diabetes as 2.5–10.7%, and the annual incidence of amputation as 0.25–1.8%.[1–10]

AETIOLOGY/ RISK FACTORS Long term risk factors for foot ulcers and amputation include duration of diabetes, poor glycaemic control, microvascular complications (retinopathy, nephropathy, and neuropathy) and peripheral vascular disease. The strongest predictors of foot complications are altered foot sensation, foot deformities, and previous foot ulcer or amputation.[1–10]

PROGNOSIS People with diabetes are at risk of foot ulcers, infections, and vascular insufficiency. Amputation is indicated if these are severe or do not improve with conservative treatment. As well as affecting

quality of life, these complications account for a large proportion of the healthcare costs of diabetes. For people with healed diabetic foot ulcers, the 5 year cumulative rate of ulcer recurrence is 66% and of amputation is 12%.[11]

AIMS OF INTERVENTION To prevent diabetic foot complications, including ulcers and amputations; and to improve ulcer healing and prevent amputations where ulcers already exist, with minimum adverse effects.

OUTCOMES Rates of development or recurrence of foot ulcers or major foot lesions; rate of amputation (surgical removal of all or part of the lower extremity; major amputation (see glossary, p 751) or minor amputation (see glossary, p 751); time ulcers take to heal, or the proportion healed in a given period; rates of hospital admission; rates of foot infection; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION What are the effects of preventive interventions?

OPTION SCREENING AND REFERRAL TO FOOT CARE CLINIC

One RCT found that a diabetes screening and protection programme (involving referral to a foot clinic if high risk features were present) reduced the risk of major amputation compared with usual care after 2 years.

Benefits: We found one systematic review (search date 1998, 1 RCT, 2002 people attending a general diabetes clinic).[12] The RCT compared a diabetes screening and protection programme with usual care over 2 years.[13] People in the diabetes screening and protection programme were screened for deficits in pedal pulses, light touch, and vibration sensation. People with persistent abnormal findings were referred to the diabetic foot clinic if they had a history of foot ulcer, were found to have a low ankle–brachial index (< 0.75), or were noted to have foot deformities. The clinic provided podiatry and protective shoes as well as education regarding foot care. Usual care consisted of the normal follow up for people in the clinic, who could be referred to the foot care clinic by a healthcare professional. The RCT found that the diabetes screening and protection programme reduced major amputation (see glossary, p 751) compared with usual care (AR 0.1% with the diabetes programme *v* 1.2% with usual care; ARR 1.1%, 95% CI 0.4% to 1.9%; NNT 91, 95% CI 53 to 250).

Harms: The RCT did not report adverse effects.[13]

Comment: None.

OPTION THERAPEUTIC FOOTWEAR

In people with diabetes and previous diabetic foot ulcer, one RCT found no significant difference in rates of foot ulceration between therapeutic footwear and usual footwear.

Foot ulcers and amputations in diabetes

Benefits: We found one systematic review (search date 1998), which identified no RCTs (see comment below).[12] We found one subsequent RCT (400 people with diabetes mellitus and previous foot ulcer but without severe deformity, mean age 62 years) comparing three treatments over 2 years: extra-depth and extra-width therapeutic shoes fitted with customised cork inserts, therapeutic shoes fitted with polyurethane inserts, and usual footwear.[14] The RCT found no significant difference in foot ulceration rates between therapeutic footwear and usual footwear (AR for foot ulceration 15% with cork insert *v* 14% with polyurethane insert *v* 17% with usual footwear; RR cork insert *v* usual footwear 0.88, 95% CI 0.51 to 1.52; RR polyurethane insert *v* usual footwear 0.85, 95% CI 0.48 to 1.48).

Harms: The RCT did not report adverse effects.[14]

Comment: The systematic review[12] identified one non-randomised controlled trial.[15] The trial alternately allocated 69 people with a previous diabetic foot ulcer to either an intervention group (in which people received therapeutic shoes) or to a control group (in which people continued to wear their ordinary shoes).[15] Therapeutic shoes were manufactured according to the Towey guidelines (deep enough to fit customised insoles and toe deformities, and made with soft thermoformable leather along with semirocker soles). All participants received information on foot care and footwear. After 1 year, the trial found that wearing therapeutic shoes reduced ulcer recurrence compared with ordinary shoes (27% with therapeutic shoes *v* 58% with ordinary shoes; ARR 31%, 95% CI 7% to 55%; NNT 4, 95% CI 2 to 14). The trial did not report any adverse effects associated with therapeutic shoes. Alternate allocation increases the possibility of confounding.

OPTION EDUCATION

One systematic review found insufficient evidence of the effects of education programmes for prevention of diabetic foot ulcers.

Benefits: We found one systematic review (search date 2001, three RCTs, one quasi randomised trial).[16] The first RCT in the review (352 people with diabetes attending 4 primary care teams, randomised by primary care team) compared structured care (a patient education session about foot care plus patient follow up reminders plus prompts to healthcare providers to examine feet and provide education) with usual care (not described).[17] It found that structured care reduced "serious foot lesions" (based on the Seattle Wound Classification Scale [see glossary, p 751])[18] compared with usual care after 12 months (OR 0.41, 95% CI 0.16 to 1.00). The second RCT in the review (266 people with diabetes attending primary care) compared foot care education (nine sessions on foot care and skin hygiene, diabetes, risk factors, diet, and weight management) with usual care.[19] It found no significant difference in ulcer and amputation rates (combined) after 1.5 years (10/127 [8%] with foot care education *v* 16/139 [12%] with usual care; OR 0.66, 95% CI 0.30 to 1.49). The third RCT in the review (530 people with diabetes without any obvious need for foot care) compared education from a podiatrist (45 minute session covering footwear, hygiene, toenail cutting, emollient cream, avoiding risk, foot gymnastics, and preventive podiatric care) plus podiatric visits of 30–60 minutes'

duration for 1 year with written foot care instructions.[20,21] It found no significant difference in amputation and ulcer rates between foot education plus podiatric visits and written foot care instructions after 7 years (amputation rate: 1/267 with education plus podiatric visits *v* 0/263 with written foot care instructions; P value undefined; ulcer rate: 0.6% with education plus podiatric visits *v* 0.6% with written instructions; P = 1.0) The quasi randomised trial in the review (227 people with diabetes, allocated according to social security number) compared a single 1 hour educational class about foot care with routine diabetes education.[22] It found that the educational session reduced ulcer recurrences and major amputation after 2 years (ulcer recurrence: 4.5% for foot care education *v* 14.7% for routine education; RR 0.31, 95% CI 0.15 to 0.65; NNT 10, 95% CI 6 to 26; major amputation: 2.8% for foot care education *v* 10.2% for routine education; RR 0.28, 95% CI 0.11 to 0.70; NNT 14, 95% CI 8 to 50).

Harms: The systematic review did not report harms.[16]

Comment: The studies included in the systematic review were of poor methodological quality.[16] The flaws included the following: only one trial had blinded outcome assessment; one trial made no comment on loss to follow up; some studies offered no comment on concealment of randomisation; the trials did not use an intention to treat approach; and the eligibility criteria with respect to risk of ulceration were described adequately in only one trial.

QUESTION What are the effects of treatments?

OPTION PRESSURE OFF-LOADING

RCTs found that pressure off-loading with total contact casting or non-removable fibreglass casts improved healing of non-infected diabetic foot ulcers compared with traditional dressing changes, removable cast walkers or half shoes, or specialised cloth shoes. One RCT found no significant difference in time to ulcer healing between a pressure off-loading felted foam dressing and a pressure relief half shoe.

Benefits: We found one systematic review (search date 1998, one relevant RCT, 40 people with diabetes and plantar foot ulcers but no signs of infection or gangrene)[23] and three subsequent RCTs.[24–26] **Versus traditional dressing changes:** The RCT in the review compared total contact casting (see glossary, p 751) versus traditional dressing changes.[27] Casts were applied by an experienced physical therapist, changed after 5–7 days, and then every 2–3 weeks until healing occurred. Control participants were provided with accommodative footwear and crutches or a walker, and were instructed to complete wet to dry dressing changes 2–3 times daily. The RCT found that total contact casting significantly increased ulcer healing and reduced infection compared with traditional dressing changes (ulcer healing: 91% with total contact casting *v* 32% with traditional dressing; ARR 59%, 95% CI 31% to 87%; NNT 2, 95% CI 1 to 3; infection: 0/21 with total contact casting *v* 5/19 with traditional dressing; $P < 0.05$).[27] **Versus removable casts/shoes:** The first subsequent RCT (63 people with diabetes mellitus and non-infected

neuropathic plantar foot ulcers) compared three treatments: total contact casting, removable cast walker, and a half shoe.[24] All participants had weekly visits for wound care and debridements. The RCT found that total contact casting increased ulcer healing compared with removable cast walkers or half shoes after 12 weeks (89% with total contact casting *v* 61% with removable cast walker or half-shoe; ARR 28%, 95% CI 5% to 51%; NNT 4, 95% CI 2 to 19). The second subsequent RCT (50 people with diabetes mellitus and non-infected neuropathic plantar foot ulcers) compared non-removable fibreglass casts with specialised cloth shoes with rigid soles and off-loading insoles over 30 days.[25] All participants had dressing changes every 2 days. It found that non-removable fibreglass casts improved ulcer healing compared with specialised cloth shoes (50% of ulcers healed with fibreglass casts *v* 21% with specialised cloth shoes; ARR 29%, 95% CI 1.4% to 57%; NNT 4, 95% CI 2 to 72). **Pressure off loading felted foam dressings versus a pressure relief half shoe:** The third subsequent RCT (61 people with diabetes mellitus and a neuropathic plantar forefoot ulcer) compared pressure off-loading felted foam dressings with a pressure relief half shoe over at least 10 weeks.[26] The RCT found no significant difference in time to ulcer healing (79.6 days with felted foam *v* 83.2 days with a half shoe, P = 0.61).

Harms: The RCT identified in the systematic review found that 3/21 (14%) people treated with total contact casting developed fungal infections requiring topical treatment. This did not prevent continued casting.[27] The other RCTs reported no adverse effects.[24–26]

Comment: Soft tissue infections and osteomyelitis are contraindications to total contact casting.

OPTION CULTURED HUMAN DERMIS

One systematic review found insufficient evidence about the effects of cultured human dermis on ulcer healing in people with non-infected diabetic foot ulcers.

Benefits: We found one systematic review (search date 1998, 2 RCTs, 331 people) comparing topical application of cultured human dermis substitute (see glossary, p 751) (weekly for 8 weeks) plus usual care versus usual care alone in people attending hospital outpatient clinics with diabetic foot ulcers with no signs of infection or severe vascular compromise.[23] All participants received wound debridement and were encouraged to avoid weight bearing on the affected limb. The review found no significant difference in ulcer healing at 12 weeks between cultured human dermis compared with usual care (+21% increase in ulcer healing with cultured human dermis compared with usual care at 12 weeks, 95% CI –13% to +36%).

Harms: One RCT identified by the systematic review found no significant difference between cultured human dermis and usual care in the rates of ulcer infections, and no effect on haematology or serum chemistry values or glycaemic control.[23] The other RCT found no significant differences in wound infection rates.

Comment: Cultured human dermis may not be widely available.

OPTION HUMAN SKIN EQUIVALENT

One RCT found that human skin equivalent increased ulcer healing rates compared with saline moistened gauze in people with chronic neuropathic non-infected foot ulceration.

Benefits: We found no systematic review. We found one RCT (208 people aged 18–80 years with diabetes mellitus and chronic neuropathic non-infected foot ulceration) comparing human skin equivalent (see glossary, p 751) (Graftskin applied weekly for a maximum of 5 weeks) with saline moistened gauze (applied weekly).[28] It found that human skin equivalent improved ulcer healing compared with saline moistened gauze after 12 weeks (56% with human skin equivalent *v* 38% with saline moistened gauze; ARI 18%, 95% CI 5% to 33%; RR 1.5, 95% CI 1.1 to 2.0; NNT 6, 95% CI 3 to 20).

Harms: The RCT found no significant serious adverse effects.[28] Wound infections and cellulitis were equally frequent in both groups. Osteomyelitis and amputations were less frequent in people receiving human skin equivalent (osteomyelitis: 2.7% with human skin equivalent *v* 10.4% with saline moistened gauze; amputations: 6.3% with human skin equivalent *v* 15.6% with saline moistened gauze).

Comment: Human skin equivalent may not be widely available.

OPTION TOPICAL GROWTH FACTORS

One systematic review found that topical growth factors increased healing rates compared with placebo in people with non-infected diabetic foot ulcers.

Benefits: We found one systematic review (search date 1998, 6 RCTs) comparing four different topical growth factors (see glossary, p 751) versus placebo in people attending hospital outpatient clinics with diabetic foot ulcers who were free of signs of infection or severe vascular compromise. All participants received wound debridement and were encouraged to avoid weight bearing on the affected limb. The systematic review did not pool the results from the RCTs.[23] Two of the identified RCTs include fewer than 10 people per treatment arm, and are excluded from this summary. The first RCT (65 people) found that treatment with a topical growth factor (arginine–glycine–aspartic acid matrix) twice weekly for up to 10 weeks increased healing rates compared with placebo (AR for non-healing: 65% with matrix *v* 92% with placebo; ARR 27%, 95% CI 6% to 48%; NNT 4, 95% CI 2 to 15; P = 0.02).[29] The second RCT (118 people) found that treatment with platelet derived growth factor (30 μg/g once daily for up to 20 weeks) increased healing rates compared with placebo (AR for non-healing: 52% with platelet derived growth factor *v* 75% with placebo; ARR 23%, 95% CI 5% to 41%; NNT 5, 95% CI 3 to 14; P = 0.01).[30] The third RCT (382 people) found that platelet derived growth factor (100 μg/g once daily for up to 20 weeks) increased healing rates compared with placebo (AR for non-healing: 50% with platelet derived growth

factor *v* 65% with placebo; ARR 15%, 95% CI 2% to 28%; NNT 7, 95% CI 4 to 42; P = 0.007).[31] The fourth RCT (81 people) found that CT-102 increased healing compared with placebo (non-healing: 20% with CT-102 *v* 71% with placebo; ARR 51%, 95% CI 19% to 84%; NNT 2, 95% CI 1 to 5; P = 0.01).[32]

Harms: The systematic review reported no growth factor related adverse effects.[23]

Comment: These therapeutic agents are not widely available and may be expensive. There has been little long term follow up of people treated with these growth factors.

OPTION SYSTEMIC HYPERBARIC OXYGEN

One RCT identified by a systematic review found that systemic hyperbaric oxygen (see glossary, p 751) plus usual care reduced amputation rates at 10 weeks compared with usual care alone in people with severely infected diabetic foot ulcers. One small RCT found no significant difference in major amputation rates (see glossary, p 751) between systemic hyperbaric oxygen plus usual care compared with usual care alone, although it may have been too small to detect a clinically important difference. One small RCT in people with non-infected neuropathic foot ulcers found no significant difference between hyperbaric oxygen plus usual care and usual care alone in ulcer healing at 4 weeks.

Benefits: **Infected foot ulcers** We found one systematic review (search date 1998, 1 RCT)[23] and one additional RCT.[33] The RCT in the systematic review (70 people with severe infected diabetic foot ulcers with full thickness gangrene or abscess, or a large infected ulcer that had not healed after 30 days) compared systemic hyperbaric oxygen (see glossary, p 751) (daily 90 minute sessions at 2.2–2.5 atmospheres) plus usual care (aggressive debridement, broad spectrum iv antibiotics, revascularisation if indicated, and optimised glycaemic control) versus usual care alone.[34] After 10 weeks, systemic hyperbaric oxygen plus usual care significantly reduced rates of major amputation compared with usual care alone (8.6% with systemic hyperbaric oxygen *v* 33% with usual care alone; RR 0.26, 95% CI 0.16 to 0.92; ARR 24%, 95% CI 4% to 45%; NNT 5, 95% CI 2 to 23). The additional RCT (30 people with chronic infected foot ulcers) compared usual care alone (including debridement, iv antibiotics, and optimised glycaemic control) versus usual care plus four treatments with systemic hyperbaric oxygen (8 x 45 minutes sessions at 3 atmospheres pressure) over 2 weeks.[33] It found no significant difference in the risk of major amputation, although it may have lacked power to detect a clinically important effect (13.3% with systemic hyperbaric oxygen *v* 46.7% with usual care alone; ARR +33%, 95% CI –1.6% to +68%). **Non-infected non-ischaemic ulcers** One small RCT (28 people with neuropathic foot ulcers) compared systemic hyperbaric oxygen therapy (90 minute sessions at 2.5 atmospheres twice daily for 2 weeks) plus

usual care versus usual care alone.[35] It found no significant difference in the proportion of completely healed ulcers or in reduction in ulcer size at 4 weeks (completely healed: 2/14 [14%] with hyperbaric treatment *v* 0/13 [0%] with control, P not reported; reduction of ulcer surface area: 62% with hyperbaric treatment *v* 22% with control, P not reported).

Harms: In the RCT identified by the systematic review, two people developed symptoms of barotraumatic otitis, but this did not interrupt treatment.[34]

Comment: The smaller RCTs comparing hyperbaric oxygen with usual care may have been too small to rule out a clinically important effect.[33,35]

GLOSSARY

Cultured human dermis consists of neonatal fibroblasts cultured *in vitro* onto a bioabsorbable mesh to produce a living, metabolically active tissue containing normal dermal matrix proteins and cytokines.

Human skin equivalent consists of two allogenic layers containing human skin cells. One layer is formed by dermal cells (human fibroblasts) and the second layer is formed by epidermal cells. Human skin equivalent produces cytokines and growth factors involved in the skin healing process.

Major amputations are above or below knee amputations.

Minor amputations involve partial removal of a foot, including toe or forefoot resections.

Pressure off-loading refers to the use of different techniques designed to minimise the amount of force applied to the ulcer site.

Seattle wound classification system is used to standardise the description of diabetic foot ulcers. It has 10 categories, from superficial wound (category 1) to deep wound involving infection and tissue necrosis (category 10).[18]

Systemic hyperbaric oxygen refers to exposing a patient to a high oxygen, high pressure environment designed to improve oxygen delivery to the ulcer site.

Topical growth factors are synthetically produced factors specifically designed to promote cellular proliferation or matrix production at an ulcer site.

Total contact casting is the application of a layer of plaster over the foot and lower leg, designed to distribute pressure evenly over the entire plantar aspect of the foot to reduce exposure of plantar ulcers to pressure, even when the person is walking.

Substantive changes

Systemic hyperbaric oxygen One RCT added;[35] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Key Messages

Intensive control of hyperglycaemia in people aged 13–75 years

- Large RCTs have found that diabetic complications increase with HbA1c concentrations above the non-diabetic range.
- One systematic review and large subsequent RCTs in people with type 1 or type 2 diabetes have found strong evidence that intensive versus conventional glycaemic control significantly reduces the development and progression of microvascular and neuropathic complications. A second systematic review has found that intensive versus conventional treatment is associated with a small reduction in cardiovascular risk.
- RCTs have found that intensive treatment increases the incidence of hypoglycaemia and weight gain, without adverse impact on neuropsychological function or quality of life.
- The benefit of intensive treatment is limited by the complications of advanced diabetes (such as blindness, end stage renal disease, or cardiovascular disease), major comorbidity, and reduced life expectancy.

Intensive control of hyperglycaemia in people with frequent severe hypoglycaemia

- The benefits of intensive treatment of hyperglycaemia are described above.
- It is difficult to weigh the benefit of reduced complications against the harm of increased hypoglycaemia. The risk of intensive treatment is increased by a history of severe hypoglycaemia or unawareness of hypoglycaemia, advanced autonomic neuropathy or cardiovascular disease, and impaired ability to detect or treat hypoglycaemia (such as altered mental state, immobility, or lack of social support). For people likely to have limited benefit or increased risk with intensive treatment, it may be more appropriate to negotiate less intensive goals for glycaemic management that reflect the person's self determined goals of care and willingness to make lifestyle modifications.

Glycaemic control in diabetes

DEFINITION Diabetes mellitus is a group of disorders characterised by hyperglycaemia (definitions vary slightly, one current US definition is fasting plasma glucose ≥ 7.0 mmol/L or ≥ 11.1 mmol/L 2 h after a 75 g oral glucose load, on 2 or more occasions). Intensive treatment is designed to achieve blood glucose values as close to the non-diabetic range as possible. The components of such treatment are education, counselling, monitoring, self management, and pharmacological treatment with insulin or oral antidiabetic agents to achieve specific glycaemic goals.

INCIDENCE/ PREVALENCE Diabetes is diagnosed in about 5% of adults aged 20 years or older in the USA.[1] A further 2.7% have undiagnosed diabetes on the basis of fasting glucose. The prevalence is similar in men and women, but diabetes is more common in some ethnic groups. The prevalence in people aged 40–74 years has increased over the past decade.

AETIOLOGY/ RISK FACTORS Diabetes results from deficient insulin secretion, decreased insulin action, or both. Many processes can be involved, from autoimmune destruction of the β cells of the pancreas to incompletely understood abnormalities that result in resistance to insulin action. Genetic factors are involved in both mechanisms. In type 1 diabetes there is an absolute deficiency of insulin. In type 2 diabetes, insulin resistance and an inability of the pancreas to compensate are involved. Hyperglycaemia without clinical symptoms but sufficient to cause tissue damage can be present for many years before diagnosis.

PROGNOSIS Severe hyperglycaemia causes numerous symptoms, including polyuria, polydipsia, weight loss, and blurred vision. Acute, life threatening consequences of diabetes are hyperglycaemia with ketoacidosis or the non-ketotic hyperosmolar syndrome. There is increased susceptibility to certain infections. Long term complications of diabetes include retinopathy (with potential loss of vision), nephropathy (leading to renal failure), peripheral neuropathy (increased risk of foot ulcers, amputation, and Charcot joints), autonomic neuropathy (cardiovascular, gastrointestinal, and genitourinary dysfunction), and greatly increased risk of atheroma affecting large vessels (macrovascular complications of stroke, myocardial infarction, or peripheral vascular disease). The physical, emotional, and social impact of diabetes and the demands of intensive treatment can also create problems for people with diabetes and their families. One systematic review (search date 1998) of observational studies in people with type 2 diabetes found a positive association between increased blood glucose concentration and mortality.[2] It found no minimum threshold level.

AIMS OF INTERVENTION To delay development and slow progression of microvascular, neuropathic, and cardiovascular complications of diabetes, while minimising adverse effects of treatment (hypoglycaemia and weight gain), and maximising quality of life.

OUTCOMES Quality of life; short term burden of treatment; long term clinical complications; risks and benefits of treatment. Both the development of complications in people who have previously been free of them, and the progression of complications. Scales of severity are

used to detect disease progression (e.g. 19 step scales of diabetic retinopathy; normoalbuminuria, microalbuminuria, and albuminuria for nephropathy; absence or presence of clinical neuropathy).

METHODS *Clinical Evidence* search and appraisal December 2002.

QUESTION **What are the effects of intensive versus conventional glycaemic control?**

OPTION **INTENSIVE VERSUS CONVENTIONAL GLYCAEMIC CONTROL**

One systematic review and three subsequent RCTs in people with type 1 and type 2 diabetes have found that intensive treatment compared with conventional treatment reduces development and progression of microvascular and neuropathic complications. A second systematic review in people with type 1 diabetes and two additional RCTs in people with type 2 diabetes found no evidence that intensive treatment increased adverse cardiovascular outcomes. Intensive treatment reduces the number of macrovascular events, but has no significant effect on the number of people who develop macrovascular disease. Intensive treatment is associated with hypoglycaemia and weight gain, but does not seem adversely to affect neuropsychological function or quality of life.

Benefits:

Microvascular and neuropathic complications: We found one systematic review (search date 1991, 16 small RCTs of type 1 diabetes),[3] and three subsequent long term RCTs.[4–6] The review and the RCTs all found that intensive treatment versus conventional treatment significantly reduced rates of retinopathy, nephropathy, and neuropathy (see table 1, p 761). In one large subsequent RCT (1441 people with type 1 diabetes), about half had no retinopathy and half had mild retinopathy at baseline.[4] At 6.5 years (the mean duration of the RCT), intensive treatment versus conventional treatment significantly reduced the progression of retinopathy and neuropathy. After a further 4 years, the benefit was maintained, regardless of whether people stayed in the groups to which they were initially randomised.[7] The difference in the median HbA1c concentration for people initially randomised to intensive or conventional care narrowed. After 6 years' follow up, people originally allocated to intensive treatment had lower rates of microalbuminuria and hypertension than those originally allocated to conventional treatment (microalbuminuria 4.5% with former intensive treatment *v* 12.3% with former conventional treatment, $P < 0.001$; hypertension 33% for former intensive treatment *v* 25% for former conventional treatment, $P < 0.001$).[8] However, another subsequent RCT compared a conventional dietary treatment policy with two different intensive treatment policies based on sulphonylurea and insulin (3867 people with newly diagnosed type 2 diabetes, age 25–65 years, fasting plasma glucose 6.1–15.0 mmol/L after 3 months' dietary treatment, no symptoms of hyperglycaemia, follow up 10 years).[6] HbA1c rose steadily in both groups. Intensive treatment was associated with a significant reduction in any diabetes related end point (40.9 *v* 46.0 events/1000 person years; RRR 12%, 95% CI 1% to 21%), but no significant effect on diabetes related deaths (10.4 *v* 11.5 deaths/1000 person years; RRR +10%, 95% CI −11%

to +27%) or all cause mortality (17.9 *v* 18.9 deaths/1000 person years; RRR +6%, 95% CI −10% to +20%). Secondary analysis found that intensive treatment was associated with a significant reduction in microvascular end points (8.6 *v* 11.4/1000 person years; RRR 25%, 95% CI 7% to 40%) compared with conventional treatment (see table 1, p 761).[6] **Cardiovascular outcomes:** We found one systematic review[9] and two additional RCTs.[5,6] The systematic review (search date 1996, 6 RCTs, 1731 people with type 1 diabetes followed for 2–8 years) found that intensive insulin treatment versus conventional treatment decreased the number of macrovascular events (OR 0.55, 95% CI 0.35 to 0.88), but had no significant effect on the number of people developing macrovascular disease (OR 0.72, 95% CI 0.44 to 1.17) or on macrovascular mortality (OR 0.91, 95% CI 0.31 to 2.65).[9] The additional RCTs included people with type 2 diabetes.[5,6] In the first RCT, the risk of major cerebrovascular, cardiovascular, and peripheral vascular events in the intensive treatment group was half that of the conventional treatment group (0.6 *v* 1.3 events/100 person years), but the event rate in this small trial was low and the results were not significant.[5] In the second RCT, intensive treatment versus conventional treatment was associated with a non-significant reduction in the risk of myocardial infarction (AR 387/2729 [14%] with intensive treatment *v* 186/1138 [16%] with conventional treatment; RRR +13%, 95% CI −2% to +27%), a non-significant increase in the risk of stroke (AR 148/2729 [5.4%] *v* 55/1138 [4.8%]; RRI +12%, 95% CI −17% to +51%), and a non-significant reduction in the risk of amputation or death from peripheral vascular disease (AR 29/2729 [1.1%] *v* 18/1138 [1.6%]; RRR +33%, 95% CI −20% to +63%).[6]

Harms:

Hypoglycaemia: We found one systematic review[10] and three additional RCTs.[5,6,11] The systematic review (search date not stated, 14 RCTs with at least 6 months' follow up and monitoring of HbA1c, 2067 people with type 1 diabetes followed for 0.5–7.5 years) found that intensive treatment versus conventional treatment increased the median incidence of severe hypoglycaemia (7.9 episodes/100 person years for intensive *v* 4.6 episodes/100 person years for conventional treatment; OR 3.0, 95% CI 2.5 to 3.6).[10] The risk of severe hypoglycaemia was associated with the degree of HbA1c lowering in the intensive treatment groups ($P = 0.005$). The three additional RCTs included people with type 2 diabetes with lower baseline rates of hypoglycaemia. In the first RCT (110 people), there was no significant difference in rates of hypoglycaemia between groups.[5] In the second RCT (3867 people), the rates of major hypoglycaemic episodes per year were 0.7% with conventional treatment, 1.0% with chlorpropamide, 1.4% with glibenclamide, and 1.8% with insulin. People in the intensive treatment group had significantly more hypoglycaemic episodes than those in the conventional group ($P < 0.0001$).[6] In the third RCT (1704 overweight people), major hypoglycaemic episodes occurred in 0.6% of overweight people in the metformin treated group.[11]
Weight gain: Four RCTs found more weight increase with intensive treatment than with standard treatment.[4–6,12] One RCT found weight remained stable in people with type 1 diabetes in the conventional treatment group, but body mass index increased by

5.8% in the intensive treatment group (95% CI not presented; $P < 0.01$).[12] In the second RCT (1441 people with type 1 diabetes) intensive treatment was associated with increased risk of developing a body weight more than 120% above the ideal (12.7 cases/100 person years with intensive treatment *v* 9.3 cases/100 person years with conventional treatment; RR 1.33). At 5 years, people treated intensively gained 4.6 kg more than people treated conventionally (CI not provided for weight data).[4] In the third RCT, the increase in body mass index from baseline to 6 years was not significant in either group (intensive treatment group 20.5–21.2 kg/m^2, conventional treatment group 20.3–21.9 kg/m^2).[5] In the fourth RCT, weight gain at 10 years was significantly higher in people with type 2 diabetes in the intensive treatment group compared with people in the conventional treatment group (mean difference 2.9 kg; $P < 0.001$), and people assigned insulin had a greater gain in weight (4.0 kg) than those assigned chlorpropamide (2.6 kg) or glibenclamide (1.7 kg).[6] We found one systematic review (search date 1996, 10 RCTs)[13] and one subsequent RCT[11] comparing metformin and sulphonylurea. Meta-analysis in the review found that sulphonylurea was associated with an increase in weight from baseline, and metformin with a decrease (difference 2.9 kg, 95% CI 1.1 kg to 4.4 kg). In the subsequent RCT, overweight participants randomly assigned to intensive blood glucose control with metformin had a similar change in body weight to the conventional treatment group, and less increase in mean body weight than people receiving intensive treatment with sulphonylureas or insulin.[11] **Neuropsychological impairment:** We found no systematic review on neuropsychological impairment, but found two RCTs.[14–17] One RCT (102 people) compared intensified with standard treatment in people with type 1 diabetes. It found no cognitive impairment associated with hypoglycaemia after 3 years.[14,15] The second RCT found that intensive treatment did not affect neuropsychological performance.[16] People who had repeated episodes of hypoglycaemia did not perform differently from people who did not have repeated episodes.[17] **Quality of life:** We found three RCTs that reported quality of life in people undergoing intensive versus conventional treatment.[18–20] Together, they suggested that quality of life is lowered by complications, but is not lowered directly by intensive versus conventional treatment. The first RCT (1441 people) found that intensive treatment did not reduce quality of life in people with type 1 diabetes.[18] Severe hypoglycaemia was not consistently associated with a subsequent increase in distress caused by symptoms or decline in the quality of life. However, in the primary prevention intensive treatment group, repeated severe hypoglycaemia (3 or more events resulting in coma or seizure) tended to increase the risk of distress caused by symptoms. The second RCT (77 adolescents with type 1 diabetes) found that behavioural intervention plus intensive diabetes management versus intensive diabetes management alone significantly improved quality of life, diabetes and medical self efficacy, and HbA1c after 1 year (7.5% *v* 8.5%; $P = 0.001$).[19] The behavioural intervention included six small group sessions and monthly follow up aimed at social problem solving, cognitive behaviour modification, and conflict resolution. The third RCT of intensive versus conventional

treatment of type 2 diabetes assessed quality of life in two large cross-sectional samples at 8 and 11 years after randomisation (disease specific measures in 2431 people and generic measures in 3104 people), and also in a small cohort (diabetes specific quality of life measures in 374 people 6 months after randomisation and annually thereafter for 6 years).[20] The cross-sectional studies found no significant effect of intensive versus conventional treatment on scores for mood, cognitive mistakes, symptoms, work satisfaction, or general health. The longitudinal study also found no significant difference in quality of life scores other than a small increase in the number of symptoms in people allocated to conventional than to intensive treatment. In the cross-sectional studies, people who had macrovascular or microvascular complications in the past year had lower quality of life than people without complications. People treated with insulin who had two or more hypoglycaemic episodes during the previous year reported more tension, more overall mood disturbance, and less work satisfaction than those with no hypoglycaemic attacks (after adjusting for age, time from randomisation, systolic blood pressure, HbA1c, and sex). It was unclear whether frequent hypoglycaemic episodes affected quality of life, or whether people with certain personality traits or symptoms simply reported increased numbers of hypoglycaemic attacks.

Comment: We found one follow up study in people with type 1 diabetes 11.4 years after randomisation.[21] In people originally randomised to intensive treatment, it found that the fall in systolic blood pressure with upright posture (one measure of cardiovascular sympathetic dysfunction) and cardiovascular parasympathetic autonomic dysfunction (regardless of how it was measured) developed at a significantly slower pace.[21] We found one systematic review (search date 2000, 12 RCTs, 600 people with type 1 diabetes) that compared continuous subcutaneous insulin infusion with intensive insulin injections.[22] It found that continuous subcutaneous insulin infusion versus intensive insulin injections decreased mean blood glucose and glycated haemoglobin at 2.5–24 months (SMD: blood glucose 0.56, 95% CI 0.35 to 0.77, no significant heterogeneity; glycated haemoglobin 0.44, 95% CI 0.20 to 0.69, significant heterogeneity, P = 0.07).

QUESTION What is the optimum target blood glucose?

OPTION OPTIMUM TARGET BLOOD GLUCOSE

Large RCTs in people with type 1 and type 2 diabetes have found that development or progression of complications increases progressively as HbA1c increases above the non-diabetic range.

Benefits: We found no systematic review but found two large RCTs.[4,6] The first RCT (1441 people with type 1 diabetes) found that lower HbA1c was associated with a lower risk of complications.[4,23] The second RCT (3867 people with type 2 diabetes) found that, as concentrations of HbA1c were reduced, the risk of complications fell but the risk of hypoglycaemia increased.[6,20] A further analysis of the second RCT (3642 people who had HbA1c measured 3 months after

the diagnosis of diabetes and who had complete data whether or not they were randomised in the trial) found that each 1% reduction in mean HbA1c was associated with reduced risk of any diabetes related microvascular or macrovascular event (RR 0.79, 95% CI 0.76 to 0.83), diabetes related death (RR 0.79, 95% CI 0.73 to 0.85), all cause mortality (RR 0.86, 95% CI 0.81 to 0.91), microvascular complications (RR 0.63, 95% CI 0.59 to 0.67), and myocardial infarction (RR 0.86, 95% CI 0.79 to 0.92).[24] These prospective observational data suggested that there is no lower glycaemic threshold for the risk of complications; the better the glycaemic control, the lower the risk of complications. They also suggested that the rate of increase of risk for microvascular disease with hyperglycaemia is greater than that for macrovascular disease.

Harms: Both RCTs found that hypoglycaemia was increased by intensive treatment.[20,23]

Comment: It is difficult to weigh the benefit of reduced complications against the harm of increased hypoglycaemia. The balance between benefits and harms of intensive treatment in type 1 diabetes may be less favourable in children under 13 years or in older adults, and in people with repeated severe hypoglycaemia or unawareness of hypoglycaemia. Similarly, the balance between benefits and harms of intensive treatment in type 2 diabetes may be less favourable in people aged over 65 years or in those with longstanding diabetes. The benefit of intensive treatment is limited by the complications of advanced diabetes (such as blindness, end stage renal disease, or cardiovascular disease), major comorbidity, and reduced life expectancy. The risk of intensive treatment is increased by a history of severe hypoglycaemia or unawareness of hypoglycaemia, advanced autonomic neuropathy or cardiovascular disease, and impaired ability to detect or treat hypoglycaemia (such as altered mental state, immobility, or lack of social support). For people likely to have limited benefit or increased risk with intensive treatment, it may be more appropriate to negotiate less intensive goals for glycaemic management that reflect the person's self determined goals of care and willingness to make lifestyle modifications.

QUESTIONS

INTERVENTIONS

Key Messages

- For information on the effects of lifestyle interventions to achieve weight loss see changing behaviour, p 98.
- **Diethylpropion** One systematic review found that diethylpropion promotes modest weight loss compared with placebo in healthy obese adults. We found two case reports describing pulmonary hypertension and psychosis with diethylpropion. We found insufficient evidence on weight regain and long term safety. A European Commission review concluded that a link between diethylpropion and heart and lung problems could not be excluded.
- **Fluoxetine** One systematic review found that fluoxetine promotes modest weight loss compared with placebo in healthy obese adults. We found insufficient evidence on weight regain and long term safety of fluoxetine in obesity. One systematic review of antidepressant treatment has found an association between selective serotonin reuptake inhibitors and uncommon but serious adverse events, including bradycardia, bleeding, granulocytopenia, seizures, hyponatraemia, hepatotoxicity, serotonin syndrome, and extrapyramidal effects.
- **Mazindol** One systematic review found that mazindol promotes modest weight loss compared with placebo in healthy obese adults. We found one case report of pulmonary hypertension diagnosed 1 year after stopping treatment with mazindol. We found one case series of mazindol in people with stable cardiac disease that reported cardiac events such as atrial fibrillation and syncope. We found insufficient evidence on weight regain and long term safety.

- **Orlistat** Systematic reviews and subsequent RCTs have found that, in addition to a low energy diet, orlistat modestly increases weight loss compared with placebo in healthy obese adults and in obese people with diabetes, hyperlipidaemia, and hypertension. One RCT in people with hypercholestererolaemia found that orlistat plus fluvastatin increased weight loss compared with orlistat or fluvastatin alone. Adverse effects such as oily spotting from the rectum, flatulence, and faecal urgency occurred in a high proportion of people taking orlistat. We found insufficient evidence on weight regain and long term safety.
- **Phentermine** One systematic review found that phentermine promotes modest weight loss compared with placebo in healthy obese adults. We found insufficient evidence on weight regain and long term safety. A European Commission review concluded that a link between phentermine and heart and lung problems could not be excluded.
- **Sibutramine** Systematic reviews and RCTs have found that sibutramine promotes modest weight loss compared with placebo in healthy obese adults and in obese people with diabetes and hypertension. One RCT has found that sibutramine is more effective than placebo for weight maintenance after weight loss in healthy obese adults, but weight regain occurs when sibutramine is discontinued. Sibutramine was temporarily suspended from the market in Italy for use in obesity because of concerns about severe adverse reactions, including arrhythmias, hypertension, and two deaths resulting from cardiac arrest. Two RCTs found no difference in the incidence of valvular heart disease between sibutramine and placebo, although these trials may have been too small to detect clinically important differences. One RCT found that sibutramine achieved greater weight loss than either orlistat or metformin.
- **Sibutramine plus orlistat (insufficient evidence to compared with sibutramine alone)** We found insufficient evidence about the effects of sibutramine plus orlistat and sibutramine alone.
- **Dexfenfluramine** One systematic review has found that dexfenfluramine promotes weight loss compared with placebo in healthy obese adults. Dexfenfluramine has been associated with valvular heart disease and pulmonary hypertension.
- **Fenfluramine** One systematic review found that fenfluramine promotes modest weight loss compared with placebo in healthy obese adults. Fenfluramine has been associated with valvular heart disease and pulmonary hypertension.
- **Fenfluramine plus phentermine** One RCT has found that fenfluramine plus phentermine promotes weight loss compared with placebo. The combination of fenfluramine plus phentermine has been associated with valvular heart disease and pulmonary hypertension.
- **Phenylpropanolamine** One systematic review has found that phenylpropanolamine promotes modest weight loss compared with placebo in healthy obese adults. One case control study found that phenylpropanolamine increased risk of haemorrhagic stroke in the first 3 days of use.

DEFINITION Obesity is a chronic condition characterised by an excess of body fat. It is most often defined by the body mass index (BMI) (see glossary, p 774) a mathematical formula that is highly correlated with body fat. BMI is weight in kilograms divided by height in metres squared (kg/m^2). Worldwide, people with BMIs between 25–30 kg/m^2 are categorised as overweight, and those with BMIs above 30 kg/m^2 are categorised as obese.[1,2] Nearly 5 million US adults used prescription weight loss medication between 1996 and 1998. A quarter of users were not overweight, suggesting that

weight loss medication may be inappropriately used. This is thought to be especially the case among women, white people, and Hispanic people.[3] The National Institutes of Health has issued guidelines for obesity treatment, which indicate that all obese adults (BMI ≥ 30 kg/m^2) and all adults with a BMI of 27 kg/m^2 or more and concomitant risk factors or diseases are candidates for drug treatment.[1]

INCIDENCE/ PREVALENCE Obesity has increased steadily in many countries since 1900. In the UK in 2001, it was estimated that 21% of men and 24% of women were obese.[4] In the past decade alone, the prevalence of obesity in the USA has increased from 22.9% between 1988 and 1994, to 30.5% between 1999 and 2000.[5]

AETIOLOGY/ RISK FACTORS Obesity is the result of long term mismatches in energy balance where daily energy intake exceeds daily energy expenditure.[6] Energy balance is modulated by a myriad of factors, including metabolic rate, appetite, diet, and physical activity.[7] Although these factors are influenced by genetic traits, the increase in obesity prevalence in the past few decades cannot be explained by changes in the human gene pool, and is more often attributed to environmental changes that promote excessive food intake and discourage physical activity.[7,8] Obesity may also be induced by drugs (e.g. high dose glucocorticoids), or be secondary to a variety of neuroendocrine disorders such as Cushing's syndrome and polycystic ovary syndrome.[9]

PROGNOSIS Obesity is a risk factor for several chronic diseases, including hypertension, dyslipidaemia, diabetes, cardiovascular disease, sleep apnoea, osteoarthritis, and some cancers.[1] The relationship between increasing body weight and mortality is curvilinear, where mortality is highest among adults with low body weight (BMI < 18.5 kg/m^2) and among adults with the highest body weight (BMI > 35 kg/m^2).[2] Results from five prospective cohort studies and 1991 national statistics suggest that the number of annual deaths attributable to obesity among US adults is about 280 000.[10] Obese adults also have more annual admissions to hospital, more outpatient visits, higher prescription drug costs, and worse health related quality of life than normal weight adults.[11,12]

AIMS OF INTERVENTION To achieve realistic gradual weight loss, and prevent the morbidity and mortality associated with obesity, without undue adverse effects.

OUTCOMES We found no studies that used the primary outcomes of functional morbidity or mortality. Proxy measures include mean weight loss (kg), number of people losing 5% or more of baseline body weight, and number of people maintaining weight loss.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION What are the effects of drug treatments in adults?

OPTION SIBUTRAMINE

Systematic reviews and subsequent RCTs have found that that sibutramine promotes modest weight loss compared with placebo in healthy obese adults (body mass index 25–40 kg/m^2) and in obese people with diabetes and hypertension. One RCT has found that sibutramine is also more effective than placebo for weight maintenance after weight loss in healthy obese adults, but weight regain occurs when sibutramine is discontinued. Sibutramine was temporarily suspended from the market in Italy for use in obesity because of concerns about severe adverse reactions, including arrhythmias, hypertension, and two deaths resulting from cardiac arrest. Two RCTs found no difference in the incidence of valvular heart disease between sibutramine and placebo, although these trials may have lacked power to detect clinically important differences. One RCT found that sibutramine achieved greater weight loss than either orlistat or metformin. We found insufficient evidence about the effects of sibutramine plus orlistat compared with sibutramine alone.

Benefits:

Versus placebo: We found two systematic reviews (search date 2000, 11 RCTs;[13] and 2002, 3 RCTs[14]) and six subsequent RCTs.[15–20] The first systematic review[13] and five subsequent RCTs[15–19] compared sibutramine versus placebo. The review pooled data for groups of RCTs with similar follow up.[13] The review found that sibutramine 10–20 mg daily reduced weight more than placebo after 8 weeks (3 RCTs, 106 people; WMD –3.40 kg, 95% CI –4.22 kg to –2.58 kg).[13] It also found that sibutramine 10–20 mg daily achieved weight loss of 5% or greater more frequently than placebo after 6 months (2 RCTs, 207 people; RR for > 5% weight loss: sibutramine *v* placebo 2.1, 95% CI 1.7 to 2.6).[13] The second systematic review (485 healthy obese people and 444 obese people with hypertension) included only double blind RCTs that compared sibutramine 15–20 mg daily versus placebo and had at least 1 year of follow up.[14] Losses to follow up were high (range 42% to 51%). It found that sibutramine significantly increased weight loss at 1 year compared with placebo (WMD –4.25 kg, 95% CI –3.56 kg to –4.93 kg).[14] The first subsequent RCT (1001 healthy obese adults) compared intermittent sibutramine (15 mg daily for weeks 1–12, 19–30, and 37–48); continuous sibutramine 15 mg daily, and placebo for 48 weeks.[15] Only 79% of people completed this study. It found no significant difference between intermittent and continuous sibutramine: both regimens reduced weight more than placebo (–3.3 kg with intermittent sibutramine *v* –3.8 kg with continuous sibutramine *v* +0.2 kg with placebo; $P < 0.001$). The second subsequent RCT (184 healthy obese people) compared sibutramine 10 or 20 mg daily versus placebo for 6 months.[16] It found that sibutramine significantly reduced weight compared with placebo (–9.3 kg with 10 mg sibutramine *v* –11.7 kg with 20 mg sibutramine *v* –4.6 kg with placebo; $P < 0.001$). The third and fourth subsequent RCTs compared sibutramine versus placebo in obese adults with type 2 diabetes.[17,18] The third subsequent RCT (134 people) compared sibutramine 15 mg daily versus placebo for 6 months.[17] It found that sibutramine significantly reduced weight

compared with placebo (–4.5 kg with sibutramine *v* –1.7 kg with placebo; P < 0.001). The fourth subsequent RCT (132 people) compared sibutramine 15 or 20 mg daily versus placebo for 1 year.[18] Only 74% of people completed this study. It found that sibutramine significantly reduced weight compared with placebo (–5.5 kg with sibutramine 15 mg *v* –8.0 kg with sibutramine 20 mg *v* –1.7 kg with placebo; P < 0.001). The fifth subsequent RCT (605 healthy obese adults) compared sibutramine for weight maintenance versus placebo for 24 months.[19] People were prescribed sibutramine 10 mg daily plus a calorie reduction diet for 6 months. A total of 467 people with more than 5% weight loss were then randomly assigned to sibutramine 10–20 mg daily or placebo for an additional 18 months. Only 56% of people completed the full 24 months of the study. The RCT found that a greater proportion of people maintained 80% or more of their original weight loss at 24 months with sibutramine compared with placebo (43% with sibutramine *v* 16% with placebo; P < 0.001). The sixth subsequent RCT (57 Hispanic adults with obesity and hypertension) compared sibutramine 10 mg daily versus placebo for 24 weeks.[20] It found that sibutramine significantly reduced weight compared with placebo (weight change: –5.5 kg with sibutramine 10 mg *v* –3.4 kg with placebo; P < 0.05). **Versus orlistat or metformin:** We found one RCT (150 obese women) comparing three treatments: sibutramine 20 mg daily; orlistat (120 mg 3 times daily); and metformin (850 mg twice daily) for 6 months.[21] All people were also instructed to follow a reduced calorie diet. The RCT found that sibutramine achieved greater weight loss than either orlistat or metformin (–13.0 kg with sibutramine *v* –8.0 kg with orlistat *v* –9.0 kg with metformin; sibutramine *v* orlistat and sibutramine *v* metformin P < 0.0001). **Sibutramine plus orlistat:** We found one RCT (34 women who had completed 1 year of sibutramine plus lifestyle modification), which compared sibutramine 10–15 mg daily plus orlistat (120 mg 3 times daily) versus sibutramine plus placebo for weight maintenance.[22] Only 76% of the women completed the study. Mean body weight did not change significantly in either group over a 16 week period (+0.1 kg with sibutramine plus orlistat *v* +0.5 kg with sibutramine plus placebo).

Harms:

Versus placebo: We found no evidence about safety beyond 24 months of treatment. The second systematic review found that sibutramine significantly increased blood pressure compared with placebo (increase in systolic blood pressure: 0.8 mm Hg, 95% CI 0.6 mm Hg to 1.1 mm Hg; increase in diastolic blood pressure ranged from 0.7 mm Hg to 3.3 mm Hg, P < 0.05 for all three studies, significant heterogeneity was found).[14] Common adverse effects were headache, dry mouth, anorexia, constipation, insomnia, rhinitis, and pharyngitis occurring in 10–30% of people taking sibutramine compared with 8–19% of people on placebo (significance of difference not reported).[13] Mean increases in systolic and diastolic blood pressure (1–3 mm Hg) and heart rate (4–5 beats/minute) have been reported in people taking sibutramine at doses of 5–20 mg daily.[13] We found two RCTs that reported the effects of sibutramine on heart valve function.[16,23] The first RCT (210 obese people) compared sibutramine versus placebo for 12 months.[23] It found no significant difference in the incidence of valvular disease

between sibutramine and placebo (3/133 [2.3%] with sibutramine 15–20 mg daily *v* 2/77 [2.6%] with placebo; OR 0.87, 90% CI 0.19 to 3.97). The trial did not report on efficacy. The second RCT (184 healthy obese people) compared sibutramine 10 or 20 mg daily versus placebo.[16] It reported no change in valvular appearance on echocardiogram in any group (no statistical comparisons between or within groups reported). The sixth RCT (57 people with hypertension) found no significant difference in the need for antihypertensive treatment between sibutramine and placebo (P value not reported).[20] Sibutramine was temporarily suspended from the market in Italy in March 2002 in response to 50 reported adverse reactions, including seven severe adverse reactions (tachycardia, hypertension, and arrhythmia) and two deaths resulting from cardiac arrest. The Central European Committee for Proprietary Medicinal Products (CPMP) completed a review of sibutramine in June 2002, and concluded that the risk–benefit profile of sibutramine remains in favour of benefit. To date, none of the other regulatory agencies, including the Medicines Control Agency, UK; the Food and Drug Administration, USA; Health, Canada; and the Therapeutics Goods Administration, Australia, have taken any regulatory actions against the drug.[24] **Versus orlistat or metformin:** One RCT reported dry mouth, insomnia, constipation, and hypertension with sibutramine, and abdominal discomfort with orlistat and metformin.[21] **Sibutramine plus orlistat:** One RCT found that people who received sibutramine plus orlistat experienced more soft stools, bowel movements, oily evacuation, and more faecal urge than sibutramine alone (soft stools: 50.0% with sibutramine plus orlistat *v* 9.1% with sibutramine alone; increased frequency of bowel movements: 50.0% with sibutramine plus orlistat *v* 9.1% with sibutramine alone; oily evacuation: 42.9% with sibutramine plus orlistat *v* 0% with sibutramine alone; more faecal urgency: 42.9% with sibutramine plus orlistat *v* 9.1% with sibutramine alone).[22]

Comment: Most of the RCTs provided concomitant dietary interventions, and about 25% also provided an exercise intervention. The RCTs examining incidence of heart valve dysfunction with sibutramine and placebo may have been too small to detect clinically important effects. Two RCTs (in three publications) provided information on weight regain after discontinuing sibutramine treatment.[19,25,26] A crossover study (82 people) found that people averaged 43% weight regain at 6 months after stopping sibutramine 10 mg daily.[25,26] The placebo arm of a 2 year weight maintenance study found that 115 people averaged 55% weight regain at 18 months after stopping sibutramine 10 mg daily.[19]

OPTION PHENTERMINE

One systematic review found that phentermine promotes modest weight loss compared with placebo in healthy obese adults. We found insufficient evidence on weight regain and long term safety. A European Commission review concluded that a link between phentermine and heart and lung problems could not be excluded.

Benefits: We found one systematic review (search date 1999, 6 relevant RCTs, 368 participants) comparing phentermine 15–30 mg daily versus placebo in healthy obese adults, with mean follow up of

13.2 weeks (range 2–24 weeks).[27] The review found that phentermine produced significantly more weight loss than placebo (effect size: < 0.6 [information presented graphically]; difference in weight loss between phentermine and placebo in the six RCTs ranged from 0.6–6.0 kg). The review also compared phentermine with other agents (diethylpropion, dexfenfluramine, fenfluramine, fluoxetine, mazindol, orlistat, phenylpropanolamine, and sibutramine) and found no significant difference in effect size between phentermine and the other agents (based on 95% CIs presented graphically).[27]

Harms: The systematic review did not make any comment on adverse effects.[27] Phentermine given alone has not been associated with valvular heart disease.[28] A European Commission review reported that, although no new safety problems were identified with phentermine, a link between phentermine and "heart and lung problems could not be totally excluded".[29]

Comment: Most of the people treated with phentermine received additional lifestyle treatment.[27] High withdrawal rates have been reported for phentermine.

OPTION MAZINDOL

One systematic review found that mazindol promotes modest weight loss compared with placebo in healthy obese adults. We found one case report of pulmonary hypertension diagnosed 1 year after stopping treatment with mazindol. We found one case series of mazindol in people with stable cardiac disease that reported cardiac events such as atrial fibrillation and syncope. We found insufficient evidence on weight regain and long term safety.

Benefits: We found one systematic review (search date 1999, 22 relevant RCTs, 906 participants) comparing mazindol 1–3 mg daily versus placebo in healthy obese adults with mean follow up of 11 weeks (range 2–20 weeks).[27] The review found that mazindol significantly increased weight loss compared with placebo (effect size: < 0.5; difference in weight loss between mazindol and placebo in the 22 RCTs ranged from 0.1–7.3 kg). The review also compared mazindol with other agents (diethylpropion, dexfenfluramine, fenfluramine, fluoxetine, orlistat, phenylpropanolamine, phentermine, and sibutramine) and found no significant difference in effect size between mazindol and the other agents (based on 95% CIs presented graphically) except sibutramine (effect size: 0.95) and fenfluramine (effect size: 0.85).[27]

Harms: The systematic review did not comment on adverse effects.[27] We found a single case report of pulmonary hypertension diagnosed 12 months after stopping mazindol that had been taken for 10 weeks.[30] One case series of mazindol in people with stable cardiac disease reported several cardiac events (3 episodes of atrial fibrillation and 2 of syncope in 15 people receiving mazindol for 12 weeks).[31] The frequency of serious adverse events with this agent remains unclear.

Comment: None.

OPTION DIETHYLPROPION

One systematic review found that diethylpropion promotes modest weight loss compared with placebo in healthy obese adults. We found two case reports describing pulmonary hypertension and psychosis with diethylpropion. We found insufficient evidence on weight regain and long term safety. A European Commission review concluded that a link between diethylpropion and heart and lung problems could not be excluded.

Benefits: We found one systematic review (search date 1999, 9 relevant RCTs, 353 people) comparing diethylpropion 75 mg daily versus placebo in healthy obese adults with mean follow up of 17.6 weeks (range 6–52 weeks).[27] The review found that diethylpropion significantly increased weight loss compared with placebo (effect size: < 0.55 [information presented graphically]; difference in weight loss between diethylpropion and placebo in the 9 RCTs ranged from 1.6–11.5 kg). The review also compared diethylpropion with other agents (dexfenfluramine, fenfluramine, fluoxetine, mazindol, orlistat, phenylpropanolamine, phentermine, and sibutramine), and found no significant difference in effect size between diethylpropion and the other agents (based on 95% CIs presented graphically).[27]

Harms: The systematic review did not comment on adverse effects.[27] Case reports have described pulmonary hypertension and psychosis in users of diethylpropion.[32,33] The frequency of serious adverse events with this diethylpropion remains unclear. A European Commission review of the risks and benefits of diethylpropion concluded that randomised trials do not adequately show efficacy for weight loss.[29] Although no new safety problems were identified with diethylpropion, the Commission commented that a link between diethylpropion and "heart and lung problems could not be totally excluded".

Comment: None.

OPTION FLUOXETINE

One systematic review found that fluoxetine promotes modest weight loss compared with placebo in healthy obese adults. We found insufficient evidence on weight regain and long term safety of fluoxetine in obesity. One systematic review of antidepressant treatment has found an association between selective serotonin reuptake inhibitors and uncommon but serious adverse events, including bradycardia, bleeding, granulocytopenia, seizures, hyponatraemia, hepatotoxicity, serotonin syndrome, and extrapyramidal effects.

Benefits: We found one systematic review (search date 1999, 11 relevant RCTs, 1219 people) comparing fluoxetine 32.5–60.0 mg daily versus placebo in healthy obese adults with mean follow up of 27.5 weeks (range 6–60 weeks).[27] The review found that fluoxetine produced significant weight loss compared with placebo (effect size: < 0.45 [information presented graphically]; difference in weight loss between fluoxetine and placebo in the 11 RCTs ranged from 0.2–7.4 kg). The review also compared fluoxetine versus other

agents (diethylpropion, dexfenfluramine, fenfluramine, mazindol, orlistat, phenylpropanolamine, phentermine, and sibutramine) and found no significant difference in effect size between fluoxetine and the other agents (based on 95% CIs) except sibutramine (effect size: 0.95) and fenfluramine (effect size: 0.85).[27]

Harms: The systematic review did not comment on adverse effects.[27] One older systematic review (search date 1998) of antidepressant treatment found that selective serotonin reuptake inhibitors were associated with a 10–15% incidence of anxiety, diarrhoea, dry mouth, headache, and nausea.[34] The review also found an association between selective serotonin reuptake inhibitors and uncommon but serious adverse events, including bradycardia, bleeding, granulocytopenia, seizures, hyponatraemia, hepatotoxicity, serotonin syndrome (see glossary, p 774), and extrapyramidal effects (see glossary, p 774).

Comment: None.

OPTION FENFLURAMINE, DEXFENFLURAMINE, OR FENFLURAMINE PLUS PHENTERMINE

One systematic review found that fenfluramine, dexfenfluramine, or fenfluramine plus phentermine promotes modest weight loss compared with placebo in healthy obese adults. Dexfenfluramine, fenfluramine, and fenfluramine plus phentermine have been associated with valvular heart disease and pulmonary hypertension.

Benefits: **Fenfluramine:** We found one systematic review (search date 1999, 14 relevant RCTs, 577 people) comparing fenfluramine 39–120 mg daily with placebo in healthy obese adults with mean follow up of 9.7 weeks (range 4–18 weeks).[27] The review found that fenfluramine produced significant weight loss (effect size: > 0.85 [information presented graphically]; difference in weight loss between fenfluramine and placebo in the 14 RCTs ranged from 0.1–5.0 kg). The review found no significant difference in effect size between fenfluramine and the other agents (based on 95% CIs presented graphically) except sibutramine (effect size: 0.95). **Dexfenfluramine:** We found one systematic review (search date 1999, 14 relevant RCTs, 1269 people) comparing dexfenfluramine 30–130 mg daily versus placebo in healthy obese adults with mean follow up of 30 weeks (range 4–56 weeks).[27] The review found that dexfenfluramine produced significantly more weight loss than placebo (effect size: < 0.45 [information presented graphically]; difference in weight loss between dexfenfluramine and placebo in the 14 RCTs ranged from 0.2–10.0 kg). The review found no significant difference in effect size between dexfenfluramine and the other agents (based on 95% CIs presented graphically) except sibutramine (effect size: 0.95) and fenfluramine (effect size: 0.85). **Fenfluramine plus phentermine:** We found one RCT (121 people, 30–80% overweight), which found that phentermine 15 mg daily plus fenfluramine 60 mg daily reduced weight significantly more than placebo after treatment for 6 months (–14.3 kg with phentermine plus fenfluramine *v* –4.6 kg with placebo; mean difference –9.7 kg, 95% CI –12.0 to –7.4 kg).[35] The trial found that weight loss ceased at 18 weeks of treatment; weight regain was noted after 60 weeks of treatment.

Harms: **Dexfenfluramine, fenfluramine, fenfluramine plus phentermine:** These agents have been associated with valvular heart disease and primary pulmonary hypertension.[36,37] We found one systematic review (search date 2001, 41 RCTs, 7 observational studies with 1279 people), which examined the effect of fenfluramine, dexfenfluramine, and the combination of fenfluramine or dexfenfluramine plus phentermine on valvular heart disease.[38] It found only one case of mitral regurgitation in the 41 RCTs that reported adverse effects, and in this case, the mitral regurgitation was considered to be due to myocardial infarction rather than drug treatment. In observational studies, the drugs were associated with a significant increase in aortic and mitral regurgitation (aortic regurgitation: RR 2.32, 93% CI 1.79 to 3.01, attributable rate 4.9%; mitral regurgitation: RR 1.55, 95% CI 1.06 to 2.25, attributable rate 1.0%). One case control study (95 people with primary pulmonary hypertension and 355 matched controls) found a history of fenfluramine use was associated with increased risk of primary pulmonary hypertension (OR 6.3, 95% CI 3.0 to 13.2). The odds ratio was higher among people who had taken fenfluramine in the past year (OR 10.1, 95% CI 3.4 to 29.9), and among people treated for more than 3 months (OR 23.1, 95% CI 6.9 to 77.7).[39]

Comment: None.

OPTION PHENYLPROPANOLAMINE

One systematic review found that phenylpropanolamine promotes modest weight loss compared with placebo in healthy obese adults. One case control study found that phenylpropanolamine increased risk of haemorrhagic stroke in the first 3 days of use.

Benefits: We found one systematic review (search date 1999, 7 relevant RCTs, 321 people) comparing phenylpropanolamine 57–75 mg daily versus placebo in healthy obese adults with mean follow up of 7.4 weeks (range 2–14 weeks).[27] The review found that phenylpropanolamine produced significant weight loss (effect size: < 0.5 [information presented graphically]; difference in weight loss between phenylpropanolamine and placebo ranged from 0.3–2.0 kg). The review also compared phenylpropanolamine versus other agents (diethylpropion, dexfenfluramine, fenfluramine, fluoxetine, mazindol, orlistat, phentermine, and sibutramine), and found no significant difference in effect size between phenylpropanolamine and the other agents (based on 95% CIs presented graphically) except sibutramine (effect size: 0.95) and fenfluramine (effect size: 0.85).[27]

Harms: A case control study (men and women aged 18–49 years) found that phenylpropanolamine used as an appetite suppressant increased the risk of haemorrhagic stroke within the first 3 days of use (adjusted OR 15.9, lower confidence limit 2.04; P = 0.013). For the association between phenylpropanolamine in appetite suppressants and risk for haemorrhagic stroke among women, the adjusted odds ratio was 16.6 (lower confidence limit 2.2; P = 0.011).[40]

Comment: None.

OPTION ORLISTAT

Systematic reviews and subsequent RCTs have found that, in addition to a low energy diet, orlistat modestly increases weight loss compared with placebo in healthy obese adults and in obese people with diabetes, hyperlipidaemia, and hypertension. One RCT in people with hypercholesterolaemia found that orlistat plus fluvastain increased weight loss compared with orlistat or fluvastatin alone. Adverse effects such as oily spotting from the rectum, flatulence, and faecal urgency occurred in a high proportion of people taking orlistat. We found insufficient evidence on weight regain and long term safety.

Benefits:

Versus placebo: We found two systematic reviews (search dates 2000[41] and 2002[14]), and four subsequent RCTs.[42–45] The first review (14 RCTs) pooled RCTs with similar study designs.[41] Studies were excluded if they did not separately analyse people who were not overweight or obese. The 11 published RCTs in the systematic review (5124 adults with mean body mass index [see glossary, p 774] > 30 kg/m^2) found no significant difference in weight after 12 weeks between orlistat (50–60 mg 3 times daily) plus reduced calorie diet and placebo plus reduced calorie diet (2 RCTs: WMD –1.24 kg, 95% CI –2.65 kg to +0.16 kg).[41] However, higher dose orlistat (120 mg 3 times daily) was associated with greater weight loss than placebo at 12 weeks (1 RCT: mean weight loss 4.74 kg with orlistat *v* 2.98 kg with placebo; P = 0.001).[41] Two trials of 6 months' duration were not included in the pooling. The first 6 month RCT (119 people) compared orlistat (120 mg 3 times daily) versus placebo. All people received an energy restricted diet. At 6 months, orlistat reduced weight more than placebo (mean weight loss: 10.75 kg with orlistat *v* 7.34 kg with placebo; P < 0.05).[46] The second 6 month RCT (605 people on a reduced energy diet) compared orlistat (30, 60, 120, or 240 mg 3 times daily) with placebo. All doses of orlistat significantly increased weight loss at 6 months compared with placebo (weight loss from baseline: 6.5% with placebo *v* 8.5% with orlistat 30 mg; P value not reported; *v* 8.8% with orlistat 60 mg; P ≤ 0.002; *v* 9.8% with orlistat 120 mg; P ≤ 0.001; *v* 9.3% with orlistat 240 mg; P ≤ 0.001).[47] The review found similar results at 2 years. Two trials examining change in body weight using orlistat (120 mg 3 times daily) or placebo for 2 years were pooled. People taking orlistat had significantly greater weight loss (WMD –3.19 kg, 95% CI –4.25 kg to –2.12 kg).[41] One included RCT compared effects of orlistat (30, 60, and 120 mg 3 times daily) versus placebo on weight regain after 6 months of diet plus exercise counselling.[41] It found that orlistat reduced weight regain compared with placebo (orlistat 120 mg *v* placebo P < 0.001).[48] The second systematic review (11 RCTs, 6021 obese people) only included RCTs with at least 1 year of follow up.[14] The included RCTs had high loss to follow up (range 11–61%). The review found that orlistat (120 mg 3 times daily) significantly increased weight loss at 1 year compared with placebo (WMD –2.70 kg, 95% CI –2.27 kg to –3.12 kg). The first subsequent RCT (376 adults with type 2 diabetes, hypercholesterolaemia, or hypertension) found that dietary counselling plus orlistat (120 mg 3 times daily) significantly increased the proportion of people who lost 5% or more of

their initial body weight compared with placebo (54% with orlistat *v* 41% with placebo; P < 0.001). However, dietary counselling plus orlistat did not significantly increase weight reduction of 10% or more (AR 19% with dietary counselling plus orlistat *v* 14.6% with placebo).[42] The second subsequent RCT (294 people with hypercholesterolaemia) compared orlistat (120 mg 3 times daily) versus placebo for 24 weeks. It found that orlistat significantly increased weight loss compared with placebo (mean weight loss: 4.66 kg with orlistat *v* 1.88 kg with placebo; P < 0.001).[43] The third subsequent RCT (343 people with type 2 diabetes mellitus) compared orlistat (120 mg 3 times daily) versus placebo for 24 weeks.[44] It found that orlistat significantly increased weight loss compared with placebo (mean weight loss: 4.24 kg with orlistat *v* 2.58 kg with placebo; P = 0.0003).[44] The fourth subsequent RCT (99 people with hypercholesterolaemia) compared four treatments over 1 year: orlistat (120 mg 3 times daily); fluvastatin (80 mg 4 times daily); orlistat (120 mg 3 times daily) plus fluvastatin (80 mg 4 times daily), and placebo.[45] It found no significant difference in weight loss between orlistat alone and placebo (8.6 kg with orlistat alone *v* 7.6 kg with placebo, P not reported).

Orlistat plus fluvastatin: One RCT (99 people with hypercholesterolaemia; described above)[45] found that orlistat plus fluvastatin significantly increased weight loss compared orlistat alone, fluvastatin alone, or placebo (mean weight loss: 11.4 kg with orlistat plus fluvastatin *v* 8.6 kg with orlistat *v* 8.0 kg with fluvastatin *v* 7.6 kg with placebo; P < 0.05).[45]

Harms: Gastrointestinal adverse events such as loose stools, increased defaecation, abdominal pain, nausea and vomiting, oily spotting from the rectum, flatulence, and faecal urgency were more common with orlistat than placebo (48–95% with orlistat [120 mg 3 times daily] *v* 18–68% with placebo)[41–43] The second systematic review (search date 2002) found that fatty or oily stools, faecal urgency, and oily spotting occurred in 15–30% of people taking orlistat.[14] It found that blood concentration of fat soluble vitamins (A, D, E) and β carotene were reduced by orlistat treatment, and vitamin D was the most frequently affected. However, no study reported clinical vitamin deficiency as an end point.[14] Fat soluble vitamin supplements are deemed necessary.[41] One subsequent RCT (343 people with type 2 diabetes mellitus) found that orlistat significantly increased gastrointestinal adverse effects and increased withdrawals because of adverse effects compared with placebo (gastrointestinal effects: 65% with orlistat *v* 37% with placebo; withdrawals: 4.7% with orlistat *v* 2.9% with placebo; P value not reported).[44]

Comment: We found seven subsequent RCTs comparing orlistat versus placebo in obese adults that were excluded owing to high losses to follow up.[49–55] People in six of the seven trials in one systematic review were selected for participation after losing weight on a preliminary low calorie diet with placebo for 4–5 weeks before randomisation.[56] Because of the high rates of gastrointestinal adverse effects associated with orlistat, authors have queried whether blinded evaluation is possible. At the end of a "double blinded" 16 week trial, 22/26 [85%] people correctly identified their treatment group.[22]

GLOSSARY

Body mass index (BMI) Expressed as weight in kilograms divided by height in metres squared (kg/m^2). In the USA and UK, individuals with body mass indexes of 25–30 kg/m^2 are considered overweight; those with body mass indexes above 30 kg/m^2 are considered obese.

Extrapyramidal effects Include acute dystonia, a Parkinsonism-like syndrome, and akathisia.

Serotonin syndrome Clinical features include agitation, ataxia, diaphoresis, diarrhoea, fever, hyper-reflexia, myoclonus, shivering, and changes in mental status. The occurrence and severity of syndrome does not seem to be dose related.

Substantive changes

Sibutramine One systematic review[14] and one RCT[20] added; categorisation unchanged.

Fenfluramine, dexfenfluramine, or fenfluramine plus phentermine One systematic review added;[38] categorisation unchanged.

Orlistat One systematic review[14] and two RCTs[44,45] added; categorisation unchanged.

QUESTIONS

INTERVENTIONS

Prevention of cardiovascular events in diabetes

REVASCULARISATION

Beneficial

Coronary artery bypass graft compared with percutaneous transluminal coronary angioplasty 800

Stent plus glycoprotein IIb/IIIa inhibitors in people undergoing percutaneous transluminal coronary angioplasty 802

Trade off between benefits and harms

Coronary artery bypass graft compared with percutaneous transluminal coronary angioplasty plus stent 800

Unknown effectiveness

Percutaneous transluminal coronary angioplasty compared with thrombolysis. 801

*No RCT but observational evidence suggests some benefit.

See glossary, p 803

Key Messages

Smoking cessation

- **Smoking cessation** We found no RCTs on promotion of smoking cessation specifically in people with diabetes. Observational evidence and extrapolation from evidence in people without diabetes suggest that promotion of smoking cessation is likely to reduce cardiovascular events.

Blood pressure

- **Antihypertensive treatment (compared with no antihypertensive treatment)** One systematic review and RCTs have found that blood pressure lowering with antihypertensive agents in people with diabetes and hypertension reduces cardiovascular morbidity and mortality compared with no antihypertensive treatment.
- **Lower target blood pressures** Large RCTs including people with diabetes and hypertension have found that control of blood pressure to a target diastolic blood pressure of no more than 80 mm Hg reduces the risk of major cardiovascular events. One RCT in normotensive people with diabetes found that intensive blood pressure lowering reduced cerebral vascular events but found no significant difference in cardiovascular death, myocardial infarction, congestive heart failure, or all cause mortality.
- **Different antihypertensive drugs** Systematic reviews and RCTs have found that angiotensin converting enzyme inhibitors, diuretics, β blockers, and calcium channel blockers all reduce cardiovascular morbidity and mortality in people with diabetes and hypertension. However, there are differences in the types of adverse effects reported with different antihypertensive drugs. RCTs have found that people taking atenolol gained more weight than those taking captopril, an increase in risk of congestive heart failure with lisinopril or amlodipine compared with chlorthalidone, a higher frequency of headache with diltiazem compared with diuretics or β blockers, and a higher rate of withdrawal from treatment because of adverse effects with atenolol compared with losartan.

Dyslipidaemia

- **Statins** One systematic review and RCTs have found that statins reduce cardiovascular morbidity and mortality compared with placebo.

- **Aggressive versus moderate lipid lowering with statins** One RCT found that, compared with usual care, treatment with atorvastatin to achieve a target low density lipoprotein concentration below 2.6 mmol/L (< 100 mg/dL) reduces cardiovascular morbidity and mortality. Another RCT found no significant difference between a lower target low density lipoprotein (1.55–2.20 mmol/L) using lovastatin, along with cholestyramine if necessary, and a moderate target low density lipoprotein (3.36–3.62 mmol/L) in 4 year event rate for myocardial infarction and death.
- **Fibrates** One RCT found that gemfibrozil reduced cardiovascular events over 5 years compared with placebo whereas another smaller RCT found no significant difference. One RCT found that bezafibrate reduced cardiovascular events compared with placebo.
- **Low versus standard statin dose in older people** One RCT found no significant difference in cardiovascular events between low dose pravastatin (5 mg/day) and standard dose pravastatin (10–20 mg/day) over 4 years.

Antiplatelet drugs

- **Adding glycoprotein IIb/IIIa inhibitors to heparin in acute coronary syndromes** We found no RCTs comparing glycoprotein IIb/IIIa inhibitors versus no antiplatelet treatment. One RCT in people presenting with unstable angina or acute myocardial infarction without ST segment elevation found that addition of tirofiban (a glycoprotein IIb/IIIa inhibitor) to heparin reduced the composite outcome of death, myocardial infarction, or refractory ischaemia at 180 days compared with heparin alone. This RCT found no significant difference between tirofiban plus heparin and heparin alone in risk of bleeding in people already taking aspirin.
- **Clopidogrel** We found no RCTs comparing only clopidogrel versus placebo. One RCT in people with diabetes and with recent ischaemic stroke, myocardial infarction, or established peripheral arterial disease found no significant difference between clopidogrel and aspirin at 28 days in cardiovascular events. This RCT also found a lower proportion of people hospitalised for a bleeding event with clopidogrel than with aspirin.
- **Prophylactic aspirin** One systematic review found that, compared with controls, antiplatelet treatment mainly with aspirin did not significantly reduce the combined risk of non-fatal myocardial infarction, non-fatal stroke, death from a vascular cause, or death from an unknown cause in people with diabetes and cardiovascular disease diagnosis. The review found that antiplatelet treatment was associated with an increase in the risk of major extracranial haemorrhage and haemorrhagic stroke, but the results for people with diabetes were not reported separately.
- **Adding clopidogrel to aspirin in acute coronary syndromes** One RCT in people presenting with unstable angina or non-Q-wave myocardial infarction and also taking aspirin found no significant reduction in cardiovascular events after 12 months with addition of clopidogrel compared with placebo. This RCT also found a higher proportion of major bleeds with addition of clopidogrel than with placebo.

Blood glucose control

- **Intensive versus conventional glycaemic control** One systematic review found that, compared with conventional glycaemic control, intensive glycaemic control for more than 2 years reduced the occurrence of first major cardiovascular event in people with type 1 diabetes. Two RCTs found no significant

difference in cardiovascular morbidity and mortality with intensive compared with conventional glycaemic control in people with type 2 diabetes. These RCTs also found an increase in weight gain and hypoglycaemic episodes with intensive compared with conventional treatment.

- **Metformin versus diet alone in overweight or obese people with type 2 diabetes** One RCT in overweight or obese people with type 2 diabetes found that intensive treatment with metformin compared with conventional treatment with diet alone reduced myocardial infarction but not stroke over 5 years. This RCT found no significant increase in major hypoglycaemic episodes in the metformin group compared with the diet only group.

Multiple risk factor treatment

- **Intensive multiple risk factor treatment** One RCT found that, compared with conventional treatment according to clinical guidelines, intensive treatment of multiple risk factors with strict treatment goals in people with type 2 diabetes and microalbuminuria reduced cardiovascular disease over 8 years. Multiple risk factor treatment included simultaneously targeting diet, exercise, glycaemic control, blood pressure, treatment of microalbuminuria, and antiplatelet treatment. We found no systematic review or RCTs comparing treatment of multiple risk factors with treatment of a single risk factor for cardiovascular outcomes.

Revascularisation

- **Coronary artery bypass graft (CABG) compared with percutaneous transluminal coronary angioplasty (PTCA)** One systematic review found that, in people with diabetes, CABG reduced all cause mortality at 4 years after initial revascularisation compared with PTCA, but found no significant difference at 6.5 years. One large RCT in people with diabetes and multivessel coronary artery disease has found that CABG reduces mortality or myocardial infarction within 8 years compared with PTCA. Another smaller RCT found a non-significant reduction in mortality with CABG compared with PTCA at 4 years.
- **Stent plus glycoprotein IIb/IIIa inhibitors in people undergoing PTCA** RCTs in people with diabetes undergoing PTCA have found that the combination of stent and a glycoprotein IIb/IIIa inhibitor reduces cardiovascular morbidity and mortality compared with stent plus placebo.
- **CABG compared with PTCA plus stent** One RCT in people with diabetes and multivessel coronary artery disease found no significant difference, at time of discharge, between CABG and PTCA plus stent in cardiovascular morbidity or mortality but found an increase in risk of stroke. However, the same RCT found that, compared with PTCA plus stent, CABG reduced cardiovascular risk at 1 year.
- **PTCA compared with thrombolysis** We found no systematic review or RCTs comparing PTCA versus thrombolysis for prevention of cardiovascular events in people with diabetes. One RCT, in people with diabetes presenting with an acute myocardial infarction, found no significant difference between PTCA and thrombolysis with alteplase in single outcome of death or composite outcome of death, reinfarction, or disabling stroke at 30 days.

DEFINITION **Diabetes mellitus:** See definition under glycaemic control in diabetes, p 753. **Cardiovascular disease (CVD):** Atherosclerotic disease of the heart and/or the coronary, cerebral, or peripheral vessels leading to clinical events such as acute myocardial infarction (see glossary, p 803), congestive heart failure, sudden cardiac

death, stroke, gangrene, and/or need for revascularisation procedures. **Population:** In previous versions of *Clinical Evidence* we attempted to differentiate between primary and secondary prevention in this topic. However, in middle aged and older people with type 2 diabetes this distinction may not be clinically important. We are not aware of any intervention that has been shown to be effective in secondary prevention but ineffective in primary prevention, or vice versa, in people with diabetes. In most cases a large proportion of people with diabetes entered into CVD prevention trials are middle aged and older with additional CVD risk factors, and a large portion of these actually have undiagnosed CVD.

INCIDENCE/ PREVALENCE

Diabetes mellitus is a major risk factor for CVD. In the USA, a survey of deaths in 1986 suggested that 60–75% of people with diabetes die from cardiovascular causes.[1] The annual incidence of CVD is increased in people with diabetes (men: RR 2–3; women: RR 3–4, adjusted for age and other cardiovascular risk factors).[2] About 45% of middle aged and older white people with diabetes have evidence of coronary artery disease compared with about 25% of people without diabetes in the same populations. In a Finnish population based cohort study (1059 people with diabetes and 1373 people without diabetes, aged 45–64 years), the 7 year risk of acute myocardial infarction was as high in adults with diabetes without previous cardiac disease (20.2/100 person years) as it was in people without diabetes with previous cardiac disease (18.8/100 person years).[3]

AETIOLOGY/ RISK FACTORS

Diabetes mellitus increases the risk of CVD. Cardiovascular risk factors in people with diabetes include conventional risk factors (age, prior CVD, cigarette smoking, hypertension, dyslipidaemia, sedentary lifestyle, family history of premature CVD) and more diabetes specific risk factors (elevated urinary protein excretion, poor glycaemic control). Conventional risk factors for CVD contribute to an increase in the relative risk of CVD in people with diabetes to about the same extent as in those without diabetes (see aetiology under primary prevention, p 163). One prospective cohort study (164 women and 235 men with diabetes [mean age 65 years] and 437 women and 1099 men without diabetes [mean age 61 years] followed for mortality for a mean of 3.7 years after acute myocardial infarction) found that significantly more people with diabetes died compared with people without diabetes (116/399 [29%] with diabetes *v* 204/1536 [13%] without diabetes; RR 2.2, 95% CI 1.8 to 2.7).[4] It also found that the mortality risk after myocardial infarction associated with diabetes was higher for women than for men (adjusted HR 2.7, 95% CI 1.8 to 4.2 for women *v* 1.3, 95% CI 1.0 to 1.8 for men). Physical inactivity is a significant risk factor for cardiovascular events in both men and women. Another cohort study (5125 women with diabetes) found that participation in little (< 1 hour/week) or no physical activity compared with physical activity for at least 7 hours a week was associated with doubling of the risk of a cardiovascular event.[5] A third cohort study (1263 men with diabetes, mean follow up 12 years) found that low baseline cardiorespiratory fitness increased overall mortality compared with moderate or high fitness (RR 2.9, 95% CI 2.1 to 3.6), and overall mortality was higher in those

reporting no recreational exercise in the previous 3 months than in those reporting any recreational physical activity in the same period (RR 1.8, 95% CI 1.3 to 2.5).[6] The absolute risk of CVD is almost the same in women as in men with diabetes. Diabetes specific cardiovascular risk factors include the duration of diabetes during adulthood (the years of exposure to diabetes before age 20 years add little to the risk of CVD); raised blood glucose concentrations (reflected in fasting blood glucose or HbA1c [see glossary, p 803]); and any degree of microalbuminuria (albuminuria 30–299 mg/24 hours).[7] People with diabetes and microalbuminuria have a higher risk of coronary morbidity and mortality than do people with normal levels of urinary albumin and a similar duration of diabetes (RR 2–3).[8,9] Clinical proteinuria increases the risk of mortality from cardiac events in people with type 2 diabetes (RR 2.61, 95% CI 1.99 to 3.43)[10] and type 1 diabetes (RR 9)[7,11,12] compared with people with the same type of diabetes who have normal albumin excretion. An epidemiological analysis of people with diabetes enrolled in the Heart Outcomes Prevention Evaluation cohort study (3498 people with diabetes and at least 1 other cardiovascular risk factor, age > 55 years, of whom 1140 [32%] had microalbuminuria at baseline; 5 years' follow up) found higher risk for major cardiovascular events in those with microalbuminuria (albumin : creatinine ratio [ACR] ≥ 2.0 mg/mmol) than in those without microalbuminuria (adjusted RR 1.97, 95% CI 1.68 to 2.31), and for all cause mortality (RR 2.15, 95% CI 1.78 to 2.60).[13] It also found an association between ACR and the risk of major cardiovascular events (ACR 0.22–0.57 mg/mmol: RR 0.85, 95% CI 0.63 to 1.14; ACR 0.58–1.62 mg/mmol: RR 1.11, 95% CI 0.86 to 1.43; ACR 1.62–1.99 mg/mmol: RR 1.89, 95% CI 1.52 to 2.36).

PROGNOSIS Diabetes mellitus increases the risk of mortality or serious morbidity after a coronary event (RR 1.5–3.0).[2,3,14,15] This excess risk is partly accounted for by increased prevalence of other cardiovascular risk factors in people with diabetes. A systematic review (search date 1998, 15 prospective cohort studies) found that, in people with diabetes admitted to hospital for acute myocardial infarction, "stress hyperglycaemia" was associated with significantly higher mortality in hospital compared with lower blood glucose levels (RR 1.7, 95% CI 1.2 to 2.4).[16] One large prospective cohort study (91 285 men aged 40–84 years) found higher all cause and coronary heart disease (CHD) mortality at 5 years' follow up in men with diabetes than in men without coronary artery disease or diabetes (age adjusted RR 3.3, 95% CI 2.6 to 4.1 in men with diabetes and without coronary artery disease *v* RR 2.3, 95% CI 2.0 to 2.6 in healthy people; RR 5.6, 95% CI 4.9 to 6.3 in men with coronary artery disease but without diabetes *v* RR 2.2, 95% CI 2.0 to 2.4 in healthy people; RR 12.0, 95% CI 9.9 to 14.6 in men with both risk factors *v* RR 4.7, 95% CI 4.0 to 5.4 in healthy people).[17] Multivariate analysis did not materially alter these associations. Diabetes mellitus alone is associated with a twofold increase in risk for all cause death, with a threefold increase in risk of death from CHD, and, in people with pre-existing CHD, with a 12-fold increase in risk of death from CHD compared with people with neither risk factor.[17]

AIMS OF INTERVENTION To reduce mortality and morbidity from cardiovascular disease with minimum adverse effects.

OUTCOMES Incidence of fatal or non-fatal acute myocardial infarction; congestive heart failure; sudden cardiac death; coronary revascularisation; stroke; gangrene; angiographic evidence of coronary, cerebral, vascular, or peripheral arterial stenosis; all cause mortality.

METHODS *Clinical Evidence* search and appraisal October 2003. We searched for systematic reviews and RCTs with at least 10 confirmed clinical cardiovascular events among people with diabetes. Studies reporting only intermediate end points (e.g. regression of plaque on angiography, lipid changes) were not included. Most of the evidence comes from subgroup analyses of large RCTs that included people with diabetes. As with all subgroup analyses, and studies with small numbers, these results must be interpreted as suggestive rather than definitive.

QUESTION What are the effects of promoting smoking cessation in people with diabetes?

OPTION PROMOTING SMOKING CESSATION

We found no RCTs on promotion of smoking cessation specifically in people with diabetes. Observational evidence and extrapolation from people without diabetes suggest that promotion of smoking cessation is likely to reduce cardiovascular events.

Benefits: We found no systematic review or RCTs on promotion of smoking cessation specifically in people with diabetes.

Harms: We found no RCTs.

Comment: Observational studies have found that cigarette smoking is associated with increased cardiovascular death in people with diabetes. Smoking cessation in people without diabetes has been found to be associated with reduced risk. People with diabetes are likely to benefit from smoking cessation at least as much as people who do not have diabetes but have other risk factors for cardiovascular events (see smoking cessation under secondary prevention of ischaemic cardiac events, p 197).

QUESTION What are the effects of controlling blood pressure in people with diabetes?

OPTION ANTIHYPERTENSIVE TREATMENT VERSUS NO ANTIHYPERTENSIVE TREATMENT

One systematic review and RCTs have found that, in people with diabetes and hypertension, blood pressure lowering with antihypertensive agents reduces cardiovascular morbidity and mortality compared with no antihypertensive treatment.

Benefits: We found two systematic reviews,[18,19] and one meta-analysis of major RCTs.[20] The second systematic review (search date 2002) did not attempt to pool the results of RCTs identified.[19] We found

four RCTs,[21–24] that were subsequent to the first systematic review.[18] The first systematic review (search date 2000) found that, compared with controls, blood pressure lowering with antihypertensive agents significantly reduced mortality but found no significant effect on myocardial infarction (6 RCTs, 7572 people with diabetes with or without diagnosis of cardiovascular disease [CVD], aged > 50 years; mortality: 10 deaths/1000 person years in treatment arms *v* 19 deaths/1000 person years in control arms; RR 0.51, 95% CI 0.38 to 0.69; myocardial infarction: 14/1000 person years in treatment arms *v* 16/1000 person years in control arms; rate ratio 0.76, 96% CI 0.51 to 1.01).[18] A meta-analysis of large RCTs of angiotensin converting enzyme (ACE) inhibitors and β blockers found that, compared with placebo, both ACE inhibitors and β blockers reduced risk of all cause mortality (6 RCTs of ACE inhibitors *v* placebo, 2398 people with diabetes and left ventricular dysfunction; all cause mortality: RR 0.84, 95% CI 0.070 to 1.0; 3 RCTs of β blockers *v* placebo, 1883 people with diabetes, all cause mortality: RR 0.77, 95% CI 0.61 to 0.96).[20] The first subsequent RCT found that, compared with placebo, antihypertensive treatment with nitrendipine or enalapril with or without hydrochlorothiazide significantly reduced all cardiovascular events over a median of 2 years but found no significant difference for all cause mortality (1 RCT, 495 people with diabetes without a diagnosis of CVD, aged ≥ 60 years with blood pressure 165–220/< 95 mm Hg; all CVD events over median 2 years: 13/252 [5.2%] with antihypertensive treatment *v* 31/240 [12.9%] with placebo; ARR 8%, 95% CI 3% to 10%; RR 0.4, 95% CI 0.21 to 0.75; NNT 13, 95% CI 10 to 31; all cause mortality: 16/252 [6.3%] with antihypertensive treatment *v* 26/240 [10.8%] with placebo; ARR +4.5%, 95% CI –0.7% to +7.4%; RR 0.59, 95% CI 0.32 to 1.06).[21] The second subsequent RCT found no significant difference between antihypertensive treatment with irbesartan or amlodipine and placebo in cardiovascular composite outcomes over 2.6 years (1 RCT, 1715 people with type 2 diabetes, hypertension and nephropathy, aged 30–70 years; 172/579 [30%] with irbesartan *v* 161/569 [28%] with placebo; HR 0.90, 95% CI 0.74 to 1.10; 161/567 [28%] with amlodipine *v* 161/569 [28%] with placebo; HR 1.00, 95% CI 0.83 to 1.21; 172/579 [30%] with irbesartan *v* 161/567 [28%] with amlodipine; HR 0.90, 95% CI 0.74 to 1.10).[25] The third subsequent RCT found no significant difference between antihypertensive treatment with irbesartan and placebo in non-fatal cardiovascular events over 2 years (1 RCT, 590 people with type 2 diabetes, microalbuminuria, and hypertension, mean age 58 years; 8/194 [4.1%] with irbesartan *v* 17/201 [8.5%] with placebo; RR 0.49, 95% CI 0.22 to 1.10).[23] The fourth subsequent RCT found that, compared with placebo, antihypertensive treatment with ramipril significantly reduced major cardiovascular events and death from any cause over 4.5 years (1 RCT, 3 arm study, 9541 people aged ≥ 55 years with diabetes and additional CVD risk factors such as diagnosed coronary vascular disease, current smoker, hypercholesterolaemia, hypertension, or microalbuminuria; major cardiovascular event such as coronary vascular disease death, acute myocardial infarction [see glossary, p 803], or stroke: 277/1808 [15.3%] with ramipril *v* 351/1769 [19.8%] with placebo; RR 0.75, 95% CI 0.64

to 0.88; ARR 4.5%; NNT 22, 95% CI 14 to 43; death from any cause: 196/1808 [10.8%] with ramipril *v* 248/1769 [14.0%] with placebo; RR 0.76, 95% CI 0.67 to 0.92; ARR 3.2%; NNT 32, 95% CI 19 to 98).[24] The relative effect of ramipril was present in all subgroups regardless of hypertensive status, microalbuminuria, type of diabetes, and nature of diabetes treatment (diet, oral agents, or insulin). The RCT also compared vitamin versus placebo and found no significant effect on morbidity or mortality.[24,26,27]

Harms: The systematic review[18] and first subsequent RCT[21] gave no information on adverse effects. An earlier report of the second subsequent RCT[25] had stated that the RCT found a significantly higher incidence of hyperkalaemia resulting in discontinuation of treatment with irbesartan than with amlodipine or placebo (11/579 [1.9%] with irbesartan *v* 3/567 [0.5%] with amlodipine *v* 2/569 [0.4%] with placebo; P = 0.01 for both comparisons).[22] The third subsequent RCT stated that significantly more people had "serious adverse events" with irbesartan than with placebo but it did not state what they were (15.4% with irbesartan *v* 22.8% with placebo).[23] The fourth subsequent RCT found that cough was 5% more frequent with the ACE inhibitor (ramipril) than with placebo.[24]

Comment: None.

OPTION DIFFERENT ANTIHYPERTENSIVE DRUGS

Systematic reviews and RCTs have found that angiotensin converting enzyme inhibitors, diuretics, β blockers, and calcium channel blockers all reduce cardiovascular morbidity and mortality in people with diabetes and hypertension. However, there are differences in the types of adverse effects reported for different antihypertensive drugs. RCTs have found that people taking atenolol gained more weight than those taking captopril, an increase in risk of congestive heart failure with lisinopril compared with chlorthalidone, a higher frequency of headache with diltiazem than with diuretics or β blockers, and a higher rate of withdrawal from treatment because of adverse effects with atenolol than with losartan.

Benefits: We found two systematic reviews,[19,28] and two subsequent RCTs.[29,30] The first systematic review (search date 2002) did not attempt to pool the results of RCTs identified.[19] We have reported the results of the second systematic review (search date 2000),[28] the relevant RCTs identified by the first systematic review[19] and the two subsequent RCTs.[29,30] **Angiotensin converting enzyme (ACE) inhibitors versus calcium channel blockers:** One systematic review[28] identified two RCTs comparing ACE inhibitors (fosinopril, enalapril) versus calcium channel blockers (amlodipine, nisoldipine) in people with diabetes without a diagnosis of cardiovascular disease (CVD).[31,32] The review found that ACE inhibitors significantly reduced combined cardiovascular events compared with calcium channel blockers but it found no significant reduction in acute myocardial infarction (see glossary, p 803), stroke, or death in people with diabetes without a diagnosis of CVD (2 RCTs; combined cardiovascular events — cardiovascular death, acute myocardial infarction, congestive heart failure, stroke, pulmonary

infarction, angina: 34/424 [8%] with ACE inhibitors *v* 70/426 [16%] with calcium channel blockers; ARR 8%, 95% CI 4% to 13%; RR 0.49, 95% CI 0.33 to 0.72; NNT 13, 95% CI 7 to 25; death: 17/424 [4.0%] with ACE inhibitors *v* 22/426 [5.2%] with calcium channel blockers; ARR 1%; RR 0.78, 95% CI 0.42 to 1.44; acute myocardial infarction: 15/424 [4%] with ACE inhibitors *v* 38/426 [9%] with calcium channel blockers; ARR 5%, 95% CI 2% to 9%; RR 0.40, 95% CI 0.22 to 0.71; NNT 19, 95% CI 12 to 46; stroke: 11/424 [2.6%] with ACE inhibitors *v* 21/426 [4.9%] with calcium channel blockers; ARR 2.3%; RR 0.53, 95% CI 0.26 to 1.08).[31,32] The subsequent RCT compared ACE inhibitors (enalapril, lisinopril), calcium channel blockers (felodipine, isradipine), β blockers (atenolol, metoprolol, pindolol), and diuretics (hydrochlorothiazide plus amiloride).[33] It found that, compared with calcium channel blockers, ACE inhibitors significantly reduced fatal and non-fatal myocardial infarctions (1 RCT, 719 people with diabetes without a diagnosis of CVD, mean age 76 years, mean blood pressure 190/99 mm Hg; 17/235 [7%] with ACE inhibitors *v* 32/231 [14%] with calcium channel blockers; RR 0.51, 95% CI 0.28 to 0.92). However, it found no significant difference between groups in the incidence of major cardiovascular events over 4 years (major cardiovascular events per 1000 person years: 64.2 with ACE inhibitors *v* 67.7 with calcium channel blockers *v* 75.0 with β blockers or diuretics). **ACE inhibitors versus β blockers:** One RCT[34] identified in a systematic review[28] found no significant difference between captopril and atenolol in number of cardiovascular events over 8.4 years (1 RCT, 758 people with diabetes without a diagnosis of CVD; cardiovascular events: 102/400 [25.5%] with captopril *v* 75/358 [20.9%] with atenolol; ARI +5%, 95% CI −1% to +11%; RR 1.22, 95% CI 0.94 to 1.58). **ACE inhibitors versus β blockers or diuretics:** One RCT[35] identified by the systematic review[28] found that, compared with diuretics or β blockers, captopril significantly reduced acute myocardial infarction, stroke, or death (1 RCT, 572 people with or without a diagnosis of CVD; acute myocardial infarction, stroke, or death: 46/263 [17.5%] with diuretics/β blockers *v* 35/309 [11.3%] with captopril; RR 0.65, 95% CI 0.43 to 0.97). **ACE inhibitors or calcium channel blockers versus diuretics:** One RCT found no significant difference between lisinopril or amlodipine and chlorthalidone in 6 year fatal cardiac heart disease, non-fatal myocardial infarction, fatal and non-fatal stroke, or all cause mortality (1 RCT, 12 063 people with diabetes and established hypertension, aged ≥55 years; primary outcome of non-fatal myocardial infarction plus coronary heart disease death: chlorthalidone *v* lisinopril: RR 1.00, 95% CI 0.87 to 1.14; amlodipine *v* chlorthalidone: RR 1.04, 95% CI 0.94 to 1.14; absolute numbers for the diabetic subgroup not reported, results presented graphically).[36] **Angiotensin II receptor antagonists versus β blockers:** One RCT found that, compared with atenolol, losartan significantly reduced composite cardiovascular outcomes over 4 years (1 RCT, 1195 people with diabetes with or without a diagnosis of CVD, aged 55–80 years; composite cardiovascular outcomes — mortality, stroke, and myocardial infarction: 103/586 [17.6%] with losartan *v* 139/609 [22.8%] with atenolol; RR 0.77, 95% CI 0.61 to 0.97; NNT 19, 95% CI 11 to

142).[37] **Calcium channel blockers versus diuretics or β blockers:** One RCT identified by the systematic review[19] found no significant difference between diltiazem and conventional antihypertensive treatment with diuretic, β blocker, or a combination of the two in fatal or non-fatal stroke, myocardial infarction, and other cardiovascular death (1 RCT, 727 people with diabetes and diastolic pressure ≥ 100 mm Hg on 2 occasions, aged 50–74 years; fatal or non-fatal stroke, myocardial infarction, and other cardiovascular death: 44/351 [12.5%] with diltiazem *v* 44/376 [11.7%] with conventional treatment; RR 1.07, 95% CI 0.72 to 1.59.[38] One subsequent RCT found no significant difference between modified release verapamil and a diuretic or β blocker in the composite outcomes of myocardial infarction, stroke, or cardiovascular death over 3 years (3239 people with diabetes and hypertension with or without CVD diagnosis, aged ≥ 55 years, myocardial infarction, stroke, or cardiovascular death: 101/1616 [6.3%] with verapamil *v* 116/1623 [7.1%] with diuretic or β blocker; RR 0.86, 95% CI 0.66 to 1.12).[29] A second subsequent RCT found no significant difference between nifedipine and co-amilozide (amiloride plus hydrochlorothiazide) in composite outcome of cardiovascular death, myocardial infarction, heart failure, or stroke over a mean of 4 years (1302 people with diabetes and hypertension with or without CVD diagnosis, aged 55–80 years; cardiovascular death, myocardial infarction, heart failure, or stroke: 54/651 [8.3%] with nifedipine *v* 55/655 [8.4%] with co-amilozide, RR 0.99, 95% CI 0.69 to 1.4).[30]

Harms:

ACE inhibitors versus calcium channel blockers: One systematic review[28] and a subsequent RCT[33] gave no information on adverse effects. **ACE inhibitors versus β blockers:** One RCT identified in the systematic review found that people taking atenolol gained more weight than did those taking captopril (3.4 kg with atenolol *v* 1.6 kg with captopril; P = 0.02).[34] Over the first 4 years of the trial people allocated to atenolol had higher mean HbA1c (see glossary, p 803) (7.5% with atenolol *v* 7.0% with captopril; P = 0.004). However, no significant difference was found between groups over the subsequent 4 years. No significant difference was found between atenolol and captopril in rates of hypoglycaemia, lipid concentrations, tolerability, blood pressure lowering, or prevention of disease events. **ACE inhibitors versus β blockers or diuretics:** One RCT gave no information on adverse effects.[35] **ACE inhibitors or calcium channel blockers versus diuretics:** One RCT found an increased risk of congestive heart failure with lisinopril than with chlorthalidone (RR 1.22, 95% CI 1.05 to 1.42) and with amlodipine than with chlorthalidone (RR 1.42, 95% CI 1.23 to 1.64).[36] A previous report for this RCT described an increased risk of combined coronary vascular disease events with doxazosin than with chlorthalidone when these agents were used to treat hypertension (coronary heart disease, death, non-fatal myocardial infarction, stroke, angina, coronary revascularisation, congestive heart failure, and peripheral arterial disease: RR 1.24, 95% CI 1.12 to 1.38).[39] The doxazosin arm of the RCT was terminated because of this increase in risk.[39] **Angiotensin II receptor antagonists versus β blockers:** One RCT found that discontinuation of treatment because of adverse effects was less common with losartan than with atenolol (2/586 [0.3%] with losartan *v* 9/609 [1.5%] with

atenolol; RR 0.23, 95% CI 0.05 to 1.06; P = 0.065).[37] Adverse events that occurred with significantly greater frequency with losartan than with atenolol were bradycardia (1% with atenolol *v* 9% with losartan; P < 0.0001), cold extremities (4% with atenolol *v* 6% with losartan; P < 0.0001), albuminuria (5% with atenolol *v* 6% with losartan; P = 0.0002), hyperglycaemia (5% with atenolol *v* 7% with losartan; P = 0.007), asthenia/fatigue (15% with atenolol *v* 17% with losartan; P = 0.001), back pain (10% with atenolol *v* 12% with losartan; P = 0.004), dyspnoea (10% with atenolol *v* 14% with losartan; P < 0.0001), and lower extremity oedema (12% with atenolol *v* 14% with losartan; P = 0.002).[37] **Calcium channel blockers versus diuretics or β blockers:** One RCT identified by the systematic review[19] found significantly greater frequency of headache with diltiazem than with diuretics or β blockers (8.5% with diltiazem *v* 5.7% with diuretics or β blockers; P < 0.001).[38] One subsequent RCT found a higher frequency of withdrawal from the study because of constipation with calcium channel blockers than with β blockers or diuretics (216/8179 [2.6%] with calcium channel blockers *v* 28/8297 [0.3%] with β blockers or diuretics).[29] The second subsequent RCT did not comment on adverse effects of treatment.[30]

Comment: The evidence suggests that thiazide-like diuretics, β blockers, ACE inhibitors, and calcium channel blockers all significantly reduce cardiovascular events in people with diabetes. The results of one large RCT cast doubt on the conclusions of earlier, smaller studies suggesting that ACE inhibitors are superior to calcium channel blockers.[36] The RCT indicates that chlorthalidone is at least as effective as an ACE inhibitor as initial treatment for hypertension in terms of prevention of major cardiovascular events.[36] It is unclear whether ACE inhibitors and β blockers are equivalent. In most RCTs, combination treatment with more than one agent was required to achieve target blood pressures. One large RCT found that the ACE inhibitor ramipril, which reduces urinary protein excretion, also reduced cardiovascular morbidity and mortality in older diabetic people with other cardiac risk factors.[24] The relative cardioprotective effect of the ACE inhibitor was present to the same extent in people with or without hypertension, and with or without microalbuminuria.

OPTION TARGET BLOOD PRESSURE

Large RCTs including people with diabetes and hypertension have found that tighter control of blood pressure to a target diastolic blood pressure of no more than 80 mm Hg or less reduces the risk of major cardiovascular events. One RCT in normotensive people with diabetes found that intensive blood pressure lowering reduced cerebral vascular accidents but found no significant difference in cardiovascular death, myocardial infarction, congestive heart failure, or all cause mortality.

Benefits: We found no systematic review but found three RCTs.[34,40–42] The first RCT found that, compared with moderate target blood pressure (≤ 180/105 mm Hg), tight target blood pressure (≤ 150/85 mm Hg) significantly reduced fatal or non-fatal acute myocardial infarction (see glossary, p 803) and stroke but found no significant difference

for peripheral vascular events over 8.4 years (1 RCT, 1148 people with hypertension managed with atenolol or captopril; fatal or non-fatal acute myocardial infarction: 107/758 [14%] with tight blood pressure target *v* 83/390 [21%] with moderate blood pressure target; RR 0.66, 95% CI 0.51 to 0.86, NNT 14, 95% CI 9 to 35; stroke: 38/758 [5.0%] with tight blood pressure target *v* 34/390 [8.7%] with moderate blood pressure target; RR 0.58, 95% CI 0.37 to 0.90; NNT 27, 95% CI 18 to 116; peripheral vascular events: 8/758 [1.1%] with tight blood pressure target *v* 8/390 [2.1%] with moderate blood pressure target; RR 0.52, 95% CI 0.20 to 1.36).[34,40] The second RCT found that the risk of major cardiovascular events was reduced by 50% over 3.8 years with a target diastolic blood pressure of 80 mm Hg or less compared with a target blood pressure of 90 mm Hg or less (1 multicentre RCT, 3 arm study, 1501 people with hypertension managed with felodipine, ACE inhibitors, β blockers, or diuretics; major cardiovascular events: 22/499 [4.4%] with target blood pressure ≤ 80 mm Hg *v* 45/501 [9.0%] with target blood pressure ≤ 90 mm Hg; RR 0.5, 95% CI 0.3 to 0.8; NNT 22, 95% CI 16 to 57).[41] The third RCT found a significantly lower incidence of cerebral vascular accidents with a target diastolic blood pressure of 10 mm Hg below baseline using nisoldipine or enalapril compared with unchanged baseline diastolic blood pressure of 80–89 mm Hg with placebo over 5.3 years (1 RCT, 480 people with type 2 diabetes and baseline blood pressure < 140/90 mm Hg being managed with nisoldipine or enalapril; cerebral vascular accidents: 4/237 [1.7%] with target diastolic blood pressure of 10 mm Hg below baseline *v* 13/243 [5.4%] with unchanged baseline diastolic blood pressure of 80–89 mm Hg; OR 3.29, CI 1.06 to 10.25; NNT 27, 95% CI 14 to 255).[42] The RCT found no significant difference in cardiovascular death, myocardial infarction, congestive heart failure, or all cause mortality. The RCT also found that, in a subgroup of people with type 2 diabetes and peripheral arterial disease at baseline (ankle : brachial index < 0.90), intensive blood pressure lowering to a mean of 128/75 mm Hg compared with no blood pressure reduction significantly reduced major cardiovascular events (1 RCT, 53 people, CVD death, non-fatal myocardial infarction, non-fatal stroke, heart failure requiring hospital admission, or pulmonary infarction: 3/22 [13.6%] with intensive blood pressure lowering *v* 12/31 [38.7%] with no blood pressure reduction; ARR 0.25%, 95% CI 0.03 to 0.47, NNT 4, 95% CI 2 to 37).[43]

Harms: We found no good evidence of a threshold below which it is harmful to lower blood pressure. One RCT found that a significantly greater proportion of people gained weight with atenolol than with captopril (mean weight gain over 9 years: 3.4 kg with atenolol *v* 1.6 kg with captopril; P = 0.02) but it found no significant difference in hypoglycaemia or weight gain with tight blood pressure control (≤ 150/85 mm Hg) compared with moderate blood pressure control (≤ 180/105 mm Hg).[34,40] The second RCT comparing tight versus moderate blood pressure control did not provide information on adverse effects.[41] The third RCT in normotensive people gave no information on adverse effects.[42]

Prevention of cardiovascular events in diabetes

Comment: Aggressive lowering of blood pressure in people with diabetes and hypertension reduces cardiovascular morbidity and mortality. In most trials, combination treatment with more than one agent was required to achieve target blood pressures.

QUESTION What are the effects of treating dyslipidaemia in people with diabetes?

OPTION FIBRATES

One RCT found that gemfibrozil reduced cardiovascular events over 5 years compared with placebo. Another smaller RCT found no significant difference. One RCT found that bezafibrate reduced cardiovascular events compared with placebo.

Benefits: We found two systematic reviews (search date 2000[18] and search date not reported[44]). Neither of these systematic reviews included pooling or summary estimates across the fibrate trials. We have reported results of individual RCTs identified by at least one of the systematic reviews. One RCT found that gemfibrozil did not significantly reduce myocardial infarction or cardiac death over 5 years compared with placebo (1 RCT, 135 men aged 40–55 years with diabetes without a diagnosis of cardiovascular disease [CVD]: 2/59 [3.4%] events with gemfibrozil *v* 8/76 [10.5%] with placebo; ARR +7.1%, 95% CI −2.1% to +16.8%; RR 0.32, 95% CI 0.07 to 1.46).[45] A second RCT found that, compared with placebo, gemfibrozil 1200 mg daily significantly reduced coronary heart disease, death, stroke, or non-fatal acute myocardial infarction (see glossary, p 803) over 5 years (1 RCT, 769 people aged < 74 years with diabetes and CVD diagnosis: 105/388 [27%] events with gemfibrozil *v* 141/381 [37%] events with placebo; HR 0.68, 95% CI 0.53 to 0.88).[46] A third RCT found that bezafibrate significantly reduced myocardial infarction or new ischaemic changes on electrocardiogram over 3 years compared with placebo (1 RCT, 164 people aged 35–65 years with type 2 diabetes without a diagnosis of CVD; 5/64 [7.8%] events with bezafibrate *v* 16/64 [25%] events with placebo; ARR 17.2%, 95% CI 4.6% to 30.1%; RR 0.31, 95% CI 0.12 to 0.80; NNT 6, 95% CI 5 to 20).[47] A fourth RCT found no significant difference in the proportion of people who either had myocardial infarction or died after 39 months of treatment between fenofibrate 200 mg daily and placebo (1 RCT, 418 people with diabetes and with or without CVD diagnosis, mean age 57 years; 15/207 [7.2%] events with fenofibrate *v* 21/211 [9.9%] events with placebo; ARR +2.7%, 95% CI −2.8% to +8.3%; RR 0.73, 95% CI 0.39 to 1.37).[48] This RCT was underpowered for myocardial infarction and death, but there were trends toward reduced risk of myocardial infarction with fenofibrate (9 with fenofibrate *v* 12 with placebo) and death (6 with fenofibrate *v* 9 with placebo). A benefit for fenofibrate in reducing myocardial infarction and death is suggested and certainly cannot be excluded.

Harms: The systematic reviews[18,44] did not comment on adverse effects. One RCT reported no significant difference between fenofibrate and placebo in gallbladder symptoms (0.5% with fenofibrate *v* 1.4% with placebo), liver toxicity (1.5% with fenofibrate *v* 0% with placebo), muscle pain (0% with fenofibrate *v* 0.5% with placebo), joint pain (3.4% with fenofibrate *v* 2.5% with placebo), or cancer (2.4% with fenofibrate *v* 3.3% with placebo).[48]

Comment: None.

OPTION STATINS

One systematic review and RCTs have found that statins reduce cardiovascular morbidity and mortality compared with placebo. One RCT found that treatment with atorvastatin to achieve a target low density lipoprotein below 2.6 mmol/L reduces cardiovascular morbidity and mortality compared with usual care. Another RCT found no significant difference between use of lovastatin, plus cholestyramine if necessary, to achieve lower target low density lipoprotein of 1.55–2.20 mmol/L and a moderate target low density lipoprotein of 3.36–3.62 mmol/L in 4 year event rate for myocardial infarction and death. One RCT found no significant difference in cardiovascular events in older people with low dose pravastatin 5 mg daily and standard dose pravastatin 10–20 mg daily over 4 years.

Benefits: We found one systematic review,[18] five subsequent RCTs,[49–53] and one additional RCT.[54] We also found a systematic review that did not conduct a meta-analysis for RCTs evaluating statins, but provided a commentary on the quality of data on people with diabetes included in such trials (see comment below).[44] **Versus placebo:** The systematic review (search date 2000) found that pravastatin or simvastatin significantly reduced cardiovascular events over 6 years compared with placebo (3 RCTs,[55–57] 1570 people: 34 events per 1000 person years with statins *v* 44 events with placebo per 1000 person years; RR 0.77, 95% CI 0.62 to 0.96; person years needed to treat 120, 95% CI 61 to 4856).[18] One RCT identified in the systematic review found no significant difference between lovastatin and placebo in myocardial infarction, unstable angina, or sudden cardiac death over 5 years (4/84 [4.8%] events with lovastatin *v* 6/71 [8.5%] events with placebo; ARR +3.7%, 95% CI –5.6% to +11.9%; RR 0.56, 95% CI 0.16 to 1.91).[58] The first subsequent RCT found that, compared with placebo, simvastatin significantly reduced all cause mortality, non-fatal myocardial infarction, coronary heart disease (CHD), death, total stroke, or any revascularisation over 5 years in people with diabetes aged 40–80 years regardless of whether or not they had previous vascular disease (1 RCT, among the 1981 people in the trial with diabetes and previous CHD: 325/972 [33.4%] events with simvastatin *v* 381/1009 [37.8%] events with placebo; ARR 4.3%; NNT 23, 95% CI 12 to 897; among 1070 people with diabetes and previous non-coronary vascular disease but without previous CHD: major cardiovascular disease [CVD] events: 141/551 [25.6%] with simvastatin *v* 171/519 [32.9%] with placebo; ARR 7.5%; NNT 14, 95% CI 8 to 49; among 2912 people with diabetes but no previous CHD or other vascular disease: major CVD events: 135/1455 [9.3%] with simvastatin *v* 196/1457 [17.2%] with placebo; ARR 4.2, NNT 24, 95%

CI 16 to 53).[49] By the end of the study 38% of those allocated to placebo were taking a statin not used in the study.[49] The second subsequent RCT found that fluvastatin significantly reduced cardiac death, non-fatal myocardial infarction, and reintervention over 4 years compared with placebo (1 RCT, 202 people aged 18–80 years with diabetes and a diagnosis of CVD: 26/120 [21%] events with fluvastatin *v* 31/82 [37.8%] events with placebo; ARR 0.161, 95% CI 0.033 to 0.290; NNT 7, 95% CI 4 to 30).[50] The third subsequent RCT found no significant difference in cardiac death or non-fatal myocardial infarction between pravastatin 40 mg daily and placebo over 4.8 years (1 RCT, 3638 people aged ≥ 55 years with type 2 diabetes and additional CHD risk factors; CHD death plus non-fatal myocardial infarction: RR 0.89, 95% CI 0.71 to 1.10; absolute numbers not reported, results presented graphically).[51] Baseline low density lipoprotein (LDL) cholesterol was required to be in the range 3.1–4.9 mmol/L for people with no known CHD and 2.6–3.3 mmol/L for those with previously diagnosed CHD. Usual care could include lipid lowering agents at the primary care physician's discretion.[51] The fourth subsequent RCT found no significant difference in cardiovascular death or myocardial infarction between atorvastatin 10 mg daily and placebo over 3 years (1 RCT, 2532 people aged 40–79 years with diabetes, hypertension, total cholesterol ≤ 6.5 mmol/L and at least 2 other cardiovascular risk factor but without coronary artery disease diagnosis; cardiovascular death, or myocardial infarction: RR 0.84, 95% CI 0.55 to 1.28).[52]

Aggressive versus moderate lipid lowering: One RCT[59] identified by a systematic review[18] found no significant difference between aggressive lipid lowering and moderate lipid lowering in 4 year event rate for myocardial infarction and death (1 RCT, 116 people aged 21–74 years with type 2 diabetes and a diagnosis of CVD; 4 year event rate for death: 6.5 with aggressive lipid lowering *v* 9.6 with moderate lipid lowering; RR 0.67, 99% CI 0.12 to 3.75; 4 year event rate for myocardial infarction: 4.8 with aggressive lipid lowering *v* 11.6 with moderate lipid lowering; RR 0.40, 99% CI 0.07 to 2.47). The RCT used lovastatin and cholestyramine as necessary to achieve the targets for aggressive lipid lowering (LDL cholesterol 1.55–2.20 mmol/L [60–85 mg/dL]) and moderate lipid lowering (LDL cholesterol 3.36–3.62 mmol/L [130–140 mg/dL]). This RCT had limited power because of the small number of people enrolled who had diabetes.[59] A subsequent RCT found that, compared with usual care, treatment with atorvastatin to achieve a target LDL of below 2.6 mmol/L (< 100 mg/dL) significantly reduced the risk of all cause mortality, non-fatal myocardial infarction, unstable angina, congestive heart failure, revascularisation, and stroke over 3 years (1 RCT, 313 people with a diagnosis of CVD, mean age 58 years: RRR 0.42; P = 0.0001; results presented graphically). The atorvastatin dose was titrated from 10 mg daily to a maximum of 80 mg daily to achieve a target LDL cholesterol of below 2.6 mmol/L. Usual care consisted of treatment by the family practitioner, which could include diet, exercise, weight loss and/or drug treatment including lipid lowering agents; 14% of people in the usual care group received any lipid lowering agents.[53] **Low versus standard statin dose in older people:** One subsequent RCT found no significant difference in cardiovascular events between low dose pravastatin

5 mg daily and standard dose pravastatin 10–20 mg daily over 4 years (1 RCT, 199 people aged > 60 years with diabetes: 17/104 [16.3%] events with low dose pravastatin *v* 15/95 [15.8%] events with standard dose pravastatin; ARR +0.006%, 95% CI –0.097 to +0.108).[54]

Harms: **Versus placebo:** One systematic review (search date 2000) did not report on adverse effects.[18] The first subsequent RCT evaluated the effects of simvastatin compared with placebo on adverse outcomes other than cardiovascular events in people with diabetes.[49] The RCT found no significant difference between simvastatin and placebo for withdrawal from treatment because of elevated liver enzymes (48 [0.5%] with simvastatin *v* 35 [0.3%] with placebo), muscle symptoms (49 [0.5%] with simvastatin *v* 50 [0.5%] with placebo), or hospital admission due to chronic obstructive pulmonary disease/asthma (132 [1.3%] with simvastatin *v* 150 [1.5%] with placebo). The second subsequent RCT conducted a safety analysis for fluvastatin compared with placebo in 1640 people. It found no significant difference between fluvastatin and placebo in the proportion of people withdrawing from treatment (174/822 [21%] with fluvastatin *v* 196/818 [24%] with placebo; RR 0.88, 95% CI 0.74 to 1.06).[50] The third subsequent RCT specifically stated that no data on adverse effects were collected.[51] The fourth subsequent RCT found no significant difference in serious adverse events or liver enzyme changes between those allocated atorvastatin and those allocated placebo.[52] **Aggressive versus moderate lipid lowering:** One RCT did not report any adverse events.[59] The subsequent RCT found no significant difference between atorvastatin and usual care in the proportion of people withdrawn from the study because of elevated liver enzymes.[53] **Low versus standard statin dose in older people:** One RCT comparing low versus standard pravastatin dose found no significant difference in adverse events between groups.[54]

Comment: We found one RCT that is of major importance.[49] The RCT is interesting because it was not necessary to have an abnormal lipid profile or prior vascular disease to be enrolled and it provides the first clear evidence that statin treatment is effective for primary prevention of CVD.[49] The relative risk reductions for major cardiovascular events were similar with or without previous CHD, and with lower and higher initial LDL cholesterol. The results of this RCT suggest that treatment with a statin is likely to be beneficial in most diabetic people who are at significant risk of CHD, regardless of initial LDL level and regardless of whether they have previous CVD. Furthermore, this and other studies provided stronger evidence for the value of treatment with statins per se, rather than for targeting any specific LDL cholesterol level. Besides this RCT,[49] most published RCTs with sufficient power to detect effects on cardiovascular events have enrolled comparatively few people with diabetes or have excluded them altogether. The available evidence is, therefore, based almost entirely on subgroup analyses of larger trials in which there was generally little information regarding the type and duration of diabetes, severity of complications, and metabolic control.[44] The statin versus placebo trial published after both systematic reviews was terminated early due to high efficacy of atorvastatin in

the overall study population (HR for cardiovascular death plus non-fatal myocardial infarction 0.64, 95% CI 0.050 to 0.083).[52] Although the difference was not significant in the diabetic subgroup, the confidence intervals for diabetic and non-diabetic subgroups overlapped one another. Several large ongoing trials are evaluating the effects of fibrates in people with diabetes.

QUESTION What are the effects of antiplatelet drugs in people with diabetes?

OPTION PROPHYLACTIC ASPIRIN

One systematic review found that, compared with controls, antiplatelet treatment mainly with aspirin did not significantly reduce the combined risk of non-fatal myocardial infarction, non-fatal stroke, death from a vascular cause, or death from an unknown cause in people with diabetes and cardiovascular disease diagnosis. The review found that antiplatelet treatment was associated with an increase in the risk of major extracranial haemorrhage and haemorrhagic stroke, but the results for people with diabetes were not reported separately.

Benefits: We found one systematic review (search date 1997),[60] and one additional RCT.[61] The review found that, compared with controls, antiplatelet treatment mainly with aspirin did not significantly reduce the combined risk of non-fatal myocardial infarction, non-fatal stroke, death from a vascular cause, or death from an unknown cause (9 RCTs, 4961 people with diabetes and cardiovascular disease [CVD] diagnosis; 403/2568 [15.7%] with antiplatelet treatment *v* 426/2558 [16.7%] with control; RR 0.94, 95% CI 0.83 to 1.07). This non-significant 6% relative risk reduction was in contrast to the finding of highly significant 25% relative risk reduction for the same outcomes in the full meta-analysis (people with or without diabetes combined).[60] The largest RCT included in the systematic review found that aspirin 650 mg daily significantly reduced fatal or non-fatal myocardial infarction but not stroke over 5 years compared with placebo (1 RCT, 3711 people aged 18–70 years with diabetes; fatal or non-fatal myocardial infarction: 241/1856 [13%] with aspirin *v* 283/1855 [15%] with placebo; RR 0.851, 95% CI 0.726 to 0.998; NNT 44, 95% CI 22 to 3490; fatal or non-fatal stroke: 92/1856 [5%] with aspirin *v* 78/1855 [4%] with placebo; RR 1.179, 95% CI 0.878 to 1.583 [calculated by *Clinical Evidence*]).[62] The additional RCT found that aspirin significantly reduced the risk of acute myocardial infarction (see glossary, p 803) over 5 years compared with placebo (1 RCT, 533 male physicians with diabetes but no diagnosis of CVD: 11/275 [4.0%] with aspirin *v* 26/258 [10.1%] with placebo; RR 0.39, 95% CI 0.20 to 0.79; NNT 16, 95% CI 12 to 47).[61] **Versus clopidogrel:** See benefits of clopidogrel, p 795. **Aspirin plus clopidogrel:** See benefits of clopidogrel, p 795.

Harms: In the systematic review, doses of aspirin ranged from 75–1500 mg daily. Most RCTs used aspirin 75–325 mg daily.[60] Doses higher than 325 mg daily increased the risk of haemorrhagic adverse effects without improving preventive efficacy. No difference in efficacy or adverse effects was found in the dose range 75–325 mg daily. The

systematic review found that antiplatelet treatment was associated with a 50% relative increase in the risk of major extracranial haemorrhage and a 22% relative increase in risk of haemorrhagic stroke. These results were for the overall meta-analysis; results were not reported separately for the people with diabetes.[60] The largest RCT in people with diabetes within the systematic review (3711 people with diabetes, duration 5 years) found no significant increase in the risks of vitreous, retinal, gastrointestinal, or cerebral haemorrhage with aspirin 650 mg daily compared with placebo.[62] The additional RCT found no significant difference in adverse events between aspirin and placebo.[61]

Comment: We found insufficient evidence to define precisely which people with diabetes should be treated with aspirin. The risk of CVD is low before 30 years of age; most white adults with diabetes aged over 30 years are at increased risk of CVD. Widely accepted contraindications to aspirin treatment include aspirin allergy, bleeding tendency, anticoagulant treatment, recent gastrointestinal bleeding, and clinically active liver disease.[63]

OPTION CLOPIDOGREL

We found no RCTs comparing only clopidogrel versus placebo. One RCT in people with diabetes and with recent ischaemic stroke, myocardial infarction, or established peripheral arterial disease found no significant difference between clopidogrel and aspirin at 28 days in cardiovascular events. This RCT also found a lower proportion of people hospitalised for a bleeding event with clopidogrel than with aspirin. One RCT in people presenting with unstable angina or non-Q-wave myocardial infarction and also taking aspirin found no significant reduction in cardiovascular events after 12 months with addition of clopidogrel compared with placebo. This RCT also found a higher proportion of major bleeds with clopidogrel than with placebo.

Benefits: **Versus placebo:** We found no RCTs comparing only clopidogrel versus placebo. **Versus aspirin:** One RCT in people in people with diabetes and with recent ischaemic stroke, myocardial infarction, or established peripheral arterial disease found no significant difference between clopidogrel and aspirin at 28 days in cardiovascular events (1 RCT, 3866 people, mean age 64 years; angina, vascular death, myocardial infarction, all cause stroke, and readmission to hospital for ischaemic events: 299/1914 [15.6%] with clopidogrel *v* 345/1952 [17.7%] with aspirin; ARR +2.1%, 95% CI –0.3% to +4.4%; RR 0.88, 95% CI 0.77 to 1.02).[64] **Adding clopidogrel to aspirin:** One RCT in people presenting with unstable angina or non-Q-wave myocardial infarction and also taking aspirin found no significant reduction in cardiovascular events after 12 months with addition of clopidogrel compared with placebo (1 RCT, 2840 people with diabetes, mean age 64 years; cardiovascular death, non-fatal myocardial infarction, or stroke at 12 months: 200/1405 [14.2%] with clopidogrel *v* 240/1435 [16.7%] with placebo; RR 0.85, 95% CI 0.71 to 1.01).[65] People were randomised within 24 hours of an acute event and were given either given clopidogrel 300 mg bolus then 75 mg daily plus aspirin 75–325 mg daily or placebo plus aspirin.[65]

Harms: **Versus placebo:** One RCT found that a significantly lower proportion of people were hospitalised for a bleeding event with clopidogrel than with aspirin at 28 days (1 RCT, 3866 people, mean age 64 years; hospital admission for a bleeding event: 34/1914 [1.8%] with clopidogrel *v* 55/1952 [2.8%] with aspirin; RRR 37.0%, 95% CI 3.8% to 58.7%; P = 0.031).[64] **Adding clopidogrel to aspirin:** One RCT in people presenting with unstable angina or non-Q-wave myocardial infarction and also taking aspirin found a significantly higher proportion of major bleeds with clopidogrel than with placebo (3.7% with clopidogrel *v* 2.7% with placebo; RR 1.38, 95% CI 1.13 to 1.67; P = 0.001).[65]

Comment: None.

OPTION GLYCOPROTEIN IIB/IIIA INHIBITORS

We found no RCTs comparing glycoprotein IIb/IIIa inhibitors versus no antiplatelet treatment. One RCT in people presenting with unstable angina or acute myocardial infarction without ST segment elevation found that the addition of tirofiban (a glycoprotein IIb/IIIa inhibitor) to heparin reduced the composite outcome of death, myocardial infarction, or refractory ischaemia at 180 days compared with heparin alone. This RCT found no significant difference between tirofiban plus heparin and heparin alone in risk of bleeding in people already taking aspirin.

Benefits: We found no RCTs comparing glycoprotein IIb/IIIa inhibitors versus no antiplatelet treatment. **Adding glycoprotein IIb/IIIa inhibitors to heparin:** One RCT, in people with diabetes presenting with unstable angina or acute myocardial infarction (see glossary, p 803) without ST segment elevation, found that addition of tirofiban (a glycoprotein IIb/IIIa inhibitor) to heparin compared with heparin alone significantly reduced the composite outcome of death, myocardial infarction, or refractory ischaemia at 180 days (1 RCT, 362 people already taking aspirin, mean age 65 years: 19/169 [11.2%] with tirofiban plus heparin *v* 37/193 [19.2%] with heparin alone; ARR 8.0%, 95% CI 0.7% to 15.3%; RR 0.586, 95% CI 0.351 to 0.980; P = 0.03; NNT 13, 95% CI 7 to 146).[66] **Adjunct to percutaneous coronary revascularisation:** See benefits of intracoronary stenting plus glycoprotein IIb/IIIa inhibitors, p 802.

Harms: **Adding glycoprotein IIb/IIIa inhibitors to heparin:** One RCT found no significant difference between tirofiban plus heparin and heparin alone in risk of bleeding in people already taking aspirin (9.5% with tirofiban plus heparin *v* 8.3% with heparin alone; RR 1.16, 95% CI 0.56 to 2.39).[66]

Comment: None.

QUESTION **What are the effects of blood glucose control in prevention of cardiovascular disease in people with diabetes?**

OPTION BLOOD GLUCOSE CONTROL

One systematic review found that, compared with conventional glycaemic control, intensive glycaemic control for more than 2 years reduced the occurrence of first major cardiovascular event in people with type 1 diabetes. Two RCTs found no significant difference in cardiovascular morbidity and mortality with intensive compared with conventional glycaemic control in people with type 2 diabetes. These RCTs also found an increase in weight gain and hypoglycaemic episodes with intensive compared with conventional treatment. One RCT in overweight or obese people with type 2 diabetes found that intensive treatment with metformin compared with conventional treatment with diet alone reduced myocardial infarction but not stroke over 5 years. This RCT found no significant increase in major hypoglycaemic episodes in the metformin group compared with the diet only group.

Benefits:

We found one systematic review (search date 1996),[67] and three subsequent RCTs.[68–70] **Intensive versus conventional glycaemic control in type 1 diabetes:** The systematic review found that, compared with conventional glycaemic control, intensive glycaemic control for more than 2 years significantly reduced the occurrence of first major cardiovascular event in people with type 1 diabetes (6 RCTs, 1731 people aged 30–42 years with type 1 diabetes; first major cardiovascular event: 27/961 [2.8%] events with intensive control *v* 55/970 [5.7%] events with conventional glycaemic control; OR 0.55, 95% CI 0.35 to 0.88).[67] Major macrovascular events were defined as fatal or non-fatal myocardial infarction, sudden cardiac death, revascularisation procedure, angina with confirmed coronary artery disease, stroke, lower limb amputation, peripheral arterial events, and peripheral vascular disease. Conventional glycaemic control consisted of one or two daily injections of insulin without self adjustment of insulin dosage according to blood or urine glucose monitoring results. Intensive glycaemic control consisted of three or more injections of insulin with the dosage adjusted according to self monitoring of blood glucose levels.[67] **Intensive versus conventional glycaemic control in type 2 diabetes:** One RCT in people with type 2 diabetes found no significant difference between intensive and conventional glycaemic control in myocardial infarction or stroke over 5 years (1 RCT, 1138 people with type 2 diabetes but without a diagnosis of cardiovascular disease [CVD], mean age 54 years; myocardial infarction: 387/2729 [14.2%] with intensive control *v* 186/1138 [16.3%] with conventional control; RR 0.84, 95% CI 0.71 to 1.00; P = 0.052; stroke: 148/2729 [5.4%] with intensive control *v* 55/1138 [4.8%] with conventional control; RR 1.11, 95% CI 0.81 to 1.51).[69] Another RCT in people with type 2 diabetes found no significant difference between intensive insulin treatment with a stepped plan designed to achieve near normal blood sugar levels and standard once daily insulin injection in the rate of new cardiovascular events over 27 months (1 RCT, 153 men with type 2

diabetes, mean age 60 years, many of whom had previous cardiovascular events; new cardiovascular events: 24/75 [32%] with intensive treatment *v* 16/80 [20%] with standard treatment; RR 1.60, 95% CI 0.92 to 2.50).[70] **Metformin versus diet alone in overweight or obese people with type 2 diabetes:** One RCT in overweight or obese people with type 2 diabetes found that intensive treatment with metformin compared with conventional treatment with diet alone significantly reduced myocardial infarction but not stroke over 5 years (1 RCT, 753 people without a diagnosis of CVD, mean age 53 years; myocardial infarction: 39/342 [11%] with metformin *v* 73/411 [18%] with diet alone; RR 0.61, 95% CI 0.41 to 0.89; stroke: 12/342 [3.5%] with metformin *v* 23/411 [5.6%] with diet alone; RR 0.59, 95% CI 0.29 to 1.18).[68]

Harms:

Intensive versus conventional glycaemic control in type 1 diabetes: The systematic review did not comment on harms.[67] The largest RCT included in the review found that weight gain and waist to hip ratio were significantly increased in the intensive treatment group compared with conventional treatment (weight gain: $P \leq 0.001$; waist to hip ratio: $P = 0.02$).[71] **Intensive versus conventional glycaemic control in type 2 diabetes:** One RCT found that intensive treatment significantly increased weight gain and hypoglycaemic episodes compared with conventional treatment ($P < 0.0001$).[69] A second RCT found significantly higher mild and moderate hypoglycaemic events with intensive treatment compared with conventional treatment (16.5 events a patient a year with intensive treatment *v* 1.5 events a patient a year with conventional treatment; $P < 0.001$). However, it was noted that some hypoglycaemic episodes may not have been detected in the conventional treatment group because of less frequent measurement of blood glucose levels.[70] **Metformin versus diet alone in overweight or obese people with type 2 diabetes:** One RCT found no significant increase in major hypoglycaemic episodes in the metformin group compared with the diet only group (0.6% with metformin *v* 0.7% with diet only).[68]

Comment:

The role of intensive glucose lowering in primary prevention of cardiovascular events remains unclear. However, such treatment clearly reduces the risk of microvascular disease and does not increase the risk of CVD. The potential of the largest RCT in people with type 2 diabetes to show an effect of tighter glycaemic control was limited by the small difference achieved in median HbA1c (see glossary, p 803) between intensive and conventional treatment and the relatively low risk of CVD.[68,69] In contrast, in another primary prevention trial, a larger 1.9% difference in median HbA1c was achieved between groups, but the young age of the participants and consequent low incidence of cardiovascular events limited the power of the study to detect an effect of treatment on incidence of CVD.[71,72] The RCT of insulin in type 2 diabetes included men with a high baseline risk of cardiovascular events and achieved a 2.1% absolute difference in HbA1c.[70] The RCT was small and the observed difference between groups could have arisen by chance.

QUESTION **What are the effects of treating multiple risk factors in prevention of cardiovascular disease in people with diabetes?** New

OPTION **INTENSIVE MULTIPLE RISK FACTOR TREATMENT**

We found no systematic review or RCTs comparing treatment of multiple risk factors with treatment of a single risk factor for cardiovascular outcomes. One RCT found that, compared with conventional treatment according to clinical guidelines, intensive treatment of multiple risk factors with strict treatment goals in people with type 2 diabetes and microalbuminuria reduces cardiovascular disease over 8 years. Multiple risk factor treatment included simultaneously targeting diet, exercise, glycaemic control, blood pressure, treatment of microalbuminuria, and antiplatelet treatment.

Benefits: We found no systematic review or RCTs comparing treatment of multiple risk factors with treatment of a single risk factor for cardiovascular outcomes. **Intensive versus conventional treatment:** We found one RCT comparing intensive treatment of multiple risk factors versus conventional treatment of multiple risk factors.[73] The RCT found that, compared with conventional treatment, intensive treatment of multiple risk factors in people with type 2 diabetes and microalbuminuria significantly reduced cardiovascular disease (CVD) over 8 years (1 RCT, 160 people including 39 with CVD diagnosis, mean age 55 years; combined outcome of death from CVD, non-fatal myocardial infarction, non-fatal stroke, revascularisation, or amputation: HR 0.47, 95% CI 0.24 to 0.73; ARR 20.0%, 95% CI 5.7% to 34.0%, NNT 5, 95% CI 3 to 18). The intensive treatment group received a stepwise treatment plan with strict treatment goals and included behaviour modification (diet, exercise, smoking cessation) and drug treatment for aggressive management of blood glucose, blood pressure, dyslipidaemia, microalbuminuria, and aspirin treatment for people with ischaemic CVD. The conventional treatment group received treatment for multiple risk factors according to clinical guidelines from their general practitioner.

Harms: **Intensive versus conventional treatment:** The RCT did not specifically evaluate adverse events.[73] It found no significant difference in the incidence of minor episodes of hypoglycaemia between intensive and conventional treatment of multiple risk factors (42/80 [53%] with intensive treatment *v* 39/80 [49%] with conventional treatment; $P = 0.5$). Severe hypoglycaemia requiring assistance from another person occurred at some point in 5/80 (6.3%) people in the intensive treatment group and in 12/80 (15%) people in the conventional treatment group. One person in the intensive treatment group was hospitalised for a bleeding ulcer.[73]

Comment: **Intensive versus conventional treatment:** All people in the RCT had microalbuminuria at baseline so their cardiovascular risk would have been higher than in people with diabetes without microalbuminuria. However, the conventional treatment group received high quality care, based on guidelines, and the risk reductions from the intensive treatment might have been greater if the comparison had been with "usual care" in the community.[73]

Prevention of cardiovascular events in diabetes

QUESTION What are the effects of revascularisation procedures in people with diabetes?

OPTION CORONARY ARTERY BYPASS VERSUS PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

One systematic review found that, in people with diabetes, coronary artery bypass graft (CABG) reduced all cause mortality at 4 years after initial revascularisation compared with percutaneous transluminal coronary angioplasty (PTCA) but found no significant difference at 6.5 years. One large RCT in people with diabetes and multivessel coronary artery disease has found that CABG reduces mortality or myocardial infarction within 8 years compared with PTCA. Another smaller RCT found a non-significant reduction in mortality with CABG compared with PTCA at 4 years. One RCT in people with diabetes and multivessel coronary artery disease found no significant difference, at time of discharge, between CABG and PTCA plus stent in cardiovascular morbidity or mortality but found an increase in risk of stroke. However, the same RCT found that, compared with PTCA plus stent, CABG reduced cardiovascular risk at 1 year.

Benefits:

Without stenting: One systematic review (search date 2001) found that, in people with diabetes, coronary artery bypass graft (CABG) significantly reduced all cause mortality at 4.0 years after initial revascularisation compared with percutaneous transluminal coronary angioplasty (PTCA) but it found no significant difference at 6.5 years (3 RCTs: 537 people with diabetes; all cause mortality at 4.0 years: ARR 8.6%, 95% CI 2.2% to 15.0%; $P < 0.01$; all cause mortality at 6.5 years; ARR 3.9%, 95% CI −17.0% to 25.0%; $P = 0.71$).[74] The systematic review identified four RCTs. Two RCTS reported results at 4.0 and 6.5 years, one only at 4.0 years and one only at 6.5 years.[74] Two RCTs identified by the systematic review compared CABG versus PTCA, without stenting or a glycoprotein IIb/IIIa inhibitor.[75,76] The first RCT found that CABG significantly reduced the proportion of people who died or suffered Q wave myocardial infarction over a mean of 7.7 years compared with PTCA (1 RCT, 353 people with diabetes and 2 or 3 vessel coronary disease, mean age 62 years: 60/173 [34.7%] with CABG *v* 85/170 [50%] with PTCA; ARR 15%, 95% CI 5% to 26%; RR 0.69, 95% CI 0.54 to 0.89; NNT 7, 95% CI 4 to 20).[75] This survival benefit was confined to those receiving at least one internal mammary graft. The second RCT found no significant difference in mortality 4 years after CABG or PTCA (1 RCT, 125 people, mean age 61 years; mortality: 8/63 [12.5%] with CABG *v* 14/62 [22.6%] with PTCA; RR 0.56, 95% CI 0.25 to 1.25; ARR +9.9%, 95% CI −3.4% to +23.1%).[76] **With stenting:** One RCT found no significant difference in people with diabetes treated with CABG or PTCA in short term risks (up to discharge) of composite end point of death, myocardial infarction, repeat CABG, and repeat PTCA (1 RCT, 208 people with diabetes and 2 or 3 vessel coronary disease; composite outcome of death, myocardial infarction, repeat CABG, and repeat PTCA: 9/96 [9.4%] with CABG *v* 11/112 [9.8%] with PTCA; RR 1.05, 95% CI 0.45 to 2.42).[77]

Harms: **Without stenting:** The systematic review did not report on harms.[74] One RCT found higher inhospital mortality among people with diabetes (1.2% after CABG *v* 0.6% after PTCA) and myocardial infarction during the initial admission to hospital (5.8% after CABG *v* 1.8% after PTCA), but these differences were not found to be significant.[75] The second RCT did not report on harms.[76] **With stenting:** One RCT found a significant increase in risk of stroke with CABG compared with PTCA (4 with CABG *v* 0 with PTCA plus stent; P = 0.04). However, at 1 year the same RCT also found a significantly higher incidence of the composite end point with PTCA plus stenting (1 RCT, 208 people with diabetes and 2 or 3 vessel coronary disease; composite outcome of death, myocardial infarction, repeat CABG, and repeat PTCA: 41/112 [36%] with PTCA plus stent *v* 15/96 [15.6%] with CABG; RR 2.34, 95% CI 1.38 to 3.96; NNH 5, 95% CI 4 to 11).[77]

Comment: None.

OPTION PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY COMPARED WITH THROMBOLYSIS

We found no systematic review or RCTs comparing percutaneous transluminal coronary angioplasty versus thrombolysis for prevention of cardiovascular events in people with diabetes. One RCT, in people with diabetes presenting with an acute myocardial infarction, found no significant difference between percutaneous transluminal coronary angioplasty and thrombolysis with alteplase in single outcome of death or composite outcome of death, reinfarction, or disabling stroke at 30 days.

Benefits: We found no systematic review or RCTs comparing percutaneous transluminal coronary angioplasty (PTCA) versus thrombolysis for prevention of cardiovascular events in people with diabetes. **In people presenting with acute myocardial infarction:** One RCT found no significant difference between PTCA and thrombolysis with alteplase in single outcome of death or composite outcome of death, reinfarction, or disabling stroke at 30 days (1 RCT, 177 people with diabetes, mean age 65 years, presenting with acute myocardial infarction [see glossary, p 803] within 12 hours of chest pain onset; single outcome of death: 8/99 [8.1%] after PTCA *v* 5/78 [6.4%] after alteplase; RR 1.26, 95% CI 0.43 to 3.71; composite outcome of death, reinfarction, or disabling stroke: 11/99 [11%] after PTCA *v* 13/78 [17%] after alteplase; RR 0.67, 95% CI 0.32 to 1.41).[78] The RCT found no significant difference in 30 day mortality among people with diabetes (8/99 [8.1%] after PTCA *v* 5/78 [6.4%] after alteplase).

Harms: **In people presenting with acute myocardial infarction:** One RCT did not report on adverse effects of PTCA and thrombolysis with alteplase.[68]

Comment: None.

OPTION INTRACORONARY STENTING PLUS GLYCOPROTEIN IIB/IIIA INHIBITORS

RCTs in people with diabetes undergoing percutaneous transluminal coronary angioplasty have found that the combination of stent and a glycoprotein IIb/IIIa inhibitor reduces cardiovascular morbidity and mortality compared with stent plus placebo.

Benefits: We found one non-systematic review of individual patient data[79] and two subsequent RCTS.[80,81] **Versus placebo:** The non-systematic review[79] pooled data from three placebo controlled trials of percutaneous coronary intervention: EPILOG,[82] EPISTENT,[83–85] and EPIC.[86] The non-systematic review found that, compared with placebo, abciximab (a glycoprotein IIb/IIIa inhibitor) significantly reduced overall mortality at 1 year (1462 people with diabetes, mean age 60.9 years; mortality: 22/888 [2.5%] with abciximab *v* 26/574 [4.5%] with placebo; 0.547, 95% CI 0.313 to 0.956; P = 0.03).[79] The first subsequent RCT found that, compared with placebo, eptifibatide (a glycoprotein IIb/IIIa inhibitor) significantly reduced the composite outcome of death or myocardial infarction but found no significant difference for single outcome of death at 1 year (1 RCT, 466 people with diabetes undergoing non-urgent coronary stent implantation, mean age 62 years; composite outcome of death or myocardial infarction: 18/232 [7.8%] with eptifibatide *v* 31/234 [13.4%] with placebo; HR 0.57, 95% CI 0.32 to 1.02; P = 0.001; single outcome of mortality: 3/232 [1.3%] with eptifibatide *v* 8/234 [3.5%] with placebo; HR 0.37, 95% CI 0.10 to 1.41; P = 0.28).[81] **Comparison of glycoprotein IIb/IIIa inhibitors:** The second subsequent RCT found no significant difference between tirofiban and abciximab in composite outcomes of death or myocardial infarction at 30 days and 6 months, or overall mortality at 1 year (1 RCT, 1117 people with diabetes having percutaneous coronary interventions, mean age 62 years; composite outcomes of death or myocardial infarction: at 30 days: 33/560 [5.9%] with tirofiban *v* 29/557 [5.2%] with abciximab; HR 1.14, 95% CI 0.69 to 1.87; P = 0.6; at 6 months: 46/560 [8.2%] with tirofiban *v* 42/557 [7.5%] with abciximab; HR 1.09, 95% CI 0.72 to 1.65; P = 0.7; overall mortality at 1 year: 2.9% with tirofiban *v* 2.1% with abciximab; P = 0.4, absolute numbers not reported).[80]

Harms: **Versus placebo:** One non-systematic review of individual patient data found that there was slightly greater bleeding in people given abciximab than in those given placebo (major bleeding: 4.3% with abciximab *v* 3.0% with placebo; minor bleeding: 6.9% with abciximab *v* 6.3% with placebo; intracranial haemorrhage: 0% with abciximab *v* 0.17% with placebo). None of these differences were significant.[79] The subsequent RCT report on any adverse events associated with eptifibatide.[70] **Comparison of glycoprotein IIb/IIIa inhibitors:** One RCT found no significant difference between abciximab and tirofiban in major bleeding events (P = 0.725).[81]

Comment: For people with diabetes undergoing percutaneous procedures, the combination of stent and glycoprotein IIb/IIIa inhibitor reduces restenosis rates and serious morbidity. It is unclear whether these

adjunctive treatments would reduce morbidity, mortality, and restenosis associated with percutaneous revascularisation procedures to the levels seen with coronary artery bypass grafting. The study comparing abciximab versus tirofiban and the study comparing eptifibatide versus placebo were both insufficiently powered to detect reductions in major cardiovascular events in the subgroups of people with diabetes.

GLOSSARY

Acute myocardial infarction is infarction that occurs when circulation to a region of the heart is obstructed and necrosis is occurring; clinical symptoms include severe pain, pallor, perspiration, nausea, dyspnoea, and dizziness. Myocardial infarction is gross necrosis of the myocardium as a result of interruption of blood supply usually caused by atherosclerosis of the coronary arteries; myocardial infarction without pain or other symptoms (silent infarction) is common in people with diabetes.

HbA1c The haemoglobin A1c test is the most common laboratory test of glycated haemoglobin (haemoglobin that has glucose irreversibly bound to it). HbA1c provides an indication of the "average" blood glucose over the preceding 3 months. The HbA1c is a weighted average over time of the blood glucose level; many different glucose profiles can produce the same level of HbA1c.

Substantive changes

Antihypertensive treatment versus no antihypertensive treatment One meta-analysis added;[20] conclusions unchanged.

Different antihypertensive drugs Two RCTs added;[29,30] conclusions unchanged.

Statins One RCT added;[52] conclusions unchanged.

Prophylactic aspirin One systematic review added;[60] evidence for value of aspirin for prevention of cardiovascular events in people with diabetes is less strong than previously thought; categorisation changed to Trade-off between benefits and harms.

Clopidogrel Evidence re-evaluated; categorisation changed to Likely to be beneficial.

Blood glucose control One systematic review added;[67] categorisation changed to Likely to be beneficial.

Coronary artery bypass versus percutaneous transluminal coronary angioplasty One systematic review added;[74] conclusions unchanged.

QUESTIONS

INTERVENTIONS

CLINICAL (OVERT) HYPOTHYROIDISM

Beneficial

Levothyroxine (L-thyroxine)* . . .809

Unknown effectiveness

Levothyroxine (L-thyroxine) plus liothyronine 810

SUBCLINICAL HYPOTHYROIDISM

Unknown effectiveness

Levothyroxine (L-thyroxine) 810

*No RCT evidence, but there is clinical consensus that levothyroxine is beneficial in clinical (overt) hypothyroidism. A placebo controlled trial would be considered unethical.

See glossary, p 812

Key Messages

Clinical (overt) hypothyroidism

- **Levothyroxine (L-thyroxine)** We found no RCTs comparing levothyroxine (L-thyroxine) versus placebo, although there is consensus that treatment is beneficial. Treating clinical (overt) hypothyroidism with thyroid hormone (levothyroxine; L-thyroxine) can induce hyperthyroidism and reduce bone mass in postmenopausal women and increase the risk of atrial fibrillation.
- **Levothyroxine (L-thyroxine) plus liothyronine** We found insufficient evidence about the effects of levothyroxine (L-thyroxine) plus liothyronine versus levothyroxine alone in people with clinical (overt) hypothyroidism. Thyroid hormone treatment can induce hyperthyroidism and reduce bone mass in postmenopausal women and increase the risk of atrial fibrillation.

Subclinical hypothyroidism

- **Levothyroxine (L-thyroxine)** One RCT in women with biochemically defined subclinical hypothyroidism found no significant difference between levothyroxine (L-thyroxine) and placebo for dry skin, cold intolerance, and constipation at 1 year. The RCT may, however, have lacked power to exclude a clinically important difference between treatments. Another RCT found no significant difference in health related quality of life scores between levothyroxine and placebo. One RCT found inconclusive results about the effect of levothyroxine versus placebo on cognitive function in people with subclinical hypothyroidism. One RCT found that levothyroxine improved left ventricular function at 6 months compared with placebo. Treating subclinical hypothyroidism with thyroid hormone can induce hyperthyroidism and reduce bone mass in postmenopausal women and increase the risk of atrial fibrillation.

Primary hypothyroidism

DEFINITION Hypothyroidism is characterised by low levels of blood thyroid hormone. **Clinical (overt) hypothyroidism** is diagnosed on the basis of characteristic clinical features consisting of mental slowing, depression, dementia, weight gain, constipation, dry skin, hair loss, cold intolerance, hoarse voice, irregular menstruation, infertility, muscle stiffness and pain, bradycardia, hypercholesterolaemia, combined with a raised blood level of thyroid stimulating hormone (TSH) (serum TSH levels > 12 mU/L), and a low serum thyroxine (T_4 — see glossary, p 812) level (serum T_4 < 60 nmol/L). **Subclinical hypothyroidism** is diagnosed when serum TSH is raised (serum TSH levels > 4 mU/L) but serum thyroxine is normal and there are no symptoms or signs, or only minor symptoms or signs, of thyroid dysfunction. **Primary hypothyroidism** is seen after destruction of the thyroid gland because of autoimmunity (the most common cause), or medical intervention such as surgery, radioiodine, and radiation. **Secondary hypothyroidism** is seen after pituitary or hypothalamic damage, and results in insufficient production of TSH. Secondary hypothyroidism is not covered in this review. **Euthyroid sick syndrome** is diagnosed when triiodothyronine (T_3 — see glossary, p 812) levels are low, serum thyroxine is low and TSH levels are normal or low. Euthyroid sick syndrome is not covered in this review.

INCIDENCE/ PREVALENCE Hypothyroidism is more common in women than in men (in the UK, female : male ratio of 6 : 1). One study (2779 people in the UK with a median age of 58 years) found the incidence of clinical (overt) hypothyroidism was 40/10 000 women per year and 6/10 000 men per year. The prevalence was 9.3% in women and 1.3% in men.[1] In areas with high iodine intake, the incidence of hypothyroidism can be higher than in areas with normal or low iodine intake. In Denmark, where there is moderate iodine insufficiency, the overall incidence of hypothyroidism is 1.4/10 000 per year increasing to 8/10 000 per year in people older than 70 years.[2] The incidence of subclinical hypothyroidism increases with age. Up to 10% of women over the age of 60 years have subclinical hypothyroidism (evaluated from data from the Netherlands and USA).[3,4]

AETIOLOGY/ RISK FACTORS Primary thyroid gland failure can occur as a result of chronic autoimmune thyroiditis, postradioactive iodine treatment, or thyroidectomy. Other causes include drug adverse effects (e.g. amiodarone and lithium), transient hypothyroidism due to silent thyroiditis, subacute thyroiditis, or postpartum thyroiditis.

PROGNOSIS Hypothyroidism results in mental slowing, depression, dementia, weight gain, constipation, dry skin, hair loss, cold intolerance, hoarse voice, irregular menstruation, infertility, muscle stiffness and pain, bradycardia, and hypercholesterolaemia. In people with subclinical hypothyroidism, the risk of developing overt hypothyroidism is described in the UK Whickham Survey (25 years' follow up; for women: OR 8, 95% CI 3 to 20; for men: OR 44, 95% CI 19 to 104; if both a raised TSH and positive antithyroid antibodies were present; for women: OR 38, 95% CI 22 to 65; for men: OR 173, 95% CI 81 to 370). For women, the survey found an annual risk of 4.3%/year (if both raised serum TSH and antithyroid antibodies were present), 2.6%/year (if raised serum TSH was present alone);

the minimum number of people with raised TSH and antithyroid antibodies who would need treating to prevent this progression to clinical (overt) hypothyroidism in one person over 5 years is 5–8.[1] **Cardiovascular disease:** A large cross-sectional study (25 862 people with serum TSH between 5.1–10 mU/L) found significantly higher mean total cholesterol concentrations in hypothyroid people compared with euthyroid people (5.8 *v* 5.6 mmol/L).[3] Another study (124 elderly women with subclinical hypothyroidism, 931 euthyroid women) found a significantly increased risk of myocardial infarction in women with subclinical hypothyroidism (OR 2.3, 95% CI 1.3 to 4.0) and for aortic atherosclerosis (OR 1.7, 95% CI 1.1 to 2.6).[4] **Mental health:** Subclinical hypothyroidism is associated with depression.[5] People with subclinical hypothyroidism may have depression that is refractory to both antidepressant drugs and thyroid hormone alone. Memory impairment, hysteria, anxiety, somatic complaints, and depressive features without depression have been described in people with subclinical hypothyroidism.[6]

AIMS OF INTERVENTION To eliminate the symptoms of hypothyroidism and maximise quality of life.

OUTCOMES Quality of life and neuropsychological impairments (evaluated by congestive function tests, memory tests, reaction time, self rating mood scales, and depression scores); cardiovascular disease (episodes of atrial fibrillation and ischaemic events); cardiac function (evaluated by echocardiography); changes in body composition (measured by osteodensitometry or bioimpedance measurements); prevention of progression from subclinical to overt hypothyroidism; adverse effects of treatments (bone mass, fracture rate, development of hyperthyroidism).

METHODS *Clinical Evidence* search and appraisal April 2003, with an additional manual search of reference lists.

QUESTION What are the effects of treatments for clinical (overt) hypothyroidism?

OPTION LEVOTHYROXINE (L-THYROXINE) FOR CLINICAL (OVERT) HYPOTHYROIDISM

We found no RCTs comparing levothyroxine (L-thyroxine) versus placebo, although there is consensus that treatment is beneficial. Treating clinical (overt) hypothyroidism with thyroid hormone (levothyroxine; L-thyroxine) can induce hyperthyroidism and reduce bone mass in postmenopausal women and increase the risk of atrial fibrillation.

Benefits: We found no RCTs comparing levothyroxine versus placebo in people with clinical hypothyroidism, although there is consensus that treatment is beneficial (see comment below).

Harms: We found no RCTs comparing levothyroxine versus placebo in people with clinical hypothyroidism. Over-treatment with levothyroxine may cause hyperthyroidism. **Fracture rate:** One longitudinal observational study (1180 people on levothyroxine followed for an average of 8.6 years) found no significant increase in fracture rate between levothyroxine and control.[7] **Bone mass:** We found one

systematic review (search date not stated, 13 RCTs) in a total of 441 premenopausal women and 317 postmenopausal women.[8] All women had received prolonged levothyroxine treatment with reduced serum TSH concentration but normal T_4 and T_3 (see glossary, p 812) values. In premenopausal women (average age 40 years, treated with levothyroxine 164 μg/day for 8.5 years leading to suppressed serum TSH) the review found no significant difference between levothyroxine and control in bone mass after 8.5 years (2.7% less bone mass with levothyroxine *v* control; P reported as non significant). In postmenopausal women (average age 61.2 years, treated with levothyroxine 171 μg/day for 9.9 years leading to suppressed serum TSH), it found that levothyroxine significantly reduced bone mass compared with control after 9.9 years (bone mass 9.0% lower with levothyroxine than control, 95% CI 2.4% to 15.7%). **Atrial fibrillation:** One observational study found that in people aged over 60 years taking levothyroxine, a low serum TSH concentration (≤0.1 mU/L) was associated with an increased risk of atrial fibrillation (diagnosed by electrocardiogram) at 10 years (incidence of atrial fibrillation, 28% in people with low TSH *v* 11% in people with normal TSH values; RR 3.1, 95% CI 1.7 to 5.5).[9]

Comment: A placebo controlled trial would be considered unethical.

OPTION **LEVOTHYROXINE (L-THYROXINE) PLUS LIOTHYRONINE FOR CLINICAL (OVERT) HYPOTHYROIDISM**

We found insufficient evidence about the effects of levothyroxine (L-thyroxine) plus liothyronine versus levothyroxine alone in people with clinical (overt) hypothyroidism. Thyroid hormone treatment can induce hyperthyroidism and reduces bone mass in postmenopausal women and increase the risk of atrial fibrillation.

Benefits: We found no systematic review and no RCTs that met our inclusion criteria.

Harms: See harms of levothyroxine for clinical hypothyroidism, p 809.

Comment: We found two small crossover RCTs, which did not provide pre-crossover results.[10,11] The results reported in these RCTs are at risk of being confounded by the pre-crossover treatments. Therefore we excluded these studies.

QUESTION **What are the effects of treatments for subclinical hypothyroidism?**

OPTION **LEVOTHYROXINE (L-THYROXINE) FOR SUBCLINICAL HYPOTHYROIDISM**

One RCT in women with biochemically defined subclinical hypothyroidism found no significant difference between levothyroxine (L-thyroxine) and placebo for dry skin, cold intolerance, and constipation at 1 year. The RCT may, however, have lacked power to exclude a clinically important difference between treatments. Another RCT found no significant difference in health related quality of life scores between levothyroxine and placebo. One RCT found inconclusive results about the effect of levothyroxine versus placebo on cognitive function in people with

subclinical hypothyroidism. One RCT found that levothyroxine improved left ventricular function at 6 months compared with placebo. Treating subclinical hypothyroidism with thyroid hormone can induce hyperthyroidism and reduce bone mass in postmenopausal women and increase the risk of atrial fibrillation.

Benefits: We found no systematic review, but found four RCTs evaluating the effect of levothyroxine in people with subclinical hypothyroidism.[12–15] **General symptoms:** We found two RCTs.[12,14] The first RCT compared levothyroxine (50 μg/day) versus placebo in 33 women with increased thyroid stimulating hormone (TSH); normal serum thyroxine and normal free T_4 and T_3 (see glossary, p 812), and on average, two of the following symptoms: muscle cramps, dry skin, cold intolerance, fatigue, or constipation.[12] Physical examination revealed no signs of hypothyroidism, apart from dry or coarse skin, which was present in about 50% of women in each group. The RCT examined the effects of treatment on general symptoms (evaluated by a questionnaire in participants stating if they were feeling better, unchanged, or worse) for 1 year. It found no significant difference in overall symptom improvement between levothyroxine and placebo (8/17 [47%] people with levothyroxine *v* 3/16 [19%] people with placebo; P = 0.14, recalculated by *Clinical Evidence*).[12] The second RCT (40 women with increased TSH and normal T_4) compared levothyroxine versus placebo for 6 months. The RCT found no significant difference between levothyroxine and placebo in health related quality of life scores (Hospital Anxiety and Depression Scale and the 30-item General Health Questionnaire).[14] **Cognitive function:** We found one RCT (37 people, aged > 55 years, TSH >6.0 mU/L, normal T_4, T_3, and thyroxine binding globulin) comparing levothyroxine (25 μg/day for 4 weeks then 50 μg/day) versus placebo for 10 months. It found no significant difference between levothyroxine and placebo in any outcome except in one psychometric memory score, based on a battery of cognitive function tests evaluating memory.[13] No firm conclusions could be drawn from these findings. **Cardiac function:** We found one RCT (20 people with increased TSH, and normal T_4 and T_3 for least 1 year) which compared the effects of levothyroxine (50 μg/day) versus placebo on cardiac function for 1 year.[15] Cardiac function was evaluated by conventional two-dimensional Doppler echocardiography and ultrasonic videodensitometry. The RCT found that levothyroxine significantly improved left ventricular function compared with placebo at 6 months (increased isovolumic relaxation time, P < 0.03; peak A, P < 0.01; pre-ejection/ejection time ratio, P < 0.03; cyclic variation index, P < 0.05).[15]

Harms: One RCT did not report on adverse effects.[12] The second RCT found a significant worsening in anxiety scores with levothyroxine versus placebo (P = 0.03).[14] In the third RCT, 2/18 (11%) people taking levothyroxine withdrew because of complications (1 had increased angina and 1 had new onset atrial fibrillation).[13] The fourth RCT did not report on adverse effects.[15]

Comment: None.

Primary hypothyroidism

GLOSSARY

T_3 is used as an abbreviation for endogenous tri-iodothyronine in medical and biochemical reports.

T_4 is used as an abbreviation for endogenous thyroxine in medical and biochemical reports.

Key Messages

- **Topical non-steroidal anti-inflammatory drug eye drops** One RCT found no significant difference between non-steroidal anti-inflammatory drug and placebo eye drops in clinical cure rate after 21 days. Three RCTs found no significant difference between non-steroidal anti-inflammatory drugs and steroid eye drops in clinical cure rate after 14 or 21 days.
- **Topical steroid eye drops** One small RCT found no significant difference with steroid (betamethasone phosphate/clobetasone butyrate) eye drops compared with placebo eye drops in symptom severity after 14 or 21 days. Two RCTs found no significant difference between prednisolone and rimexolone, in the anterior chamber cell count (a marker of disease severity). One RCT found that prednisolone increased the proportion of people with fewer than five anterior chamber cells per examination field compared with loteprednol after 28 days. The results of a second RCT comparing prednisolone with loteprednol were difficult to interpret. RCTs found that rimexolone and loteprednol were less likely than prednisolone to be associated with increased intraocular pressure, although differences were not statistically significant. Three RCTs found no significant difference between steroid and non-steroidal anti-inflammatory drug eye drops in clinical cure rate after 14 or 21 days.

Acute anterior uveitis

DEFINITION Anterior uveitis is inflammation of the uveal tract, and includes iritis and iridocyclitis (see glossary, p 817). It can be classified according to its clinical course into acute or chronic anterior uveitis, or according to its clinical appearance into granulomatous or non-granulomatous anterior uveitis. Acute anterior uveitis is characterised by an extremely painful red eye, often associated with photophobia and occasionally with decreased visual acuity. Chronic anterior uveitis is defined as inflammation lasting over 6 weeks. It is usually asymptomatic, but many people have mild symptoms during exacerbations.

INCIDENCE/ PREVALENCE Acute anterior uveitis is rare with an annual incidence of 12/100 000 population.[1] It is particularly common in Finland (annual incidence 22.6/100 000 population, prevalence 68.7/100 000 population), probably owing to genetic factors such as the high frequency of HLA-B27 in the Finnish population.[2] It is equally common in men and women and more than 90% of cases occur in people older than 20 years of age.[2,3]

AETIOLOGY/ RISK FACTORS No cause is identified in 60–80% of people with acute anterior uveitis. Systemic disorders that may be associated with acute anterior uveitis include ankylosing spondylitis; Reiter's syndrome; juvenile chronic arthritis; Kawasaki syndrome; infectious uveitis; Behçet's syndrome; inflammatory bowel disease; interstitial nephritis; sarcoidosis; multiple sclerosis; Wegener's granulomatosis; Vogt-Koyanagi-Harada syndrome; and masquerade syndromes (see glossary, p 817). Acute anterior uveitis also occurs in association with HLA-B27 expression not linked to any systemic disease, and may also be the manifestation of an isolated eye disorder such as Fuchs' iridocyclitis, Posner-Schlossman syndrome, or Schwartz syndrome. Acute anterior uveitis may also occur after surgery or as an adverse drug or hypersensitivity reaction.[2,3]

PROGNOSIS Acute anterior uveitis is often self limiting, but we found no evidence about how often it resolves spontaneously, in which people, or over what length of time. Complications include posterior synechiae (see glossary, p 817), cataract, glaucoma, and chronic uveitis. In a study of 154 people (232 eyes) with acute anterior uveitis (119 people HLA-B27 positive), visual acuity was better than 20/60 in 209/232 (90%) eyes, 20/60 or worse in 23/232 (10%) eyes, including worse than 20/200 (classified as legally blind) in 11/232 (5%) eyes.[4]

AIMS OF INTERVENTION To reduce inflammation; to relieve pain; and to prevent complications and loss of visual acuity, with minimal adverse effects.

OUTCOMES Degree of inflammation using scores that register cell counts and flare in the anterior chamber; keratic precipitates; ciliary flush; and severity of symptoms (photophobia and pain). Scores include the number of anterior chamber cells per examination field — a clinical marker of disease severity.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION What are the effects of topical anti-inflammatory eye drops?

OPTION TOPICAL STEROID EYE DROPS

One small RCT found no significant difference with steroid (betamethasone phosphate/clobetasone butyrate) eye drops compared with placebo eye drops in symptom severity after 14 or 21 days. Two RCTs found no significant difference between prednisolone and rimexolone, in the anterior chamber cell count (a marker of disease severity). One RCT found that prednisolone increased the proportion of people with fewer than five anterior chamber cells per examination field compared with loteprednol after 28 days. The results of a second RCT comparing prednisolone with loteprednol were difficult to interpret. RCTs found that rimexolone and loteprednol were less likely than prednisolone to be associated with increased intraocular pressure, although differences were not statistically significant. RCTs found no significant difference between steroid and non-steroidal anti-inflammatory drug eye drops in clinical cure rate after 14 or 21 days.

Benefits: We found no systematic review. **Versus placebo:** We found one RCT (60 people) that compared three treatments: betamethasone phosphate 1% (2 drops every 2 hours), clobetasone butyrate 0.1% (2 drops every 2 hours), and placebo.[5] The RCT found no significant difference with steroid (betamethasone phosphate/clobetasone butyrate) compared with placebo eye drops in symptom severity after 14 or 21 days (results presented graphically; see comment below). **Versus each other:** We found two papers reporting four RCTs.[6,7] Two RCTs (183 people and 93 people) compared prednisolone 1% versus rimexolone 1% eye drops.[6] The larger RCT (183 people) found no significant difference in the number of anterior chamber cells per examination field after 28 days (see comment below; 0.4 cells per examination field with rimexolone *v* 0.2 cells per examination field with prednisolone, difference 0.2 cells per examination field, CI not reported; P = 0.16). The smaller RCT (83 people) also found no significant difference in the number of anterior chamber cells per examination field after 28 days (see comment below; 0.3 cells per examination field with rimexolone *v* 0.2 cells per examination field with prednisolone, difference 0.1 cells per examination field; CI not reported; P = 0.40).[6] Two RCTs (175 people and 70 people) compared prednisolone 1% versus loteprednol 0.5% eye drops.[7] The larger RCT (175 people) found that prednisolone significantly increased the proportion of people with fewer than five anterior chamber cells per examination field after 28 days compared with loteprednol (5 people lost to follow up; 77/89 [87%] with prednisolone *v* 58/81 [72%] with loteprednol; RR 1.20, 95% CI 1.03 to 1.42; NNT 7, 95% CI 4 to 35). The smaller RCT (70 people; see comment below) found more people had fewer than five anterior chamber cells per examination field with prednisolone compared with loteprednol but the difference was not significant.[7] **Versus topical non-steroidal anti-inflammatory drug eye drops:** See topical non-steroidal anti-inflammatory drug eye drops, p 816.

Acute anterior uveitis

Harms: In the RCTs, adverse events were generally mild, resolved without treatment, and did not result in permanent damage.[5–7] In the smaller RCT comparing loteprednol versus prednisolone eye drops, 4/70 (6%) people were withdrawn because of adverse effects: cystoid macular oedema and ocular symptoms in the loteprednol group, and interstitial keratitis and increased age-related macular degeneration in the prednisolone group.[7] **Raised intraocular pressure:** The largest RCT found clinically significant increases in intraocular pressure (defined as > 10 mm Hg from baseline) more frequently with prednisolone versus rimexolone and with prednisolone versus loteprednol, although the differences were not statistically significant (11/94 [12%] people with prednisolone *v* 6/89 [7%] people with rimexolone; RR 1.7, 95% CI 0.7 to 4.5;[6] 6/91 [7%] people with prednisolone *v* 1/84 [1%] people with loteprednol; RR 5.5, 95% CI 0.7 to 45.0[7]). Widely known adverse effects of topical steroid eye drops include local irritation, hyperaemia, oedema, and blurred vision. Rarely, topical eye drops have been associated with glaucoma, cataract, and herpes simplex keratitis.

Comment: In the RCT comparing steroid eye drops versus placebo, 12/60 (20%) people did not complete the trial and analysis of data was not by intention to treat.[5] Of these, 4/12 (33%) people were withdrawn from the placebo group because of the severity of their anterior uveitis. The trial was too small to rule out any clinically important effect of topical steroids. In the RCTs comparing prednisolone versus rimexolone, people were excluded from analysis for a variety of reasons (23/183 [13%] in the larger RCT and 8/93 [9%] in the smaller RCT).[6] The smaller RCT of prednisolone versus loteprednol enrolled people in the USA and UK; however, it only reported results for the subgroup of people recruited from the USA.[7] This makes the results difficult to interpret. Topical steroids have been standard treatment for anterior uveitis since the early 1950s, especially for people with acute or severe uveitis.

OPTION TOPICAL NON-STEROIDAL ANTI-INFLAMMATORY DRUG EYE DROPS

One RCT found no significant difference between non-steroidal anti-inflammatory drug and placebo eye drops in clinical cure rate after 21 days. Three RCTs found no significant difference between non-steroidal anti-inflammatory drug and steroid eye drops in clinical cure rate after 14 or 21 days.

Benefits: We found no systematic review. **Versus placebo:** We found one RCT (100 people) that compared three treatments: non-steroidal anti-inflammatory drug (NSAID) (tolmetin 5%), steroid (prednisolone 0.5%), and placebo (sterile saline 0.9%) eye drops (see *v* topical steroids below).[8] People were asked to instil two drops every 2 hours during the waking period plus atropine 1% eye drops once daily. The RCT found no significant difference between NSAIDs and placebo eye drops in clinical cure rate after 21 days (15/32 [47%] with tolmetin *v* 16/32 [50%] with placebo; RR 0.9, 95% CI 0.6 to 1.6). **Versus topical steroids:** We found three RCTs.[8–10] The first

RCT (71 people) compared three treatments: prednisolone disodium phosphate 0.5%, betamethasone disodium phosphate 0.1%, and tolmetin sodium dihydrate 5%.[9] People were asked to instil one drop every 2 hours during the waking period, and all received atropine 1% eye drops once daily. The RCT found no significant difference between an NSAID (tolmetin sodium dihydrate) and steroid (prednisolone disodium phosphate/betamethasone disodium phosphate) eye drops in clinical cure rate after 21 days (see comment below; 12/21 [57%] people with tolmetin sodium dihydrate *v* 31/39 [79%] with prednisolone disodium phosphate/betamethasone disodium phosphate; RR 1.4, 95% CI 0.9 to 2.1).[9] The second RCT (49 people) compared NSAID eyedrops (indometacin [indomethacin] 0.1%) with steroid (dexamethasone 1%) eye drops given six times daily.[10] Most people (equal numbers in each group) also received atropine eye drops three times daily. The RCT found a lower proportion of people clinically cured after 14 days with indometacin but the difference was of borderline significance (see comment below; 12/25 [48%] people with indometacin *v* 18/24 [75%] people with dexamethasone; RR 0.6, 95% CI 0.4 to 1.0). The third RCT (100 people) compared three treatments: steroid (prednisolone 0.5%), NSAID (tolmetin 5%), and placebo eye drops (sterile saline 0.9%) (see *v* placebo above).[8] It found no significant difference between NSAIDs and steroid eye drops in clinical cure rate after 21 days (see comment below; 15/32 [47%] people with tolmetin *v* 22/32 [69%] people with prednisolone; RR 0.7, 95% CI 0.4 to 1.1).

Harms: See harms of topical steroid treatments, p 816. In the RCT comparing NSAID with steroid eye drops, 6/20 (30%) people receiving NSAID eye drops reported a transient stinging sensation in their eyes.[9] In the RCT comparing indometacin 0.1% with dexamethasone 1% eye drops, more people receiving indometacin reported eye irritation, although the difference was not significant (7/25 [28%] people with indometacin *v* 3/24 [13%] people with dexamethasone; RR 2.2, 95% CI 0.7 to 7.8).[10]

Comment: Two RCTs used "clinical cure" as an outcome measure, although neither defined this term.[8,9] The third RCT defined "clinical cure" as absence of clinical signs or symptoms suggestive of inflammation.[10] The RCT comparing NSAID with placebo eye drops reported that 6/71 (8%) people did not complete the trial,[8] and the first RCT comparing NSAID with steroid eye drops reported that 11/71 (15%) people did not complete the trial.[9] Neither of these RCTs analysed data by intention to treat.

GLOSSARY

Iridocyclitis Inflammation of both iris and ciliary body. Cells are present in the anterior chamber and in the vitreous.

Iritis Inflammation of the iris. Cells are seen in the anterior chamber but not in the vitreous.

Masquerade syndromes Comprise a group of disorders that occur with intraocular inflammation and are often misdiagnosed as a chronic idiopathic uveitis.

Posterior synechiae Adhesions between the iris and the lens capsule.

Age related macular degeneration

Search date July 2003

Jennifer Arnold and Shirley Sarks

QUESTIONS

INTERVENTIONS

See glossary, p 830

Key Messages

Prevention of progression

- **Antioxidant vitamin and zinc supplementation** One systematic review has found modest evidence from one large RCT that, in people with early to late age related macular degeneration, antioxidant vitamins plus zinc supplements reduce the risk of progression and vision loss over 6 years compared with placebo.
- **Laser to drusen** Two RCTs provided insufficient evidence that laser to drusen decreased incidence of late age related macular degeneration, choroidal neovascularisation, or geographic atrophy. One RCT found that laser improved visual acuity after 2 years compared with no treatment, but not compared with subthreshold treatment. The second, larger RCT found no significant difference between laser and no treatment in visual acuity after 1 year. However, subgroup analysis found improved visual acuity where laser treatment had reduced the number of drusen by 50% or more. The RCT also found that, in people with unilateral (but not bilateral) drusen, laser increased the short term incidence of choroidal neovascularisation compared with no treatment.

Age related macular degeneration

Treatment

- **Photodynamic treatment with verteporfin** Two systematic reviews in people with age related macular degeneration have found that photodynamic treatment with verteporfin reduces the risk of moderate or severe loss of visual acuity and of legal blindness after 1–2 years in selected people compared with placebo. Photodynamic treatment with verteporfin was associated with an initial loss of vision and photosensitive reactions in a small proportion of people.
- **Thermal laser photocoagulation** Four large RCTs have found that, in people with well demarcated exudative age related macular degeneration, thermal laser photocoagulation reduces severe visual loss after 2–5 years compared with no treatment, but may be associated with an immediate and permanent reduction in visual acuity. RCTs found no significant difference in visual acuity between different laser wavelengths. Choroidal neovascularisation recurs within 2 years in about half of those treated.
- **Submacular surgery** Two small RCTs provided insufficient evidence on the effects of submacular surgery.
- **External beam radiation** Five RCTs found conflicting evidence of the effect of low dose external beam radiation compared with placebo or no treatment in people with exudative age related macular degeneration. However, the two largest, highest quality RCTs found no significant effect in the proportion of people with moderate vision loss, suggesting the treatment is unlikely to be beneficial. We found insufficient evidence on long term safety, although RCTs found no evidence of toxicity to the optic nerve or retina after 12–24 months.
- **Subcutaneous interferon alfa-2a** One large RCT found that, compared with placebo, subcutaneous interferon alfa-2a (an antiangiogenesis drug) increased visual loss after 1 year, although the difference was not significant. The RCT also found evidence of serious ocular and systemic adverse effects.

DEFINITION Age related macular degeneration (AMD) has three clinical stages: **early AMD** marked by drusen (see glossary, p 830) and pigmentary change, and usually associated with normal vision; **late or sight threatening AMD** associated with a decrease in central vision; and **end stage or blinding AMD**. Late stage AMD has two forms: atrophic (or dry) AMD, characterised by geographic atrophy (see glossary, p 830); and exudative (or wet) AMD, characterised by choroidal neovascularisation (see glossary, p 830), which eventually causes a disciform scar.

INCIDENCE/ PREVALENCE AMD is a common cause of blindness registration in industrialised countries. Atrophic AMD is more common than the more sight threatening exudative AMD, affecting about 85% of people with AMD.[1] End stage (blinding) AMD is found in about 2% of all people aged over 50 years, and incidence rises with age (0.7–1.4% of people aged 65–75 years; 11–19% of people aged > 85 years).[2–4]

AETIOLOGY/ RISK FACTORS Proposed hypotheses for the cause of AMD involve vascular factors and oxidative damage coupled with genetic predisposition.[5] Age is the strongest risk factor. Ocular risk factors for the development of exudative AMD include the presence of soft drusen (see glossary, p 830), macular pigmentary change, and choroidal neovascularisation in the other eye. Systemic risk factors include hypertension,

smoking, and a family history of AMD.[5–7] Hypertension, diet (especially intake of antioxidant micronutrients), and oestrogen use are suspected as causal agents, but the effects of these factors remain unproved.[5]

PROGNOSIS AMD impairs central vision, which is required for reading, driving, face recognition, and all fine visual tasks. **Atrophic AMD** progresses slowly over many years, and time to legal blindness (see glossary, p 830) is highly variable (usually about 5–10 years).[8,9] **Exudative AMD** is more often threatening to vision; 90% of people with severe visual loss (see glossary, p 831) due to AMD have the exudative type. This condition usually manifests with a sudden worsening and distortion of central vision. One study estimated (based on data derived primarily from cohort studies) that the risk of developing exudative AMD in people with bilateral soft drusen was 1–5% at 1 year and 13–18% at 3 years.[10] The observed 5 year rate in a population survey was 7%.[11] Most eyes (estimates vary from 60–90%) with exudative AMD progress to legal blindness and develop a central defect (scotoma) in the visual field.[12–15] Peripheral vision is preserved, allowing the person to be mobile and independent. The ability to read with visual aids depends on the size and density of the central scotoma and the degree to which the person retains sensitivity to contrast. Once exudative AMD has developed in one eye, the other eye is at high risk (cumulative estimated incidence: 10% at 1 year, 28% at 3 years, and 42% at 5 years).[16]

AIMS OF INTERVENTION To minimise loss of visual acuity and central vision; to preserve the ability to read with or without visual aids; to optimise quality of life; to minimise adverse effects of treatment.

OUTCOMES Visual acuity; rates of legal blindness; contrast sensitivity; quality of life; visual fields; rate of progression to late AMD; rate of adverse effects of treatment. Visual acuity is measured using special eye charts (logMAR charts, usually the Early Treatment of Diabetic Retinopathy Study [ETDRS] chart), although many studies do not specify which chart was used. In this review, it may be assumed that the logMAR or ETDRS charts have been used unless otherwise stated. Stable vision is usually defined as loss of two lines or less on the ETDRS chart. Moderate visual loss (see glossary, p 830) is defined as a loss of greater than three lines and severe visual loss is defined as a loss of greater than six lines. Loss of vision to legal blindness (< 20/200) is also used as an outcome.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of interventions to prevent progression of age related macular degeneration?

OPTION ANTIOXIDANT VITAMIN AND MINERAL SUPPLEMENTS

One systematic review has found modest evidence from one large RCT that, in people with early to late age related macular degeneration, antioxidant vitamins plus zinc supplements reduce the risk of progression and vision loss over 6 years compared with placebo.

Age related macular degeneration

Benefits: We found one systematic review (search date 2001, 7 RCTs, 4119 people).[17] Six of the trials reported were small with inconsistent results and these studies are not considered further. The remaining, large RCT identified by the review (3640 people aged 55–80 years) included people with at least moderate drusen (see glossary, p 830) in both eyes or choroidal neovascularisation or geographic atrophy (see glossary, p 830) in one eye.[18] It compared four treatments: placebo, zinc (total daily dose, zinc 80 mg plus copper 2 mg), antioxidants (total daily dose, vitamin C 500 mg plus vitamin E 400 IU plus beta-carotene 15 mg), and zinc plus antioxidants. Overall it found that compared with placebo, zinc plus antioxidants significantly reduced the proportion of people progressing to advanced AMD (OR 0.72, 99% CI 0.52 to 0.98) or moderate vision loss (see glossary, p 830) (OR 0.73, 99% CI 0.54 to 0.99) over a 6 year period.[18] The RCT defined progression to advanced AMD as the development of choroidal neovascularisation or geographic atrophy. Only 15/1063 people with early AMD (moderate bilateral drusen) developed advanced AMD (5 year incidence 1.5%) and the effect of supplementation compared with placebo was found to be higher when these people were excluded (antioxidants plus zinc: OR 0.66, 99% CI 0.47 to 0.91; zinc alone: OR 0.71, 99% CI 0.52 to 0.99; antioxidants alone: OR 0.76, 99% CI 0.55 to 1.05).[18]

Harms: In the large RCT, 71% of people were taking 75% or more of their tablets at 5 years.[18] There was little evidence of harm in the large RCT although it found an increase in yellow skin discolouration in people taking antioxidants (151/1823 [8.3%] with antioxidants *v* 108/1798 [6.0%] with placebo; OR 1.4, 95% CI 1.1 to 1.8; $P < 0.01$) and in admission to hospital for genitourinary complications in people taking zinc (134/1783 [7.5%] with zinc *v* 90/1838 [4.9%] with placebo; OR 1.6, 95% CI 1.2 to 2.1; $P < 0.01$). However, harmful effects of long term supplementation with the dosages used in the RCT cannot be ruled out.[18] High dose zinc supplementation may result in gastrointestinal intolerance. There is evidence from other (non-ophthalmic) studies suggesting potentially harmful effects of beta-carotene in smokers with an increased risk of lung cancer.[19,20]

Comment: The high dosages given in this study cannot be achieved by dietary intake alone. The study was conducted in relatively well nourished Americans (57% of people were taking zinc or antioxidant vitamins before enrolment, and 67% took additional multivitamin supplements to recommended daily allowance levels during the study). Trials in populations with different nutritional statuses are required. We found no evidence on the effects of supplements in people with no AMD or early signs of the disease (early drusen only) or established late AMD (choroidal neovascularisation or geographic atrophy) in both eyes benefit from antioxidant vitamin and zinc supplementation. An allied systematic review (search date 2002) found that there is no evidence that supplements prevent AMD in people with no signs of the disease.[21] Results are awaited from four large ongoing studies in the USA and Australia that address this question.

OPTION LASER TO DRUSEN

Two RCTs provided insufficient evidence that laser to drusen decreased incidence of late age related macular degeneration, choroidal neovascularisation, or geographic atrophy. One RCT found that laser improved visual acuity after 2 years compared with no treatment, but not compared with subthreshold treatment. The second, larger RCT found no significant difference between laser and no treatment in visual acuity after 1 year. However, subgroup analysis found improved visual acuity where laser treatment had reduced the number of drusen by 50% or more. The RCT also found that, in people with unilateral (but not bilateral) drusen, laser increased the short term incidence of choroidal neovascularisation compared with no treatment.

Benefits: We found no systematic review. **Versus no treatment:** We found two RCTs (4 publications).[22–25] The first RCT (229 eyes, 75 people with unilateral drusen (see glossary, p 830) and 77 people with bilateral drusen; see comment below) compared three treatments: diode laser (see glossary, p 830) at a threshold level (visible burns; 63 eyes), diode laser at a subthreshold level (invisible burns; 57 eyes), and no laser treatment (109 eyes).[22] It found that laser treatment at either level (threshold or subthreshold) significantly increased visual acuity compared with no laser treatment after 2 years (improvement of ≥ 2 lines: 12/105 [11%] with laser treatment *v* 0/91 [0%] with no treatment; NNT 9, 95% CI 6 to 25). The RCT found no significant difference between threshold and subthreshold treatment in visual acuity after 2 years (improvement of ≥ 2 lines: 8/56 [14%] with threshold treatment *v* 4/49 [8%] with subthreshold treatment; RR 1.80, 95% CI 0.56 to 5.50). The second RCT (120 eyes with unilateral drusen, 312 eyes with bilateral drusen, 276 people; see comment below) compared argon-green laser (see glossary, p 830) versus no laser treatment.[23–25] It found no significant difference between laser treatment and no laser treatment in visual acuity after 1 year (AR for improvement of ≥ 1 line: 60/167 [36%] with laser treatment *v* 48/183 [26%] with no laser treatment; RR 1.40, 95% CI 1.00 to 1.88; AR for reduction of ≥ 1 line: 44/167 [26%] with laser treatment *v* 65/183 [36%] with no laser treatment; RR 0.70, 95% CI 0.54 to 1.02). We also found three small RCTs which found results consistent with to the larger RCTs cited above.[26–28]

Harms: Macular laser treatment may induce choroidal neovascularisation (CNV) (see glossary, p 830) and retinal atrophy. The first RCT found no significant difference between threshold and subthreshold laser treatment in the proportion of eyes with CNV after 24 months (7/56 [12%] with threshold laser treatment *v* 4/49 [8%] with subthreshold laser treatment; RR 1.50, 95% CI 0.45 to 4.68).[22] In the second RCT, early analysis found that in the subgroup of people with unilateral drusen, argon-green laser compared with no laser treatment significantly increased the incidence of CNV (estimated 12 month incidence 10/59 [17%] with laser treatment *v* 2/61 [3%] with no laser treatment; $P < 0.05$; CI not reported; see comment below).[24] Both RCTs found that laser induced retinal atrophy was uncommon, with 2/120 (2%) treated eyes affected in one study,[24] and 1/105 (1%) treated eyes affected in the other.[22]

Comment: Both the RCTs sought to minimise CNV by using low intensity and subthreshold laser burns and by positioning laser burns at a distance (generally > 500 μm) from the fovea centre. The first RCT reported that 196/229 (86%) eyes completed 24 months' follow up, although it is not clear whether analysis of data was by intention to treat.[22] The second RCT ceased enrolment and treatment prematurely because of a higher incidence of CNV within the first 12 months in people receiving laser treatment with unilateral (but not with bilateral) drusen.[23–25] The second RCT reported that 351/432 (81%) eyes completed 12 months' follow up, although analysis of data was not by intention to treat and people with CNV were excluded.[23,24] It found limited evidence from a subgroup analysis that improved visual acuity was more likely with a greater reduction in drusen after 1 year (AR for improvement of ≥ 1 line: 36/77 [48%] in eyes with ≥ 50% reduction in drusen *v* 24/90 [27%] in eyes with < 50% reduction; RR 1.80, 95% CI 1.16 to 2.66). There is now considerable interest in preventive strategies for people with high risk drusen. One model estimates that a preventive measure of 10% efficacy in people with bilateral drusen would more than halve the risk of developing legal blindness (see glossary, p 830) relative to current treatment.[29] Other RCTs of laser to drusen are either ongoing[30] or planned.[22,23]

QUESTION What are the effects of treatments for exudative age related macular degeneration?

OPTION THERMAL LASER PHOTOCOAGULATION

Four large RCTs have found that, in people with well demarcated exudative age related macular degeneration, thermal laser photocoagulation reduces severe visual loss after 2–5 years compared with no treatment, but may be associated with an immediate and permanent reduction in visual acuity. RCTs found no significant difference in visual acuity between different laser wavelengths. Choroidal neovascularisation recurs within 2 years in about half of those treated.

Benefits: We found no systematic review. **Versus no treatment:** We found four large unblinded multicentre RCTs in selected populations with exudative age related macular degeneration comparing laser photocoagulation versus no treatment (see table 1, p 834).[12–15,31–33] We also found four smaller RCTs that included a wider range of people.[34–37] All four large RCTs found that laser treatment significantly reduced the risk of severe visual loss (see glossary, p 831) after 3 years' follow up compared with no treatment. Participants differed in terms of the position of the choroidal neovascularisation (CNV) (see glossary, p 830) on the retina, whether far, near, or under the centre of fixation (extrafoveal,[12,14] juxtafoveal,[15,31] or subfoveal[13,32,33]). The study of extrafoveal CNV found that laser photocoagulation significantly reduced severe visual loss compared with no treatment (see table 1, p 834).[12,14] Results were similar in eyes with juxtafoveal CNV (see table 1, p 834) (see comment below).[15,31] The two RCTs in people with subfoveal CNV (new and recurrent disease) also found that laser photocoagulation reduced severe visual loss compared with no treatment, although it was

associated with an immediate and permanent loss of visual acuity in the treated groups.[13] Of the four smaller RCTs, one RCT (127 eyes) found that fovea sparing laser photocoagulation significantly reduced the risk of deteriorating visual acuity compared with no treatment (AR for loss of < 3 lines after 12 months: 28/68 [41%] with laser treatment *v* 12/59 [20%] with no treatment; RR 2.00, 95% CI 1.13 to 3.61; NNT 5, 95% CI 3 to 16).[34] The other three RCTs found no significant difference between scatter (non-confluent) laser and no treatment in occult CNV, but were likely to have lacked power to exclude clinically important effects.[35–37] **Different wavelengths:** We found three RCTs comparing different laser wavelengths for CNV.[38,39] All three RCTs found no significant difference between krypton-red and argon-green laser (see glossary, p 830) in visual acuity after a maximum of 5 years. **Versus submacular surgery:** See glossary, p 831. See benefits of submacular surgery, p 827. **Effects in people with CNV identified by indocyanine green angiography:** We found no RCTs.

Harms: Laser destroys new vessels and surrounding retina, and the resultant scar causes a corresponding defect in the central visual field. If the laser is applied to subfoveal lesions, or if the laser burn spreads to the fovea, visual acuity will be impaired; two of the RCTs described immediate loss of visual acuity with laser treatment (an average loss of 3 lines).[13,33] We found no evidence of other adverse effects.

Comment: The RCT examining effects of laser in eyes with juxtafoveal CNV found evidence from subgroup analysis that benefit may be limited to eyes with CNV that is of the pure classic (see glossary, p 830) type (no occult element) on fluorescein angiography (237/496 [48%] of randomised eyes; OR 2.2, 95% CI 1.4 to 3.4).[15,31] The benefits of laser photocoagulation depend on accurate, complete treatment requiring high quality angiography and trained, experienced practitioners.[12–15,31–33] The risk of immediate loss of visual acuity with laser photocoagulation may limit its acceptability.

OPTION EXTERNAL BEAM RADIATION

Five RCTs found conflicting evidence of the effect of low dose external beam radiation compared with placebo or no treatment in people with exudative age related macular degeneration. However, the two largest, highest quality RCTs found no significant effect in the proportion of people with moderate vision loss, suggesting the treatment is unlikely to be beneficial. We found insufficient evidence on long term safety, although RCTs found no evidence of toxicity to the optic nerve or retina after 12–24 months.

Benefits: We found no systematic review. **Low dose external beam radiation:** We found three large[40–42] and two smaller RCTs.[43,44] The first large RCT (205 people with new subfoveal choroidal neovascularisation [see glossary, p 830]) found no significant difference between external beam radiation to the macula (8 fractions of 2 Gy) and placebo in the risk of moderate visual loss (see glossary, p 830) 1 year after treatment (51% with radiotherapy treatment *v* 53% with placebo; P = 0.88; CI and absolute numbers

not reported; see comment below).[40] The second large RCT (203 people) found no significant difference between external beam radiation (6 fractions of 2 Gy) and observation in the risk of moderate or severe visual loss (see glossary, p 831) 1 or 2 years after treatment (moderate visual loss: 53/93 [57%] with external beam radiation *v* 52/91 [57%] with observation at 12 months, P = 0.91; 61/87 [70%] with external beam radiation *v* 71/87 [82%] with observation at 24 months, P = 0.08; severe visual loss: 26/93 [28%] with external beam radiation *v* 37/91 [41%] with observation at 12 months, P = 0.06; 31/87 [36%] with external beam radiation *v* 44/87 [51%] with observation at 24 months, P = 0.29).[41] The third large RCT (161 people) found that external beam radiation (4 fractions of 2 or 4 Gy) significantly reduced the mean number of lines of vision lost compared with placebo (1 Gy) 18 months after treatment (mean number of lines of vision lost: 1.73 with total of 8 Gy radiation *v* 3.23 with placebo, P = 0.011; 1.93 with total of 16 Gy *v* 3.23 with placebo, P = 0.05).[42] The two smaller RCTs similarly found conflicting evidence.[43,44] The first of these (83 people) found no significant difference between external beam radiation (7 fractions of 2 Gy) and placebo (sham radiation) in visual acuity after 12 months (mean number of lines lost: 4.14 with radiotherapy treatment *v* 3.39 with placebo; P = 0.35; CI not reported) or in angiographic outcomes (lesion size/progression of CNV, see comment below).[43] The second small RCT found that external beam radiation significantly reduced mean visual loss after 2 years compared with observation (1 RCT, 101 people; P < 0.0001; CI and absolute numbers not reported).[44] **High dose external beam radiation:** We found one RCT.[45] The RCT (74 people with new subfoveal CNV) compared external beam radiation (4 fractions of 6 Gy) delivered to the macula versus observation.[45] It found no significant difference between treatments in the risk of moderate or severe visual loss after 12 months (32.0% with radiotherapy treatment *v* 52.2% observation; AR –20%, 95% CI –44% to +4%, absolute numbers not available).

Harms: **Low dose external beam radiation:** The five RCTs[40–44] found that there were no radiation related adverse events up to 24 months' follow up, although one study[41] noted decreased tear film production and stability in the treated group. **High dose external beam radation:** The RCT reported that no harms were observed.[45]

Comment: In the first RCT, no treatment benefit was detected for subgroups of people classified as having some classic CNV (83 people, 41 treated, 42 control) or occult only lesions (122 people, 60 treated, 62 control) on the basis of fluorescein angiography (occult lesions: 47% with radiotherapy treatment *v* 49% with placebo; P = 0.80; classic/mixed lesions: 58% with radiotherapy treatment *v* 58% with placebo; P = 0.47; CI not reported; absolute numbers not available).[40] In the first RCT, we could not replicate the percentages presented in the paper from the raw data provided for cataract and dry eye symptom results. Results for the third RCT are only expressed as change in the mean vision, and percentages with moderate or severe vision loss are not given.[42] We also found one small exploratory RCT[46] that was under powered but found similar results to the larger RCT cited above.[45] Radiotherapy is potentially

toxic to the retina, optic nerve, lens, and lacrimal system, with toxic effects sometimes manifesting up to 2 years after treatment.[47] The biological effects of external beam radiation, both benefits and harms, depend on the dose in each fraction, the number of fractions delivered, and the time between each fraction. Total doses of up to 25 Gy, delivered in daily fractions of 2 Gy or less, are generally claimed not to cause damage to the retina or optic nerve. Uncontrolled pilot studies suggest that the main risks using the present dosing and delivery techniques are cataract formation (2/41 [5%] people in one series)[48] and transient dry eye symptoms (10/75 [13%] in a second case series).[49] One case series using total doses of 16–20 Gy in fraction sizes of 4–5 Gy found radiation toxicity of the optic nerve, retina, or choroid in 20/231 (9%) eyes after 12–24 months.[50] Another case series of proton beam radiation found radiation retinopathy in 11/27 (41%) eyes exposed to higher doses after 12 months.[51] A two centre case series of people treated with external beam radiation (5–10 fractions of 2 Gy/fraction) reported an abnormal choroidal vascular growth pattern associated with macular bleeding and exudation, and marked loss of visual acuity.[52] This change was detected in 12/95 (12%) people and 7/98 (7%) people after 3–12 months. Experience from pilot studies and case series suggests that, although higher radiation doses may be more effective in inducing regression of CNV, they carry an increased risk of sight threatening toxicity. RCTs with less than 2 years' follow up may miss important adverse effects. Further RCTs are underway using both low and high dose external beam radiotherapy.

OPTION SUBMACULAR SURGERY

Two small RCTs provided insufficient evidence on the effects of submacular surgery.

Benefits: We found no systematic review. **Versus no treatment:** We found no RCTs. **Versus laser photocoagulation:** We found one small RCT exploratory under powered study that found no significant difference between submacular surgery (see glossary, p 831) and laser photocoagulation in the proportion of eyes with improved visual acuity after 2 years (70 people with recurrent subfoveal choroidal neovascularisation [see glossary, p 830] after previous laser photocoagulation treatment) defined as visual acuity better than or no more than 1 line worse than baseline as measured on a modified Bailey-Lovie chart (14/28 [50%] with surgery *v* 20/31 [65%] with laser treatment; RR 0.80, 95% CI 0.49 to 1.22).[53] **Versus alternative surgical techniques:** We found one RCT (80 eyes with exudative age related macular degeneration [AMD]) comparing submacular surgery plus subretinal injection of tissue plasminogen activator versus submacular surgery plus subretinal injection of a control solution (balanced salt solution).[54] It found no significant difference in the proportion of eyes with any visual improvement (5/40 [12%] with surgery plus tissue plasminogen activator *v* 6/40 [15%] with surgery plus control; RR 0.80, 95% CI 0.28 to 2.51) or with fluorescein angiographic evidence of active

choroidal neovascularisation after 1 year (7/40 [18%] with surgery plus tissue plasminogen activator *v* 8/40 [20%] with surgery plus control; RR 0.90, 95% CI 0.35 to 2.18). However, confidence intervals were wide and the study may have lacked power to exclude clinically important effects.

Harms: Submacular surgery may threaten vision itself or necessitate further surgical intervention. However, we found no information on the frequency of adverse events. The largest case series of people with AMD and non-AMD treated with submacular surgery reported cataract formation (in up to 40%), retinal detachment (5–8%), recurrent new vessel formation (18–35% within 12 months), and macular complications (no rates reported).[55]

Comment: Most evidence for submacular surgery currently comes from small uncontrolled case series (< 50 people with AMD) with short follow up times, often including people with other types of macular degeneration. These series found that few people with AMD had improved vision with surgery.[47,55] Comparing results is difficult because of evolving surgical techniques, changes in outcome measures, and variations in follow up. Several large non-blinded RCTs are currently recruiting and will compare standardised surgical technique versus no treatment in new and haemorrhagic choroidal neovascularisation in people with AMD (Bressler S, personal communication, 1999). Other surgical techniques are being developed in volunteers, including macular translocation and retinal pigment epithelial transplantation, but these have yet to be evaluated formally.

OPTION SUBCUTANEOUS INTERFERON ALFA-2A

One large RCT found that, compared with placebo, subcutaneous interferon alfa-2a (an antiangiogenesis drug) increased visual loss, although the difference was not significant. The RCT also found evidence of serious ocular and systemic adverse effects.

Benefits: We found no systematic review. We found one RCT (481 people with subfoveal choroidal neovascularisation (see glossary, p 830) due to age related macular degeneration comparing three doses of subcutaneous interferon alfa-2a (1.5, 3, and 6 million IU 3 times/week for 1 year) versus placebo.[56] It found that interferon alfa-2a at all doses was associated with a non-significant reduction in visual acuity after 52 weeks compared with placebo (see comment below; AR for reduction of ≥ 3 lines: 142/286 [50%] with interferon alfa-2a *v* 40/105 [38%] with placebo; RR 1.20, 95% CI 0.90 to 1.62).[56]

Harms: Adverse effects of interferon alfa-2a were common and potentially severe in this RCT[56] and in other poorer quality RCTs. Effects included fatigue and influenza-like symptoms, gastrointestinal symptoms (including nausea, diarrhoea, and loss of appetite), and central and peripheral nervous system effects (including headaches and dizziness). Although at least one adverse event was reported in 90/105 (86%) people taking placebo, the proportion of people on active treatment who suffered adverse effects increased with dose, as did the severity of adverse effects. The RCT reported that 20/286 (7%) people receiving interferon alfa-2a developed interferon associated retinopathy (retinal haemorrhages or cotton wool spots).[56]

Comment: In the RCT, 90/481 (18%) of people did not complete the trial and analysis of data was not by intention to treat.[56] There is widespread interest in safe, effective antiangiogenesis drugs for prophylaxis in exudative age related macular degeneration. Several drugs are currently under clinical study. RCTs are currently investigating the use of intraocular or periocular steroids and antivascular endothelial growth factor.

OPTION PHOTODYNAMIC TREATMENT WITH VERTEPORFIN

Two systematic reviews in people with age related macular degeneration have found that photodynamic treatment with verteporfin reduces the risk of moderate or severe loss of visual acuity and of legal blindness after 1–2 years compared with placebo. Photodynamic treatment with verteporfin was associated with an initial loss of vision and photosensitive reactions in a small proportion of people.

Benefits: We found two systematic reviews (search date 2002,[57] and not reported[58]). Both reviews identified the same two RCTs (3 publications; 948 people with new and recurrent subfoveal choroidal neovascularisation (see glossary, p 830) due to age related macular degeneration), which compared photodynamic treatment (see glossary, p 830) with verteporfin (see glossary, p 831) (6 mg/m^2 body surface area) versus placebo (photodynamic treatment with 5% dextrose solution).[59–61] Treatments were repeated as necessary every 3 months. The first systematic review performed a meta-analysis and found that photodynamic treatment with verteporfin significantly reduced the risk of moderate (see glossary, p 830) and severe visual loss (see glossary, p 831) compared with placebo at 24 months (moderate visual loss: OR 0.77, 95% CI 0.69 to 0.87; severe visual loss: OR 0.62, 95% CI 0.50 to 0.76).[57] The second systematic review did not perform a meta-analysis because of baseline differences between the two trials (see comment below).[58] However, it re-examined data for the outcome of legal blindness (see glossary, p 830) (< 20/200). It found that, in both RCTs, photodynamic treatment reduced the risk of legal blindness compared with placebo at 24 months (first RCT:[59] 165/402 [41%] with photodynamic treatment with verteporfin *v* 114/207 [55%] with placebo; ARR 14%, 95% CI 6% to 22%; second RCT:[60,61] 26/225 [26%] with photodynamic treatment with verteporfin *v* 50/114 [44%] with placebo; ARR 18%, 95% CI 7% to 28%).

Harms: Verteporfin is a photosensitive dye and care must be taken to avoid leakage into surrounding tissues during infusion and exposure to bright light soon after treatment. Advice in the study was to avoid light for 48 hours, but some photosensitive reactions were observed in treated people after 3–5 days.[57] The treatment was well tolerated but was more likely than the control intervention to cause a transient decrease in vision, injection site reactions, photosensitivity, and infusion related low back pain. Severe loss of vision (> 20 letters or 4 lines) was recorded in 10/225 people (4%) in the first RCT[60,61] and in 3/402 (< 1%) people in the second RCT[59] within 7 days of treatment, although some visual recovery occurred in most cases. The risk seems to be higher in people with occult and no CNV. The possibility of rare but severe adverse events remains.

Age related macular degeneration

Comment: There were important differences in the populations recruited into the RCTs. The first RCT included people with some classic CNV and vision of about 20/40 to 20/200.[59] The second RCT included people with better vision or with no evidence of classic CNV and vision better than 20/100.[60,61] The first systematic review performed subgroup analyses based on baseline CNV lesion classification.[57] It found greater benefit in people with only classic lesions (RR of moderate vision loss at 24 months for photodynamic treatment *v* placebo: 0.88, 95% CI 0.74 to 1.04 if occult CNV was present; 0.42, 95% CI 0.30 to 0.60 if occult CNV was absent). However, it found that the amount of classic CNV in the lesion had no significant effect on the benefit from treatment (RR of moderate vision loss at 24 months for photodynamic treatment: 0.77, 95% CI 0.64 to 0.92 if no classic CNV was present; 0.93, 95% CI 0.77 to 1.14 if classic CNV consisted of 1–49% of the lesion; 0.60, 95% CI 0.48 to 0.75 if classic CNV consisted of ≥ 50% of the lesion; P = 0.066). Most people treated with photodynamic treatment with verteporfin will continue to lose visual acuity. Although benefit was shown for people with vision better than 20/100 or 20/200, it is not known what the impact of treatment is on those with poorer vision.

GLOSSARY

Choroidal neovascularisation (CNV) New vessels in the choroid, classified by fluorescein angiography: in terms of its position in relation to the fovea — extrafoveal, juxtafoveal, or subfoveal; in terms of its appearance — classic (well defined) or occult (poorly defined); and in terms of its borders — well demarcated or poorly demarcated.

Drusen Small, yellow, bright objects, often near the macula, seen by ophthalmoscopy. They are located under the basement membrane of the retinal pigment epithelium. They are present in many older people with normal vision, but a greater proportion of large drusen indicate higher risk of subsequent loss of acuity from age related macular degeneration.

Geographic atrophy A feature of atrophic age related macular degeneration, characterised by atrophy of the retina and inner choroidal layers at the macular leaving only the deep choroidal vessels visible.

Laser (diode, krypton, argon-green) Lasers used in ophthalmology that produce focused light of different specific wavelengths.

Legal blindness Visual acuity less than 20/200. A reading of 20/200 (or 6/60 in metric) on the Snellen chart means that a person can see at 20 feet (or 6 m) what a normally sighted person can see at 200 feet (or 60 m).

Moderate vision loss Loss of three or more lines of distance vision measured on a special eye chart, corresponding to a doubling of the visual angle.

Photodynamic treatment A two step procedure of intravenous infusion of a photosensitive dye followed by application of a non-thermal laser that activates the dye. The treatment aims to cause selective closure of the choroidal new vessels.

Predominantly classic choroidal neovascularisation Choroidal neovascularisation in which more than 50% of lesion area consists of classic choroidal neovascularisation on fluorescein angiography.

Severe vision loss Loss of six or more lines of distance vision measured on a special eye chart, corresponding to a quadrupling of the visual angle.
Submacular surgery Removal of haemorrhage, choroidal neovascularisation, or both after vitrectomy.
Verteporfin A photosensitive dye used in photodynamic treatment.

Substantive changes

Photodynamic treatment with verteporfin Two systematic reviews added;[57,58] conclusions unchanged.

Competing interests: JA was a clinical investigator in the study of photodynamic treatment using verteporfin, funded by Novartis/QLT, and has been supported by Novartis for attendance at conferences and symposia. SS none declared.

TABLE 1 **Laser photocoagulation of choroidal neovascularisation (CNV) versus observation in exudative age related macular degeneration: results of Macular Photocoagulation Study Group RCTs (see text, p 824).**

Site of CNV (type of laser)	Number of eyes	Severe visual loss (6 or more lines)	Vision level treated *v* control	Rate of recurrence in treated eyes
Extrafoveal CNV (argon-blue-green)[12,14]	236	RR 1.5 at 6 months to 5 years; P = 0.001	≥ 20/40 at 3 years; 33% *v* 22%	54% at 5 years
Juxtafoveal CNV (krypton-red)[15,31]	496	RR 1.2 at 6 months to 5 years; P = 0.04	≥ 20/40 at 3 years; 13% *v* 7%	76% at 5 years (classic CNV only)
New subfoveal CNV (argon-green or krypton)[13,32,33]	373	20% treated *v* 37% control at 2 years; P < 0.01	> 20/200 at 4 years; 12% *v* 11%	44% at 3 years
Recurrent subfoveal CNV (argon-green or krypton)[13,32,33]	206	9% treated *v* 28% control at 2 years; P = 0.03	> 20/200 at 3 years; 25% *v* 12%	39% at 3 years

CNV, choroidal neovascularisation.

Propamidine isetionate

Key Messages

- **Antibiotic treatment in culture positive bacterial conjunctivitis** One systematic review has found that antibiotics (polymyxin–bacitracin, ciprofloxacin, or ofloxacin) increase rates of clinical and microbiological cure compared with placebo. Four RCTs found no significant difference among antibiotics in clinical or microbiological cure. One RCT found that fusidic acid increased clinical cure rate compared with chloramphenicol. One RCT found that topical netilmicin increased clinical cure rate compared with topical gentamicin. One RCT found that topical levofloxacin increased microbiological cure rate, but not clinical cure rate, compared with topical ofloxacin.
- **Empirical antibiotic treatment of suspected bacterial conjunctivitis** One systematic review found limited evidence from one RCT that topical norfloxacin increased rates of clinical and microbiological improvement or cure after 5 days compared with placebo. RCTs comparing different topical antibiotics versus each other found no significant difference in rates of clinical or microbiological cure. One RCT found no significant difference between topical polymyxin–bacitracin ointment and oral cefixime for clinical or microbiological improvement or cure.

Bacterial conjunctivitis

DEFINITION Conjunctivitis is any inflammation of the conjunctiva, generally characterised by irritation, itching, foreign body sensation, and watering or discharge. Bacterial conjunctivitis may often be distinguished from other types of conjunctivitis by the presence of a yellow–white mucopurulent discharge. There is also usually a papillary reaction (small bumps with fibrovascular cores on the palpebral conjunctiva, appearing grossly as a fine velvety surface). Bacterial conjunctivitis is usually bilateral. This review covers non-gonococcal bacterial conjunctivitis.

INCIDENCE/ PREVALENCE We found no good evidence on the incidence or prevalence of bacterial conjunctivitis.

AETIOLOGY/ RISK FACTORS Conjunctivitis may be infectious (caused by bacteria or viruses) or allergic. In adults, bacterial conjunctivitis is less common than viral conjunctivitis, although estimates vary widely (viral conjunctivitis has been reported to account for 8–75% of acute conjunctivitis).[1–3] *Staphylococcus* species are the most common pathogens for bacterial conjunctivitis in adults, followed by *Streptococcus pneumoniae* and *Haemophilus influenzae*.[4,5] In children, bacterial conjunctivitis is more common than viral, and is mainly caused by *H influenzae*, *S pneumoniae*, and *Moraxella catarrhalis*.[6,7]

PROGNOSIS Most bacterial conjunctivitis is self limiting. One systematic review (search date 2001) found clinical cure or significant improvement with placebo within 2–5 days in 64% of people (99% CI 54% to 73%).[8] Some organisms cause corneal or systemic complications, or both. Otitis media may develop in 25% of children with *H influenzae* conjunctivitis,[9] and systemic meningitis may complicate primary meningococcal conjunctivitis in 18% of people.[10]

AIMS OF INTERVENTION To achieve rapid cure of inflammation, and to prevent complications, with minimum adverse effects of treatment.

OUTCOMES Time to cure or improvement. **Clinical signs/symptoms:** hyperaemia, discharge, papillae, follicles, chemosis, itching, pain, photophobia. Most studies used a numbered scale to grade signs and symptoms. Some studies also included evaluation by investigators and participants regarding success of treatment. **Culture results:** These are proxy outcomes usually expressed as the number of colonies, sometimes with reference to a threshold level. Results were often classified into categories such as eradication, reduction, persistence, and proliferation.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION **What are the effects of empirical treatment with antibiotics in adults and children with suspected bacterial conjunctivitis?**

OPTION **EMPIRICAL TREATMENT WITH ANTIBIOTICS**

One systematic review found limited evidence from one RCT that topical norfloxacin increased rates of clinical and microbiological improvement or cure after 5 days compared with placebo. RCTs comparing different topical antibiotics versus each other found no significant difference in

rates of clinical or microbiological cure. One RCT found no significant difference between topical polymyxin–bacitracin ointment and oral cefixime for clinical or microbiological improvement or cure.

Benefits: **Versus placebo:** We found one systematic review (search date 2001, 1 RCT, 284 adults; 50% of participants were culture positive) comparing topical norfloxacin versus placebo (see table A on web extra).[8] It found that norfloxacin significantly increased rates of clinical and microbiological improvement or cure after 5 days compared with placebo (88%, 95% CI 81% to 93% with norfloxacin *v* 72%, 95% CI 63% to 79% with placebo; $P < 0.01$; see comment below). **Versus each other:** We found no systematic review but found 27 RCTs conducted in adults and children (see table A on web extra).[2,11–36] These RCTs found no significant difference between different topical antibiotics and each other in rates of clinical or microbiological cure. **Versus oral antibiotics:** We found one RCT (80 children).[37] It found no significant difference between polymyxin–bacitracin ointment plus oral placebo and topical placebo plus oral cefixime in clinical improvement or bacteriological failure rates (failure rate: 15/40 [37.5%] with cefixime *v* 7/40 [17.5%] with polymyxin–bacitracin; $P = 0.07$).

Harms: **Versus placebo:** One RCT identified by the review reported minor adverse events in 4.2% of people for norfloxacin compared with 7.1% for placebo (P value not reported).[5] One non-systematic review reported four cases of aplastic anaemia with topical chloramphenicol and three cases of Stevens–Johnson syndrome with topical sulphonamides.[38] However, the review did not report the number of people using these drugs, making it difficult to exclude other possible causes of aplastic anaemia. **Versus each other:** See table A on web extra.[2,11–36]

Comment: The placebo controlled RCT identified by the review did not assess the effect of topical antibiotics on antibiotic resistance.[5] Most other trials included children as well as adults, and the ratio of children to adults was usually not specified. The comparisons of lomefloxacin versus chloramphenicol and fusidic acid, the comparison of norfloxacin versus fusidic acid, and the comparison of tobramycin versus fusidic acid were single blind. One RCT found that a significantly greater proportion of participants rated topical tobramycin as more inconvenient than the viscous preparation of fusidic acid, because of a difference in the frequency of administration.[35] The RCT also found that adherence among children was significantly higher with fusidic acid.

QUESTION What are the effects of topical antibiotics in adults and children with culture positive bacterial conjunctivitis?

OPTION TOPICAL ANTIBIOTICS IN PEOPLE WITH CULTURE POSITIVE BACTERIAL CONJUNCTIVITIS

One systematic review has found that antibiotics (polymyxin–bacitracin, ciprofloxacin, or ofloxacin) increase rates of both clinical and microbiological cure compared with placebo. Four RCTs found no significant difference among antibiotics in clinical or microbiological cure.

Bacterial conjunctivitis

One RCT found that fusidic acid increased clinical cure rate compared with chloramphenicol. One RCT found that topical netilmicin increased clinical cure rate compared with topical gentamicin. One RCT found that topical levofloxacin increased microbiological cure rate, but not clinical cure rate, compared with topical ofloxacin.

Benefits:

Versus placebo: We found one systematic review (search date 2000, 3 RCTs) in people with culture positive bacterial conjunctivitis, which compared antibiotics (polymyxin–bacitracin, ciprofloxacin, and ofloxacin) versus placebo (see table A on web extra).[8] The first RCT identified by the review (84 children with culture proven *H influenzae* and *S pneumoniae* bacterial conjunctivitis) found that topical polymyxin–bacitracin significantly increased clinical cure after 3–5 days compared with placebo but found no significant difference after 8–10 days (3–5 days: 62% with antibiotic *v* 28% with placebo; $P < 0.02$; 8–10 days: 91% with antibiotic *v* 72% with placebo; $P > 0.05$).[17] The RCT found that topical polymyxin–bacitracin significantly increased microbiological cure rates after both 3–5 days and 8–10 days compared with placebo. The second RCT (177 people, age not specified) found that ciprofloxacin significantly increased microbiological cure rates after 3 days compared with placebo (132/140 [94%] with antibiotic *v* 22/37 [59%] with placebo; RR 1.59, 95% CI 1.21 to 2.08).[18] The third RCT identified by the review, which compared antibiotics versus placebo, is published only in abstract form (see comment below).[19] **Versus each other:** We found no systematic review but found seven RCTs (see table A on web extra).[18,20–24,39] The first RCT (139 children) found that fusidic acid significantly increased clinical cure rate compared with chloramphenicol (85% with fusidic acid *v* 48% with chloramphenicol; $P < 0.0001$).[20] The second RCT (251 people) found no significant difference in reduction or eradication of bacteria between ciprofloxacin and tobramycin after 7 days (94.5% with ciprofloxacin *v* 91.9% with tobramycin; $P > 0.5$).[18] The third RCT (141 children) found no significant difference in clinical cure between ciprofloxacin and tobramycin (87% with ciprofloxacin *v* 90% with tobramycin; $P > 0.05$) or in microbiological cure rate (90% with ciprofloxacin *v* 84% with tobramycin; $P = 0.29$) after 7 days.[21] The fourth RCT (156 children) compared three treatments: trimethoprim–polymyxin, gentamicin, and sulfacetamide (sulphacetamide).[22] It found no significant difference in clinical cure rate between any of the treatments (84% with trimethoprim–polymyxin *v* 88% with gentamicin *v* 89% with sulfacetamide; $P > 0.1$) or in microbiological cure rate (83% with trimethoprim–polymyxin *v* 68% with gentamicin *v* 72% with sulfacetamide; $P > 0.1$) after 2–7 days. The fifth RCT (40 people) found no significant difference in symptom resolution between lomefloxacin and ofloxacin after 7 days (88% with lomefloxacin *v* 75% ofloxacin; $P < 0.08$).[23] The sixth RCT (121 people) found that topical netilmicin (0.3%) administered as one or two drops to affected eyes four times daily significantly increased clinical cure rate after both 5 and 10 days compared with 0.3% topical gentamicin ($P = 0.01$ after 5 days; $P = 0.001$ after 10 days; other results presented graphically).[24] The seventh RCT (423 adult and children entered, 208 included in per protocol analysis; see comment below) found that topical levofloxacin 0.5% for 5 days

significantly increased microbiological cure rate but found no significant difference in clinical cure rate at 6–10 days compared with topical ofloxacin 0.3% (microbiological cure: 89% with levofloxacin *v* 80% with ofloxacin; P = 0.034; clinical cure: 76% with levofloxacin *v* 76% with ofloxacin; P > 0.05).[39]

Harms: **Versus each other:** The sixth RCT found no significant difference between topical netilmicin and topical gentamicin in the rate of adverse reactions (redness, itching, and burning).[24] The seventh RCT found no significant difference between topical levofloxacin and topical ofloxacin in treatment related adverse effects (15/207 [7.3%] ofloxacin *v* 10/206 [4.9%] with levofloxacin).[39] The following minor adverse effects of topical antibiotics compared with each other were reported in RCTs that included people with suspected bacterial conjunctivitis: punctuate epithelial erosions (35% for tobramycin *v* 20% for ciprofloxacin); bad taste (20% for norfloxacin *v* 6% for fusidic acid); stinging (50% for norfloxacin *v* 37% for fusidic acid); and burning (33% with gentamicin *v* 20% with lomefloxacin; 1.45% with levofloxacin *v* 0.97% with ofloxacin).[13,25,26,39]

Comment: One RCT included in the review (abstract only; 132 people, age not specified) found that ofloxacin significantly increased clinical and microbiological improvement after 2 days compared with placebo (64% with ofloxacin *v* 22% with placebo; P < 0.001).[19] In the seventh RCT (423 people entered) comparing antibiotics versus each other, 215 people were excluded from the per protocol analysis because of a negative baseline culture, missing postbaseline data, and violations of either entry criteria or protocol.[39] None of the RCTs addressed the effect on antibiotic resistance of using topical antibiotics in bacterial conjunctivitis, which would be of interest given the self limiting nature of the disease. The age of the study participants was not always specified and no RCTs reported any patient orientated outcomes or assessed rates of reinfection.

QUESTIONS

INTERVENTIONS

See glossary, p 846

Key Messages

- **Manual extracapsular extraction (better than intracapsular extraction)** One RCT found that manual extracapsular extraction plus intraocular lens implant improved visual acuity and quality of life compared with intracapsular extraction plus aphakic glasses. The RCT also found a higher rate of complications with intracapsular extraction plus aphakic glasses.
- **Phaco extracapsular extraction (better than manual extracapsular extraction)** One RCT identified by a systematic review found improved vision up to 1 year after phaco extracapsular extraction plus foldable posterior chamber intraocular lens implant compared with manual extracapsular extraction plus rigid posterior chamber intraocular lens implant. The RCT and a systematic review of observational studies found that a higher proportion of people had complications with manual extracapsular extraction than with phaco extracapsular extraction.

Cataract

DEFINITION **Cataracts** are cloudy or opaque areas in the lens of the eye (which should usually be completely clear). This results in changes that can impair vision. **Age related (or senile) cataract** is defined as cataract occurring in people over 16 years of age in the absence of known mechanical, chemical, radiation trauma. **Cataract surgery** is indicated when the chances of significant improvement of visual function outweigh the risks of a poor outcome from such surgery. It is not dependent on reaching a specific visual acuity standard. Other indications for cataract surgery include facilitation of treatment or monitoring of concurrent posterior segment disease such as laser treatment for proliferative diabetic retinopathy or to correct a difference in the refractive power of the two eyes or treat lens induced ocular disease.[1] Cataract extraction and intraocular lens implantation can be performed using a variety of techniques including manual extracapsular cataract extraction, phaco extracapsular extraction (phacoemulsification), and intracapsular cataract extraction. **Population:** This chapter covers surgery for age related cataract. It does not cover cataract in people with diabetes mellitus or recurrent uveitis — conditions that can affect the surgical outcome.

INCIDENCE/ PREVALENCE Cataract accounts for over 40% of world blindness — around 38 million people.[2] In a rural setting in the USA, the prevalence of visually significant cataract ranged from approximately 5% at the age of 65 years to around 50% in people older than 75 years.[3] The relative incidence of non-senile cataract within this population is so small that this can be taken as the effective incidence of senile cataract.

AETIOLOGY/ RISK FACTORS Diet, smoking,[4] and exposure to ultraviolet light[5] are thought to be risk factors in the development of age related cataract. In addition, there may be a genetic predisposition to development of age related cataract in a proportion of the population.[6]

PROGNOSIS Age related cataract progresses with age, the rate of progression being unpredictable. We found no evidence for spontaneous regression or for the effectiveness of any non-invasive intervention.

AIMS OF INTERVENTION To restore vision and to improve quality of life with minimal adverse effects of treatment.

OUTCOMES Uncorrected visual acuity; corrected visual acuity; speed and stability of visual rehabilitation; quality of life (including accidents); adverse effects of treatment such as endophthalmitis, vitreous loss, cystoid macular oedema and induced astigmatism (see glossary, p 846), retinal detachment.

METHODS *Clinical Evidence* search and appraisal March 2003.

QUESTION **What are the effects of surgery for age related cataract without other ocular co-morbidity?** New

OPTION MANUAL EXTRACAPSULAR CATARACT EXTRACTION

One RCT found that manual extracapsular extraction plus intraocular lens implant improved visual acuity and quality of life compared with intracapsular extraction plus aphakic glasses. The RCT also found a higher rate of complications with intracapsular extraction plus aphakic glasses then with manual extracapsular extraction plus intraocular lens implant.

Benefits:

Versus no extraction: We found no systematic review or RCTs comparing manual extracapsular extraction (see glossary, p 846) versus no extraction. There is consensus that the clinical and quality of life benefits of modern cataract removal are such that an RCT that includes non-intervention would be unethical. **Versus intracapsular extraction:** See glosssary, p 846. We found one RCT comparing manual extracapsular extraction plus intraocular lens implant versus intracapsular extraction plus aphakic glasses, with follow up lasting 1 year.[7–9] The RCT found that manual extracapsular extraction plus intraocular lens implant significantly improved visual acuity and quality of life compared with intracapsular extraction plus aphakic glasses (1 RCT, 3400 people aged range 40–75 years: best corrected vision 20/40 or better at 1 year: 1420/1474 [96.3%] with manual extracapsular extraction *v* 1271/1401 [90.7%] with intracapsular extraction; $P < 0.00001$; visual function and quality of life as assessed using a specifically designed and validated questionnaire showed an effect size difference 12 months after surgery of 0.61 in favour of manual extracapsular extraction in general visual function; 99% CI 0.33 to 0.89; $P < 0.00001$). In the study an effect size of 0.5 was considered "medium" and one of 0.8 was considered "large". **Versus phaco extracapsular extraction:** See glossary, p 846. See benefits of phaco extracapsular extraction, p 844.

Harms:

Versus intracapsular extraction: The RCT followed patients for 1 year and then reviewed random samples of the participants at 3 and 4 years.[7–10] It found a significantly higher rate of complications with intracapsular extraction plus aphakic glasses than with manual extracapsular extraction plus intraocular lens implant (clinical cystoid macular oedema [see glossary, p 846] at 6 months after surgery: 70/1558 [4%] *v* 26/1559 [2%]; RR 2.7, 95% CI 1.7 to 4.3; cumulative complications over the first year after surgery: 203/1401 [14%] *v* 113/1474 [8%]; RR 2.7, 95% CI 1.7 to 4.3; 4 year incidence of grade II or III [grading: I minor peripheral opacity only; II present in central zone with mild obscuration of fundus detail; III as II but with marked obscuration of fundus detail] posterior capsule opacification [see glossary, p 846] in a sample of the manual extracapsular extraction patients: 43/327 [13.1%]; 95% CI 9.7% to 17.3%). **Versus phaco extracapsular extraction:** See harms of phaco extracapsular extraction, p 844.

Comment: The RCT has particular relevance to the situation in the developing world.[7–10] The setting was a high volume service with experienced surgeons, and therefore the findings should be generalised with caution. The study also looked at two separate variables. The difference in visual acuity outcomes is accounted for by the combination of surgical technique and optical correction, whereas the complication differences result purely from different surgical technique. The posterior capsule opacification rate was less than might be expected given the techniques and intraocular lenses in use in the study.

OPTION PHACO EXTRACAPSULAR EXTRACTION (PHACOEMULSIFICATION)

We found no systematic review or RCTs comparing phaco extracapsular extraction versus no extraction. One RCT identified by a systematic review found improved vision up to 1 year after phaco extracapsular extraction plus foldable posterior chamber intraocular lens implant compared with manual extracapsular extraction plus rigid posterior chamber intraocular lens implant. The RCT and a systematic review of observational studies found that a higher proportion of people had complications with manual extracapsular extraction than with phaco extracapsular extraction.

Benefits: **Versus no extraction:** We found no systematic review or RCTs comparing phaco extracapsular extraction (see glossary, p 846) versus no extraction. There is consensus that the clinical and quality of life benefits of modern cataract removal are such that an RCT that includes non-intervention would be unethical. **Versus manual extracapsular extraction:** See glossary, p 846. We found one systematic review (search date 2001),[11] which identified one RCT that met the inclusion criteria.[12] The RCT found that phaco extracapsular extraction (phacoemulsification) plus foldable posterior chamber intraocular lens implant significantly improved vision up to 1 year after surgery compared with manual extracapsular extraction plus rigid posterior chamber intraocular lens implant (1 RCT, 476 people aged over 40 years, mean age 72.3 years [standard error 0.6 years] in the manual extracapsular extraction group *v* 71.1 years [standard error 0.6 years] in the phaco extracapsular extraction group: significantly higher proportion of good combined vision and refraction results at 6 weeks: 164/237 [69%] with phaco extracapsular extraction *v* 128/225 [57%] with manual extracapsular extraction; OR 1.22, 95% CI 1.06 to 1.40; proportion achieving 20/30 vision unaided: at 3 weeks 80/244 [33%] with phaco extracapsular extraction *v* 26/229 [11%] with manual extracapsular extraction; OR 2.89, 95% CI 1.93 to 4.33; at 1 year 87/224 [39%] with phaco extracapsular extraction *v* 42/215 [20%] with manual extracapsular extraction; OR 1.99, 95% CI 1.45 to 2.73). Primary outcome measure was visual acuity (20/30 or better and refraction within 1 dioptre of planned) and secondary outcome was unaided visual acuity.[11]

Harms: **Versus no extraction:** We found no systematic review or RCTs comparing phaco extracapsular extraction versus no extraction. **Versus manual extracapsular extraction:** The RCT identified by

the systematic review[11] found that a significantly greater proportion of people had complications with manual extracapsular extraction than with phaco extracapsular extraction (complications during surgery: 48/233 [21%] with manual extracapsular extraction *v* 17/246 [7%] with phaco extracapsular extraction; $P < 0.0001$; posterior capsule opacification (see glossary, p 846) at 1 year: 68/232 [29%] with manual extracapsular extraction *v* 48/245 [20%] with phaco extracapsular extraction; OR 1.7, 95% CI 1.1 to 2.7; laser capsulotomy rates: absolute numbers not given; OR 2.1, 95% CI 1.0 to 4.5; suture removal within 3 months of surgery: 85/232 [37%] with manual extracapsular extraction *v* 8/245 [3%] with phaco extracapsular extraction; $P < 0.0001$).[12] The RCT evaluated the level of astigmatism and its course during follow up, capsule rupture, and vitreous loss (see glossary, p 846) during surgery, and the incidence of posterior capsule opacification during 1 year of follow up as primary outcomes, and perioperative difficulties and other complications (both serious and rare, and uncommon but visually impairing) as secondary outcomes.[12]
We also found another systematic review (search date not stated; earliest and latest papers cited dated 1979 and 1991, respectively; 90 observational studies) assessing complications following manual extracapsular cataract extraction with posterior chamber intraocular lens implantation, phaco extracapsular cataract extraction with posterior chamber intraocular lens implantation, or intracapsular cataract extraction with flexible anterior chamber intraocular lens implantation.[13] Major complications found by the systematic review were endophthalmitis (see glossary, p 846) (16 studies, 30 656 eyes: 0.13%, 95% CI 0.09% to 0.17%), retinal detachment (42 studies, 33 603 eyes: 0.7%, 95% CI 0.6% to 0.8%), and bullous keratopathy (27 studies, 15 971 eyes: 0.3%, 95% CI 0.2% to 0.4%). Less serious complications showing statistically significant differences ($P < 0.05$) — all in favour of phaco extracapsular extraction — were as follows: angiographic cystoid macular oedema (see glossary, p 846) (phaco extracapsular extraction 2.62% [2 studies, 873 eyes] *v* manual extracapsular cataract extraction 8.91% [2 studies, 393 eyes]), iris trauma (phaco extracapsular extraction 0.7% [2 studies, 2033 eyes] *v* manual extracapsular cataract extraction 4.0% [6 studies, 1314 eyes]), and vitreous loss (phaco extracapsular extraction 0.24% [4 studies, 2732 eyes] *v* manual extracapsular cataract extraction 1.08% [22 studies, 7284 eyes]).

Comment: Phaco extracapsular extraction (phacoemulsification) has largely superseded manual extracapsular cataract extraction in the developed world, based on clinical impression. The one RCT is therefore important as a randomised study of the two techniques.[12] The study was specifically designed to employ operating surgeons who were experienced in both techniques. The level of postoperative vision targeted was more demanding than in the studies reported in the other systematic review.[13] This reflects the more demanding expectations in relation to outcomes that were prevalent when the study was designed, as compared with the 1980s, when most studies included in the earlier systematic review were conducted.

Cataract

GLOSSARY

Cystoid macular oedema is not true oedema but a condition in which fluid accumulates in cyst-like spaces in the outer plexiform layer of the retina. It is usually self limiting but can result in permanent reduction in visual acuity. It is thought to be associated with breakdown of the blood–retina barrier and is more common after complicated surgery.

Endophthalmitis is literally inflammation of some or all parts of the eye. It is normally, if not qualified as in this topic, taken to be the condition caused by postoperative infection.

Induced astigmatism is the change in refractive power of the cornea in different meridians as a result of the change in shape caused by surgical incisions.

Intracapsular extraction is removal of the entire lens and capsule.

Manual extracapsular extraction is removal of the anterior capsule and lens contents (nucleus and cortex) *en bloc* without using ultrasound or other methods of breaking up the nucleus before removal. The posterior capsule is left behind. This technique is commonly referred to as "extracapsular extraction".

Phaco extracapsular extraction (phacoemulsification) is use of ultrasound to break up the lens nucleus for less invasive extraction through a smaller incision. The posterior capsule is left behind as in manual extracapsular extraction. This technique is commonly referred to as "phacoemulsification".

Posterior capsule opacification is opacification of the posterior capsule (which is left behind at the end of an extracapsular or phaco cataract extraction). When it occurs it is usually progressive and can result in reduced visual function.

Snellen visual acuity is a measure of one aspect of vision, namely the ability to discriminate two points in a 100% contrast target (pure black and white). For example, 6/6 (20/20) is considered as "normal vision" whereas 6/60 (20/200) indicates that the person can read at 6 metres a letter that a person with "normal vision" could read at 60 metres.

Vitreous loss is loss of the vitreous gel that normally fills the posterior segment (behind the lens) of the eye. Its loss during intracapsular cataract surgery, or in the presence of rupture of the posterior capsule in extracapsular surgery can give rise to potentially sight threatening complications.

Prevention of diabetic retinopathy (see glycaemic control in diabetes, p 753)

In this chapter terms used in the UK are written in normal text, and visual acuities are presented in units of metres; where terms used in the USA are different they are written in italics and visual acuities are presented in units of feet (see table 1, p 857).

See glossary, p 854

Key Messages

Diabetic retinopathy

- **Control of diabetes** See glycaemic control in diabetes, p 753.
- **Control of hypertension** See primary prevention, p 163.

- **Macular photocoagulation to macular microaneurysus in people with clinically significant macular oedema** One large RCT has found that laser photocoagulation to the macula reduces visual loss at 3 years in eyes with macular oedema plus mild to moderate diabetic retinopathy compared with no treatment. There was some evidence of greater benefit in eyes with better vision. Subgroup analysis found that focal laser treatment reduced visual loss in eyes with clinically significant macular oedema, particularly in people in whom the centre of the macula was involved or imminently threatened.
- **Peripheral retinal laser photocoagulation in people with preproliferative (*moderate/severe non-proliferative**) retinopathy and maculopathy** RCTs in eyes with preproliferative retinopathy and maculopathy have found that peripheral retinal photocoagulation reduces the risk of severe visual loss at 5 years compared with no treatment.
- **Peripheral retinal laser photocoagulation in people with proliferative retinopathy** RCTs have found that peripheral retinal photocoagulation reduces the risk of severe visual loss at 2–3 years compared with no treatment. One RCT in eyes with high risk proliferative diabetic retinopathy found that low intensity argon laser reduced vitreous haemorrhage and macular oedema compared with standard intensity argon laser. It found no significant difference between treatments for visual acuity, although it may have lacked power to detect clinically important effects.
- **Grid photocoagulation to zones of retinal thickening in people with diabetic maculopathy** One RCT found that grid photocoagulation improved visual acuity in treated eyes at 12 months and at 24 months compared with no treatment. Photocoagulation reduced the risk of moderate visual loss by 50–70% compared with no treatment.
- **Macular photocoagulation in people with maculopathy but without clinically significant macular oedema** We found no RCTs of macular photocoagulation in this population.
- **Peripheral retinal laser photocoagulation in people with background or preproliferative (*non-proliferative**) retinopathy without maculopathy** We found no RCTs in people with background or preproliferative retinopathy without maculopathy.

Vitreous haemorrhage

- **Vitrectomy in people with severe vitreous haemorrhage and proliferative retinopathy (if performed early)** One RCT found that early vitrectomy reduced visual loss at 1, 2, and 3 years in eyes with severe vitreous haemorrhage and proliferative retinopathy compared with deferred (for 1 year) vitrectomy.
- **Vitrectomy in people with maculopathy** The role of vitrectomy in this population remains unclear.

*Terms in italics indicate US definitions

DEFINITION Diabetic retinopathy is characterised by varying degrees of microaneurysms, haemorrhages, exudates *(hard exudates)*, venous changes, new vessel formation, and retinal thickening. It can involve the peripheral retina, the macula, or both. The range of severity of retinopathy includes background *(mild non-proliferative)*, preproliferative *(moderate/severe non-proliferative)*, proliferative and advanced retinopathy (see glossary, p 854). Involvement of the macula can be focal, diffuse, ischaemic (see glossary, p 855), or mixed.

Diabetic retinopathy

INCIDENCE/ PREVALENCE Diabetic eye disease is the most common cause of blindness in the UK, responsible for 12% of registrable blindness in people aged 16–64 years.[1]

AETIOLOGY/ RISK FACTORS Risk factors include age, duration and control of diabetes, raised blood pressure, and raised serum lipids.[2]

PROGNOSIS Natural history studies from the 1960s found that at least half of people with proliferative diabetic retinopathy progressed to Snellen visual acuity (see glossary, p 855) of less than 6/60 (*20/200*) within 3–5 years.[3–5] After 4 years' follow up, the rate of progression to less than 6/60 *(20/200)* visual acuity in the better eye was 1.5% in people with type 1 diabetes; 2.7% in people with non-insulin requiring type 2 diabetes, and 3.2% in people with insulin requiring type 2 diabetes.[6]

AIMS OF INTERVENTION To prevent visual disability, partial sight and blindness; to improve quality of life, with minimum adverse effects.

OUTCOMES Visual acuity (measured using a Snellen chart, unless otherwise stated — see glossary, p 855). Incidence of visual disability (visual acuity 6/24 [*20/80*] or worse in the better eye), partial sight registration (visual acuity 6/60 [*20/200*] or worse in the better eye), and registrable blindness (visual acuity 3/60 [*10/200*] or worse in the better eye). Much of the published data used eyes as the unit of analysis rather than people. Significant loss of vision is often defined as loss of two or more Snellen lines of acuity (vision measured on standard Snellen chart) roughly equivalent to doubling of the visual angle (visual angle is the angle subtended at the eye of the smallest letter visible by that eye) — a measure used extensively in research.

METHODS *Clinical Evidence* search and appraisal May 2003. Additional papers were identified from manual searches. Figures for numbers needed to treat and numbers needed to harm refer to the number of eyes rather than patients.

QUESTION **What are the effects of treatment for diabetic retinopathy?**

OPTION **PERIPHERAL RETINAL LASER PHOTOCOAGULATION**

RCTs have found that peripheral retinal photocoagulation reduces the risk of severe visual loss in eyes with preproliferative (*moderate/severe non-proliferative*) retinopathy and maculopathy, proliferative retinopathy, and proliferative retinopathy with high risk characteristics compared with no treatment. We found no RCTs in people with preproliferative (*moderate/severe non-proliferative*) retinopathy without maculopathy. We found no evidence that one type of laser is better than another. One RCT in eyes with high risk proliferative diabetic retinopathy found that low intensity argon laser reduced vitreous haemorrhage and macular oedema compared with standard intensity argon laser, although the study may have lacked power to detect clinically important effects on visual acuity.

Benefits: **Versus no treatment:** We found no systematic review, but found six RCTs (7 publications) (see table 2, p 858),[7–13] which recruited people with different grades of diabetic retinopathy, and compared

different regimens of peripheral retinal photocoagulation with no treatment or with deferred treatment. Two RCTs recruited only people with proliferative diabetic retinopathy (see glossary, p 855); both found that peripheral photocoagulation significantly reduced the risk of blindness after 2 or 3 years compared with no treatment (see table 2, p 858).[7,8] Two large RCTs recruited people with either preproliferative (see glossary, p 855) (*moderate/severe non-proliferative*) or proliferative retinopathy.[9,10,13] Both found that early photocoagulation decreased the risk of severe visual loss at 5 years compared with no early photocoagulation, but in one of the RCTs, the rate of severe visual loss was low and the effect was not significant (see table 2, p 858). A subgroup analysis[14] of one of these RCTs[10,13] found that the benefit was significant in people with type 2 diabetes and with severe preproliferative (*severe non-proliferative*) or early proliferative retinopathy without high risk characteristics (see glossary, p 855) (data presented graphically). The other two RCTs recruited only people with preproliferative (*moderate/severe non-proliferative*) diabetic retinopathy, but most of the people in these RCTs had diabetic maculopathy.[11,12] Both RCTs found that peripheral photocoagulation significantly reduced the risk of visual deterioration at 5 years compared with no treatment. We found no RCTs of photocoagulation in people with preproliferative (*moderate/severe non-proliferative*) retinopathy who have not yet developed maculopathy (see table 2, p 858).
Different types of laser: We found no systematic review. A large multicentre RCT found no difference in effectiveness between krypton red and argon laser in the treatment of proliferative diabetic retinopathy with new vessels on the disc.[15] A smaller RCT (42 eyes with proliferative diabetic retinopathy) compared argon with double frequency YAG lasers and found no difference in rates of regression of new vessels after mean follow up of 29 months.[16] **Low versus standard intensity laser:** We found one RCT (50 people; 65 eyes with high risk proliferative diabetic retinopathy), which compared low intensity argon laser (minimum energy to produce barely visible blanching of the epithelium, median 235 mW; mean follow up of 22.4 months) versus standard intensity argon laser (median 450 mW; mean followup of 21.6 months).[17] It found no significant difference between treatments in visual acuity (mean visual acuity on logMAR chart (see glossary, p 855) 0.18 in eyes treated with low intensity laser *v* 0.27 in eyes treated with standard intensity laser, P = 0.231).

Harms:

Adverse effects were reported as being more common in the photocoagulation arm and include loss of visual field and visual acuity,[16,18,19] increased glare,[20] reduced contrast[20,21] and colour sensitivity,[22] temporary choroidal effusion, anterior uveitis, worsening macular oedema, and pain during treatment. Most studies were too small to provide accurate estimates of the frequency of these adverse effects, and they probably overestimate the risks because they used old treatment protocols. In one RCT, using an argon treatment protocol that has since been modified in current practice, constriction of visual field to within 45° of fixation occurred in 5% of eyes (NNH 20), constriction within 30° in 0%, and loss of vision by two or more Snellen lines in 3% (NNH 33).[9] **Fractionation:** One

RCT found that adverse effects (including exudative retinal detachment, choroidal detachment, and angle closure) were reduced if photocoagulation was administered in multiple sessions spaced over time rather than in a single session [23] **Different types of laser:** We found no clear evidence of different rates of complications with different lasers. Argon blue/green causes temporarily reduced colour sensation in treating surgeons. Dye laser[24] and orange laser (600 nm)[25] may be more painful than argon for peripheral retinal photocoagulation.[23] **Low versus standard intensity laser:** The RCT comparing low with high intensity laser found that low intensity laser significantly reduced clinically significant macular oedema and vitreous haemorrhage (see glossary, p 855) compared with standard intensity laser, but found no significant difference for choroidal detachment or neurotrophic keratopathy (clinically significant macular oedema: 1 eye treated with low intensity laser *v* 7 with standard intensity, $P = 0.023$; vitreous haemorrhage: no eyes *v* 6 eyes, $P = 0.009$; choroidal detachment: no eyes *v* 3 eyes, $P = 0.103$; neurotrophic keratopathy: no eyes *v* 2 eyes, $P = 0.224$).[17]

Comment: Limited prospective observational data suggest that peripheral retinal photocoagulation should be repeated until there is evidence of regression.[25] We found no evidence that theoretical advantages with certain lasers are reflected in significant improvements in clinical outcomes. Studies of visual field loss do not consider field loss before laser photocoagulation; one study found significant field loss in people with diabetes before laser compared with people without diabetes ($P < 0.01$).[26] We found one meta-analysis[27] of photocoagulation versus no treatment for diabetic retinopathy; its results are difficult to interpret because it was not based on a published systematic review, it did not include the largest RCT,[10] and it included one RCT of macular photocoagulation.[28]

OPTION MACULAR LASER PHOTOCOAGULATION FOR MACULOPATHY

RCTs have found that laser photocoagulation to the macula reduces visual loss at 2–3 years in eyes with macular oedema plus mild to moderate preproliferative *(moderate/severe non-proliferative)* diabetic retinopathy compared with no treatment. There was some evidence of greater benefit in eyes with better vision. Subgroup analysis in one large RCT found that focal laser treatment reduced visual loss in eyes with clinically significant macular oedema compared with no treatment, particularly in people in whom the centre of the macula was involved or imminently threatened. Effects of photocoagulation in other categories of maculopathy remain unclear. We found no evidence that one type of laser is better than another in diabetic maculopathy.

Benefits: **Versus no treatment:** We found no systematic review. We found three RCTs comparing macular argon laser photocoagulation with no treatment in eyes with maculopathy, two using focal treatment to micoraneurysms,[28–30] and one using a grid to zones of thickened retina.[31] **Focal treatment to microaneurysms:** The first RCT (39 people with symmetrical macular oedema and preproliferative [*moderate/severe non-proliferative*] diabetic retinopathy — see

glossary, p 855), found no significant difference in the incidence of visual deterioration between photocoagulation and no treatment after 2 years, but the study may have lacked power to detect a clinically important difference (visual deterioration of 30 completing eyes: 7/30 [23%] eyes with laser *v* 13/30 [43%] eyes with no treatment; RR 0.54, 95% CI 0.25 to 1.16).[28] The second and much larger RCT (2244 people with macular oedema plus mild to moderate pre-plofierative retinopathy) compared focal laser treatment (see glossary, p 855) using an argon laser versus no treatment.[30] It found that laser photocoagulation significantly reduced the risk of moderate visual loss compared with no treatment after 3 years (RR 0.50, 95% CI 0.47 to 0.53; NNT 8 eyes, 95% CI 7 to 12). Subgroup analysis found that focal laser treatment was significantly more effective in eyes with clinically significant macular oedema (see glossary, p 854), particularly in people in whom the centre of the macula was involved or imminently threatened.[13,32] The benefit was less in eyes with less extensive macular oedema. However, this may have been because both groups had low rates of visual loss from baseline. **Grid laser to zones of retinal thickening:** The third RCT (160 eyes with diffuse maculopathy with or without clinically significant macular oedema) found that grid laser photocoagulation (see glossary, p 855) significantly reduced loss of visual acuity compared with no treatment at 12 months (RR 0.84; NNT 4 eyes, 95% CI 3 eyes to 9 eyes) and at 24 months (RR 0.78, 95% CI 0.60 to 0.96; NNT 3 eyes, 95% CI 2 eyes to 7 eyes).[31] Photocoagulation reduced the risk of moderate visual loss (defined as a doubling of the visual angle, equivalent to loss of about two Snellen lines) by 50–70%.[30,31] **Different types of laser:** We found no systematic review. Several small RCTs have found no difference between argon, diode, krypton red, and dye lasers in people with diabetic maculopathy.

Harms: Uncontrolled studies reported that loss of contrast sensitivity and visual acuity occurred after direct application of the laser to the centre of the fovea. We found no accurate estimates of the frequency of adverse effects. **Focal treatment to microaneurysms:** The largest RCT found no significant difference in the frequency of immediate visual loss in treated compared with untreated people.[30] One prospective observational study reported a 40% reduction in macular function measured using the pattern electroretinogram in people undergoing focal argon paramacular treatment.[33] Other complications include laser damage to the centre of the fovea and induction of choroidal neovascularisation, but we found no reliable data on frequency. **Grid laser to zones of retinal thickening:** In the relevant RCT, paracentral grid like scotomas or haze were visible to most people treated with grid photocoagulation, but the data were insufficient to estimate the frequency of this effect.[31]

Comment: The benefits of laser photocoagulation are less notable in people with maculopathy than in those with proliferative retinopathy. RCTs are needed to compare efficacy and harm of focal and grid laser

protocols (see glossary, p 855). We found no evidence that theoretical advantages of certain types of laser result in significant improvements in clinical outcomes. The RCT examining grid laser to zones of retinal thickening had some loss to follow up.[31] The 12 month analysis was conducted on 149 people and the 24 month analysis on 79 people.

QUESTION What are the effects of treatments for vitreous haemorrhage?

OPTION VITRECTOMY

One RCT with 4 years' follow up found that vitrectomy reduced visual loss if performed early in people with vitreous haemorrhage, especially in those with severe proliferative retinopathy. Its role in people with both vitreous haemorrhage and diabetic maculopathy remains unclear.

Benefits: We found no systematic review. **In retinopathy:** We found one RCT comparing early vitrectomy or deferral of vitrectomy for 1 year in 616 eyes with proliferative retinopathy and recent severe vitreous haemorrhage (see glossary, p 855) (reducing visual acuity to ≤ 2/60 [*5/200*]).[34] At 1, 2, and 3 years after treatment, eyes in the early treatment group were significantly more likely to have visual acuity of at least 6/12 (*20/40*) than those in the deferred treatment group (at 2 years: RR with vitrectomy *v* deferred vitrectomy for visual acuity < 6/12 0.84; ARR 10%; NNT 10, 95% CI 6 to 29; see comment below). **In maculopathy:** We found no RCTs.

Harms: A retrospective study of 260 eyes treated with vitrectomy reported neovascular glaucoma in 6%, retinal detachment in 8%, and cataract in 27%.[35] Glaucoma was more likely in people with associated preoperative retinal detachment. In one RCT, the use of preoperative intravitreal tissue plasminogen activator failed to reduce the rate of complications in 56 patients undergoing vitrectomy for the complications of proliferative diabetic retinopathy.[36]

Comment: Four year follow up data were available for 370/616 eyes in the RCT.[34] Subgroup analyses found a greater benefit in people with type 1 diabetes than in those with type 2 diabetes, and found greater benefit in people with more severe levels of proliferative retinopathy (visual acuity at least 10/20: 59% with early treatment and 35% with deferred treatment in people with type 1 diabetes *v* 14% with early treatment and 11% with deferred treatment in people with type 2 diabetes; 44% with early treatment and 40% with deferred treatment in eyes with least severe new vessels *v* 35% with early treatment and 10% with deferred treatment in eyes with very severe new vessels).[37]

GLOSSARY

Advanced retinopathy Retinopathy characterised by tractional retinal detachment (see below), vitreous haemorrhage obscuring fundus details, or both.

Background retinopathy (*mild non-proliferative*) Characterised by microaneurysms, small haemorrhages, and exudates *(hard exudates)*.

Clinically significant macular oedema Characterised by one or more of the following: retinal thickening at or within 500 μm of the centre of the fovea; exudates

(hard exudates) at or within 500 μm of the centre of the fovea when accompanied by retinal thickening; one or more disc area(s) of thickening extending to within one disc diameter of the centre of the fovea. This is a clinical feature of maculopathy common to many eyes with maculopathy and indicates a significant threat to vision.

Diffuse exudative maculopathy Characterised by thickened oedematous retina at the fovea, often with cystic changes.

Focal exudative maculopathy Characterised by exudates *(hard exudates)* within one disc diameter of the centre of the fovea or circinate rings of exudates *(hard exudates)* within the macula.

Focal laser treatment Laser applied directly to microaneurysms.

Grid laser treatment Laser applied in a grid pattern to zones of retinal thickening, zones of capillary non-perfusion, or both.

High risk characteristics (1) New vessels at the disc extending over at least a third of the disc area; and/or (2) new vessels at the disc extending over less than a third of the disc area or new vessels elsewhere extending over at least half of the disc area, both in the presence of vitreous or pre-retinal haemorrhage.

Ischaemic maculopathy Characterised by zones of capillary non-perfusion visible only on fluorescein angiography but often inferred from presence of deep blot haemorrhages within the fovea.

logMAR chart A tool for measuring visual acuity, similar to but more precise than a Snellen chart. The chart is typically read at 4 m and scored from the total number of letters read. A score of 1.0 is equivalent to Snellen acuity 6/60 and indicates that all 5 letters on the top line, but no others, were read. A score of 0.1 is equivalent to Snellen acuity 6/6.

Preproliferative retinopathy Mild, moderate, or severe *(moderate or severe non-proliferative)* depending on number/location of lesions; characterised by cotton wool spots, deep round haemorrhages, venous beading, loops and reduplication, and intraretinal microvascular anomalies.

Proliferative retinopathy Characterised by new vessels at the disc or elsewhere.

Snellen visual acuity The Snellen chart usually includes letters, numbers, or pictures printed in lines of decreasing size, which are read or identified from a fixed distance; distance visual acuity is usually measured from a distance of 6 m *(20 feet)*. The Snellen visual acuity is written as a fraction: 6/18 means that from 6 m away the best line that can be read is a line that could normally be read from a distance of 18 m away.

Tractional retinal detachment Fibrous scar tissue between the vitreous humour and retina pulls the retina away from the underlying retinal pigment epithelium. This type of retinal detachment is most common in the proliferative diabetic retinopathy.

Vitrectomy The vitreous is the normally clear gelatinous material that fills most of the inside of the eye. The vitreous can be affected by bleeding, inflammatory cells, debris, or scar tissue. Vitrectomy involves removal of the abnormal vitreous material.

Vitreous haemorrhage Bleeding into the vitreous of the eye from blood vessels arising from the retina.

In these columns, a blank means that the RCT did not explicitly state if included people had that characteristic. 'All': only people with that characteristic were included; 'Yes': some people with that characteristic were included; 'No': all people with that characteristic were explicitly excluded.
*Where necessary, relative risks were calculated by *Clinical Evidence* using absolute risks stated in each RCT.
†RCT reported percentages and did not provide absolute numbers. Hazard ratio taken from the published report based on Cox proportional hazards model.
‡The indication for vitrectomy changed halfway through the RCT. Initially vitrectomy was performed only after onset of severe visual loss. Later, it was performed 1–6 months after severe vitreous haemorrhage.

Key Messages

Primary open angle glaucoma

- **Laser trabeculoplasty (versus control or medical treatment)** One RCT in people with newly diagnosed glaucoma found that treatment with laser trabeculoplasty plus topical medical treatment to lower intraocular pressure reduced progression of glaucoma compared with control. One RCT found that, compared with medical treatment alone, combined treatment with initial laser trabeculoplasty followed by medical treatment reduced intraocular pressure and deterioration in optic disc appearance, and improved visual fields after a mean of 7 years.

- **Topical medical treatment (some RCTs included people with primary open angle glaucoma, primary open angle glaucoma or ocular hypertension, or ocular hypertension alone)** One systematic review that included RCTs of people with primary open angle glaucoma or ocular hypertension alone found limited evidence that topical medical treatments reduced intraocular pressure after a minimum follow up of 3 months or longer compared with placebo, but found no significant difference between treatments in visual field loss on follow up of 1 year or longer. The systematic review did not clearly define the medical treatments involved. One subsequent large RCT in people with ocular hypertension but no evidence of glaucomatous damage found that topical treatment lowering intraocular pressure reduced the probability of developing primary open angle glaucoma after 5 years compared with control. One RCT found that, compared with medical treatment alone, combined treatment with initial laser trabeculoplasty followed by medical treatment reduced intraocular pressure and deterioration in optic disc appearance, and improved visual fields after a mean of 7 years. Two RCTs found that surgical trabeculectomy reduced both visual field loss and intraocular pressures compared with medical treatment, but found no significant difference between treatments in visual acuity after about 5 years.
- **Surgical trabeculectomy** Two RCTs found that surgical trabeculectomy reduced both visual field loss and intraocular pressures compared with medical treatment, but found no significant difference between treatments in visual acuity after about 5 years. Two RCTs found that surgical trabeculectomy reduced intraocular pressure compared with laser trabeculoplasty, but found mixed effects for changes in visual acuity after 5–7 years. Observational studies have found limited evidence that surgical trabeculectomy may reduce central vision.
- **Laser trabeculoplasty (versus surgical treatment)** Two RCTs found that laser trabeculoplasty reduced intraocular pressures less than surgical trabeculectomy, but found mixed effects for changes in visual acuity after 5–7 years.

Normal tension glaucoma

- **Medical treatments for lowering intraocular pressure in normal pressure glaucoma** One RCT found that surgical or medical treatment reduced progression of visual field loss after 8 years compared with no treatment.
- **Surgical treatments for lowering intraocular pressure in normal pressure glaucoma** One RCT found that surgical or medical treatment reduced progression of visual field loss after 8 years compared with no treatment, but found that surgery increased cataract formation after 8 years.

Acute angle closure glaucoma

- **Medical treatments of acute angle closure glaucoma** We found no placebo controlled RCTs, but strong consensus suggests that medical treatments are effective. One RCT found no significant difference in intraocular pressure after 2 hours with low dose pilocarpine versus an intensive pilocarpine regimen versus pilocarpine ocular inserts. We found no RCTs of other medical treatments.
- **Surgical treatments of acute angle closure glaucoma** We found no placebo controlled RCTs, but strong consensus suggests that surgical treatments are effective. One RCT found no significant difference between surgical iridectomy and laser iridotomy in visual acuity or intraocular pressure after 3 years.

Glaucoma

DEFINITION

Glaucoma is a group of diseases characterised by progressive optic neuropathy. It is usually bilateral but asymmetric and may occur at any point within a wide range of intraocular pressures. All forms of glaucoma show optic nerve damage (cupping and/or pallor) associated with peripheral visual field loss. **Primary open angle glaucoma** occurs in people with an open drainage angle and no secondary identifiable cause. Although the understanding of the natural history of these conditions is not complete, it is thought that the problem starts with an intraocular pressure that is too high for the optic nerve even though, in a significant proportion (about 40%), this may be within statistically defined normal range. The term ocular hypertension generally applies to eyes with an intraocular pressure greater than the statistical upper limit of normal (about 21 mm Hg). However, only a relatively small proportion of eyes with raised intraocular pressure have an optic nerve that is vulnerable to its effects (about 10%). But because intraocular pressure is the main and only modifiable risk factor for the disease, studies on the effectiveness of reducing intraocular pressure often include people with both ocular hypertension and primary open angle glaucoma. Previously, trialists were anxious about withholding active treatment in overt primary open angle glaucoma so many placebo or no treatment trials selected people just with ocular hypertension. Trials comparing treatments often include both, but in these, the outcome is usually intraocular pressure alone. **Normal tension glaucoma** occurs in people with intraocular pressures that are consistently below 21 mm Hg (2 standard deviations above the population mean). **Acute angle closure glaucoma** is a rapid and severe rise in intraocular pressure caused by physical obstruction of the anterior chamber drainage angle.

INCIDENCE/ PREVALENCE

Glaucoma occurs in 1–2% of white people aged over 40 years, rising to 5% at 70 years. Primary open angle glaucoma accounts for two thirds of those affected, and normal tension glaucoma for about a quarter.[1,2] In black people glaucoma is more prevalent, presents at a younger age with higher intraocular pressures, is more difficult to control, and is the main irreversible cause of blindness in black populations of African origin.[1,3] Glaucoma related blindness is responsible for 8% of new blind registrations in the UK.[4]

AETIOLOGY/ RISK FACTORS

The major risk factor for developing primary open angle glaucoma is raised intraocular pressure. Lesser risk factors include family history and ethnic origin. The relationship between systemic blood pressure and intraocular pressure may be an important determinant of blood flow to the optic nerve head and, as a consequence, may represent a risk factor for glaucoma.[5] Systemic hypotension, vasospasm (including Raynaud's disease and migraine), and a history of major blood loss have been reported as risk factors for normal tension glaucoma in hospital based studies. Risk factors for acute angle closure glaucoma include family history, female sex, being long sighted, and cataract. A recent systematic review did not find any evidence supporting the theory that routine pupillary dilatation with short acting mydriatics was a risk factor for acute angle closure glaucoma.[6]

PROGNOSIS Advanced visual field loss is found in about 20% of people with primary open angle glaucoma at diagnosis,[7] and is an important risk factor for glaucoma related blindness.[8] Blindness results from gross loss of visual field or loss of central vision. Once early field defects have appeared, and where the intraocular pressure is greater than 30 mm Hg, untreated people may lose the remainder of the visual field in 3 years or less.[9] As the disease progresses, people with glaucoma have difficulty moving from a bright room to a darker room, and judging steps and kerbs. Progression of visual field loss is often slower in normal tension glaucoma. Acute angle glaucoma leads to rapid loss of vision, initially from corneal oedema and subsequently from ischaemic optic neuropathy.

AIMS OF INTERVENTION To prevent progression of visual field loss and to minimise adverse effects of treatment.

OUTCOMES Visual acuity; visual fields; onset of glaucoma. Optic disc cupping and intraocular pressure are surrogate outcomes.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments for established primary open angle glaucoma?

OPTION TOPICAL MEDICAL TREATMENT

One systematic review that included RCTs of people with primary open angle glaucoma or ocular hypertension alone found limited evidence that topical medical treatments reduced intraocular pressure after a minimum follow up of 3 months or longer compared with placebo, but found no significant difference between treatments in visual field loss on follow up of 1 year or longer. The systematic review did not clearly define the medical treatments involved. One subsequent large RCT in people with ocular hypertension but no evidence of glaucomatous damage found that topical treatment lowering intraocular pressure reduced the probability of developing primary open angle glaucoma after 5 years compared with control. One RCT found that, compared with medical treatment alone, combined treatment with initial laser trabeculoplasty followed by medical treatment reduced intraocular pressure and deterioration in optic disc appearance, and improved visual fields after a mean of 7 years. Two RCTs found that surgical trabeculectomy reduced both visual field loss and intraocular pressures compared with medical treatment, but found no significant difference between treatments in visual acuity after about 5 years.

Benefits: We found one systematic review (search date 1991, 16 placebo controlled RCTs, 86 comparative RCTs, 5000 people; see comment below)[10] and one subsequent RCT.[11] The systematic review included RCTs of people with primary open angle glaucoma, primary open angle glaucoma or ocular hypertension, and ocular hypertension alone.[10] The review found six placebo controlled RCTs with a minimum follow up of 3 months or longer. It found that medical treatment significantly reduced mean intraocular pressure after a minimum follow up of 3 months or longer compared with placebo (6 RCTs, 452 people; mean reduction in intraocular pressure

4.9 mm Hg, 95% CI 2.5 mm Hg to 7.3 mm Hg).[10] The review found three placebo controlled RCTs that provided data on visual field loss. Follow up in the three RCTs was in excess of 1 year. It found no significant difference between medical treatment and placebo in visual field loss after follow up of 1 year or longer (3 RCTs, 306 people; pooled OR for any worsening of visual field loss 0.75, 95% CI 0.42 to 1.35).[10] The subsequent large RCT (1636 people, age 40–80 years, raised intraocular pressure, no evidence of glaucomatous damage) compared topical treatment (any commercially available topical ocular hypotensive medication) versus close observation.[11] People in the RCT had an intraocular pressure between 24–32 mm Hg in one eye and between 21–32 mm Hg in the other eye. The aim of treatment was to reduce intraocular pressure by at least 20%. The development of primary open angle glaucoma was defined by a reproducible visual field abnormality or reproducible optic disc deterioration in one or both eyes.[11] Disc and visual field changes were determined by masked certified readers and then by a masked end point committee. The average reduction in intraocular pressure was 22.5 ± 9.9% with topical treatment compared with 4 ± 11.6% with control.[11] The RCT found that topical treatment significantly reduced the cumulative probability of developing primary open angle glaucoma after 5 years compared with control (Kaplan-Meier; 4.4% with treatment *v* 9.5% with control; HR 0.40, 95% CI 0.27 to 0.59; see comment below). **Versus laser trabeculoplasty:** See benefits of laser trabeculoplasty, p 865. **Versus surgical trabeculoplasty:** See benefits of surgical trabeculoplasty, p 866.

Harms: Systemic adverse effects of topical treatments are uncommon but may be serious, including exacerbation of chronic obstructive airways disease after use of non-selective topical β blockers. Non-selective topical β blockers can also cause systemic hypotension and reduction in resting heart rate.[12] The subsequent RCT in people with ocular hypertension found that a significantly higher percentage of people in the treatment group reported ocular symptoms (57% with treatment *v* 47% with control; $P < 0.001$) or symptoms affecting the skin, hair, or nails (23% with treatment *v* 18% with control; $P < 0.001$).[11] The most common symptoms affecting the eyes were dryness, tearing, and itching.

Comment: The systematic review did not separately report the inclusion/exclusion criteria or the topical medical treatments or regimens used in the placebo controlled RCTs included in the review.[10] The review reported that in general, over all included studies (102 RCTs), treatment schedules and selection and eligibility criteria varied widely across trials.[10] The subsequent RCT in people with ocular hypertension noted that the results did not imply that all people with borderline or elevated intraocular pressure should receive medication, rather, decisions should be based on individual circumstances and individual risk factors for developing primary open angle glaucoma.[11] The European Glaucoma Prevention Study is due to present its findings soon.

OPTION LASER TRABECULOPLASTY

One RCT in people with newly diagnosed glaucoma found that treatment with laser trabeculoplasty plus topical medical treatment to lower intraocular pressure reduced progression of glaucoma compared with control. One RCT found that, compared with medical treatment alone, combined treatment with initial laser trabeculoplasty followed by medical treatment reduced intraocular pressure and deterioration in optic disc appearance, and improved visual fields after a mean of 7 years. Two RCTs found that surgical trabeculectomy reduced intraocular pressure compared with laser trabeculoplasty, but found mixed effects for changes in visual acuity after 5–7 years.

Benefits: We found no systematic review, but found four RCTs.[13–16] **Versus no treatment:** One RCT (255 people, age 50–80 years, newly detected open angle glaucoma, previously untreated) compared treatment using laser trabeculoplasty (see glossary, p 869) plus topical betaxolol hydrochloride to lower intraocular pressure versus no initial treatment.[13] The progression of glaucoma was defined by objective visual field changes and/or optic disc changes in one or both eyes of the person. Disc changes were assessed by two masked graders using flicker chronoscopy. Visual field changes were determined by using pattern deviation glaucoma change probability maps. On average, treatment reduced intraocular pressure by 25% from baseline, whilst intraocular pressure was unchanged from baseline in the control group.[13] The RCT found that laser trabeculoplasty plus topical betaxolol hydrochloride significantly reduced the proportion of people with progression of glaucoma after 6 years compared with control (definite visual field and optic disc progression: 58/129 [45%] with treatment *v* 78/126 [62%] with control; P = 0.007). It found that the average time to progression was longer with laser trabeculoplasty plus topical betaxolol hydrochloride compared with control (median time to progression: 66 months with treatment *v* 48 months with control; P value not reported). **Versus medical treatment:** One RCT (203 people) found that, compared with medical treatment alone, combined treatment (initial laser trabeculoplasty followed by medical treatment) significantly reduced intraocular pressure (1.2 mm Hg greater reduction in intraocular pressure with combined treatment; P = 0.001), significantly improved visual fields (0.6 dB greater improvement with combined treatment; P < 0.001), and significantly reduced deterioration in optic disc appearance (P = 0.005) after a mean of 7 years.[14] **Versus surgical treatment:** See benefits of surgical trabeculectomy, p 866.

Harms: Adverse effects of laser trabeculoplasty are mild and include a transient rise in intraocular pressure (> 5 mm Hg in 91/271 [34%] people) and formation of peripheral anterior synechiae (see glossary, p 869) (in 93/271 [34%] people).[14] In the RCT comparing treatment with laser trabeculoplasty plus topical betaxolol hydrochloride versus no initial treatment, there was a significantly more rapid development of lens opacities in the treatment group (results presented graphically; P = 0.002).[13]

Comment: The first RCT was a multicentre trial with multiple observers, although it is not clear whether these observers were masked to the intervention.[14]

OPTION SURGICAL TRABECULECTOMY

Two RCTs found that surgical trabeculectomy reduced both visual field loss and intraocular pressures compared with medical treatment, but found no significant difference between treatments in visual acuity after about 5 years. Two RCTs found that surgical trabeculectomy reduced intraocular pressure compared with laser trabeculoplasty, but found mixed effects for changes in visual acuity after 5–7 years. Observational studies have found a reduction in central vision with surgical trabeculectomy.

Benefits: We found no systematic review. **Versus medical treatment:** We found two RCTs.[15,17] One RCT (116 people) compared trabeculectomy (see glossary, p 869) (followed by medical treatment when indicated) versus medical treatment (followed by trabeculectomy when medical treatment did not work).[17] It found no significant difference between treatments in visual acuity ($P = 0.44$; other results presented graphically; CI not reported), but found that trabeculectomy significantly reduced visual field loss compared with medical treatment ($P = 0.03$; other results presented graphically; CI not reported) after a mean of 4.6 years. The second RCT (186 people) compared three treatments: medical treatment (pilocarpine ± timolol ± a sympathomimetic), laser trabeculoplasty (see glossary, p 869), and surgical trabeculectomy.[15] It found that surgical trabeculectomy compared with both other treatments significantly reduced intraocular pressures ($P = 0.0001$; other results presented graphically; CI not reported), but found no significant difference between any of the treatments in visual acuity after 5 years (results presented graphically). **Versus initial laser trabeculoplasty:** We found two RCTs.[15,16] One RCT (776 eyes with advanced glaucoma; 451 black people, 325 white people) compared surgical trabeculectomy versus laser trabeculoplasty as initial treatments.[16] Initial surgical trabeculectomy was followed by laser trabeculoplasty and repeat surgical trabeculectomy as required; initial laser trabeculoplasty was followed by surgical trabeculectomy as required. Subgroup analysis of the RCT found that in black people initial laser trabeculoplasty significantly improved vision compared with surgical trabeculectomy (both visual acuity and visual field; $P < 0.01$; other results presented graphically; CI not reported), although in white people the RCT found no significant difference between treatments in vision after 7 years (results presented graphically). The RCT also found that in both black people and white people surgical trabeculectomy reduced intraocular pressure compared with laser trabeculoplasty (significance not reported and results presented graphically). The second RCT is described above.[15]

Harms: Surgical trabeculectomy is associated with a reduction in central vision. In one study, 83% of people lost two lines of Snellen visual acuity.[18] One RCT in people with normal tension glaucoma has found that treatment, including trabeculectomy, compared with no treatment, significantly increased cataract formation after 8 years (see harms of lowering intraocular pressure in normal tension glaucoma, p 868).[19,20]

Comment: None.

QUESTION **What are the effects of lowering intraocular pressure in people with normal tension glaucoma?**

OPTION **MEDICAL AND SURGICAL TREATMENTS**

One RCT found that surgical and/or medical treatment reduced progression of visual field loss after 8 years compared with no treatment, but found that surgery increased cataract formation after 8 years.

Benefits: We found no systematic review. We found one RCT (140 eyes in 140 people), which compared treatment to reduce intraocular pressure by 30% (with drugs or trabeculectomy (see glossary, p 869), or both; 61 eyes) versus no treatment (79 eyes).[19] Progression of visual field loss was defined by deepening of an existing scotoma, a new or expanded field defect coming close to central vision, or a fresh scotoma in a previously normal part of the visual field. Optic disc changes were photographed and independently assessed by two ophthalmologists. The RCT found that treatment significantly reduced progression of visual field loss after 8 years compared with no treatment (7/61 [12%] eyes with treatment *v* 28/79 [35%] eyes with no treatment; RR 0.32, 95% CI 0.15 to 0.70; NNT 5, 95% CI 3 to 9).[19]

Harms: The RCT found that treatment (drugs ± trabeculectomy) significantly increased cataract formation after 8 years compared with no treatment (23/61 [38%] with treatment *v* 11/79 [14%] with no treatment; RR 2.7, 95% CI 1.4 to 5.1; NNH 4, 95% CI 2 to 10).[19] Subgroup analysis found that the excess risk of cataract formation was confined to those people treated surgically (P = 0.0001). See harms of surgical trabeculectomy, p 0.

Comment: A companion paper[20] to the RCT[19] suggests that the favourable effect of intraocular pressure lowering treatment versus no treatment is evident only when the cataract inducing effect of trabeculectomy is removed. Not all cases of normal pressure glaucoma progress when untreated (40% at 5 years).[20]

QUESTION **What are the effects of treatment for acute angle closure glaucoma?**

OPTION **MEDICAL TREATMENTS**

We found no placebo controlled RCTs, but strong consensus suggests that medical treatments are effective. One RCT found no significant difference in intraocular pressure after 2 hours with low dose pilocarpine versus an intensive pilocarpine regimen versus pilocarpine ocular inserts. We found no RCTs of other medical treatments.

Benefits: **Pilocarpine versus placebo:** We found no RCTs (see comment below). **Acetazolamide plus low dose pilocarpine versus acetazolamide plus intensive pilocarpine:** We found no systematic review, but found one RCT (77 eyes) that compared three groups: initial treatment with low dose pilocarpine (2% pilocarpine drops applied to the eye twice in 1 hour); intensive pilocarpine (4% pilocarpine drops applied to the eye every 5 minutes for 1 hour or

longer); and pilocarpine ocular inserts (releasing 40 μg pilocarpine/hour).[21] All of the people in the RCT also received treatment with intravenous acetazolamide (500 mg iv). The RCT reported no significant difference in intraocular pressures after 2 hours (further data and P value not reported).

Harms: The RCT reported that ocular inserts were associated with local discomfort (statistical data not reported).[21]

Comment: RCTs of pilocarpine versus placebo would be considered unethical. There is a strong consensus that medical treatments that involve pressure lowering drugs (especially those that can be given parenterally, such as iv acetazolamide) are effective in acute angle closure glaucoma. We found no evidence from RCTs to support or challenge this view.

OPTION SURGICAL IRIDECTOMY AND LASER IRIDOTOMY

We found no placebo controlled RCTs, but strong consensus suggests that surgical treatments are effective. One RCT found no significant difference between surgical iridectomy and laser iridotomy in visual acuity or intraocular pressure after 3 years.

Benefits: **Surgical or laser procedure versus placebo:** We found no RCTs. **Surgical peripheral iridectomy versus Nd:YAG laser iridotomy:** We found no systematic review, but found one RCT (48 people with uniocular acute angle closure glaucoma) that compared peripheral iridectomy versus Nd:YAG laser iridotomy (see glossary, p 869).[22] It found no significant difference in visual acuity (0.30 logMAR units with peripheral iridectomy *v* 0.57 logMAR units with laser iridotomy; statistical data not reported) and no significant difference in intraocular pressure (intraocular pressure < 21 mm Hg: 15/21 [70%] with peripheral iridectomy *v* 19/27 [72%] with laser iridotomy; RR 1.02, 95% CI 0.71 to 1.46) after 3 years.

Harms: Surgical iridectomy (see glossary, p 869) involves an open operation on the eye, with risk of serious complications, including intraocular infection or haemorrhage. We found no published evidence quantifying these risks. Nd:YAG laser iridotomy is associated with haemorrhage from the iris, pressure spikes, and corneal oedema.[23] Nd:YAG and argon laser iridotomy can produce focal, non-progressive lens opacity.[24] In one RCT, iris haemorrhage was more common with the Nd:YAG laser but pupil distortion, iritis, and late blockage were more common with the argon laser.[25]

Comment: Management of acute angle closure glaucoma is aimed at restoring flow of aqueous humour to the anterior chamber angle and adjacent trabecular meshwork. One RCT found that the mean number of laser burns required to penetrate the iris was six with the Nd:YAG laser and 73 with the argon laser.[25] We found no placebo controlled RCTs, but strong consensus suggests that surgical treatments are effective.

GLOSSARY

Laser iridotomy Involves making a hole in the base of the iris (without opening the eye) using either an argon or Nd:YAG laser.

Laser trabeculoplasty Laser trabeculoplasty is performed with a laser, using a contact lens with an internal mirror, which allows focal burning of the pigmented trabecular meshwork.

Surgical iridectomy Opening the eye at the corneal limbus and removing a triangle of tissue from the base of the iris.

Synechiae Adhesions between the iris and surrounding structures, which can form following inflammation. Synechiae may form between the iris and the lens or between the iris and the inner surface of the cornea.

Trabeculectomy A microsurgical procedure in which a partial thickness trapdoor in the sclera is elevated at its junction with the cornea under the conjunctiva. Under the trapdoor, a small hole is fashioned from the sclera to the anterior chamber. This allows drainage of aqueous into the subconjunctival space. An iridectomy is performed at the site of the hole in the sclera.

Substantive changes

Primary open angle glaucoma: topical medical treatment One RCT added;[11] categorisation unchanged.

Primary open angle glaucoma: laser trabeculoplasty One RCT added;[13] categorisation unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 878

Key Messages

Treating epithelial keratitis

- **Interferons** One systematic review found that topical interferons (alpha or beta) increase healing after 7 and 14 days compared with placebo. The review found no significant difference between a topical interferon and a topical antiviral agent in healing after 7 days, but found that a topical interferon increased healing after 14 days. The review also found that topical interferon plus a topical antiviral agent increased healing compared with a topical antiviral agent alone after 14 days. "Healing" was not clearly defined.
- **Topical antiviral agents** One systematic review has found that topical antivirals (idoxuridine or vidarabine) increase healing after 14 days compared with placebo, and that trifluridine or aciclovir increase healing compared with idoxuridine after 7 and 14 days. The review has also found that antiviral treatment plus debridement increases healing after 7 days compared with either treatment alone. It found no significant difference in healing at 14 days

between antiviral treatment plus debridement and antiviral treatment alone. It also found no significant difference between topical antiviral agents and topical interferon in healing after 7 days, but found that topical interferon increased healing after 14 days. The review also found that adding topical interferon to a topical antiviral agent increased healing compared with the antiviral agent alone. "Healing" was not clearly defined.

- **Debridement** One systematic review has found no significant difference between debridement and no treatment. The review has also found that debridement plus antiviral treatment improves healing at 7 days compared with either treatment alone. This difference remained significant at 14 days for combined treatment compared with debridement alone.

Treating stromal keratitis

- **Topical corticosteroids** One RCT in people receiving topical antiviral treatment found that topical corticosteroids reduced progression and shortened the duration of stromal keratitis compared with placebo.
- **Oral aciclovir** One RCT in people receiving topical corticosteroids plus topical antiviral treatment found no significant difference between oral aciclovir and placebo in rates of treatment failure at 16 weeks.

Preventing recurrence of epithelial or stromal keratitis

- **Long term (1 year) oral aciclovir** One large RCT in people with at least one previous episode of epithelial or stromal keratitis found that long term oral aciclovir reduced recurrence after 1 year compared with placebo.
- **Short term (3 weeks) oral aciclovir** One RCT in people with epithelial keratitis receiving a topical antiviral agent (trifluridine) found no significant difference between short term prophylaxis with oral aciclovir and placebo in the rate of stromal keratitis or iritis at 1 year.

Preventing ocular herpes simplex in people with corneal grafts

- **Oral aciclovir** One small RCT found limited evidence that prophylactic use of oral aciclovir reduced recurrence and improved graft survival compared with placebo.

DEFINITION Ocular herpes simplex is usually caused by herpes simplex virus type 1 (HSV-1) but also occasionally by the type 2 virus (HSV-2). Ocular manifestations of HSV are varied and include blepharitis (inflammation of the eyelids), canalicular obstruction, conjunctivitis, epithelial keratitis, stromal keratitis (see glossary, p 878), iritis, and retinitis. HSV infections are classified as neonatal, primary (HSV in a person with no previous viral exposure), and recurrent (previous viral exposure with humoral and cellular immunity present).

INCIDENCE/ PREVALENCE Infections with HSV are usually acquired in early life. A US study found antibodies against HSV-1 in about 50% of people with high socioeconomic status and 80% of people with low socioeconomic status by the age of 30 years.[1] However, only about 20–25% of people with HSV antibodies had any history of clinical manifestations of ocular or cutaneous herpetic disease.[2] Ocular HSV is the most common cause of corneal blindness in high income countries and is the most common cause of unilateral corneal blindness in the world.[3] A 33 year study of the population of Rochester, Minnesota, found the annual incidence of new cases of ocular herpes simplex was 8.4/100 000 (95% CI 6.9 to 9.9) and the annual

incidence of all episodes (new and recurrent) was 20.7/100 000 (95% CI 18.3 to 23.1).[4] The prevalence of ocular herpes was 149 cases/100 000 population (95% CI 115 to 183). Twelve per cent of people had bilateral disease.[4]

AETIOLOGY/ RISK FACTORS Epithelial keratitis results from productive, lytic viral infection of the corneal epithelial cells. Stromal keratitis and iritis are thought to result from a combination of viral infection and compromised immune mechanisms. Observational evidence (346 people with ocular HSV in the placebo arm of an RCT) found that the risk of developing stromal keratitis was 4% in people with no previous history of stromal keratitis (RR 1.0) compared with 32% (RR 10, 95% CI 4.32 to 23.38) with previous stromal keratitis, but that a history of epithelial keratitis was not a risk factor for recurrent epithelial keratitis.[5] Age, sex, ethnicity, and previous experience of non-ocular HSV disease were not associated with an increased risk of recurrence.[5]

PROGNOSIS HSV epithelial keratitis tends to resolve spontaneously within 1–2 weeks. In a trial of 271 people treated with topical trifluorothymidine and randomly assigned to receive either oral aciclovir or placebo, the epithelial lesion had resolved completely or was at least less than 1 mm after 1 week of treatment with placebo in 89% of people and after 2 weeks in 99% of people.[6] Stromal keratitis or iritis occurs in about 25% of people following epithelial keratitis.[7] The effects of HSV stromal keratitis include scarring, tissue destruction, neovascularisation, glaucoma, and persistent epithelial defects. Rate of recurrence of ocular herpes for people with one episode is 10% at 1 year, 23% at 2 years, and 50% at 10 years.[8] The risk of recurrent ocular HSV infection (epithelial or stromal) has also been found to increase with the number of previous episodes reported (2 or 3 previous episodes: RR 1.41, 95% CI 0.82 to 2.42; 4 or more previous episodes: RR 2.09, 95% CI 1.24 to 3.50).[5] Of corneal grafts performed in Australia over a 10 year period, 5% were in people with visual disability or with actual or impending corneal perforation following stromal ocular herpes simplex. The recurrence of HSV in a corneal graft has a major effect on graft survival. The Australian Corneal Graft Registry has found that, in corneal grafts performed for HSV keratitis, there was at least one HSV recurrence in 58% of corneal grafts that failed over a follow up period of 9 years.[9]

AIMS OF INTERVENTION To reduce the morbidity of HSV keratitis and iritis; to reduce the risk of recurrent disease; and to improve corneal graft survival after penetrating keratoplasty (see glossary, p 878).

OUTCOMES Healing time; severity and duration of symptoms; severity of complications; rates of recurrence; corneal graft survival.

METHODS *Clinical Evidence* search and appraisal August 2003.

Ocular herpes simplex

QUESTION What are the effects of treatments in people with epithelial keratitis?

OPTION TOPICAL ANTIVIRAL AGENTS

One systematic review has found that topical antivirals (idoxuridine or vidarabine) increase healing after 14 days compared with placebo, and that trifluridine or aciclovir increase healing compared with idoxuridine after 7 and 14 days. The review has also found that antiviral treatment plus debridement increases healing after 7 days compared with either treatment alone. It found no significant difference in healing at 14 days between antiviral treatment plus debridement and antiviral treatment alone. It also found no significant difference between topical antiviral agents and topical interferon in healing after 7 days, but found that topical interferon increased healing after 14 days. The review also found that adding topical interferon to a topical antiviral agent increased healing compared with the antiviral agent alone. "Healing" was not clearly defined.

Benefits: We found one systematic review (search date 2000, 96 RCTs, 4991 people; see comment below).[10] **Versus placebo:** The review found that idoxuridine significantly increased healing after 7 days compared with placebo (10 RCTs; OR 4.05, 95% CI 2.60 to 6.30; see comment below) and after 14 days (2 RCTs; OR 4.17, 95% CI 1.33 to 13.00).[10] The review also compared vidarabine versus placebo and found no significant difference in healing after 7 days (numerical data not reported), but found that vidarabine significantly increased healing after 14 days (1 RCT; OR 5.40, 95% CI 1.42 to 20.5). **Versus each other:** The review found that compared with idoxuridine, trifluridine significantly increased healing after 7 days (3 RCTs; OR 4.74, 95% CI 2.52 to 8.91) and after 14 days (4 RCTs; OR 6.83, 95% CI 3.02 to 15.5).[10] The review also found that aciclovir significantly increased healing after 7 days compared with idoxuridine (8 RCTs; OR 5.33, 95% CI 3.33 to 8.53) and after 14 days (11 RCTs; OR 3.71, 95% CI 2.27 to 6.08), but found no significant difference between vidarabine and idoxuridine in healing after 7 days (3 RCTs; OR 1.24, 95% CI 0.72 to 2.00) or after 14 days (3 RCTs; OR 1.24, 95% CI 0.65 to 2.37). **Antiviral treatment plus physical debridement:** See benefits of debridement, p 875. **Antiviral treatment versus topical interferons:** See benefits of interferons, p 875. **Antiviral treatment plus topical interferons:** See benefits of interferons, p 875.

Harms: The review did not report harms.[10]

Comment: The outcome measure "healing" was not clearly defined.[10] The review reported that the number of people involved in the comparison of vidarabine versus placebo was small, although it did not provide any absolute numbers.

OPTION DEBRIDEMENT

One systematic review has found no significant difference between debridement and no treatment. The review has also found that debridement plus antiviral treatment improves healing at 7 days compared with either treatment alone. This difference remained significant at 14 days for combined treatment compared with debridement alone.

Benefits: We found one systematic review (search date 2000, 96 RCTs, 4991 people).[10] **Debridement alone:** The review compared different types of physicochemical debridement versus no treatment and found no significant difference in healing after 7 days (2 RCTs; OR 1.62, 95% CI 0.72 to 3.61) or after 14 days (1 RCT; OR 2.12, 95% CI 0.38 to 12.0).[10] **Debridement plus antiviral treatment:** The review found that physicochemical debridement plus an antiviral agent significantly increased healing after 7 days compared with physicochemical debridement alone (7 RCTs; OR 2.08, 95% CI 1.17 to 3.71) and after 14 days (2 RCTs; OR 10.81, 95% CI 1.81 to 64.5).[10] The review also found that physicochemical debridement plus an antiviral agent significantly increased healing compared with antiviral treatment alone after 7 days (7 RCTs; OR 2.01, 95% CI 1.21 to 3.34), but found no significant difference in healing after 14 days (significance testing not reported). One RCT identified by the review compared debridement plus aciclovir versus debridement plus idoxuridine and found no significant difference in healing after 7 or 14 days (CI not reported).

Harms: None reported.

Comment: The review found that all methods of debriding the corneal epithelium produced similar rates of re-epithelialisation.[10] The variety of treatments used in the review limits the applicability of the summary results. The review included "healed" as an outcome measure without clearly defining this term.

OPTION INTERFERONS

One systematic review has found that topical interferons (alpha or beta) increase healing after both 7 and 14 days compared with placebo. The review found no significant difference between topical interferon and a topical antiviral agent in healing after 7 days, but found that topical interferon increased healing after 14 days. The review also found that topical interferon plus a topical antiviral agent increased healing compared with a topical antiviral agent alone after 14 days. "Healing" was not clearly defined.

Benefits: We found one systematic review (search date 2000, 96 RCTs, 4991 people).[10] **Versus placebo:** The review found that topical interferons (alpha or beta) significantly increased healing after 7 days (3 RCTs; OR 2.09, 95% CI 1.15 to 3.81; see comment below) and after 14 days compared with placebo (2 RCTs; OR 3.43, 95% CI 1.30 to 9.02).[10] **Different concentrations:** One RCT identified by the review found no significant difference between low concentration interferon (< 1 MU/mL) and higher concentrations of interferon in healing after 7 days (1 RCT; OR 0.21, 95% CI 0.02 to

2.42).[10] The RCT may have been too small to exclude a clinically important difference. **Versus topical antivirals:** The review found no significant difference in healing after 7 days between topical interferon and topical antiviral agents (2 RCTs; OR 1.18, 95% CI 0.29 to 4.75), but found that topical interferon significantly increased healing compared with a topical antiviral agent after 14 days (3 RCTs; OR 3.48, 95% CI 1.06 to 11.4).[10] **Topical interferons plus antiviral agents:** The review found that topical interferon plus a topical antiviral agent significantly increased healing compared with a topical antiviral agent alone (usually trifluridine) after 7 days (8 RCTs; OR 13.3, 95% CI 7.41 to 23.9) but found no significant difference in healing after 14 days (5 RCTs; OR 2.62, 95% CI 0.91 to 7.57).[10]

Harms: The review did not report on harms.[10]

Comment: The outcome measure "healing" was not clearly defined.[10]

QUESTION **What are the effects of treatments in people with stromal keratitis?**

OPTION **TOPICAL CORTICOSTEROIDS**

One RCT in people receiving topical antiviral treatment found that topical corticosteroids reduced progression and shortened the duration of stromal keratitis compared with placebo.

Benefits: We found one RCT (106 people; see comment below) comparing topical prednisolone sodium phosphate (in decreasing concentrations over 10 weeks) versus placebo.[11] All participants received topical trifluridine. It found that prednisolone significantly reduced the persistence or progression of stromal inflammation and shortened the duration of stromal keratitis (see glossary, p 878) compared with placebo (median 26 days with corticosteroid *v* median 72 days with placebo; difference 46 days, 95% CI 14 to 58 days).

Harms: In the RCT, nine people in the steroid group reported adverse effects.[11] Four people developed dendritic epithelial keratitis (see glossary, p 878) and were removed from the trial. Four people developed toxic responses to trifluridine after week 5. These people were not withdrawn but the trifluridine was stopped. One person developed an epithelial defect and was withdrawn. Adverse events were reported in six people receiving placebo. All six were withdrawn from the study (1 person developed dendritic keratitis, 3 people developed an epithelial defect, and 2 people developed allergic conjunctivitis attributed to trifluorothymidine within the first 9 days of the trial).

Comment: The trial did not specify whether or not intention to treat analysis was performed.[11]

OPTION **ORAL ACICLOVIR**

One RCT in people receiving topical corticosteroids plus topical antiviral treatment found no significant difference between oral aciclovir and placebo in rates of treatment failure at 16 weeks.

Benefits: We found one RCT (104 people with herpes simplex virus stromal keratitis [see glossary, p 878] receiving concomitant topical corticosteroids and a topical antiviral agent [trifluridine]) of oral aciclovir.[12] The primary outcome was time to treatment failure, defined as worsening or no improvement of stromal keratitis or an adverse event. The RCT found no significant difference between aciclovir in median time to treatment failure compared with placebo (84 days with aciclovir *v* 62 days with placebo; P = 0.46; CI not reported), or in reported rates of treatment failure by week 16 (38/51 [75%] with aciclovir *v* 39/53 [74%] with placebo; RR 1.01, 95% CI 0.78 to 1.24).[12]

Harms: The RCT found that two people in the placebo group developed adverse effects attributed to trifluridine (epithelial keratopathy in 1 person and an allergic reaction in the other).[12] Other adverse effects reported included pneumonia with possible pulmonary embolus (1 person), congestive heart failure (1 person), diarrhoea (1 person), oedema of the lower extremities (1 person), and anaemia (1 person). Adverse reactions reported in the aciclovir group included toxicity to trifluorothymidine (1 person) and headache (1 person).

Comment: None.

QUESTION What are the effects of interventions to prevent recurrence of ocular herpes simplex?

OPTION ORAL ACICLOVIR

One large RCT in people with at least one previous episode of epithelial or stromal keratitis found that long term oral aciclovir reduced recurrence after 1 year compared with placebo. One RCT in people with epithelial keratitis receiving a topical antiviral agent (trifluridine) found no significant difference between short term prophylaxis with oral aciclovir and placebo in the rate of stromal keratitis or iritis at 1 year.

Benefits: We found no systematic review. We found two RCTs.[6,13] **Long term (1 year) oral aciclovir:** The first RCT (703 immunocompetent people aged ≥ 12 years who had epithelial or stromal ocular herpes simplex virus in one or both eyes within the preceding 12 months) compared oral aciclovir (400 mg twice daily for 1 year) versus placebo.[13] It found that aciclovir treatment significantly reduced the risk of any type of recurrence after 1 year (19% with aciclovir *v* 32% with placebo; RR 0.55, 95% CI 0.41 to 0.75). Prespecified subgroup analysis (337 people with at least 1 previous episode of stromal keratitis) found that aciclovir significantly reduced the risk of stromal keratitis (see glossary, p 878) compared with placebo, but only in people who had at least one prior episode (14% with aciclovir *v* 28% with placebo; RR 0.48, 95% CI 0.29 to 0.80). The RCT found no rebound in the rate of ocular herpes simplex virus in the 6 months after stopping treatment. **Short term (3 weeks) oral aciclovir:** The second RCT (287 people with epithelial keratitis (see glossary, p 878) all treated with topical trifluridine) compared a 3 week course of oral aciclovir versus placebo.[6] It found no significant

difference in the rate of stromal keratitis or iritis (11% with aciclovir *v* 10% with placebo; RR 1.04, 95% CI 0.52 to 2.10), and no significant difference in the cumulative risk of developing stromal keratitis or iritis at 1 year of follow up (12% with aciclovir *v* 11% with placebo; P = 0.92; CI not reported).

Harms: The RCT of long term treatment found that adverse effects (mostly gastrointestinal problems) were uncommon and occurred with similar frequency in both groups.[13] Thirty two people (15 aciclovir *v* 17 placebo) discontinued treatment because of adverse effects. The most common adverse effect reported was gastrointestinal upset (7 aciclovir *v* 9 placebo).

Comment: None.

QUESTION **What are the effects of interventions to prevent recurrence in people with corneal grafts?**

OPTION **ORAL ACICLOVIR**

One small RCT found limited evidence that prophylactic use of oral aciclovir reduced recurrence and improved graft survival compared with placebo.

Benefits: We found no systematic review. We found one small non-blinded RCT (22 people, 23 eyes, who had received keratoplasty [see glossary, p 878]), which compared oral aciclovir (800 or 1000 mg, 4 or 5 times orally daily, tapered during the first 12 months, for a maximum of 15 months) versus placebo.[14] Oral aciclovir was started before surgery or on the first day after surgery. The RCT found that oral aciclovir significantly reduced the number of recurrences of ocular herpes simplex compared with placebo after a mean follow up of 17 months in people receiving aciclovir and 21 months in those receiving placebo (0% with aciclovir *v* 44% with placebo; P < 0.01), and also that aciclovir significantly reduced the number of eyes with graft failure compared with usual care (14% with aciclovir treated eyes *v* 56% with placebo; P < 0.05; CI not provided).

Harms: None reported.

Comment: None.

GLOSSARY

Epithelial keratitis Inflammation of the cells that form the surface layer of the cornea.

Keratoplasty A procedure in which diseased corneal tissue is removed and replaced by donor corneal material.

Stromal keratitis Inflammation of the middle layer of the cornea. The stroma forms 90% of the corneal substance. It lies between the epithelium and Bowman's membrane anteriorly and Descemet's membrane and the endothelium posteriorly.

QUESTIONS

INTERVENTIONS

See glossary, p 887

Key Messages

Interventions to prevent scarring trachoma by reducing active trachoma

- **Promotion of face washing plus topical tetracycline (better than tetracycline alone)** One RCT found that promotion of face washing plus topical tetracycline reduced the rate of severe trachoma after 1 year compared with topical tetracycline alone. It found no significant difference in the overall rate of trachoma. However, the RCT may lack power to rule out a clinically important effect. Another RCT found that face washing (performed by a teacher) plus topical tetracycline reduced the proportion of children with trachoma after 3 months compared with no intervention.
- **Antibiotics** One systemic review provided insufficient evidence to compare antibiotics with placebo or each other in people with active trachoma. The same review found insufficient evidence on oral azithromycin versus topical tetracycline in active trachoma, and also on oral antibiotics other than azithromycin versus topical antibiotics in active trachoma. However, trials were heterogeneous and the review may not exclude clinically important effects.
- **Face washing alone** One RCT found no significant difference between face washing alone (performed by a teacher) and no intervention in the rate of trachoma in children after 3 months.
- **Fly control using insecticide** A small pilot study for an RCT found that fly control using deltamethrin reduced the incidence of trachoma after 3 months compared with no intervention.

Surgical treatments for scarring trachoma

- **Bilamellar tarsal rotation or tarsal advance and rotation (better than other types of eyelid surgery)** In people with major trichiasis, one RCT found limited evidence that bilamellar tarsal rotation increased operative success and reduced adverse effects after 2 weeks compared with eversion splinting, tarsal advance, or tarsal grooving. However, it found no significant difference between bilamellar tarsal rotation and tarsal advance and rotation in operative success after 2 weeks. A second RCT found that bilamellar tarsal rotation increased operative success after 25 months compared with tarsal advance and rotation. In both RCTs, one experienced surgeon performed most of the operations. In people with minor trichiasis, one of the RCTs found that tarsal rotation increased operative success after 25 months compared with cryoablation or electrolysis. One further RCT reporting combined results for major and minor trichiasis found no significant difference in recurrence between bilamellar tarsal rotation and tarsal advance and lid margin rotation after 3 months, although there were more minor complications (lid notching and pyogenic granuloma) with the bilamellar procedure. In this RCT, the operations were undertaken by less experienced surgeons under supervision.

DEFINITION

Active trachoma is chronic inflammation of the conjunctiva caused by infection with *Chlamydia trachomatis*. The World Health Organization classification for active trachoma defines mild trachoma (grade TF — trachomatis inflammation [follicular]) as the presence of five or more follicles in the upper tarsal conjunctiva of at least 0.5 mm in diameter. Severe trachoma (grade TI — trachomatis [intense]) is defined as pronounced inflammatory thickening of the upper tarsal conjunctiva that obscures more than half of the normal deep vessels.[1] **Scarring trachoma** is caused by repeated active infection by *C trachomatis* in which the upper eyelid is shortened and distorted (entropion) and the lashes abrade the eye (trichiasis [see glossary, p 887]). Scarring trachoma can exist without entropion/trichiasis but if entropion/trichiasis is present, there will be scarring. Blindness results from corneal opacification, which is related to the degree of entropion/trichiasis.

INCIDENCE/ PREVALENCE

Trachoma is the world's leading cause of preventable blindness and is second only to cataract as an overall cause of blindness.[2] Globally, active trachoma affects an estimated 150 million people, most of them children. About 5.5 million people are blind or at risk of blindness as a consequence. Trachoma is a disease of poverty regardless of geographical region. Scarring trachoma is prevalent in large regions of Africa, the Middle East, south west Asia, the Indian subcontinent, and Aboriginal communities in Australia, and there are also small foci in Central and South America.[2] In areas where trachoma is constantly present at high prevalence, active disease is found in more than 50% of preschool children and may have a prevalence as high as 60–90%.[3] As many as 75% of women and 50% of men over the age of 45 years may show signs of scarring disease.[4] The prevalence of active trachoma decreases with increasing age, with fewer than 5% of adults showing signs of active disease.[3] Although similar rates of active disease are observed in boys and girls, the later sequelae of trichiasis, entropion, and corneal opacification are more common in women than men.[3]

Trachoma

AETIOLOGY/ RISK FACTORS Active trachoma is associated with youth and close contact between people. Discharge from the eyes and nose may be a source of further reinfection.[5] Sharing a bedroom with someone who has active trachoma is a risk factor for infection.[6] Facial contact with flies is held to be associated with active trachoma, but studies reporting this relationship used weak methods.[7]

PROGNOSIS Corneal damage from trachoma is caused by multiple processes. Scarring trachoma may cause an inadequate tear film and a dry eye may be more susceptible to damage from inturned lashes, leading to corneal opacification. The prevalence of scarring trachoma and consequent blindness increases with age, and therefore, is most commonly seen in older adults.[8]

AIMS OF INTERVENTION To prevent active trachoma; to reduce the rate of progression to scarring trachoma; to relieve entropion and trichiasis in people with scarring trachoma; with minimal adverse effects.

OUTCOMES Rates of active trachoma; clinical signs of active trachoma using the World Health Organization grading scale; laboratory evidence of *C trachomatis* infection; eyelid position; degree of entropion/ trichiasis. RCTs conducted before 1987 may use definitions of trachoma that differ from the present World Health Organization definition.[1]

METHODS *Clinical Evidence* search and appraisal October 2003.

QUESTION **What are the effects of interventions to prevent scarring trachoma by reducing active trachoma?**

OPTION **PUBLIC HEALTH INTERVENTIONS**

Evidence from two RCTs, both with methodological weaknesses, suggests that face washing plus topical tetracycline may reduce the rate of trachoma compared with either face washing alone or topical tetracycline alone. One of the RCTs found that promotion of face washing plus topical tetracycline reduced the rate of severe trachoma after 1 year compared with topical tetracycline alone. It found no significant difference in the overall rate of trachoma. However, the RCT may have lacked power to rule out a clinically important difference. The other RCT found no significant difference between face washing alone (performed by a teacher) and no intervention in children with trachoma after 3 months and that face washing plus topical tetracycline reduced the proportion of children with trachoma after 3 months compared with no intervention. In a pilot study for an RCT, fly control using deltamethrin reduced the incidence of trachoma after 3 months compared with no intervention.

Benefits: We found one systematic review[9] and one additional RCT.[10] The systematic review (search date 1999) identified three RCTs, two of which were difficult to interpret (see comment below), and one pilot study.[9] **Promotion of face washing plus topical tetracycline versus topical tertracycline alone:** The review identified one cluster RCT (1417 children aged 1–7 years in 6 villages, see comment below on cluster randomisation) that compared promotion of face washing plus 30 days of daily topical tetracycline (ointment) versus 30 days of daily topical tetracycline alone.[11] It

found that promoting face washing plus topical tetracycline significantly reduced the risk of severe trachoma after 1 year compared with topical tetracycline alone (OR for severe trachoma 0.62, 95% CI 0.40 to 0.97), but this reduction was not significant for all grades of trachoma combined (OR for any trachoma 0.81, 95% CI 0.42 to 1.59).[11] The RCT found that when all participants from intervention and control villages were pooled, children who had a sustained clean face were significantly less likely to have active trachoma than those who never had a clean face or had a clean face at only one follow up visit during the study period (OR 0.58, 95% CI 0.47 to 0.72).[11] **Face washing alone versus face washing plus topical tetracycline versus no intervention:** The additional RCT (1143 children in 36 communities) compared three groups: daily face washing alone; daily face washing plus daily topical tetracycline (as drops for 1 week each month); and no intervention.[10] Face washing was performed by a teacher. Trachoma was defined as the presence of at least one follicle or some papillae on the upper tarsal plate (this study predated the present World Health Organization definition of trachoma — see comment below). Losses to follow up were included in the analysis as being trachoma positive. The RCT found no significant difference between face washing alone and no intervention in terms of the proportion of children with trachoma after 3 months (191/246 [78%] with face washing alone *v* 160/211 [76%] with no intervention; regression analysis, $P > 0.05$).[10] It also found that face washing plus tetracycline drops significantly reduced the proportion of children with trachoma after 3 months compared with no intervention (215/312 [69%] with face washing plus topical tetracycline *v* 160/211 [76%] with no intervention; regression analysis, $P < 0.05$).[10] **Fly control using insecticide:** See comment below.

Harms: The review and additional RCT did not report adverse effects.[9,10]

Comment: **Face washing with or without topical tetracycline:** Cluster randomisation limits the power to detect differences between groups and interpretation of results for individual children.[7,10,11] Two RCTs identified by the systematic review compared antibiotics versus health education plus face washing. It was not possible to extract data relating to the health education and face washing interventions separately.[9] The additional RCT predates the simplified World Health Organization classification of trachoma, limiting applicability of the results.[10] **Fly control using insecticide:** The systematic review[9] identified one pilot study for an RCT (414 children < 10 years) that compared spraying of deltamethrin for 3 months versus no intervention in two pairs of villages.[7] One pair of villages received deltamethrin or no intervention in the wet season and the other pair received deltamethrin or no intervention in the dry season. There were 191 children under 10 years of age in the control villages and 223 children in the intervention villages. The pilot study found that spraying of deltamethrin significantly reduced the number of new cases of trachoma (World Health Organization classification) after 3 months compared with no intervention (RR 0.25, 95% CI 0.09 to 0.64).[7]

Trachoma

OPTION ANTIBIOTICS

One systemic review of heterogeneous RCTs provided insufficient evidence to compare antibiotics with placebo or each other in people with active trachoma. The same review found insufficient evidence on oral azithromycin versus topical tetracycline in active trachoma, and also on oral antibiotics other than azithromycin versus topical antibiotics in active trachoma. However, trials were heterogeneous and the review may not exclude clinically important effects.

Benefits: We found one systematic review (search date 2001; see comment below).[12] **Versus placebo or no treatment:** The review identified nine RCTs (8 reports; 2177 people) comparing topical or oral antibiotics versus control (no treatment, placebo, or a monthly vitamin tablet) (see table 1, p 889).[10,13–19] The review did not pool results because of statistical and clinical heterogeneity (see comment below).[12] At 3 months, six RCTs found that antibiotic significantly decreased the proportion of people with active trachoma compared with control ($P < 0.05$), whereas three RCTs found no significant difference in active trachoma between antibiotic and control.[12] At 12 months, three RCTs found that antibiotic significantly reduced the proportion of people with active trachoma compared with control ($P < 0.05$); however, one RCT found no significant difference in active trachoma between antibiotic and control.[12] **Oral azithromycin versus topical tetracycline:** The review identified six RCTs (4 reports; 7666 people) comparing oral azithromycin versus topical tetracycline (see table 2, p 890).[20–23] The review did not pool results because of trial heterogeneity (see comment below).[12] At 3 months, two RCTs found that oral azithromycin significantly reduced the proportion of people with active trachoma compared with topical tetracycline ($P < 0.05$); however, four RCTs found no significant difference in active trachoma between oral azithromycin and topical tetracycline.[12] At 12 months, two RCTs found that oral azithromycin significantly reduced the proportion of people with active trachoma compared with topical tetracycline ($P < 0.05$); however, two RCTs found no significant difference in active trachoma between oral azithromycin and topical tetracycline.[12] **Oral antibiotics other than azithromycin versus topical antibiotics:** The review[12] identified three RCTs[14,16,18] of oral antibiotics other than oral azithromycin versus a topical antibiotic (see table 1, p 889). At 3 months, one RCT found that oral antibiotics significantly decreased the proportion of people with active trachoma compared with topical antibiotics ($P < 0.05$); however, two RCTs found no significant difference in active trachoma between oral antibiotics and topical antibiotics.[12] At 12 months, three RCTs found no significant difference in active trachoma between oral antibiotics and topical antibiotics.[12] **Topical tetracycline with or without face washing:** See benefits of public health interventions, p 882.

Harms: The review did not report on harms.[12]

Comment: Outcomes were reported by the systematic review at 3 and 12 months.[12] As not all the RCTs collected outcomes at those times, the review reported as 3 months those outcomes measured by RCTs

before 6 months, and as 12 months those outcomes measured by RCTs between 6 and 18 months.[12] Where more than one outcome was available, the nearest reported to 3 or 12 months was selected.[12] **Versus placebo or no treatment:** The RCTs were undertaken in various settings. Most were in children attending boarding schools.[12] The RCTs were all of moderate or poor quality and many lacked intention to treat analysis.[12] Antibiotic treatments included topical and oral doses. The review stated "no conclusions can be drawn on the effectiveness of antibiotic treatment for active trachoma but there is a suggestion of a reduction in the point prevalence of the relative risk for those treated with either oral or topical antibiotics".[12] **Oral azithromycin versus topical tetracycline:** Two of the RCTs included in the review were small and of low power.[21,23] A third cluster RCT compared mass treatment, in which people were treated irrespective of disease status and were randomly allocated by village.[22] Correlation analysis found some similarity between individuals within a cluster, limiting the validity of results. The review found no evidence regarding development of bacterial resistance.[12]

QUESTION **What are the effects of eye lid surgery for scarring trachoma (entropion and trichiasis)?**

OPTION **LID ROTATION SURGERY**

In people with major trichiasis, one RCT found limited evidence that bilamellar tarsal rotation increased operative success and fewer adverse effects after 2 weeks compared with eversion splinting, tarsal advance, or tarsal grooving. However, it found no significant difference between bilamellar tarsal rotation and tarsal advance and rotation in operative success after 2 weeks. A second RCT found that bilamellar tarsal rotation increased operative success after 25 months compared with tarsal advance and rotation. In both RCTs, one experienced surgeon performed most of the operations. In people with minor trichiasis, one of the RCTs found that tarsal rotation increased operative success after 25 months compared with cryoablation or electrolysis. One further RCT reporting combined results for major and minor trichiasis found no significant difference in recurrence between bilamellar tarsal rotation and tarsal advance and lid margin rotation after 3 months, although there were more minor complications (lid notching and pyogenic granuloma) with the bilamellar procedure. In this RCT, the operations were undertaken by less experienced surgeons under supervision.

Benefits: We found no systematic review but found three RCTs that compared surgical interventions versus each other.[24–26] In the first two RCTs, one experienced surgeon performed most of the operations.[24,25] In the third RCT, surgery was performed by second year ophthalmology residents who were trained in the techniques employed and supervised by an experienced consultant ophthalmic surgeon and senior resident.[26] The RCTs defined operative success as no lashes in contact with the globe in the primary position of gaze and complete lid closure with gentle voluntary effort. The first two RCTs reported outcomes by severity of trichiasis (see glossary, p 887) before surgery. The third RCT analysed combined results. **Major**

trichiasis: See glossary, p 887. The first RCT (165 Omani villagers, 165 eyelids) compared five surgical techniques: bilamellar tarsal rotation (see glossary, p 887); eversion splinting (see glossary, p 887); tarsal advance (see glossary, p 887); tarsal grooving (see glossary, p 887); and tarsal advance and rotation (see glossary, p 887).[24] It found that bilamellar tarsal rotation significantly increased operative success after 2 weeks compared with eversion splinting, tarsal advance, and tarsal grooving (30/44 [68%] with bilamellar tarsal rotation *v* 8/25 [32%] with eversion splinting; RR 2.13, 95% CI 1.16 to 3.91; 30/44 [68%] with bilamellar tarsal rotation *v* 11/41 [27%] with tarsal advance; RR 2.5, 95% CI 1.5 to 4.4; 30/44 [68%] with bilamellar tarsal rotation *v* 3/32 [9%] with tarsal grooving; RR 7.3, 95% CI 2.4 to 21.8). It found no significant difference between bilamellar tarsal rotation and tarsal advance and rotation in operative success after 2 weeks (30/44 [68%] with bilamellar tarsal rotation *v* 10/23 [43%] with tarsal advance and rotation; RR 1.57, 95% CI 0.94 to 2.60). However, the trial was underpowered and lacked intention to treat analysis. The second RCT (Omani villagers, 200 eyelids) compared bilamellar tarsal rotation versus tarsal advance and rotation.[25] It found that bilamellar tarsal rotation significantly increased operative success after 25 months compared with tarsal advance and rotation (HR of failure: tarsal advance and rotation *v* bilamellar tarsal rotation 3.1, 95% CI 1.9 to 5.2). **Minor trichiasis:** See glossary, p 887. The second RCT (172 eyelids) compared three treatments: bilamellar tarsal rotation, cryoablation, and electrolysis.[25] It found that bilamellar tarsal rotation significantly increased operative success after 25 months compared with both other treatments (HR of failure: electrolysis *v* bilamellar tarsal rotation 6.1, 95% CI 2.9 to 12.8; HR of failure: cryoablation *v* bilamellar tarsal rotation 7.5, 95% CI 3.6 to 15.4). **Minor and major trichiasis:** The third RCT (153 Ethiopians, 256 eyelids) compared bilamellar tarsal rotation (Weis) versus tarsal advance and rotation (Trabut).[26] Successful outcomes were similar in the two groups (99/115 (86.1%) with bilamellar tarsal rotation *v* 107/122 (87.7%) with tarsal advance and rotation) as were recurrence rates (12/115 (10.4%) with bilamellar tarsal rotation *v* 15/122 (12.3%) with tarsal advance and rotation; P = 0.711). There were four cases of over-correction in the bilamellar tarsal rotation group (4/115 [3.5%]) compared with none with tarsal advance and rotation group.

Harms: Adverse outcomes of surgery were corneal exposure, ulceration, phthisis bulbi (see glossary, p 887), and severe recurrent trichiasis.[24,27] In the first two RCTs major trichiasis and defective closure were more common after eversion splinting, tarsal advance, and tarsal grooving than after bilamellar tarsal rotation and tarsal advance and rotation (significance not reported).[24,25] Cryoablation of the eyelashes can cause necrosis of the lid margin and corneal ulcers. In the second RCT, cryoablation was the only procedure associated with onset of phthisis bulbi (2/57 [3.5%] cases).[25] The third RCT reported the non-serious complications of lid notching and pyogenic granuloma occurred significantly more frequently with bilamellar tarsal rotation (absolute numbers not reported; P = 0.002).[26] No major harms were reported.[26] Further details of harms are summarised in table 3, p 891.

Comment: In the first two RCTs definitions of major trichiasis and minor trichiasis are specific to these trials.[24,25] In both RCTs comparing surgical interventions, one experienced operator performed most of the surgery. The evidence of both benefits and harms may not be applicable to different operators, or where the quality of surgical equipment does not match those in the trials. We found one RCT (158 people with major trichiasis) looking at site of surgery that compared village versus health centre based tarsal rotation surgery for major trichiasis.[28] It found that attendance rates were not significantly different between interventions (57/86 [66%] with village based surgery *v* 32/72 [44%] with health centre based surgery; RR 1.5, CI not reported). Problems with the unit of randomisation prevented the calculation of confidence limits for the relative risks stated. The RCT found no significant difference between settings for operative success rate (defined as no evidence of trichiasis) after 3 months (intention to treat analysis by *Clinical Evidence*; 52/86 [60%] with village based surgery *v* 30/72 [42%] with health centre based surgery; RR 1.4, CI not reported).[28]

GLOSSARY

Bilamellar tarsal rotation The upper lid is cut full thickness horizontally in a line parallel and 3 mm from the eyelid margin and running from just lateral to the lacrimal punctum to the lateral canthus. Everting sutures are then placed through all layers of the lid to prevent the margin from turning inwards.
Eversion splinting The lid margin is split posterior to the lashes, the eversion of the anterior section is maintained by sutures tied over a roll of paraffin gauze.
Major trichiasis Lid closure complete; six or more lashes in contact with eyeball.
Minor trichiasis Lid closure complete; one to five lashes in contact with eyeball.
Phthisis bulbi A disorganised, shrunken eye that does not perceive light.
Tarsal advance The lid margin is split posterior to the lashes. The skin, lashes, and orbicularis are freed from the tarsal plate and retracted away from the cornea and are sutured back on to the tarsal plate, leaving a bare area of tarsus to act as the lid margin.
Tarsal advance and rotation The upper lid is everted over a speculum. The tarsal plate is fractured parallel to, and 3 mm from, the lid margin. In this operation the skin and orbicularis are not cut. The short portion of tarsal plate attached to the lid margin is then rotated through 180° and sutured into place to form the new lid margin.
Tarsal grooving A wedge of skin, orbicularis, and tarsus is removed parallel to the lid margin. Sutures through all layers act to evert the lid margin.
Trichiasis The misdirection of lashes towards the eyeball.

TABLE 1 **Interventions to prevent scarring trachoma by reducing active trachoma: RCTs of antibiotics compared with no treatment, placebo, or a monthly vitamin tablet in people with active trachoma (see text, p 884).**

Study	Treatment	Route	Dose	Duration	Comparison
10	Tetracycline	Topical	Not stated	Daily for 5 days a month for 3 months	No treatment
13	Tetracycline derivative GS2989	Topical	0.25%	Once every school day for 11 weeks	No treatment
13	Oxytetracycline	Topical	Not stated	Once every school day for 11 weeks	No treatment
14	Oxytetracycline	Topical	1%	Twice daily for 7 consecutive days every month for 12 months	Vitamin pills, orally, 1 dose every month for 12 months
14	Doxycycline	Oral	5 mg/kg	1 dose every month for 12 months	Vitamin pills, orally, 1 dose every month for 12 months
15	Trisulfapyrimidine	Oral	3.5 g/day	3 daily during 3 consecutive weeks	Lactose, orally, 3 daily for 3 weeks
15	Trisulfapyrimidine	Oral	3.5 g/day	3 daily during 3 consecutive weeks	Lactose, orally, 3 daily for 3 weeks
16	Sulfametopyridazine	Oral	0.5 g	Once daily for 5 consecutive days every week for 3 weeks	No treatment
15	Tetracycline	Topical	1%	3 times daily on 5 consecutive days every week for 6 weeks	No treatment
17	Doxycycline	Oral	2.5–4.0 mg/kg	Once daily for 5 consecutive days every week up to 28 doses in 40 days	Placebo once daily for 5 consecutive days every week up to 28 doses in 40 days
18	Sulfafurazole plus sulfadimethoxine	Topical plus oral	15%/100 mg/kg	Twice daily for 5 consecutive days every month for 5 months/biweekly for 5 months	No treatment
18	Sulfadimethoxine	Oral	100 mg/kg	Twice weekly or weekly dose for 5 months	No treatment
18	Sulfafurazole	Topical	15%	Twice daily for 5 consecutive days every month for 5 months	No treatment
19	Tetracycline	Topical	1%	Twice daily for 6 consecutive days every week for 6 weeks	No treatment

TABLE 2 **Interventions to prevent scarring trachoma by reducing active trachoma: RCTs comparing rates of active trachoma and bacteriological infection after oral azithromycin or topical tetracycline (see text, p 884).**

Study	Treatment	Dose	Duration	Comparison	Dose/duration
20	Azithromycin orally	20 mg/kg	1 dose	Topical tetracycline	Twice daily for 6 weeks
21	Azithromycin orally	20 mg/kg	1 dose, or 3 times 1 dose at weekly intervals, or 6 times 1 dose at 28 day intervals	1% topical oxytet/polymyxin plus oral placebo	Ointment once daily for 5 consecutive days monthly for 6 months
22	Azithromycin orally	20 mg/kg up to 1 g	Once a week for 3 weeks	1% topical oxytetracycline	Once daily for 6 weeks
	Women of childbearing age; erythromycin	500 mg twice daily or 250 mg 4 times daily	14 days	ND	ND
23	Azithromycin orally	20 mg/kg	1 dose	1% topical tetracycline	Twice daily for 5 consecutive days every week for 6 weeks

ND, no data.

QUESTIONS

INTERVENTIONS

*Based on observational studies and indirectly from RCTs in other settings

Covered elsewhere in *Clinical Evidence*

Preventing mother to child transmission (see HIV: mother to child transmission, p 902).

Prophylaxis against specific opportunistic infections (see HIV: opportunistic infections, p 913).

Key Messages

Prevention

- **Early diagnosis and treatment of sexually transmitted diseases** One RCT has found that early diagnosis and treatment of sexually transmitted diseases reduces the risk of acquiring HIV infection over 2 years.
- **Postexposure prophylaxis in healthcare workers** One case control study found limited evidence suggesting that postexposure prophylaxis with zidovudine may reduce the risk of HIV infection over 6 months. Evidence from other settings suggests that combining several antiretroviral drugs is likely to be more effective than zidovudine alone.
- **Presumptive mass treatment of sexually transmitted diseases** One RCT found no significant difference in the incidence of HIV over 20 months between presumptive mass treatment for sexually transmitted diseases and no treatment.

Treatment

- **Three antiretroviral drugs regimens (compared with two antiretroviral drugs regimens)** One systematic review has found that, compared with two antiretroviral drugs regimens, three drugs regimens reduce disease progression or death. Some of the reviewed trials included a non-nucleoside reverse transcriptase inhibitor as a third drug, and some a protease inhibitor.
- **Two antiretroviral drugs regimens (compared with single antiretroviral drug regimens)** Large RCTs, with follow up of 1–3 years, have found that two drugs regimens (zidovudine plus another nucleoside analogue or protease inhibitor drug) reduce the risk of new AIDS defining illnesses and death compared with zidovudine alone. Adverse events were common in all treatment groups.
- **Early versus delayed antiretroviral treatment with multidrug regimens** One systematic review compared early versus delayed antiretroviral treatment, but the RCTs were all started when zidovudine was the only drug available. Overall, the systematic review found no significant difference in the risk of AIDS free survival or overall survival with extended follow up. We found no RCTs exploring this question with two or three drug regimens.
- **Four antiretroviral drugs regimens (compared with three antiretroviral drugs regimens)** We found no systematic review or RCTs comparing four antiretroviral drugs regimens with three antiretroviral drugs regimens for clinical outcomes.

DEFINITION HIV infection refers to infection with the human immunodeficiency virus type 1 or type 2. Clinically, this is characterised by a variable period (average around 8–10 years) of asymptomatic infection, followed by repeated episodes of illness of varying and increasing severity as immune function deteriorates. The type of illness varies greatly by country, availability of specific treatments for HIV, and prophylaxis for opportunistic infections.

INCIDENCE/ PREVALENCE Worldwide estimates suggest that, by June 2001, about 51 million people had been infected with HIV, about 16 million people had died as a result, and about 16 000 new HIV infections were occurring each day.[1] About 90% of HIV infections occur in the developing world.[1] Occupationally acquired HIV infection in health-care workers has been documented in 95 definite and 191 possible cases, although this is likely to be an underestimate.[2]

AETIOLOGY/ RISK FACTORS The major risk factor for transmission of HIV is unprotected heterosexual or homosexual intercourse. Other risk factors include needlestick injury, sharing drug injecting equipment, and blood transfusion. An HIV infected woman may also transmit the virus to her baby. This has been reported in 15–30% of pregnant women with HIV infection. Not everyone who is exposed to HIV will become infected, although risk increases if exposure is repeated, at high dose, or through blood. There is at least a two to five times greater risk of HIV infection among people with sexually transmitted diseases.[3]

PROGNOSIS Without treatment, about half of people infected with HIV will become ill and die from AIDS over about 10 years. A meta-analysis of 13 cohort studies from Europe and the USA looked at 12 574 treatment naïve people starting highly active antiretroviral therapy with a combination of at least three drugs.[4] During 24 310 person

years of follow up, 1094 people developed AIDS or died. Baseline CD4 cell count and baseline HIV-1 viral load were associated with the probability of progression to AIDS or death. Other independent predictors of poorer outcome were advanced age, infection through injection drug use, and a previous diagnosis of AIDS. The CD4 cell count at initiation was the dominant prognostic factor in people starting highly active antiretroviral therapy. Genetic factors have been shown to affect response to antiretroviral treatment, but were not considered in the meta-analysis.[4]

AIMS OF INTERVENTION To reduce transmission of HIV; to prevent or delay the onset of AIDS, as manifested by opportunistic infections and cancers; to increase survival; to minimise loss of quality of life caused by inconvenience and adverse effects of current regimens.

OUTCOMES Incidence of HIV infection, new AIDS diseases, and adverse events; mortality; quality of life.

METHODS *Clinical Evidence* search and appraisal July 2003. In addition, we contacted experts in the field, and reviewed abstract books and CDs for conferences held since 1995. Trials were included if they were designed to detect differences in clinical end points. Where trials using clinical end points were unavailable, we included trials using surrogate markers known to denote higher risk of disease progression. Many trials of new treatments are of short duration, which may reflect the fact that many new drugs have only short term effects. We have included evidence on single and two drug antiretroviral regimens, because it may be useful in countries where three drug treatment is not widely available.

QUESTION What are the effects of preventative interventions?

OPTION EARLY DETECTION AND TREATMENT OF SEXUALLY TRANSMITTED DISEASES

One RCT has found that early diagnosis and treatment of sexually transmitted diseases reduces the risk of acquiring HIV infection over 2 years

Benefits: We found no systematic review. One RCT randomised 12 communities in Tanzania (about 12 000 people) to intervention or no intervention.[5] Intervention consisted of diagnosis and treatment of sexually transmitted diseases (STDs) at a local health centre (within 90 minutes' walking distance), provision of free condoms during the current STD episode, and health education by healthcare workers trained in STD case management. The RCT found that intervention significantly reduced the risk of acquiring HIV over 2 years (RR 0.58, 95% CI 0.42 to 0.79).

Harms: Syndromic case management (treating people for the most likely causes of their symptoms and signs) may result in wrong or unnecessary treatment. The RCT gave no information on this.[5]

Comment: There is a clear biological mechanism for the synergistic effect of STDs on HIV transmission, and for STD control as an HIV control strategy. The inflammation associated with STDs increases HIV shedding in genital secretions, and treating STDs reduces this

inflammation.[6] Syndromic management of STDs is more commonly used in resource limited settings. In other settings, a microbiological diagnosis is usually made, allowing specific treatment. The trial, randomised by the community and analysed by the individual, uses regression analysis in an attempt to overcome the associated cluster bias, but it is unclear whether this is successful.

OPTION PRESUMPTIVE SEXUALLY TRANSMITTED DISEASE TREATMENT

One RCT found no significant difference in the incidence of HIV over 20 months between presumptive mass treatment for sexually transmitted diseases and no treatment.

Benefits: We found no systematic review. One RCT randomised 10 communities in Uganda (about 12 000 people) to intervention or no intervention.[7] Intervention consisted of treating all adults with several drugs for sexually transmitted diseases (STDs) every 10 months. Although the prevalence of some STDs fell in intervention communities, there was no significant difference in the incidence of HIV between intervention and control communities over 20 months of follow up (incidence of HIV in both groups about 1.5/100 person years; RR intervention *v* control 0.97, 95% CI 0.81 to 1.16).

Harms: Mass treatment means that many uninfected people will be unnecessarily treated for STDs, exposing them to risks of adverse drug reactions and possibly of drug resistance. The RCT gave no information on this.[7]

Comment: The negative finding of the RCT has several possible explanations other than ineffectiveness of the intervention: a high incidence of symptomatic STDs between rounds of mass treatment; a low population risk for treatable STDs; and intense exposure to HIV.[7] The trial, randomised by the community and analysed by the individual, used regression analysis in an attempt to overcome the associated cluster bias, but it is unclear whether this was successful. As many as 80% of STDs are unrecognised or asymptomatic.[8] The variable efficacy of these two interventions may reflect the epidemiological properties of mature versus emerging epidemics. Health seeking behaviour clearly will have an impact. Many sexually transmitted infections are unrecognised or asymptomatic and the analysis of these trials, using regression analysis in an attempt to overcome cluster bias, may have an effect on the reported outcomes.[9]

OPTION POSTEXPOSURE PROPHYLAXIS IN HEALTHCARE WORKERS

One case control study found limited evidence suggesting that postexposure prophylaxis with zidovudine may reduce the risk of HIV infection over 6 months. Evidence from other settings suggests that combining several antiretroviral drugs is likely to be more effective than zidovudine alone.

Benefits: We found no systematic review or RCTs. **Zidovudine alone:** One case control study from the USA and France evaluated outcomes in 31 health workers who acquired HIV infection after occupational

exposure, and outcomes in 679 controls who did not acquire HIV infection despite occupational exposure.[10] This study included people followed up for at least 6 months after exposure. HIV infection was less likely in people who received postexposure prophylaxis compared with those who did not (reduction in OR by 81%, 95% CI 43% to 94%). It found that the risk of seroconversion increased with severity of exposure; for example, a penetrating injury with a hollow, bloody needle carried the greatest risk. **Zidovudine plus other antiretroviral drugs:** We found no studies of postexposure prophylaxis using combinations of antiretroviral drugs.

Harms: Short term toxicity (including fatigue, nausea, and vomiting) and gastrointestinal discomfort have been reported by 50–75% of people taking zidovudine and caused 30% to discontinue postexposure prophylaxis.[11] Treatment studies suggest that the frequency of adverse effects is higher in people taking a combination of antiretroviral drugs (reported in 50–90%), which may reduce adherence to postexposure prophylaxis (24–36% discontinued). The risk of drug interactions is also increased. Severe adverse effects, including hepatitis and pancytopenia, have been reported in people taking combination postexposure prophylaxis, but the incidence is not known.

Comment: Case control studies are considered sufficient because experimental studies are hard to justify ethically, and are logistically difficult because of the low rate of seroconversion in exposed people. A summary of 25 studies (22 seroconversions in 6955 exposed people) found that the risk of HIV transmission after percutaneous exposure was 0.32% (95% CI 0.18% to 0.45%) and that the risk after mucocutaneous exposure was 0.03% (95% CI 0.006% to 0.19%).[2] Indirect evidence for postexposure prophylaxis comes from animal studies[10] and from a placebo controlled RCT of zidovudine in pregnant women,[12] which found a reduced frequency of mother to child HIV transmission, presumed to be caused in part by postexposure prophylaxis. RCTs have found that combinations of two, three, or more antiretroviral drugs are more effective than single drug regimens in suppressing viral replication. There is also an unquantified risk that zidovudine alone may not prevent transmission of zidovudine resistant strains of HIV. This constitutes the rationale for combining antiretroviral drugs for postexposure prophylaxis.

QUESTION What are the effects of different antiretroviral drug treatment regimens?

OPTION TWO ANTIRETROVIRAL DRUGS REGIMENS VERSUS ONE DRUG REGIMENS

Large RCTs, with follow up of 1–3 years, have found that two drugs regimens (zidovudine plus another nucleoside analogue or protease inhibitor drug) reduce the risk of new AIDS defining illnesses and death compared with ziduvudine alone. Adverse events were common in all treatment groups.

Benefits: We found one systematic review,[13] two additional RCTs,[14,15] and one subsequent RCT[16] comparing two drugs versus one drug regimens. The systematic review (search date not reported, 6 RCTs, 7700 people) compared zidovudine plus didanosine or zidovudine plus zalcitabine versus zidovudine alone.[13] Participants entered the trials with various stages of infection and were followed for an average of 29 months, during which time 2904 people developed progressive disease and 1850 died. The combined drug regimens significantly delayed disease progression compared with single drug regimens (RR for disease progression with addition of didanosine 0.74, 95% CI 0.67 to 0.82; RR with addition of zalcitabine 0.86, 95% CI 0.78 to 0.94) and death (RR with addition of didanosine 0.72, 95% CI 0.64 to 0.82; RR with addition of zalcitabine 0.87, 95% CI 0.77 to 0.98). After 3 years, the estimated percentages of people who were alive and without a new AIDS event were 53% for zidovudine plus didanosine versus 49% for zidovudine plus zalcitabine versus 44% for zidovudine alone; the percentages alive were 68% versus 63% versus 59%. The first additional RCT (940 people) comparing zalcitabine plus saquinavir (a protease inhibitor) versus either drug as monotherapy found that combination treatment significantly reduced clinical disease (RR 0.51, 95% CI 0.36 to 0.72) or death (RR 0.32, 95% CI 0.16 to 0.64) at 1 year.[14] The second additional RCT (1895 people with CD4 positive T cell counts 25–250/mm^3) found that adding lamivudine (a nucleoside analogue) to regimens containing zidovudine (zidovudine alone in 62%, zidovudine plus didanosine or zalcitabine in the rest) significantly reduced the risk of AIDS or death over about 1 year (HR 0.42, 95% CI 0.32 to 0.57).[15] The subsequent RCT (996 people who had never received antiretroviral treatment) compared zidovudine plus indinavir (a protease inhibitor) versus either zidovudine or indinavir alone.[16] It found that combination treatment significantly reduced the rate of progression to AIDS compared with zidovudine alone after a median follow up of 1 year (combination *v* zidovudine: RR 0.30, 95% CI 0.18 to 0.50). It found no significant difference between combination treatment and indinavir alone (RR 0.77, 95% CI 0.72 to 2.32).

Harms: Adverse effects such as anaemia and neutropenia were common in all groups in all of the RCTs cited above. Up to a third of participants experienced a serious adverse event, with the highest rates in people with lower CD4 counts. Adverse events led to cessation of blind treatment in about a third of participants. The addition of didanosine to zidovudine increased the risks of nausea (RR 1.8, 95% CI 1.1 to 2.9), abdominal pain (RR 1.6, 95% CI 1.0 to 2.7), and pancreatitis (RR 4.6, 95% CI 1.0 to 22.0) compared with zidovudine alone. Addition of zalcitabine increased the risk of neuropathy (RR 2.2, 95% CI 1.4 to 3.6).[13] Addition of lamivudine did not significantly increase the rate of adverse events.[15] The subsequent RCT found that frequent adverse effects in all three treatment groups were abdominal pain, fever, asthenia/fatigue, and malaise.[16] Both indinavir alone and indinavir plus zidovudine versus zidovudine significantly increased the risk of kidney stone formation

(40/332 [12%] with indinavir or indinavir plus zidovudine *v* 13/332 [4%] with zidovudine; RR 3.08, 95% CI 1.72 to 5.29; NNH 12, 95% CI 6 to 36). Overall, 2.9% of people permanently discontinued some or all of their study treatment because of adverse effects before an AIDS related clinical event.[17]

Comment: Two drug regimens often allow substantial residual viral replication in an environment where drug resistant variants have selective advantage. Resistance to these drugs tends to develop over several months to years.[17] The relevance of this is not fully understood but prior use of, and measurable resistance to, nucleoside analogue reverse transcriptase inhibitors tends to be associated with poorer virological response to new regimens that include drugs of this class.[18–20]

OPTION THREE ANTIRETROVIRAL DRUGS REGIMENS VERSUS TWO DRUGS REGIMENS

One systematic review has found that, compared with two antiretroviral drugs regimens, three drugs regimens reduce disease progression or death. Some of the reviewed trials included a non-nucleoside reverse transcriptase inhibitor as a third drug, and some a protease inhibitor.

Benefits: We found one systematic review (search date 2001, 54 RCTs, 4558 people) comparing different drug regimens.[21] The review identified 12 RCTs comparing three versus two drugs regimens. Some of the reviewed trials included a non-nucleoside reverse-transcriptase inhibitor as a third drug, and some a protease inhibitor. The review found that triple therapy significantly improved clinical outcomes compared with double therapy after less than 2 years of follow up (9 RCTs, disease progression or death: OR 0.6, 95% CI 0.5 to 0.8). The largest RCT identified by the review (3485 people with CD4 counts of 50–350/mm^3 who had low exposure to zidovudine) compared zidovudine plus zalcitabine plus saquinavir versus zidovudine plus zalcitabine or zidovudine plus saquinavir.[22] It found that triple therapy significantly reduced the risk of AIDS or death (RR of AIDS or death 0.50; CI not reported; P = 0.0001). Health related quality of life did not change significantly over 48 weeks for individuals in the triple therapy group for mental health (P = 0.146) but did for physical health (P = 0.008).[22]

Harms: In the included RCT, about 25% of people in each group had nausea, 10% diarrhoea, 10% vomiting, 10% headache, 4% abdominal pain, and 3% peripheral neuropathy.[23] There was no significant difference between people taking three versus two drugs in other adverse effects (fever, asthenia, anorexia, rash, pruritus, myalgia, insomnia, anaemia, buccal mucosa ulceration, and dyspepsia). Although metabolic toxicity and lipodystrophy are well recognised as side effects in adults,[24] in children the prevalence of clinical lipodystrophy is not yet reliably established. One trial in children comparing three drugs versus two drugs regimens, with the addition of nelfinavir, reported that the incidence of minor adverse events (vomiting, diarrhoea, cutaneous reaction, fever, and anaemia) was similar with nelfinavir and placebo groups per 100 child years (84.8 with nelfinavir, 84.4 with placebo; P = 0.26).[25] However, all diarrhoea events occurred in the nelfinavir group (P = 0.01).

Comment: Few of the trials used clinical end points. Longer term follow up of people taking protease inhibitors has found abnormal fat distribution, hyperglycaemia, and raised triglyceride and cholesterol concentrations. The clinical significance of these changes is uncertain. Many drugs interact with protease inhibitors because of inhibition of cytochrome P450. There is an urgent need for large RCTs in children. The relevance of lipodystrophy and other metabolic changes in growing children is uncertain. Treatment of children should, wherever possible, be undertaken by experts in paediatric HIV infection.

OPTION FOUR ANTIRETROVIRAL DRUGS VERSUS THREE DRUGS REGIMENS New

We found no systematic review or RCTs comparing four antiretroviral drugs regimens with three antiretroviral drugs regimens for clinical outcomes.

Benefits: We found no systematic review or RCTs comparing four antiretroviral drugs regimens with three antiretroviral drugs regimens for clinical outcomes.

Harms: We found no systematic review or RCTs comparing four antiretroviral drugs regimens with three antiretroviral drugs regimens for clinical outcomes.

Comment: Clearly, adherence to therapy, which is such an important strategy in minimising the development of viral resistance, becomes more difficult with more complex regimens. Side effects and drug interactions with four antiretroviral drug regimens are as yet poorly documented phenomena. The RCTs comparing three versus two antiretroviral drugs regimens, or four versus two antiretroviral drugs regimens, point to superior antiviral effects of an increasing number of antiretroviral agents. Many of the studies involving four antiretroviral drugs, in fact, refer to the addition of a low dose of ritonavir to three antiretroviral drugs in order to boost the effect of other antiretroviral drugs. The question of four versus three antiretroviral drug regimens for clinical end points remains unresolved.

OPTION EARLY VERSUS DELAYED ANTIRETROVIRAL TREATMENT

One systematic review compared early versus delayed antiretroviral treatment, but the RCTs were all started when zidovudine was the only drug available. Overall, the systematic review found no significant difference in the risk of AIDS free survival or overall survival with extended follow up. We found no RCTs exploring this question with two or three drug regimens.

Benefits: We found one systematic review (search date not reported, 5 RCTs, 7722 people with asymptomatic HIV mainly with CD4 counts $> 200/mm^3$) comparing zidovudine given immediately versus zidovudine deferred until the early signs of AIDS.[26] It found that immediate treatment significantly increased AIDS free survival compared with deferred treatment at 1 year (78/4431 [1.76%] with immediate zidovudine *v* 131/3291 [3.98%] with deferred zidovudine; OR 0.52, 95% CI 0.39 to 0.68), but the difference was not

significant at the end of the RCTs (median follow up of 50 months; 1026/4431 [23.2%] with immediate zidovudine *v* 882/3291 [26.8%] with deferred zidovudine; OR 0.96, 95% CI 0.87 to 1.05). Overall survival was similar in the two groups at 1 year (24/4431 [5.4%] with immediate zidovudine *v* 18/3291 [5.5%] with deferred zidovudine; OR 1.22, 95% CI 0.67 to 2.25) and at the end of the RCTs (734/4431 [16.6%] with immediate zidovudine *v* 617/3291 [18.7%] with deferred zidovudine; OR 1.04, 95% CI 0.93 to 1.16).

Harms: A meta-analysis presented pooled toxicity data in terms of events per 100 patient years.[27] In asymptomatic people, early treatment conferred a small but significant increase in the risk of anaemia (RR of haemoglobin < 8.0 g/dL; early *v* deferred treatment 2.1, 95% CI 1.1 to 4.1; AR 0.4 events per 100 person years). There was also a small increase in risk of neutropenia with early treatment (AR 1.1 events per 100 person years; CI not reported; P = 0.07). In symptomatic people, the excess incidence of severe anaemia probably reflected the high doses of zidovudine (1200–1500 mg/day; RR of severe anaemia, high *v* low dose 3.6, 95% CI 1.3 to 10). The authors advised that the toxicity results should be interpreted cautiously, because the results varied considerably.

Comment: No new trials on this question are ongoing. With three drug regimens, rates of AIDS and death are currently low and treatment is known to be beneficial up to and over a 2 year period (see benefits of three drugs regimens, p 898). Many people feel sufficiently certain about when to start treatment — based on evidence about HIV pathogenesis, resistance, immune regeneration with treatment, and long term adverse effects — and so would not consider randomisation to immediate versus deferred treatment. Decisions on when to initiate multidrug treatment are currently based on our understanding of how HIV induces immune damage, the capacity for immune regeneration while on treatment, the toxicity and inconvenience of treatment, and the risk of resistance, rather than on results of RCTs.

QUESTIONS

INTERVENTIONS

*Provided that there is access to clean water and health education

See glossary, p 910

Key Messages

- **Antiretroviral drugs** One systematic review has found that zidovudine reduces the incidence of HIV infection in infants compared with placebo. One RCT has found that the longer versus shorter courses of zidovudine ("long–long" versus "short–short" courses) given to mother and infant reduces the incidence of HIV in infants. One RCT has found that nevirapine given to the mother and to her newborn reduces the risk of HIV transmission compared with zidovudine. One RCT found no additional advantage in giving nevirapine to the mother and baby when transmission rates are already reduced by mothers receiving standard antiretroviral treatment. One RCT has found that zidovudine plus lamivudine given in the antenatal, intrapartum and postpartum periods, or in the intrapartum and postpartum periods, reduces the risk of transmission of HIV compared with placebo. One RCT found no difference in newborn HIV infection rates between nevirapine versus zidovudine plus lamivudine given to the mother during labour and to the mother and baby after delivery.
- **Avoiding breast feeding** One RCT in women with HIV who had access to clean water and health education has found that formula feeding reduces the incidence of HIV in infants after 24 months without increasing infant mortality compared with breast feeding.
- **Elective caesarean section** One RCT provided limited evidence that elective caesarean section reduced the incidence of HIV in infants at 18 months compared with vaginal delivery.
- **Immunotherapy** One RCT found no significant difference in HIV transmission to infants from mothers taking zidovudine and either HIV hyperimmune globulin or immunoglobulin without HIV antibody. However, the study may have been too small to exclude a clinically important difference.
- **Vaginal microbicides** One systematic review provided insufficient evidence about the effects of vaginal microbicides on the transmission of HIV to infants.

- **Vitamin supplements** Three RCTs found that vitamin A supplements given to HIV positive pregnant women had no significant effect on the risk of HIV infection in their infants compared with either placebo or no vitamin A. One RCT found that multivitamins given during pregnancy had no significant effect on HIV infection in their infants.

DEFINITION Mother to child transmission of HIV-1 (see glossary, p 910) infection can occur during pregnancy, in the intrapartum period, or postnatally through breast feeding.[1] By contrast, HIV-2 (see glossary, p 910) is rarely transmitted from mother to child.[2] Infected children usually have no symptoms or signs of HIV at birth, but develop them over subsequent months or years.[3]

INCIDENCE/ PREVALENCE A review of 13 cohorts found that the risk of mother to child transmission of HIV without antiviral treatment is on average about 15–20% in Europe, 15–30% in the USA, and 25–35% in Africa.[4] The risk of transmission is estimated to be 15–30% during pregnancy, with an additional risk of about 10–20% postpartum through breast feeding.[5] It has been estimated that 800 000 children below the age of 15 years were newly infected with HIV during 2001, bringing the total number of children with HIV/AIDS to 3 million worldwide.[6] Most of these children were infected from their mother and 90% live in sub-Saharan Africa.

AETIOLOGY/ RISK FACTORS Transmission of HIV to children is more likely if the mother has a high viral load.[1,7,8] Women with detectable viraemia (by p24 antigen or culture) have double the risk of transmitting HIV-1 to their infants than those who do not.[1] Breast feeding has also been shown in prospective studies to be a risk factor.[9,10] Other risk factors include sexually transmitted diseases, chorioamnionitis, prolonged rupture of membranes, and vaginal mode of delivery.[6,11–14]

PROGNOSIS About 25% of infants infected with HIV progress rapidly to AIDS or death in the first year. Some survive beyond 12 years of age.[3] One European study found a mortality of 15% in the first year of life and a mortality of 28% by the age of 5 years.[15] A recent study reported that, in children under 5 years of age in sub-Saharan Africa, HIV accounted for 2% of deaths in 1990 and almost 8% in 1999.[16] Five countries (Botswana, Namibia, Swaziland, Zambia, and Zimbabwe) had rates of HIV attributable mortality in excess of 30/1000 in children under the age of 5 years.

AIMS OF INTERVENTION To reduce mother to child transmission of HIV and improve infant survival, with minimal adverse effects.

OUTCOMES HIV infection status of the child; infant morbidity and mortality; maternal morbidity and mortality; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal May 2003.

HIV: mother to child transmission

QUESTION What are the effects of measures to reduce mother to child transmission of HIV?

OPTION ANTIRETROVIRAL DRUGS

One systematic review has found that zidovudine reduces the incidence of HIV in infants compared with placebo. One RCT has found that longer courses of zidovudine given to mother and infant reduce the incidence of HIV in infants compared with shorter courses of zidovudine. One RCT has found that nevirapine given to the mother and to her newborn reduces the risk of HIV transmission compared with zidovudine. One RCT found no additional advantage in giving nevirapine to the mother and baby when transmission rates are already reduced by mothers receiving standard antiretroviral treatment. One RCT has found that zidovudine plus lamivudine given in the antenatal, intrapartum, and postpartum periods, or during the intrapartum and postpartum periods, reduces the risk of transmission of HIV compared with placebo. One RCT found no difference in newborn HIV infection rates between nevirapine versus zidovudine plus lamivudine given to the mother during labour and to the mother and baby after delivery.

Benefits:

Zidovudine versus placebo: We found one systematic review (search date 2001, 4 RCTs, 1585 women) that compared zidovudine given to the mother before, during, or after labour with placebo (see table 1, p 912).[17] In one of the included RCTs, infants of mothers receiving zidovudine were also given zidovudine for 6 weeks after birth.[18] Meta-analysis found that zidovudine significantly reduced the incidence of HIV in infants compared with placebo (AR 79/616 [13%] with zidovudine *v* 150/634 [24%] with placebo; RR 0.54, 95% CI 0.42 to 0.69). The results were still significant when the RCT of zidovudine that used the most intensive regimen[18] was excluded from the analysis (combined results: AR 70/495 [14%] with less intensive regimens *v* 119/507 [23%] with placebo; RR 0.60, 95% CI 0.46 to 0.79).[19–21] The review found that zidovudine significantly reduced HIV transmission to infants among both breast feeding and non-breast feeding mothers (breast feeding RR 0.62, 95% CI 0.46 to 0.85; non-breast feeding RR 0.50, 95% CI 0.30 to 0.85).[17] **Alternative zidovudine regimens:** One RCT (1437 women) compared four different zidovudine regimens. Zidovudine was given to mothers from a specific time in gestation until delivery and to the infant until a specific age: "short–short" course (mother from 35 weeks, infant for up to 3 days); "long–long" (mother from 28 weeks, infant for up to 6 weeks); "short–long" (mother from 35 weeks, infant for up to 6 weeks); and "long–short" (mother from 28 weeks, infant for up to 3 days).[22] The RCT found that a "long–long" course significantly reduced HIV in infants compared with a "short–short" course (AR 9/220 [4%] with long course *v* 24/229 [10%] with short course; RR 0.39, 95% CI 0.19 to 0.82). As the "short–short" regimen seemed not to reduce transmission of HIV it was discontinued at the first interim analysis. The trial found no significant difference between a "long–long" and "short–long" (26/401 [7%] with "long–long" *v* 29/338 [9%] with "short–long" course; RR 0.76, 95% CI 0.45 to 1.25) or between "long–long" and "long–short" (26/401

[7%] with "long–long" *v* 16/340 [5%] with "long–short" course; RR 1.37, 95% CI 0.75 to 2.50). **Zidovudine versus nevirapine:** The systematic review[17] identified one unblinded RCT (626 women from a predominantly breast feeding population in Uganda) that compared zidovudine versus nevirapine.[23] It found that nevirapine (given to mothers as a single oral dose at the onset of labour and to infants as a single dose within 72 hours of birth) significantly reduced HIV in infants compared with zidovudine (given orally to women during labour and to their newborns for 7 days after birth) at 14–16 weeks (AR 37/246 [15%] with nevirapine *v* 65/250 [26%] with zidovudine; RR 0.58, 95% CI 0.40 to 0.83). **Nevirapine added to standard antiretroviral treatment:** One RCT compared nevirapine (given to mothers as a single oral dose at the onset of labour and to infants as a single dose within 72 hours of birth) versus placebo among 1506 non-breast feeding women in the USA, Europe, Brazil, and the Bahamas, who were already receiving standard antiretroviral treatment.[24] It found no significant difference between nevirapine and placebo in HIV risk in infants after 6 months (AR 9/631 [1.4%] with nevirapine *v* 10/617 [1.6%] with placebo; ARR –0.2, 95% CI –1.5 to +1.2; RR 0.88, 95% CI 0.36 to 2.15). The trial was stopped early because it was considered unlikely that a clinically important effect could be detected given the low overall HIV transmission rate. Only 1270 (84.3%) women eventually received the study treatment. **Combination antiretroviral regimens versus placebo:** One RCT (1797 predominantly breast feeding women in South Africa, Uganda, and Tanzania) compared zidovudine plus lamivudine versus placebo.[25] This combination of antiretroviral drugs significantly reduced the risk of HIV transmission at 6 weeks when given in the antenatal (from 36 weeks), intrapartum, and postpartum (to mother and baby for 1 week) periods (regimen A) (AR 16/281 [5.7%] with zidovudine plus lamivudine *v* 40/261 [15.3%] with placebo; RR 0.37, 95% CI 0.21 to 0.65; NNT 11, 95% CI 7 to 24) and during the intrapartum and postpartum periods (regimen B) (AR 24/270 [8.9%] with zidovudine plus lamivudine *v* 40/261 [15.3%] with placebo; RR 0.58, 95% CI 0.36 to 0.94; NNT 16, 95% CI 9 to 126). The RCT found that zidovudine plus lamivudine given during the intrapartum period alone (regimen C) did not significantly affect the risk of transmission at 6 weeks (AR 40/282 [14.2%] with zidovudine plus lamivudine *v* 40/261 [15.3%] with placebo; RR 0.93, 95% CI 0.62 to 1.40). However, survival analysis found no significant difference in the incidence of HIV infection in infants at 18 months (14.9%, 95% CI 9.4% to 22.8% with regimen A; 18.1%, 95% CI 12.1% to 26.2% with regimen B; 20.0%, 95% CI 12.9% to 30.1% with regimen C; and 22.2%, 95% CI 15.9% to 30.2% with placebo; P values not reported). It also found no significant difference in infant mortality at 18 months (10.1% with regimen A, 14.2% with regimen B, 12.8% with regimen C, and 13.4% with placebo, P = 0.40). **Single drug versus combination antiretroviral regimens:** One RCT (1317 women in South Africa) compared nevirapine (given to the mother during labour and to the mother and baby within 48 hours of delivery) versus zidovudine plus lamivudine (given to the mother during labour and to the mother and baby for 1 week after birth).[26] It found no significant difference between nevirapine and zidovudine

plus lamivudine in HIV infection rate at 8 weeks (excluding intrauterine infection: AR 5.7% with nevirapine *v* 3.6% with zidovudine plus lamivudine; P = 0.11; overall infection rate: 12.3% with nevirapine *v* 9.3% with zidovudine plus lamivudine; P = 0.11).

Harms:

Zidovudine versus placebo: The review found that intensive zidovudine significantly increased the risk of neonatal haematological toxicity compared with placebo (RR 1.86, 95% CI 1.18 to 2.94; specific effects undefined). No significant difference was found between less intensive regimens and placebo (RR 0.77, 95% CI 0.44 to 1.35).[17] Infants who received the most intensive regimen and were followed for 18 months had mild reversible anaemia that resolved by 12 weeks of age.[27] The same trial in uninfected infants followed for a median of 4.2 years found no significant difference between zidovudine and placebo in growth patterns, immunological parameters, or the occurrence of childhood cancers.[28] **Alternative zidovudine regimens:** The RCT found that the rate of serious adverse events in mothers and infants was similar for all regimens. The rates of severe anaemia in infants were "long–long" 1%; "long–short" 0%; "short–long" 0.3%; and "short–short" 1.3%.[22] **Zidovudine versus nevirapine:** The RCT of zidovudine versus nevirapine found no significant difference in serious adverse effects in mothers and infants (in mothers: 4.0% with zidovudine *v* 4.7% with nevirapine; in infants up to 18 months of age: 19.8% with zidovudine *v* 20.5% with nevirapine).[28] In the multicentre RCT of nevirapine, adverse events were rare and similar in the two arms. Most commonly reported was severe "non-rash toxicity", especially anaemia, which was in most cases judged to be unrelated to the study medication (in mothers: 6.2% with nevirapine *v* 6.1% with placebo; in infants: 32.9% with nevirapine *v* 27.9% with placebo). **Combination antiretroviral regimens:** One RCT found no difference in adverse effects between zidovudine plus lamivudine and placebo. For grade 3 and 4 laboratory events before week 6 (in relation to haemoglobin, leucocytes, lymphocytes, thrombocytes, creatinine, or transaminase levels) the rates in mothers were: regimen A 9%, regimen B 6%, regimen C 7%, and placebo 8%; the corresponding rates in babies were 5% in each of the groups. Congenital abnormalities for the four groups were: regimen A 7%, regimen B 8%, regimen C 6%, and placebo 7%. The rates for neurological events (up to 18 months) in infants were regimen A 2%, regimen B 4%, regimen C 4%, and placebo 3%.[25] **Single drug versus combination antiretroviral regimens:** One RCT found no significant difference in adverse effects between those receiving nevirapine and those receiving zidovudine plus lamivudine.[26] Adverse effects in mothers included deaths (0.8% with nevirapine *v* 0.6% with zidovudine plus lamivudine), obstetric procedures (24% with nevirapine *v* 26% with zidovudine plus lamivudine), rash (0.6% with nevirapine *v* 0.8% with zidovudine plus lamivudine), and caesarean section (28% with nevirapine *v* 31% with zidovudine plus lamivudine). No hepatic or haematological adverse effects were reported for either group. Adverse effects in

infants were included deaths (3% in each), respiratory disorders (16% with nevirapine *v* 17% with zidovudine plus lamivudine), infections (8% with nevirapine *v* 9% with zidovudine plus lamivudine), hepatic adverse effects (3% in each), and rash (2% with nevirapine *v* 3% with zidovudine plus lamivudine).

Comment: In the RCT comparing nevirapine versus zidovudine plus lamivudine, all women received counselling on infant feeding practices and 42% in each group chose to breast feed.[26]

OPTION AVOIDING BREAST FEEDING

One RCT in women with HIV who had access to clean water and health education has found that formula feeding reduces the incidence of HIV in infants at 24 months without increasing mortality compared with breast feeding.

Benefits: We found no systematic review. We found one RCT (425 HIV-1 [see glossary, p 910]) seropositive women with access to clean water and health education in Kenya) that found that formula feeding significantly reduced the proportion of infants with HIV at 24 months compared with breast feeding (AR 31/205 [15%] with formula feeding *v* 61/197 [31%] with breast feeding; RR 0.49, 95% CI 0.33 to 0.72; NNT 7, 95% CI 5 to 13).[5] Although infants were breast fed throughout the RCT, the greatest exposure to breast milk occurred during the first 6 months of life. The RCT found no significant difference in mortality between breast feeding and formula feeding at 24 months (AR: 39/204 [19%] with formula feeding *v* 45/197 [23%] with breast feeding; RR 0.84, 95% CI 0.57 to 1.23).[5]

Harms: The RCT did not report on adverse effects (see comment below).[5]

Comment: The RCT did not report on adherence to the intervention. In countries with high infant mortality, avoiding breast feeding may increase infant morbidity and mortality further through its effect on nutrition, immunity, maternal fertility, and birth spacing. Access to clean water and education when using formula feeds may explain the similar mortality in breast fed and formula fed infants.

OPTION ELECTIVE CAESAREAN SECTION

One RCT provided limited evidence that elective caesarean section reduced the incidence of HIV in infants at 18 months compared with vaginal delivery.

Benefits: We found one systematic review (search date not stated, 1 RCT, 436 women) that compared elective caesarean section at 38 weeks versus vaginal delivery.[29] It found that caesarean section significantly reduced HIV transmission to infants at 18 months compared with vaginal delivery (AR 3/170 [3%] with caesarean section *v* 21/200 [11%] with vaginal delivery; RR 0.16, 95% CI 0.05 to 0.55; NNT 11, 95% CI 10 to 21).[29]

HIV: mother to child transmission

Harms: No serious adverse effects were reported in either group. Postpartum fever was significantly more common in women having caesarean section compared with vaginal delivery (15/225 [7%] with caesarean section *v* 2/183 [1%] with vaginal delivery; RR 6.1, 95% CI 1.5 to 22.0; NNH 18, 95% CI 16 to 50). Postpartum bleeding, intravascular coagulation, and severe anaemia were rare in both groups.[29]

Comment: About 15% of women withdrew from the RCT or were lost to follow up. None of the women breast fed, although this was not stated as a specific exclusion criterion. More women who gave birth by caesarean section versus vaginal delivery had received zidovudine during pregnancy (70% with caesarean section *v* 58% with vaginal delivery); this means that the observed difference between groups may not have been exclusively due to the different delivery methods.[29]

OPTION IMMUNOTHERAPY

One RCT found no significant difference in HIV transmission to infants from mothers taking zidovudine and either HIV hyperimmune globulin or immunoglobulin without HIV antibody. However, the study may have been too small to exclude a clinically important difference.

Benefits: We found one systematic review (search date not stated, 1 RCT, 501 women) that compared HIV hyperimmune globulin versus immunoglobulin without HIV antibody given to women during pregnancy, the intrapartum period, and to their infants at birth.[29] Women in both groups received a standard course of zidovudine and no infants were breast fed. The RCT found no significant difference in transmission of HIV to 6 months of age between HIV hyperimmune globulin and immunoglobulin without HIV antibody regimens (4.1% with HIV hyperimmune globulin *v* 6.0% with immunoglobulin without HIV antibody; CI not reported; $P = 0.36$).[29]

Harms: The trial reported no significant adverse effects.[29]

Comment: The low overall transmission rate (5%) in this study was much lower than the anticipated rate of greater than 15% used to calculate the appropriate sample size. The trial is unable to exclude a clinically important effect of HIV hyperimmune globulin on the number of children with HIV.[29]

OPTION VAGINAL MICROBICIDES

One systematic review provided insufficient evidence about the effects of vaginal microbicides on the incidence of HIV in infants.

Benefits: We found one systematic review (search date 2002).[30] It found no RCTs, but found one quasi-randomised trial (see comment below).[31]

Harms: The review found no RCTs (see comment below).[30]

Comment: The systematic review found one quasi-randomised trial (898 women) that assessed the effectiveness of vaginal irrigation with chlorhexidine during labour for reducing the risk of transmission.

HIV positive women at a hospital in Kenya were allocated to vaginal irrigation or no irrigation during alternate weeks.[31] The trial found no evidence of a lower rate of HIV transmission after vaginal cleansing versus no cleansing (AR 63/307 [20.5%] with vaginal cleansing *v* 64/295 [21.7%] without vaginal cleansing; RR 0.95, 95% CI 0.69 to 1.29). The trial reported no adverse effects in mothers or infants. In the trial, concealment of allocation was inadequate, and the analysis did not take into account the effect of clustering. Caution is therefore warranted in interpreting the study findings.[31]

OPTION VITAMIN SUPPLEMENTS

Three RCTs found that vitamin A supplements given to HIV positive pregnant women had no significant effect on the risk of HIV infection in their infants compared with either placebo or no vitamin A. One RCT found that multivitamins given during pregnancy had no significant effect on HIV infection in their infants.

Benefits: **Vitamin A:** We found one systematic review[32] (search date 2002, 2 RCTs,[33,34] 1813 women) comparing vitamin A supplements (with or without multivitamins) versus placebo given to mothers during the antenatal and intrapartum period and one subsequent RCT.[35] The review found no significant difference between vitamin A and placebo in HIV transmission to infants (AR 123/558 [22.0%] with vitamin A *v* 109/527 [20.7%] with placebo; RR 1.07, 95% CI 0.85 to 1.34).[32] The subsequent RCT (697 pregnant women with HIV in Malawi) compared vitamin A versus no vitamin A given from 18 to 28 weeks' gestation until delivery.[35] It found no significant difference between vitamin A and no vitamin A in perinatal HIV transmission at 6 weeks and 24 months (at 6 weeks: AR 26.6% with vitamin A *v* 27.8% with no vitamin A; P = 0.76; at 24 months: 27.7% with vitamin A *v* 32.8% with no vitamin A; P = 0.21). **Multivitamins:** We found one RCT.[33] It found no significant difference between multivitamins (given to mothers during pregnancy and lactation) and placebo in HIV transmission to infants at 6 weeks (AR 16% with multivitamins *v* 16% with placebo; RR 1.04, 95% CI 0.65 to 1.66).[33]

Harms: **Vitamin A:** The systematic review[32] found no evidence of an effect of vitamin A versus placebo on the incidence of stillbirth (RR 1.06, 95% CI 0.65 to 1.75); preterm birth either less than 34 weeks (RR 0.87, 95% CI 0.59 to 1.29) or less than 37 weeks (RR 0.90, 95% CI 0.74 to 1.10); or low birth weight (< 2500 g; RR 0.88, 95% CI 0.67 to 1.15). A follow up report[36] of one RCT[33] included in the review[32] found no significant difference between vitamin A and placebo on infant death by 24 months (AR 25.9% with vitamin A *v* 24.2% with placebo; RR 1.08, 95% CI 0.84 to 1.39). **Multivitamins:** Long term follow up[36] of one RCT[33] included in the review[32] found no significant difference between multivitamins and placebo in infant death at 24 months (AR 24.1% with multivitamins *v* 26.1% with placebo; RR 0.91, 95% CI 0.71 to 1.17).

Comment: The RCTs were performed because observational studies have found an association in pregnant women between transmission of HIV and low serum levels of vitamin A.[37] We found one subgroup analysis[36] of one RCT[33] that had been included in the systematic

review.[32] The RCT originally compared four treatments taken throughout pregnancy and lactation in 1083 pregnant women with HIV-1 (see glossary, p 910) in Tanzania: vitamin A alone, multivitamins excluding vitamin A, multivitamins plus vitamin A, or placebo.[33] Subgroup analysis among infants who were HIV negative at 6 weeks of age found that vitamin A taken during pregnancy and lactation increased the risk of HIV transmission through breast feeding when compared with placebo (AR 34.2% with vitamin A *v* 25.4% with placebo; RR 1.38, 95% CI 1.09 to 1.76).[36] However, there was no significant difference between multivitamins and placebo in HIV transmission from breast feeding (AR 30.7% with multivitamins *v* 29.0% with placebo; RR 1.04, 95% CI 0.82 to 1.32). One RCT found that giving vitamin A to pregnant women reduced both the number of low birth weight infants and also the number of infants with anaemia at 6 weeks postpartum.[35]

GLOSSARY

Human immunodeficiency virus type 1 (HIV-1) is the most common cause of HIV disease throughout the world.

Human immunodeficiency virus type 2 (HIV-2) is predominantly found in West Africa and is more closely related to the simian immunodeficiency virus than to HIV-1.

Substantive changes

Antiretroviral drugs One RCT comparing nevirapine versus zidovudine plus lamivudine has been added;[26] categorisation unchanged.

Avoiding breast feeding Evidence reassessed; recategorised as Likely to be beneficial (provided that there is access to clean water and health education).

Vitamins A follow up report[36] of one RCT[33] comparing multivitamins versus placebo has been added; one RCT comparing vitamin A versus no vitamin A has been added;[35] conclusions unchanged.

HIV: prevention of opportunistic infections

Search date April 2003

John Ioannidis and David Wilkinson

QUESTIONS

INTERVENTIONS

HIV: prevention of opportunistic infections

Key Messages

Prophylaxis for *P carinii pneumonia* (PCP) and toxoplasmosis

- **Trimethoprim/sulfamethoxazole (TMP/SMX — co-trimoxazole) for PCP** Systematic reviews have found that TMP/SMX reduces the incidence of PCP compared with placebo or pentamidine. Two systematic reviews have found that TMP/SMX reduced incidence of PCP compared with dapsone (with or without pyrimethamine), although only one of these reviews found that the reduction was significant. One systematic review and one subsequent RCT found no significant difference between high and low dose TMP/SMX for PCP prophylaxis, although adverse effects were more common with the higher dose.
- **Atovaquone (no difference from dapsone or aerosolised pentamidine for PCP in people intolerant of TMP/SMX)** We found no RCTs comparing atovaquone versus placebo. RCTs found no significant difference in the incidence of PCP with atovaquone compared with dapsone or aerosolised pentamidine, both of which are regarded as effective in people intolerant of TMP/SMX.
- **Azithromycin (for PCP)** One RCT has found that azithromycin, either alone or in combination with rifabutin, reduces the risk of PCP in people receiving standard PCP prophylaxis compared with rifabutin alone.

- **TMP/SMX (for toxoplasmosis)** One RCT found no significant difference between TMP/SMX and placebo for preventing toxoplasmosis. One systematic review has found no significant difference between TMP/SMX and dapsone (with or without pyrimethamine) for preventing toxoplasmosis.

Prophylaxis for tuberculosis

- **Tuberculosis prophylaxis versus placebo (in people with positive tuberculin test)** Systematic reviews have found that in people who are HIV and tuberculin skin test positive, antituberculosis prophylaxis reduces the frequency of tuberculosis compared with placebo over 2–3 years. The reviews found no evidence of benefit in people who are HIV positive but tuberculin skin test negative. One RCT found that the benefit of prophylaxis diminished with time after treatment was stopped.
- **Isoniazid for 6–12 months (*v* combination treatment for 2 months — similar benefits, fewer harms)** RCTs found no evidence of a difference in effectiveness between regimens using combinations of tuberculosis drugs for 2–3 months and those using isoniazid alone for 6–12 months. One RCT found that multidrug regimens increased the number of people with adverse reactions resulting in cessation of treatment.

***M avium complex* (MAC) prophylaxis (no previous MAC)**

- **Azithromycin** One RCT has found that azithromycin reduces the incidence of MAC compared with placebo.
- **Clarithromycin** One RCT has found that clarithromycin reduces the incidence of MAC compared with placebo.
- **Combination treatment (rifabutin plus either clarithromycin or azithromycin)** One RCT has found that rifabutin plus clarithromycin or clarithromycin alone reduces the incidence of MAC compared with rifabutin alone. One RCT has found that rifabutin plus azithromycin reduces the incidence of MAC compared with azithromycin alone or rifabutin alone at 1 year. One systematic review and two subsequent RCTs found that toxicity, including uveitis, was more common with combination therapy compared with clarithromycin or rifabutin alone.

MAC prophylaxis (previous MAC)

- **Clarithromycin, rifabutin, and ethambutol (*v* clarithromycin plus clofazimine)** One RCT found that clarithromycin, rifabutin and ethambutol reduced MAC relapse compared with clarithromycin plus clofazimine.
- **Ethambutol added to clarithromycin plus clofazimine** One RCT found that adding ethambutol to clarithromycin and clofazimine reduced MAC relapse compared with clarithromycin plus clofazimine.
- **Rifabutin added to clarithromycin plus ethambutol** One RCT found no significant difference in survival by adding rifabutin to clarithromycin plus ethambutol in people with previous MAC.
- **Clofazimine added to ethambutol plus clarithromycin (v clofazimine plus ethambutol)** One RCT found that adding clarithromycin to clofazimine and ethambutol was associated with higher mortality compared with clofazimine plus ethambutol.

Prophylaxis for cytomegalovirus (CMV), herpes simplex virus (HSV), and varicella zoster virus (VZV)

- **Aciclovir (for HSV and VZV)** One systematic review has found that aciclovir reduces HSV and

HIV: prevention of opportunistic infections

- **Oral ganciclovir (in people with severe CD4 depletion)** One RCT has found that oral ganciclovir reduces the incidence of CMV in people with severe CD4 depletion compared with placebo. It found that 25% of people taking ganciclovir developed severe neutropenia. A second RCT found no significant differences between treatments.
- **Famciclovir (for recurrent HSV)** One small RCT found that famciclovir reduced the rate of viral shedding compared with placebo, but provided insufficient evidence on the effect of famciclovir on HSV recurrence.
- **Valaciclovir (*v* aciclovir for CMV)** One RCT has found that valaciclovir versus aciclovir reduces the incidence of CMV, but may be associated with increased mortality.

Prophylaxis for fungal disease (no previous fungal disease)

- **Fluconazole or itraconazole** RCTs in people with advanced HIV disease have found that both fluconazole and itraconazole reduce the incidence of invasive fungal infections compared with placebo. One RCT found that fluconazole reduced the incidence of invasive fungal disease and mucocutaneous candidiasis compared with clotrimazole. One RCT found no difference between high and low dose fluconazole.

Prophylaxis for fungal disease (previous fungal disease)

- **Itraconazole (for *P marneffei*)** Two RCTs have found that itraconazole reduces the incidence of relapse of *P marneffei infection and candidiasis compared with placebo.*
- **Itraconazole (for histoplasmosis)** We found no RCTs.
- **Itraconazole (*v* fluconazole for maintenance treatment of cryptococcal meningitis)** One RCT found that itraconazole increased the risk of relapse of cryptococcal meningitis compared with fluconazole.

Discontinuation of prophylaxis in people on highly active antiretroviral treatment (HAART)

- **Discontinuing prophylaxis for MAC in people with CD4 > 100/mm^3 on HAART** Two RCTs in people taking HAART found that discontinuation of prophylaxis for MAC disease did not increase the incidence of MAC disease.
- **Discontinuing prophylaxis for PCP and toxoplasmosis in people with CD4 > 200/mm^3 on HAART** One systematic review of two unblinded RCTs in people taking HAART found that discontinuation of prophylaxis did not increase the incidence of PCP. Two unblinded RCTs found that discontinuation of prophylaxis did not increase the incidence of toxoplasmosis.
- **Discontinuing prophylaxis for CMV in people with CD4 > 100/mm^3 on HAART** We found insufficient evidence on the effects of discontinuation of maintenance treatment for CMV retinitis or other end organ disease in people taking HAART.

DEFINITION Opportunistic infections are intercurrent infections that occur in people infected with HIV. Prophylaxis aims to avoid either the first occurrence of these infections (primary prophylaxis) or their recurrence (secondary prophylaxis, maintenance treatment). This review includes *Pneumocystis carinii* pneumonia (PCP), *Toxoplasma gondii* encephalitis, *Mycobacterium tuberculosis*, *Mycobacterium avium* complex (MAC) disease, cytomegalovirus (CMV) disease (most

often retinitis), infections from other herpesviruses (herpes simplex virus [HSV] and varicella zoster virus [VZV]), and invasive fungal disease (*Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Penicillium marneffei* [see glossary, p 931]).

INCIDENCE/ PREVALENCE The incidence of opportunistic infections is high in people with immune impairment. Data available before the introduction of highly active antiretroviral treatment (HAART) suggest that, with a CD4 < 250/mm^3, the 2 year probability of developing an opportunistic infection is 40% for PCP, 22% for CMV, 18% for MAC, 6% for toxoplasmosis, and 5% for cryptococcal meningitis.[1] The introduction of HAART has reduced the rate of opportunistic infections. One cohort study found that the introduction of HAART decreased the incidence of PCP by 94%, CMV by 82%, and MAC by 64%, as presenting AIDS events. HAART decreased the incidence of events subsequent to the diagnosis of AIDS by 84% for PCP, 82% for CMV, and 97% for MAC.[2]

AETIOLOGY/ RISK FACTORS Opportunistic infections are caused by a wide array of pathogens and result from immune defects induced by HIV. The risk of developing opportunistic infections increases dramatically with progressive impairment of the immune system. Each opportunistic infection has a different threshold of immune impairment, beyond which the risk increases substantially.[1] Opportunistic pathogens may infect the immunocompromised host *de novo*, but usually they are simply reactivations of latent pathogens in such hosts.

PROGNOSIS Prognosis depends on the type of opportunistic infection. Even with treatment they may cause serious morbidity and mortality. Most deaths owing to HIV infection are caused by opportunistic infections.

AIMS OF INTERVENTION To prevent the occurrence and relapse of opportunistic infections; to discontinue unnecessary prophylaxis; to minimise adverse effects of prophylaxis and loss of quality of life.

OUTCOMES First occurrence and relapse of opportunistic infections and adverse effects of treatments. We have not considered neoplastic diseases associated with specific opportunistic infections.

METHODS *Clinical Evidence* search and appraisal April 2003. We also reviewed abstract books/CDs for the following conferences held between 1995 and early 2001: European Clinical AIDS, HIV Drug Treatment, Interscience Conferences on Antimicrobial Agents and Chemotherapy, National Conferences on Human Retroviruses and Opportunistic Infections, and World AIDS Conference. We placed emphasis on systematic reviews and RCTs published after 1993.

QUESTION What are the effects of prophylaxis for *P carinii* pneumonia (PCP) and toxoplasmosis?

John Ioannidis

OPTION TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMX — CO-TRIMOXAZOLE)

Systematic reviews have found that TMP/SMX (co-trimoxazole) is more effective than pentamidine or placebo at reducing the incidence of PCP. One RCT found no significant difference between TMP/SMX and placebo

for preventing PCP or toxoplasmosis. Two systematic reviews have found that TMP/SMX reduced incidence of PCP compared with dapsone (with or without pyrimethamine), although only one of these reviews found that the reduction was significant. One systematic review has found no difference between TMP/SMX and dapsone (with or without pyrimethamine) for incidence of toxoplasmosis. One systematic review and one subsequent RCT found no significant difference between high and low dose TMP/SMX for PCP prophylaxis, although adverse effects are more common with the higher dose.

Benefits: We found two systematic reviews (search dates 1995[3] and not stated[4]). **TMP/SMX versus placebo:** The first systematic review (35 RCTs) found that prophylaxis with TMP/SMX reduced the incidence of PCP more than placebo (RR 0.32, 95% CI 0.23 to 0.46). One subsequent RCT (545 people in sub-Saharan Africa with symptomatic disease; second or third clinical stage disease in the WHO staging system [see glossary, p 931]; regardless of CD4 cell count) comparing TMP/SMX with placebo found no significant difference in incidence of PCP or toxoplasmosis.[5] **TMP/SMX versus pentamidine:** The first systematic review found that TMP/SMX compared with aerosolised pentamidine significantly reduced the incidence of PCP (RR 0.58, 95% CI 0.45 to 0.75).[3] The second systematic review found no significant difference between TMP/SMX and aerosolised pentamidine for preventing toxoplasmosis (RR 0.78, 95% CI 0.55 to 1.11).[4] **TMP/SMX versus dapsone (with or without pyrimethamine):** The first systematic review found that TMP/SMX compared with dapsone (with or without pyrimethamine) reduced the incidence of PCP, but the result did not reach significance (RR 0.61, 95% CI 0.34 to 1.10).[3] The second review found that TMP/SMX was significantly more effective in preventing PCP than dapsone/pyrimethamine (RR 0.49, 95% CI 0.26 to 0.92).[4] It found no significant difference between TMP/SMX and dapsone/pyrimethamine in preventing toxoplasmosis (RR 1.17, 95% CI 0.68 to 2.04). **High versus low dose TMP/SMX:** The first systematic review found no significant difference in the rate of PCP infection between lower dose (160/800 mg 3 times/week or 80/400 mg/day) and higher dose (160/800 mg/day) TMP/SMX (failure rate per 100 person years was 1.6, 95% CI 0.9 to 2.5 with lower dose *v* 0.5, 95% CI 0 to 2.9 with higher dose; significance not reported).[3] One subsequent RCT (2625 people) also found no significant difference in the rate of PCP infection in people receiving TMP/SMX 160/800 mg daily compared with three times weekly (3.5 *v* 4.1 per 100 person years; $P = 0.16$).[6]

Harms: **TMP/SMX:** The first systematic review found that severe adverse effects (predominantly rash, fever, and haematological effects leading to discontinuation within 1 year) occurred in more people taking higher doses of TMP/SMX than in those taking lower doses (25% *v* 15%).[3] The RCT comparing high dose with low dose TMP/SMX found that discontinuation because of adverse effects was significantly more common in people taking high doses of TMP/SMX (RR 2.14; $P < 0.001$).[6] The RCT in sub-Saharan Africa found that people on TMP/SMX were less likely to suffer a serious event (death or hospital admission, irrespective of the cause) than those on placebo, regardless of their initial CD4 cell count (HR 0.57, 95% CI 0.43 to

0.75; P < 0.001).[5] Moderate neutropenia occurred more frequently with TMP/SMX (neutropenia AR 62/271 [23%] with TMP/SMX *v* 26/244 [10%] with placebo; RR 2.1, 95% 1.4 to 3.3; NNH 8, 95% CI 5 to 14). Two RCTs (largest 377 people) found that gradual initiation of TMP/SMX may improve tolerance of the regimen compared with abrupt initiation.[7,8] Two RCTs (238 people; 50 people) found no significant benefit from acetylcysteine in preventing TMP/SMX hypersensitivity reactions in HIV infected people.[9,10] **Dapsone:** The first systematic review found that adverse effects were more frequent with high doses than low doses of dapsone (29% *v* 12%).[3] A third systematic review (search date 1996, 16 trials, 4267 people) evaluating dapsone toxicity found no significant difference in mortality between dapsone and other prophylaxis (OR for mortality for dapsone *v* other prophylaxis 1.11, 95% CI 0.96 to 1.29).[11] **Pentamidine:** Bronchospasm occurred in 3% of people taking aerosolised pentamidine 300 mg monthly.[3]

Comment: **Concomitant coverage for toxoplasmosis:** Standard TMP/SMX prophylaxis or dapsone should offer adequate coverage for toxoplasmosis. Pentamidine has no intrinsic activity against *T gondii*. Toxoplasmosis risk is probably clinically meaningful only with CD4 < 100/mm^3 and positive toxoplasma serology.[1] **Role of highly active antiretroviral treatment (HAART):** We found more than 50 RCTs on the prophylaxis of PCP and/or toxoplasmosis, but their results should be interpreted with caution because they were conducted mostly before the advent and widespread use of HAART. Although this is unlikely to affect the comparative results, HAART has resulted in a large decrease in the rate of PCP, toxoplasmosis, and other opportunistic infections; therefore, the absolute benefits of these prophylactic regimens are probably smaller when used with HAART. **Prophylaxis in Africa:** Beneficial effects of TMP/SMX in Africa may be largely because of prophylaxis for bacterial infections rather than PCP. The largest trial conducted in Africa found that TMP/SMX significantly reduced mortality and hospital admissions.[5] However, a smaller trial (100 people) found no significant effect on mortality or hospital admission, although it may have lacked power to detect a significant difference (HR for death or hospital admission 1.10, 95% CI 0.57 to 2.13).[12]

OPTION ATOVAQUONE IN TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMX — CO-TRIMOXAZOLE) INTOLERANT PEOPLE

We found no RCTs comparing atovaquone versus placebo. RCTs found no significant difference between atovaquone versus dapsone or aerosolised pentamidine in preventing PCP.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus dapsone:** One RCT (1057 people intolerant of TMP/SMX, of whom 298 had a history of PCP) found no significant difference between atovaquone 1500 mg daily compared with dapsone 100 mg daily (15.7 *v* 18.4 cases of PCP per 100 person years; P = 0.20).[13] **Versus pentamidine:** One RCT (549 people intolerant of TMP/SMX) compared high dose with low dose

atovaquone (1500 mg/day *v* 750 mg/day) with monthly aerosolised pentamidine (300 mg). It found no significant difference between the groups in the incidence of PCP (26% *v* 22% *v* 17%) or mortality (20% *v* 13% *v* 18%) after a median follow up of 11.3 months.[14]

Harms: The RCT comparing atovaquone with dapsone found that the overall risk of stopping treatment because of adverse effects was similar in the two arms (RR 0.94, 95% CI 0.74 to 1.19).[13] Atovaquone was stopped more frequently than dapsone in people who were receiving dapsone at baseline (RR 3.78, 95% CI 2.37 to 6.01), and less frequently in people not receiving dapsone at baseline (RR 0.42, 95% CI 0.30 to 0.58).

Comment: See role of highly active antiretroviral treatment in comment under TMP/SMX, p 919.

OPTION AZITHROMYCIN

One RCT has found that azithromycin, either alone or in combination with rifabutin, reduces the risk of PCP compared with rifabutin alone in people receiving standard PCP prophylaxis.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus other drugs:** We found one RCT (693 people) that compared azithromycin, rifabutin, and both drugs in combination in people who were already receiving standard PCP prophylaxis. It found that azithromycin, either alone or in combination with rifabutin, reduced the relative risk of developing PCP by 45% when compared with rifabutin alone (P = 0.008).[15]

Harms: Gastrointestinal adverse effects are common with azithromycin, but they are usually mild and do not lead to stopping treatment. The addition of rifabutin significantly increased the risk of stopping treatment (RR 1.67; P = 0.03).[16]

Comment: See role of highly active antiretroviral treatment in comment under trimethoprim/sulfamethoxazole (co-trimoxazole), p 919. The low incidence of PCP infection in people taking highly active antiretroviral treatment means that the absolute benefit of prophylaxis is smaller.

QUESTION What are the effects of antituberculosis prophylaxis in people with HIV infection?

David Wilkinson

OPTION ANTITUBERCULOSIS PROPHYLACTIC REGIMENS VERSUS PLACEBO

Two systematic reviews have found that in people who are HIV and tuberculin skin test positive, antituberculosis prophylaxis reduces frequency of tuberculosis compared with placebo over 2–3 years. The reviews found no evidence of benefit in people who are HIV positive but tuberculin skin test negative. One RCT found that the benefit of prophylaxis diminished with time after treatment was stopped.

Benefits: We found two systematic reviews.[17,18] The first systematic review (search date 2000) identified seven RCTs in 4652 HIV positive adults from Haiti, Kenya, USA, Zambia, and Uganda.[17] All compared isoniazid (6–12 months) or combination treatment (3 months) with placebo. Mean follow up was 2–3 years, and the main outcomes, stratified by tuberculin skin test positivity, were tuberculosis (either microbiological or clinical) and death. Among tuberculin skin test positive adults, antituberculosis prophylaxis significantly reduced the incidence of tuberculosis (RR compared with placebo 0.24, 95% CI 0.14 to 0.40) and was associated with a non-significant reduction in the risk of death (RR compared with placebo 0.77, 95% CI 0.58 to 1.03). Among tuberculin skin test negative adults there was no significant difference in risk of tuberculosis (RR compared with placebo 0.87, 95% CI 0.56 to 1.36) or death (RR compared with placebo 1.07, 95% CI 0.88 to 1.30). The second review (search date not stated, 7 trials, 4529 people) compared isoniazid versus placebo only.[18] Among tuberculin skin test positive participants, the incidence of tuberculosis was significantly reduced (RR compared with placebo 0.40, 95% CI 0.24 to 0.65), but again there was no significant difference among tuberculin skin test negative participants (RR compared with placebo 0.84, 95% CI 0.54 to 1.30). This review found no evidence of any impact on mortality.[18] One of the RCTs included in the systematic reviews (1053 Zambian adults; 161 tuberculin skin test positive, 517 negative, the rest unknown) comparing isoniazid versus rifampicin plus pyrazinamide versus placebo for up to 6 months recently published results at 3 years' follow up.[19] Many people taking placebo were offered isoniazid after randomisation. Intention to treat analysis found that isoniazid or rifampicin plus pyrazinamide versus placebo significantly reduced the risk of tuberculosis at 2.5 years (cumulative AR not provided; RR 0.55, 95% CI 0.32 to 0.93), although the benefit diminished over this time. We found one subsequent RCT published as a letter (see comment below).[20]

Harms: Data on adverse drug reactions were not always stratified by tuberculin skin test positivity. In the first review there was a significant increase in adverse drug reactions requiring cessation of treatment with isoniazid compared with placebo (RR 1.75, 95% CI 1.23 to 2.47).[17] In the second review, the estimated RR was 1.36 (95% CI 1.00 to 1.86).[18]

Comment: Without prophylaxis, people who are HIV and tuberculin skin test positive have a 50% or more lifetime risk of developing tuberculosis compared with a 10% lifetime risk in people who are HIV positive but tuberculin skin test negative.[21] Clinical features of tuberculosis may be atypical in people with HIV infection and diagnosis may be more difficult, disease progression more rapid, and outcome worse. The subsequent RCT published as a letter (237 HIV positive Haitian adults with negative tuberculin skin test) found no significant difference between isoniazid (300 mg) versus no treatment in mortality, or the incidence of AIDS or tuberculosis at 1 year.[20]

HIV: prevention of opportunistic infections

OPTION DIFFERENT ANTITUBERCULOSIS PROPHYLACTIC REGIMENS

RCTs found no evidence of a difference in effectiveness between regimens using combinations of tuberculosis drugs for 2–3 months and those using isoniazid alone for 6–12 months. One RCT found that multidrug regimens increased the number of people with adverse reactions resulting in cessation of treatment.

Benefits: We found no systematic review. We found six RCTs.[19,22–26] Three RCTs (750, 1583, and 393 people) compared isoniazid versus rifampicin/pyrazinamide in people who were HIV and tuberculin skin test positive.[22–24] All found no significant difference in rates of tuberculosis. The fourth RCT (1564 HIV and tuberculin skin test positive people from Uganda) compared three treatments (isoniazid alone, isoniazid plus rifampicin and isoniazid, rifampicin, and pyrazinamide) versus placebo.[25] It reported comparisons between each regimen versus placebo, but did not directly compare different regimens against each other (see comment). The fifth RCT (133 adults, mixed tuberculin skin test positive and negative) comparing isoniazid for 12 months versus isoniazid plus rifampicin for 3 months found no significant difference in the incidence of tuberculosis (AR 4.2% with isoniazid *v* 2.1% with isoniazid plus rifampicin; RR 0.51, 95% CI 0.09 to 2.8).[26] The sixth RCT (1053 Zambian adults; 161 tuberculin skin test positive, 517 negative, the rest unknown) compared isoniazid for 6 months versus rifampicin plus pyrazinamide for 3 months versus placebo.[19] Many people in the placebo group were offered isoniazid after randomisation. Intention to treat analysis found no significant difference between isoniazid versus rifampicin plus pyrazinamide in the rate of tuberculosis at any time during a mean follow up of 3 years.

Harms: One RCT found that the proportion of people discontinuing treatment increased with the number of drugs given: isoniazid 1%, isoniazid plus rifampicin 2%, and all three drugs 6%.[23]

Comment: The fourth RCT compared each of three drug regimens versus placebo, but not versus each other.[25] It found that the risk of tuberculosis was significantly reduced with isoniazid alone (RR compared with placebo 0.33, 95% CI 0.14 to 0.77), and with isoniazid and rifampicin combined (RR compared with placebo 0.40, 95% CI 0.18 to 0.86). However, it found only a non-significant trend toward reduction with isoniazid, rifampicin, and pyrazinamide combined (RR compared with placebo 0.51, 95% CI 0.24 to 1.08). There is concern about emergence of rifampicin resistance if this drug is used in antituberculosis prophylaxis, although we found no reports of this. There is a theoretical risk that widespread, unsupervised use of isoniazid alone could promote resistance to this drug, although we found no evidence that this has happened.

QUESTION **What are the effects of prophylaxis for disseminated *M avium* complex (MAC) disease for people without previous MAC disease?**

John Ioannidis

OPTION AZITHROMYCIN

One RCT has found that azithromycin significantly reduces the incidence of MAC compared with placebo.

Benefits: We found no systematic review. One RCT (174 people with AIDS and CD4 < 100/mm^3) found that azithromycin reduced the incidence of MAC more than placebo (11% *v* 25%; P = 0.004).[27]

Harms: Gastrointestinal adverse effects were more likely with azithromycin than with placebo (71/90 [79%] *v* 25/91 [28%]; NNH 2, CI not provided), but they were rarely severe enough to cause discontinuation of treatment (8% *v* 2% in the two arms; P = 0.14).[27]

Comment: Prospective cohort studies found that the risk of disseminated MAC disease increased substantially with a lower CD4 count and was clinically important only for CD4 < 50/mm^3.[1] **Role of highly active antiretroviral treatment (HAART):** Most of the RCTs of MAC prophylaxis were conducted before the widespread use of HAART. HAART reduces the absolute risk of MAC infection. The absolute risk reduction of prophylactic regimens may be smaller when used in people treated with HAART.

OPTION CLARITHROMYCIN

One RCT has found that clarithromycin reduces the incidence of MAC compared with placebo.

Benefits: We found one systematic review (search date 1997) of prophylaxis and treatment of MAC.[28] It identified one RCT (682 people with advanced AIDS) that found that clarithromycin compared with placebo significantly reduced the incidence of MAC (6% *v* 16%; HR 0.31, 95% CI 0.18 to 0.53). It found no significant difference in the death rate (32% *v* 41%; HR 0.75; P = 0.026).[29]

Harms: Adverse effects led to discontinuation of treatment in slightly more people taking clarithromycin than placebo (8% *v* 6%; P = 0.45). More people taking clarithromycin suffered altered taste (11% *v* 2%) or rectal disorders (8% *v* 3%).[27]

Comment: Prospective cohort studies found that the risk of disseminated MAC disease increased substantially with a lower CD4 count and was clinically important only for CD4 < 50/mm^3.[1] See role of highly active antiretroviral treatment in comment under azithromycin, p 920.

OPTION COMBINATION TREATMENT

One RCT has found that clarithromycin alone and clarithromycin plus rifabutin both reduce the incidence of MAC compared with rifabutin alone. One RCT found that azithromycin plus rifabutin reduced the incidence of

HIV: prevention of opportunistic infections

MAC compared with azithromycin alone or rifabutin alone. One systematic review and two subsequent RCTs found that toxicity, including uveitis, was more common with combination therapy than with clarithromycin or rifabutin alone.

Benefits: **Clarithromycin plus rifabutin:** We found no systematic review. One RCT (1178 people with AIDS) compared rifabutin versus clarithromycin versus clarithromycin plus rifabutin.[30] It found that the risk of MAC was significantly reduced in the clarithromycin alone group (RR 0.56 for clarithromycin *v* rifabutin; P = 0.005) and the combination group when compared with rifabutin alone (RR 0.43 for combination *v* rifabutin; P = 0.0003). There was no significant difference in the risk of MAC between the combination and clarithromycin arms (P = 0.36). **Azithromycin plus rifabutin:** One RCT (693 people) found that the combination of azithromycin plus rifabutin versus azithromycin alone or rifabutin alone significantly reduced the incidence of MAC at 1 year (15.3% with rifabutin *v* 7.6% for azithromycin *v* 2.8% with rifabutin plus azithromycin; P = 0.008 for rifabutin *v* azithromycin; P = 0.03 for combination *v* azithromycin).[16]

Harms: In one RCT, dose limiting toxicity was more likely with azithromycin plus rifabutin than with azithromycin alone (HR 1.67; P = 0.03).[16] In another RCT, adverse events occurred in 31% of people receiving the combination of clarithromycin and rifabutin compared with 16% on clarithromycin alone and 18% on rifabutin alone (P < 0.001).[28] Uveitis occurred in 42 people: 33 were on clarithromycin plus rifabutin, seven were on rifabutin alone, and two were on clarithromycin alone. **Uveitis:** We found one systematic review (search date 1994, 54 people with rifabutin associated uveitis).[31] It found that uveitis was dose dependent. It occurred from 2 weeks to more than 7 months after initiation of rifabutin treatment, and was more likely in people taking rifabutin and clarithromycin. In most people, uveitis resolved 1–2 months after discontinuation of rifabutin.

Comment: Prospective cohort studies found that the risk of disseminated MAC disease increased substantially with a lower CD4 count and was clinically important only for CD4 < 50/mm^3.[1] Clarithromycin may inhibit rifabutin metabolism; rifabutin may decrease levels of delavirdine and saquinavir. See role of highly active antiretroviral treatment in comment under azithromycin, p 920.

QUESTION **What are the effects of prophylaxis for disseminated *M avium* complex (MAC) disease for people with previous MAC disease?**

John Ioannidis

OPTION **COMBINATION TREATMENT**

One RCT found that adding ethambutol to clarithromycin and clofazimine reduced MAC relapse compared with clarithromycin plus clofazimine. One RCT found that adding clofazimine to clarithromycin and ethambutol was associated with higher mortality. One RCT found that clarithromycin,

rifabutin and ethambutol reduced MAC relapse compared with clarithromycin plus clofazimine. One RCT found no significant difference in survival by adding rifabutin to clarithromycin plus ethambutol.

Benefits: We found no systematic review but found four RCTs.[32–35] **Clarithromycin, clofazimine, and ethambutol versus clarithromycin and clofazimine:** The first RCT (95 people) found that the combination of clarithromycin 1000 mg daily, clofazimine, and ethambutol was associated with significantly fewer relapses of MAC than the combination of clarithromycin plus clofazimine without ethambutol (68% relapsed in 3 drug regimen *v* 12% in 2 drug regimen at 36 weeks; P = 0.004).[32] **Clarithromycin, clofazimine, and ethambutol versus clarithromycin and ethambutol:** The second RCT (106 people) found that the addition of clofazimine to clarithromycin and ethambutol did not improve clinical response and was associated with higher mortality (see harms below).[33] **Clarithromycin, rifabutin, and ethambutol versus clarithromycin and clofazimine:** The third RCT (144 people) found that the combination of clarithromycin, rifabutin, and ethambutol reduced the relapse rate of MAC compared with clarithromycin plus clofazimine.[34] **Clarithromycin and ethambutol versus rifabutin, clarithromycin, and ethambutol:** The fourth RCT (198 people) found no significant difference in survival between people taking clarithromycin plus ethambutol and people taking clarithromycin plus ethambutol plus rifabutin.[35]

Harms: The second RCT, which added clofazimine to clarithromycin plus rifabutin, found higher mortality in the clofazimine arm (62% with clofazimine *v* 38% without clofazimine; P = 0.012).[33] High doses of clarithromycin (1000 mg twice daily)[36,37] and clofazimine[33] increased mortality. One RCT (85 people) comparing clarithromycin 500 mg twice daily versus 1000 mg twice daily found that, after a median follow up of 4.5 months, more people died with the higher dose (17/40 [43%] with 1000 mg twice daily *v* 10/45 [22%] with 500 mg twice daily; ARI 20%, 95% CI 0.2% to 33%; NNH 5, 95% CI 3 to 470).[36] A similar difference was seen in another RCT (154 people).[37] Combinations of drugs may lead to increased toxicity. Optic neuropathy may occur with ethambutol, but has not been reported in RCTs in people with HIV, where the dose and symptoms were carefully monitored.[35,36]

Comment: The observed increased mortality associated with clofazimine and high doses of clarithromycin has led to avoidance of these drugs.

QUESTION What are the effects of prophylaxis for cytomegalovirus (CMV), herpes simplex virus (HSV), and varicella zoster virus (VZV)?

John Ioannidis

OPTION GANCICLOVIR

One RCT has found that oral ganciclovir reduces the incidence of CMV in people with severe CD4 depletion compared with placebo. It found that 25% of people who did not take ganciclovir developed severe neutropenia. A second RCT found no significant differences.

HIV: prevention of opportunistic infections

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[38,39] The first RCT (725 people with a median CD4 count of 22/mm^3) found that oral ganciclovir halved the incidence of CMV compared with placebo (event rate 16% *v* 30%; P = 0.001).[38] The second RCT (994 HIV-1 infected people with CD4 < 100/mm^3 and CMV seropositivity) found no significant difference in the rate of CMV in people taking oral ganciclovir compared with placebo (event rates 13.1 *v* 14.6 per 100 person years; HR 0.92, 95% CI 0.65 to 1.27).[39] Both RCTs found no significant difference in overall mortality.

Harms: In the first RCT, severe neutropenia that required granulocyte colony stimulating factor was more common with ganciclovir versus placebo (24% *v* 9%).[38]

Comment: Differences in the results of RCTs may have arisen by chance or owing to protocol variability; for example, no baseline ophthalmologic examinations were performed in the second trial.[39] The low incidence of CMV disease in people taking highly active antiretroviral treatment, and the high rates of adverse events, means that the clinical value of oral ganciclovir in people who have not had active CMV disease is unclear.

OPTION ACICLOVIR AND VALACICLOVIR

One systematic review has found that aciclovir does not reduce the incidence of CMV disease, but reduces HSV and VZV infection and overall mortality in people at different clinical stages of HIV infection compared with placebo. One RCT found that valaciclovir reduced the incidence of CMV disease more than aciclovir, but non-significantly increased mortality.

Benefits: We found one systematic review of individual patient data (search date not stated, 8 RCTs) in people with HIV infection (ranging from asymptomatic infection to full-blown AIDS).[40] It found no significant difference in protection against CMV disease between aciclovir compared with no treatment or placebo. However, aciclovir significantly reduced overall mortality (RR 0.81; P = 0.04) and HSV and VZV infections (P < 0.001 for both).[40] One RCT (1227 CMV seropositive people with CD4 < 100/mm^3) compared valaciclovir, high dose aciclovir, and low dose aciclovir. It found increased mortality in the valaciclovir group, which did not reach statistical significance (P = 0.06).[41] The CMV rate was lower in the valaciclovir group than the aciclovir groups (12% *v* 18%; P = 0.03).

Harms: One RCT found that toxicity and early medication discontinuations were significantly more frequent in the valaciclovir arm (1 year discontinuation rate: 51% for valaciclovir *v* 46% for high dose aciclovir *v* 41% for low dose aciclovir).[39]

Comment: The survival benefit with aciclovir is unclear. The absolute risk reduction may be higher in people who have frequent HSV or VZV infections.

OPTION FAMCICLOVIR

One small RCT found that famciclovir reduced the rate of viral shedding compared with placebo, but provided insufficient evidence on the effect of famciclovir on HSV recurrence.

Benefits: We found no systematic review. One small crossover placebo controlled RCT (48 people) found that famciclovir suppressed HSV in people with frequent recurrences (HSV was isolated in 9/1071 famciclovir days *v* 122/1114 placebo days; $P < 0.001$).[42] Breakthrough reactivations on famciclovir were short lived and often asymptomatic.

Harms: Famciclovir was well tolerated, and the incidence of adverse effects was similar in both groups.

Comment: The conclusions of this study are difficult to interpret. The randomisation process allocated participants to groups, but the intention to treat analysis involved the number of days with symptoms rather than the number of participants who improved. There was no assessment of statistical significance of clinical outcomes. The trial's analysis is impeded by a high withdrawal rate.

QUESTION What are the effects of prophylaxis for invasive fungal disease in people without previous fungal disease?

John Ioannidis

OPTION AZOLES

RCTs in people with advanced HIV disease have found that both fluconazole and itraconazole reduce the incidence of invasive fungal infections compared with placebo. One RCT found that fluconazole reduced the incidence of invasive fungal disease and mucocutaneous candidiasis more than clotrimazole. One RCT found no difference between high and low dose fluconazole.

Benefits: We found no systematic review. **Fluconazole versus placebo:** One RCT (323 women with CD4 ≤ 300/mm^3) found that fluconazole versus placebo significantly reduced the incidence of candidiasis (44% *v* 58% suffered at least 1 episode of candidiasis; RR 0.56, 95% CI 0.41 to 0.77).[43] **Itraconazole versus placebo:** We found three RCTs.[44–46] The first RCT (295 people with advanced HIV disease) found that itraconazole reduced the incidence of invasive fungal infections ($P = 0.0007$).[44] It found no significant effect on recurrent or refractory candidiasis. The second RCT (129 people with CD4 cell count < 200/mm^3) also found that itraconazole reduced invasive fungal infections compared with placebo after a median of about 40 weeks (AR 1.6% with itraconazole *v* 16.7% with placebo; RR 0.1; $P = 0.003$; CI not stated).[45] In the third RCT (344 people with CD4 cell count < 300/mm^3), itraconazole did not significantly reduce invasive fungal infections compared with placebo (AR 5.9% with itraconazole *v* 7.0% with placebo; $P = 0.42$).[46] However, the study may have lacked power to detect clinically important differences. **High dose versus low dose fluconazole:** One RCT (636 people) compared fluconazole 200 mg daily with

400 mg once weekly and found no difference in the rate of invasive fungal infections over a follow up of 74 weeks (8% *v* 6%; ARR +2.2%, 95% CI −1.7% to +6.%).[47] However, the incidence of candidiasis was twice as common in people taking the weekly dose. **Fluconazole versus clotrimazole:** One RCT found that fluconazole reduced the incidence of invasive fungal disease and mucocutaneous candidal infections compared with clotrimazole (4% *v* 11%; hazard ratio 3.3, 95% CI 1.5 to 7.6).[48]

Harms: Congenital anomalies have occurred in a few children born to mothers receiving fluconazole. Itraconazole is embryotoxic and teratogenic in animals. Trials have therefore excluded pregnant women. Azoles may interact with antiretroviral regimens.[49] Azole drugs inhibit the metabolism of some drugs such as terfenadine. Theoretically they may increase the risk of sudden death because of ventricular tachycardia.

Comment: Azoles effectively reduce invasive fungal disease. Any absolute benefit is probably even lower in people treated with highly active antiretroviral treatment. Lack of evidence of any survival benefit, potential for complex drug interactions with current antiretroviral regimens, and potential for developing resistant fungal isolates means that there is doubt about routine antifungal prophylaxis in HIV infected people without previous invasive fungal disease.

QUESTION What are the effects of prophylaxis for invasive fungal disease in people with previous fungal disease?

John Ioannidis

OPTION AZOLES

Two RCTs found that itraconazole reduced the incidence of relapse of *P marneffei* infection and candidiasis compared with placebo. One RCT found that itraconazole increased the relapse of cryptococcal meningitis compared with fluconazole. We found no RCTs on intraconazole for histoplasmosis.

Benefits: We found no systematic review. **Itraconazole versus placebo:** One RCT (71 people with AIDS in Asia) found that itraconazole significantly reduced the relapse of *P marneffei* infection (see glossary, p 931) compared with placebo (0/36 [0%] v 20/35 [57%] relapsed within 1 year; $P < 0.001$).[50] A second RCT (44 people with HIV infection and candidiasis, treated with itraconazole 200 mg for 4 weeks before randomisation) compared prophylaxis with itraconazole versus placebo for 24 weeks. It found that itraconazole reduced relapse rates (5/24 [21%] with itraconazole v 14/20 [70%] with placebo; ARR 49%, 95% CI 19% to 64%; NNT 2, 95% CI 2 to 5) and increased the time interval before relapse occurred (median time to relapse: itraconazole 8.0 weeks v placebo 10.4 weeks; $P = 0.001$).[51] **Itraconazole versus fluconazole:** One RCT (108 people with HIV infection) found that fluconazole reduced relapses of successfully treated cryptococcal meningitis more than itraconazole (13/57 [23%] with itraconazole v 2/51 [4%] with fluconazole; ARR 19%, 95% CI 6.2% to 31.7%; RR 0.17, 95% CI 0.04 to 0.71; NNT 5, 95% CI 3 to 16).[52] The trial was stopped early because of the higher rate of relapse with itraconazole.

Harms: In one RCT, discontinuation of itraconazole occurred in two people because of skin rashes, one because of severe anaemia, and one because of gastrointestinal effects compared with none taking fluconazole.[52]

Comment: Recurrent infection is common in people with previous *C neoformans*, *H capsulatum*, and *P marneffei* infections. Lifelong maintenance may be needed in the presence of immune impairment.

QUESTION What are the effects of discontinuing prophylaxis against opportunistic pathogens in people on highly active antiretroviral treatment (HAART)?

John Ioannidis

OPTION DISCONTINUATION OF PROPHYLAXIS FOR *P CARINII* PNEUMONIA (PCP) AND TOXOPLASMOSIS IN PEOPLE WITH CD4 > 200/MM^3 ON HAART

One systematic review of two unblinded RCTs found that discontinuation of prophylaxis did not increase the incidence of PCP. Two unblinded RCTs found that discontinuation of prophylaxis did not increase the incidence of toxoplasmosis.

Benefits: **PCP:** We found one systematic review (search date 2001, 2 RCTs, 3584 people, two non-randomised controlled trials, and 10 studies with other designs) about the effects of discontinuing prophylaxis.[53] The review found a low incidence of PCP in people discontinuing both primary and secondary prophylaxis after a mean of 1.5 years (7/3035 [0.23%] with discontinuing primary prophylaxis and 1/549 [0.18%] discontinuing secondary prophylaxis; mean annual incidence over 1.5 years 0.23%, 95% CI 0.10% to 0.46%; no statistical heterogeneity among studies). Neither of the two RCTs identified in the review found any cases of PCP after discontinuation (first RCT: 587 people with satisfactory response to HAART, CD4 > 200/mm^3, and viral load < 5000 copies/mm^3 for > 3 months, AR for PCP or toxoplasma encephalitis at median 20 months 0%, whether or not prophylaxis continued;[54] second RCT: 708 people taking HAART, CD4 > 200/mm^3 for 3 months, AR for PCP at 6 months 0%).[55] **Toxoplasmosis:** We found two RCTs.[55,56] The first, which was included in the systematic review, found no cases of toxoplasma encephalitis at 6 months in people discontinuing prophylaxis (see PCP above).[55] The second RCT (302 people with a satisfactory response to HAART) compared discontinuation with continuation of toxoplasma prophylaxis.[56] After a median of 10 months it found no episodes of toxoplasma encephalitis in either group.

Harms: The systematic review found no direct harms from discontinuing prophylaxis.[53]

Comment: The risk of PCP may increase after discontinuing prophylaxis in people who do not respond to antiretroviral treatment. We found no direct evidence of the effects of different HAART regimens on the risk of PCP or toxoplasmosis. Antiretroviral regimens with different mechanisms of action may have different clinical effects on opportunistic infections and HIV disease progression, despite inducing

satisfactory suppression of HIV-1 replication and adequate CD4 responses. Also, CD4 cell count is an incomplete marker of immune reconstitution. It is possible that people with the same CD4 count may have different immune deficits regarding control of PCP and other opportunistic pathogens. An extensive amount of research is being conducted on other parameters of immune reconstitution, but the clinical implications are uncertain at present. One decision analysis based on the systematic review suggested that, in the long term, discontinuation of PCP prophylaxis in people who respond to HAART should result in fewer PCP episodes and fewer prophylaxis related adverse effects.[53]

OPTION DISCONTINUATION OF PROPHYLAXIS FOR *M AVIUM* COMPLEX (MAC) DISEASE IN PEOPLE WITH CD4 > 100/MM^3 ON HAART

Two RCTs found that discontinuation of prophylaxis for MAC disease did not increase the incidence of MAC disease.

Benefits: We found no systematic review but we found two RCTs. The first RCT (520 people without previous MAC disease, with CD4 > 100/mm^3 in response to HAART) compared azithromycin with placebo.[57] There were no episodes of confirmed MAC disease in either group over a median follow up of 12 months. The second RCT (643 people with CD4 > 100/mm^3 in response to HAART) compared azithromycin 1200 mg once weekly versus placebo. Over a median follow up of 16 months there was no significant difference in the incidence of MAC between the groups (2/321 [0.62%] with placebo *v* 0/322 [0%] with azithromycin; difference +0.5 events per 100 person years, 95% CI –0.2 to +1.2 events per 100 person years).[58]

Harms: In both RCTs, adverse effects leading to discontinuation of treatment were more common with azithromycin than with placebo (7% *v* 1%, P = 0.002; 8% *v* 2%, P < 0.001).[57,58]

Comment: It is not clear whether different antiretroviral regimens have different clinical effects on opportunistic infections and on the need for specific prophylaxis.

OPTION DISCONTINUATION OF MAINTENANCE TREATMENT FOR CYTOMEGALOVIRUS (CMV) IN PEOPLE WITH A CD4 > 100/MM^3 ON HAART

We found insufficient evidence on the effects of discontinuation of maintenance treatment for CMV retinitis or other end organ disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no evidence from systematic reviews or RCTs.

Comment: We found several small case series (see table 1, p 934).[59–68] Of the two studies with the longest follow-up, one found no relapses in 41 people after a mean of 20.4 months from discontinuing maintenance treatment[59] and the other found only 1 relapse among 36 people after a median follow up of 21 months from discontinuing treatment.[68] The relapse occurred in a person with immunological failure (CD4 62/mm^3). However, another study with mean follow up

of 14.5 months found five (29%) relapses among 17 participants who withdrew from maintenance; all of them occurred after the CD4 cell count had dropped again to below 50/mm^3 (8 days/10 months after this event).[62] In one case series, 12/14 (86%) participants had evidence of immune reconstitution retinitis even before starting withdrawal of prophylaxis.[61] Worsening uveitis was associated with a substantial vision loss (> 3 lines) in three participants. It is difficult to conduct a RCT with adequate power to exclude modest differences in relapse rates. The observational evidence suggests that withdrawal of CMV maintenance treatment may be considered in selected people in whom CMV disease is in remission, CD4 > 100mm^3, and HIV replication remains suppressed. We found no clear evidence on whether CMV viral load should be considered in the decision to withdraw from maintenance. One small case series found that relapses were associated with a drop in the CD4 cell count.[62] However, we found no randomised or other reliable evidence about when to restart CMV maintenance treatment.

GLOSSARY

***Penicillium marneffei* infection** A common opportunistic infection in southeast Asia.

The WHO staging system for HIV infection and disease consists of a "clinical axis" that is represented by a sequential list of clinical conditions believed to have prognostic significance, which subdivides the course of HIV infection into four clinical stages; and a "laboratory axis" that subdivides each clinical stage into three strata according to CD4 cell count or total lymphocyte count.

TABLE 1 **Observational studies of discontinuation of cytomegalovirus maintenance treatment in people with previous cytomegalovirus disease (see text, p 930).**

Ref	Criteria for discontinuation	Participants	Follow up (months)	Relapses
62*	CD4 >70	17	14.5 (mean)	5
63	CD4 ≥ 75	8	8 (median)	0
61	CD4 >150	14	16.4 (mean)	0
64	CD4 297 (median)	15	8 (median)	0
65	CD4 >100	8	11.4 (mean)	0
66*	CD4 183 (median)	11	5 (median)	0
67	CD4 >150 VL < 200/mL –ve CMV by PCR	7	9 (median)	0
59	CD4 > 143	41	20.4 (mean)	0
60	CD4 > 75 VL < 30 000/mL	48	11 (mean)	2
68	CD4 > 100 VL < 500 or CD4 >150 VL < 10 0000 copies/mL	36	21 (median)	1

Studies with more than five people are included. CD4 count is measured in cells/mm^3.
*McDonald et al[66] is an early report of the same study followed by the Torriani et al[62] report. All relapses in the latter report occurred in people who had already experienced a decrease of CD4 to < 50 cells/mm^3.
CMV, cytomegalovirus; PCR, polymerase chain reaction; Ref, reference; VL, viral load (HIV-1 RNA in plasma).

Pneumocystis carinii pneumonia in people with HIV

Prophylaxis for *Pneumocystis carinii* pneumonia and other AIDS-related opportunistic infections (see HIV: prevention of opportunistic infections, p 913).

See table 1, p 948

Key Messages

- **Adjuvant corticosteroids for mild *Pneumocystis carinii* pneumonia** We found insufficient evidence on the effects of adjuvant corticosteroids in the early treatment of mild *Pneumocystis carinii* pneumonia in people infected with HIV (see definition, p 936).
- **Adjuvant corticosteroids for moderate to severe *Pneumocystis carinii* pneumonia** One systematic review has found that adjuvant corticosteroids reduce mortality when used early in the treatment of moderate to severe *Pneumocystis carinii* pneumonia (see definition, p 936).
- **Atovaquone** We found no RCTs comparing atovaquone versus placebo or no treatment as the first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. One RCT found that atovaquone was less effective than TMP–SMX. One RCT found that atovaquone was equally effective as intravenous pentamidine. Adverse effects requiring termination of treatment occurred less frequently with atovaquone than with TMP–SMX or intravenous pentamidine.

Pneumocystis carinii pneumonia in people with HIV

- **Clindamycin–primaquine** RCTs found clindamycin–primaquine to be as effective as TMP–SMX as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV, with no significant difference in rates of serious adverse effects.
- **Pentamidine (aerosolised)** We found no RCTs comparing aerosolised pentamidine versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. Two RCTs found no significant difference in mortality between aerosolised pentamidine and TMP–SMX, but found lower rates of serious adverse effects with aerosolised pentamidine. One RCT found no significant difference in mortality or treatment failure between aerosolised and intravenous pentamidine.
- **Pentamidine (intravenous)** We found no RCTs comparing intravenous pentamidine versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. Three RCTs found that intravenous pentamidine was as effective as TMP–SMX and found no difference in rates of serious adverse effects. One RCT found no significant difference between intravenous pentamidine and atovaquone, but atovaquone caused fewer adverse effects requiring termination of treatment.
- **TMP–dapsone (trimethoprim–dapsone)** We found no RCTs comparing TMP–dapsone versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. RCTs have found that TMP–dapsone is as effective as TMP–SMX, with similar rates of adverse effects. One RCT found that TMP–dapsone was as effective as clindamycin–primaquine.
- **TMP–SMX (trimethoprim–sulfamethoxazole; co-trimoxazole)** We found no RCTs comparing TMP–SMX versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. RCTs have found that TMP–SMX is more effective than atovaquone or aerosolised pentamidine. RCTs have found that TMP–SMX is as effective as clindamycin–primaquine, trimethoprim–dapsone, and intravenous pentamidine. RCTs have found that adverse events requiring termination of treatment are more frequent with TMP–SMX than atovaquone or aerosolised pentamidine.
- **Treatment after failure of first line therapy** We found no systematic review and no RCTs comparing the effectiveness or adverse effects of different treatments following failure of first line therapy for *Pneumocystis carinii* pneumonia in people infected with HIV. One systematic review of cohort studies suggests that clindamycin–primaquine may be more effective than alternative treatments in this situation.

DEFINITION *Pneumocystis carinii* pneumonia (PCP) is caused by an opportunistic fungal infection in people with impaired immune function. Most cases occur in people infected with HIV, in whom PCP is an AIDS defining illness. The pneumonia is generally classified as **mild** if P_aO_2 is greater than 70 mm Hg on room air and/or the alveolar–arterial oxygen gradient is less than 35 mm Hg. It is generally classified as **moderate/severe** if the P_aO_2 is less than 70 mm Hg and/or the alveolar–arterial oxygen gradient is greater than 35 mm Hg. This chapter focuses on the treatment of PCP in adults infected with HIV. Prevention of PCP is covered under HIV: prevention of opportunistic infections, p 913.

INCIDENCE/ PREVALENCE PCP is the commonest AIDS defining illness in developed nations.[1] It is probably also common throughout the developing world, although the prevalence is harder to assess here because of difficulties in making the diagnosis. Prior to the widespread use of prophylaxis it was estimated that up to 80% of people with AIDS would eventually develop PCP.[2] Widespread use of prophylaxis against PCP and of highly active antiretroviral therapy has dramatically reduced the incidence of this infection (see HIV: prevention of opportunistic infections, p 913).

AETIOLOGY/ RISK FACTORS Risk factors for PCP include HIV infection, primary immune deficiencies, prematurity, cancer, use of immune suppressants following organ transplantation, and prolonged use of high dose corticosteroids. HIV infection is now responsible for the vast majority of cases of PCP. Among adults with HIV infection, those with a CD4 count below 200 cells/mm^3 are at highest risk, and the median CD4 count at diagnosis of PCP is around 50 cells/mm^3.[3]

PROGNOSIS It is generally believed that without treatment PCP would almost certainly be fatal in a person with AIDS. For ethical reasons, no studies have examined short term prognosis without treatment. People with AIDS and PCP frequently have other serious opportunistic infections, which can adversely affect their prognosis.

AIMS OF INTERVENTION To reduce mortality due to PCP and minimise adverse effects of treatment.

OUTCOMES Mortality, treatment failure (requiring change of treatment), and adverse effects.

METHODS *Clinical Evidence* search and appraisal November 2003. We placed emphasis on systematic reviews of RCTs and large RCTs. We considered smaller RCTs and systematic reviews of non-controlled studies if large, placebo controlled RCTs were not available. Studies of the treatment of PCP can be hard to analyse because many participants swapped treatment arms if they did not respond to, or experienced toxicity with, their initial treatment allocation. Many studies allowed clinicians to use their own discretion when deciding if a change in treatment was warranted, without having rigorous, predefined criteria for the change. Some patients may have changed treatments before they had adequate opportunity to respond to the initial treatment allocation. Mortality and treatment failure rates were usually compared on an intention to treat basis but many authors analysed adverse events using an on-treatment analysis. To ensure comparability between studies, all statistics comparing dichotomous outcomes were recalculated using 2 x 2 χ^2 tests with Yates' correction factor, except for comparisons where the sample size was less than 40, when Fisher's exact test was used. The studies reviewed in this chapter included only HIV infected people, except where otherwise specified. Most studies were carried out in the developed world, with an over-representation of white men. Although some studies included teenagers, there were few data from this group, and most studies excluded pregnant women and children; it was therefore hard to draw conclusions about the effects of treatment in these groups. Trimethoprim–sulfamethoxazole (TMP–SMX; co-trimoxazole) is generally regarded as the standard therapy for PCP, and most studies used this as their comparator.

Pneumocystis carinii pneumonia in people with HIV

QUESTION **What are the effects of first line treatments for PCP in people infected with HIV?** New

OPTION TMP–SMX (TRIMETHOPRIM–SULFAMETHOXAZOLE; CO-TRIMOXAZOLE)

We found no RCTs comparing TMP–SMX versus placebo or no treatment as the first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. RCTs have found that TMP–SMX is more effective than atovaquone or aerosolised pentamidine. RCTs have found that TMP–SMX is as effective as clindamycin–primaquine, trimethoprim–dapsone, and intravenous pentamidine. RCTs have found that adverse events requiring termination of treatment are more frequent with TMP–SMX than with atovaquone or aerosolised pentamidine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus aerosolised pentamidine:** See benefits of aerosolised pentamidine, p 938. **Versus intravenous pentamidine:** See benefits of intravenous pentamidine, p 940. **Versus atovaquone:** See benefits of atovaquone, p 941. **Versus clindamycin–primaquine:** See benefits of clindamycin–primaquine, p 942. **Versus trimethoprim–dapsone:** See benefits of trimethoprim–dapsone, p 943.

Harms: We found no systematic review. The adverse effects requiring termination of treatment that most frequently occurred in people receiving TMP–SMX were skin rashes, severe nausea and vomiting, raised liver enzymes, fever, and leucopaenia.[4–8] Nausea and vomiting were reported in some studies to occured in as many as 40% of people, causing termination of treatment in 5–10%.[4,5,7] Skin rashes occurred in as many as 30–45% of people, causing termination of treatment in 10–15%.[4,5,7,8] **Versus placebo:** We found insufficient evidence. **Versus aerosolised pentamidine:** See harms of aerosolised pentamidine, p 939. **Versus intravenous pentamidine:** See harms of intravenous pentamidine, p 940. **Versus atovaquone:** See harms of atovaquone, p 941. **Versus clindamycin–primaquine:** See harms of clindamycin–primaquine, p 942. **Versus trimethoprim–dapsone:** See harms of trimethoprim–dapsone, p 943.

Comment: None.

OPTION PENTAMIDINE (AEROSOLISED)

We found no RCTs comparing aerosolised pentamidine versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. Two RCTs found no significant difference in mortality between aerosolised pentamidine and TMP–SMX, but found lower rates of serious adverse effects with aerosolised pentamidine. One RCT found no significant difference in mortality or treatment failure between aerosolised and intravenous pentamidine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus intravenous pentamidine:** We found one RCT (45 people with suspected *Pneumocystis carinii* pneumonia [PCP], 38

people with confirmed PCP). There was no significant difference in mortality between treatments (2/17 [11.8%] with aerosolised pentamidine *v* 0/21 [0%] with iv pentamidine; RR could not be calculated; P = 0.19, Fisher's exact test), nor was there a significant difference in rates of treatment failure (2/17 [11.8%] with aerosolised pentamidine *v* 4/21 [19.0%] with iv pentamidine; RR 0.62, 95% CI 0.13 to 2.98; P = 0.67, Fisher's exact test).[9] The wide confidence interval suggests that the trial had insufficient power to detect a clinically important difference between treatments. There was a higher rate of early recrudescence in people treated with aerosolised pentamidine compared with intravenous pentamidine (7/20 [35%] with aerosolised pentamidine *v* 0/18 [0%] with iv pentamidine; P = 0.009, Fisher's exact test).[9] **Versus TMP–SMX:** We found two RCTs.[4,5] The first RCT (46 people with confirmed PCP categorised as mild [P_aO_2 > 70 mm Hg on room air], of whom 45 [75%] were evaluated) compared aerosolised pentamidine 600 mg/day versus trimethoprim 20 mg/kg/day plus sulfamethoxazole 100 mg/kg/day given intravenously in four doses. It found no significant difference in rates of treatment failure (5/22 [22.7%] with pentamidine *v* 8/23 [34.8%] with TMP–SMX; RR 0.65, 95% CI 0.25 to 1.69; P = 0.57).[4] The second RCT (367 adults with presumed PCP categorised as mild to moderate [alveolar–arterial oxygen gradient < 55 mm Hg on room air], diagnosis of PCP confirmed in 287 [80%]) compared aerosolised pentamidine 600 mg/day versus trimethoprim 15 mg/kg/day plus sulfamethoxazole 75 mg/kg/day given intravenously for at least 5 days followed by oral treatment. It found no significant difference in mortality at 35 days (12/182 [6.6%] with pentamidine *v* 17/185 [9.2%] with TMP–SMX; RR 0.72, 95% CI 0.35 to 1.46; P = 0.47). Rates of treatment failure were significantly higher with aerosolised pentamidine (94/182 [51.6%] with pentamidine *v* 22/185 [11.9%] with TMP–SMX; RR 4.34, 95% CI 2.86 to 6.59; P < 0.001).[5]

Harms: We found no systematic review. **Versus placebo:** We found insufficient evidence. **Versus intravenous pentamidine:** The RCT found no significant difference in the rates of major adverse effects requiring termination of treatment (0/17 [0%] with aerosolised pentamidine *v* 3/21 [14.3%] with iv pentamidine; RR cannot be calculated; P = 0.24, Fisher's exact test). There were significantly fewer major plus minor adverse effects in those receiving aerosolised pentamidine (2/17 [11.8%] with aerosolised pentamidine *v* 11/21 [52.4%] with iv pentamidine; RR 0.22, 95% CI 0.06 to 0.88; P = 0.02, Fisher's exact test).[9] **Versus TMP–SMX:** In both RCTs, serious adverse effects occurred significantly less frequently with aerosolised pentamidine than with TMP–SMX (0/22 [0%] with pentamidine *v* 7/24 [29.2%] with TMP–SMX; RR cannot be calculated as no events occurred with pentamidine; P = 0.02;[4] 17/179 [9.5%] with pentamidine *v* 73/187 [39.0%] with TMP–SMX; RR 0.24, 95% CI 0.15 to 0.40; P < 0.001).[5]

Comment: Adverse effects in people receiving aerosolised pentamidine rarely require termination of treatment because systemic absorption of the drug is minimal.[4] **Versus TMP–SMX:** Both RCTs excluded people with severely impaired respiratory function. These people may be expected to have done less well with aerosolised pentamidine due to reduced drug delivery.[4,5]

OPTION PENTAMIDINE (INTRAVENOUS)

We found no RCTs comparing intravenous pentamidine versus placebo or no treatment as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. Three RCTs found that intravenous pentamidine was as effective as TMP–SMX and found no difference in rates of serious adverse effects. One RCT found no significant difference between intravenous pentamidine and atovaquone, but atovaquone caused fewer adverse effects requiring termination of treatment.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus aerosolised pentamidine:** See benefits of aerosolised pentamidine, p 938. **Versus TMP–SMX:** We found three RCTs (41,[6] 70,[7] and 163[8] people with confirmed *Pneumocystis carinii* pneumonia [PCP]). The first RCT compared intravenous pentamidine 4 mg/kg/day for 21 days versus trimethoprim 20 mg/kg/day plus sulfamethoxazole 100 mg/kg/day given intravenously in four doses. It found no significant difference in mortality (1/20 [5.0%] with pentamidine *v* 5/20 [25.0%] with TMP–SMX; RR 0.20, 95% CI 0.03 to 1.56; P = 0.18).[6] However, the wide confidence interval suggests that the trial had insufficient power to rule out important differences in mortality. The second RCT compared intravenous pentamidine 4 mg/kg/day for 17 to 21 days versus trimethoprim 15 to 20 mg/kg/day plus sulfamethoxazole 75 to 100 mg/kg/day given intravenously until clinical improvement occurred, followed by oral treatment. It found significantly higher mortality and need for respiratory support with intravenous pentamidine at the end of treatment (13/33 [39.4%] with pentamidine *v* 5/36 [13.9%] with TMP–SMX; RR 2.84, 95% CI 1.13 to 7.10; P = 0.03).[7] The third RCT compared intravenous pentamidine 4 mg/kg/day for 21 days versus intravenous trimethoprim 20 mg/kg/day plus intravenous sulfamethoxazole 100 mg/kg/day. At the end of treatment, it found no significant difference in mortality (18/68 [26.5%] with iv pentamidine *v* 30/92 [32.6%] with TMP–SMX; RR 0.81, 95% CI 0.50 to 1.33; P = 0.51) or in rates of treatment failure requiring change of therapy (27/68 [39.7%] with pentamidine *v* 39/92 [42.4%] with TMP–SMX; RR 0.94, 95% CI 0.64 to 1.37; P = 0.86).[8] **Versus atovaquone:** See benefits of atovaquone, p 941.

Harms: We found no systematic review. The adverse effects requiring termination of treatment that most frequently occured in people receiving intravenous pentamidine were raised liver enzymes, raised serum creatinine, hyponatraemia, hypoglycaemia, leucopaenia, and rash.[6–8] **Versus placebo:** We found insufficient evidence. **Versus aerosolised pentamidine:** See harms of aerosolised pentamidine, p 939. **Versus TMP–SMX:** The first and third RCTs found no significant difference in rates of major adverse reactions (14/32 [43.8%] with pentamidine *v* 13/32 [40.6%] with TMP–SMX; RR 1.08, 95% CI 0.61 to 1.91; P = 1.00;[6] 17/68 [25%] with pentamidine *v* 31/92 [33.7%] with TMP–SMX; RR 0.74, 95% CI 0.45 to 1.23; P = 0.31).[8] In the second RCT, only one adverse event (in a person receiving pentamidine) required termination of treatment.[7] **Versus atovaquone:** See harms of atovaquone, p 941.

Comment: None.

OPTION ATOVAQUONE

We found no RCTs comparing atovaquone versus placebo or no treatment as the first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. One RCT found that atovaquone was less effective than TMP–SMX. One RCT found that atovaquone was equally effective as intravenous pentamidine. Adverse effects requiring termination of treatment occurred less frequently with atovaquone than with TMP–SMX or intravenous pentamidine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus TMP–SMX:** We found one RCT (408 people with suspected *Pneumocystis carinii* pneumonia [PCP], diagnosis histologically confirmed in 322 people) comparing oral atovaquone 750 mg three times daily for 21 days versus oral trimethoprim 320 mg three times daily plus oral sulfamethoxazole 1600 mg three times daily.[10] Among the people in whom PCP was confirmed, those receiving atovaquone had significantly higher rates of treatment failure (28/138 [20.3%] with atovaquone *v* 10/146 [6.8%] with TMP–SMX; RR 2.96, 95% CI 1.50 to 5.87; P = 0.002) and mortality (11/160 [6.9%]) with atovaquone *v* 1/162 [0.6%] with TMP–SMX; RR 11.14, 95% CI 1.45 to 85.27; P = 0.008). **Versus intravenous pentamidine:** We found one non-blinded RCT (144 people with suspected PCP, diagnosis confirmed in 109) comparing oral atovaquone 750 mg three times daily for 21 days versus intravenous pentamidine 3–4 mg/kg/day. Among those with confirmed PCP, there was no significant difference in rates of treatment failure (16/56 [28.6%]) with atovaquone *v* 9/53 [17.0%] with pentamidine; RR 1.68, 95% CI 0.81 to 3.47; P = 0.23).[11] The wide confidence interval suggests that the trial had insufficient power to detect a clinically important difference between treatments.

Harms: We found no systematic review. The adverse effects requiring termination of treatment that most frequently occured in people receiving atovaquone were rash and raised liver enzymes.[10–12] **Versus placebo:** We found no RCTs. **Versus TMP–SMX:** In one RCT (reported in two papers) adverse effects requiring a change in treatment were significantly less frequent with atovaquone (19/203 [9.4%] with atovaquone *v* 50/205 [24.4%] with TMP–SMX; RR 0.38, 95% CI 0.23 to 0.63; P < 0.0001).[10,12] **Versus intravenous pentamidine:** In one RCT adverse events requiring termination of treatment were significantly less frequent with atovaquone (5/73 [6.8%] with atovaquone *v* 29/71 [40.8%] with pentamidine; RR 0.17, 95% CI 0.07 to 0.41; P < 0.0001).[11]

Comment: None.

OPTION CLINDAMYCIN–PRIMAQUINE

RCTs found clindamycin–primaquine to be as effective as TMP–SMX as first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV, with no significant difference in rates of serious adverse effects.

Pneumocystis carinii pneumonia in people with HIV

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus TMP–SMX:** We found three RCTs (65,[13] 181,[14] and 87[15] people with confirmed *Pneumocystis carinii* pneumonia [PCP]). The first RCT compared a 21 day course of clindamycin (600 mg given intravenously four times daily for 10 days followed by 450 mg given orally four times daily for 11 days) plus oral primaquine 15 mg/day versus trimethoprim 240 mg four times daily plus sulfamethoxazole 1200 mg four times daily given intravenously for the first 10 days then orally. There was no significant difference in rates of treatment failure among the people in whom PCP was confirmed (3/27 [11.1%] with clindamycin–primaquine *v* 2/22 [9.1%] with TMP–SMX; RR 1.22, 95% CI 0.22 to 6.68; P = 0.81).[13] The wide confidence interval suggests that the trial had insufficient power to detect a clinically important difference between treatments. The second RCT compared a 21 day course of three treatments: oral clindamycin 600 mg three times daily plus oral primaquine 30 mg daily versus oral trimethoprim 320 mg three times daily plus oral sulfamethoxazole 1600 mg three times daily versus oral trimethoprim 320 mg three times daily plus oral dapsone 100 mg daily. At 2 months, there was no significant difference between clindamycin–primaquine and TMP–SMX in mortality (2/58 [3.4%] with clindamycin–primaquine *v* 4/64 [6.3%] with TMP–SMX; RR 0.55, 95% CI 0.10 to 2.90; P = 0.77) or in rates of therapeutic failure on or before day 21 (4/58 [6.9%] with clindamycin–primaquine *v* 6/64 [9.4%] with TMP–SMX; RR 0.74, 95% CI 0.22 to 2.48; P = 0.87).[14] The results of the third treatment arm are discussed under trimethoprim–dapsone (see benefits of trimethoprim–dapsone option, p 943). The third RCT compared intravenous or oral clindamycin 450 mg four times daily plus oral primaquine 15 mg daily versus oral trimethoprim 320 mg three times daily plus intravenous or oral sulfamethoxazole 1600 mg four times daily. There was no significant difference in mortality (1/45 [2.2%] with clindamycin–primaquine *v* 2/42 [4.8%] with TMP–SMX; RR 0.47, 95% CI 0.04 to 4.96; P = 0.95) or in rates of therapeutic failure (11/45 [24.4%] with clindamycin–primaquine *v* 9/42 [21.4%] with TMP–SMX; RR 1.14, 95% CI 0.53 to 2.47; P = 0.94).[15] The wide confidence interval suggests that the trial had insufficient power to detect clinically important differences in mortality between treatments.

Harms: We found no systematic review. The adverse effects requiring termination of treatment that most frequently occured in people receiving clindamycin–primaquine were rash, raised liver enzymes, leucopaenia, anaemia, and methaemoglobinaemia.[13–15] **Versus placebo:** We found insufficient evidence. **Versus TMP–SMX:** In the first two RCTs there was no significant difference in rates of adverse effects that required a change in treatment (6/27 [22.2%] with clindamycin–primaquine *v* 4/22 [18.2%] with TMP–SMX; RR 1.22, 95% CI 0.39 to 3.80; P = 0.99;[13] 19/58 [32.8%] with clindamycin–primaquine *v* 23/64 [35.9%] with TMP–SMX; RR 0.91, 95% CI 0.56 to 1.49; P = 0.86[14]). The third RCT reported

lower rates of serious adverse events with clindamycin–primaquine, but this was not significant if the 2 x 2 χ^2 test with Yates' correction factor was performed (13/45 [28.9%] with clindamycin–primaquine *v* 21/42 [50.0%] with TMP–SMX; RR 0.58, 95% CI 0.33 to 1.00; P = 0.07).[15]

Comment: None.

OPTION TMP–DAPSONE (TRIMETHOPRIM–DAPSONE)

We found no RCTs comparing TMP–dapsone versus placebo or no treatment as the first line treatment for *Pneumocystis carinii* pneumonia in people infected with HIV. RCTs have found that TMP–dapsone is as effective as TMP–SMX, with similar rates of adverse effects. One RCT found that TMP–dapsone was as effective as clindamycin–primaquine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus TMP–SMX:** We found two RCTs (60[16] and 181[14] people with confirmed *Pneumocystis carinii* pneumonia [PCP]). The first study compared a 21 day course of oral trimethoprim 20 mg/kg/day plus oral dapsone 100 mg/day versus oral trimethoprim 20 mg/kg/day plus oral sulfamethoxazole 100 mg/kg/day. There was no significant difference in rates of treatment failure (2/30 [6.7%] with TMP–dapsone *v* 3/30 [10%] with TMP–SMX; RR 0.67, 95% CI 0.12 to 3.71; P = 1.00).[16] The second RCT compared a 21 day course of three treatments: oral clindamycin 600 mg three times daily plus oral primaquine 30 mg daily versus oral trimethoprim 320 mg three times daily plus oral sulfamethoxazole 1600 mg three times daily versus oral trimethoprim 320 mg three times daily plus oral dapsone 100 mg daily. At 2 months there was no significant difference between TMP–dapsone and TMP–SMX in mortality (2/59 [3.4%] with TMP–dapsone *v* 4/64 [6.3%] with TMP–SMX; RR 0.54, 95% CI 0.10 to 2.85; P = 0.75) or in rates of therapeutic failure on or before day 21 (7/59 [11.9%] with TMP–dapsone *v* 6/64 [9.4%] with TMP–SMX; RR 1.27, 95% CI 0.45 to 3.55; P = 0.88).[14] The results of the third treatment arm are discussed below. **Versus clindamycin–primaquine:** The second RCT discussed above found no significant difference between TMP–dapsone and clindamycin–primaquine in mortality (2/59 [3.4%] with TMP–dapsone *v* 2/58 [3.4%] with clindamycin–primaquine; RR 0.98, 95% CI 0.14 to 6.75; P = 0.62) or in rates of therapeutic failure on or before day 21 (7/59 [11.9%] with TMP–dapsone *v* 4/58 [6.9%] with clindamycin–primaquine; RR 1.72, 95% CI 0.53 to 5.56; P = 0.55).[14] The wide confidence interval suggests that the trial had insufficient power to detect a clinically important difference in mortality between treatments.

Harms: We found no systematic review. The adverse effects requiring termination of treatment that most frequently occured in people receiving TMP–dapsone were rash, vomiting, and raised liver enzymes.[14,16] **Versus placebo:** We found insufficient evidence. **Versus TMP–SMX:** The first RCT reported lower rates of major adverse events with TMP–dapsone, although this did not reach statistical significance when the 2 x 2 χ^2 test with Yates' correction factor was used (9/30 [30.0%] with TMP–dapsone *v* 17/30 [56.7%]

with TMP–SMX; RR 0.53, 95% CI 0.28 to 0.99; P = 0.07).[16] The second RCT found no significant difference in rates of adverse effects requiring a change in dose or treatment between TMP–dapsone and TMP–SMX (19/59 [32.2%] with TMP–dapsone *v* 23/64 [35.9%] with TMP–SMX; RR 0.90, 95% CI 0.55 to 1.47; P = 0.81).[14] **Versus clindamycin–primaquine:** The second RCT found no significant difference in the rate of adverse effects requiring a change in dose or treatment between TMP–dapsone and clindamycin–primaquine (19/59 [32.2%] with TMP–dapsone *v* 19/58 [32.8%] with clindamycin–primaquine; RR 0.98, 95% CI 0.58 to 1.66; P = 0.89).[14]

Comment: None.

QUESTION **What are the effects of treatment for *Pneumocystis carinii* pneumonia in people infected with HIV who have not responded to first line treatment?** New

We found no systematic review and no RCTs comparing the effectiveness or adverse effects of different treatments following failure of first line therapy for *Pneumocystis carinii* pneumonia in people infected with HIV. One systematic review of cohort studies suggests that clindamycin–primaquine may be more effective than alternative treatments in this situation.

Benefits: We found no systematic review and no RCTs comparing different treatments for *Pneumocystis carinii* pneumonia (PCP) in people infected with HIV who had experienced treatment failure with first line therapy.

Harms: We found no systematic review and no RCTs.

Comment: We found one systematic review of cohort studies of treatment in people with PCP following failure of first line therapy. This included a meta-analysis (497 people with confirmed PCP, although 41 of these people did not have AIDS) comparing pentamidine, TMP–SMX, clindamycin–primaquine, trimetrexate, eflornithine, and atovaquone. More people responded to clindamycin–primaquine than to the other treatments (42–44/48 [87.5–91.7%] with clindamycin–primaquine *v* 64/164 [39.0%] with pentamidine *v* 27/51 [52.9%] with TMP–SMX *v* 47/159 [29.6%] with trimetrexate *v* 40/70 [57.1%] with eflornithine *v* 4/5 [80.0%] with atovaquone).[17] As these results were obtained from different cohort studies, it is difficult to make direct comparisons between the treatments, and the results should be interpreted with caution.

QUESTION **What are the effects of adjuvant corticosteroids for *Pneumocystis carinii* pneumonia in people infected with HIV?** New

One systematic review has found that adjuvant corticosteroids reduce mortality when used early in the treatment of moderate to severe *Pneumocystis carinii* pneumonia (see definition, p 936). We found insufficient evidence on the effects of adjuvant corticosteroids in the early treatment of mild *Pneumocystis carinii* pneumonia (see definition, p 936).

Benefits: We found one systematic review and two subsequent RCTs. The review (search date 1991, 4 RCTs, 326 people with confirmed *Pneumocystis carinii* pneumonia [PCP]) found that corticosteroids decreased mortality and respiratory failure in people with moderate to severe PCP (initial $P_aO_2 < 70$ mm Hg on room air or an alveolar–arterial gradient > 35 mm Hg), when initiated within 72 hours of starting specific antibiotic therapy.[18] No meta-analysis was performed. The largest RCT included in the review was not blinded. This trial (333 people with suspected PCP, 251 with confirmed or probable PCP were eligible for analysis) compared prednisone 40 mg twice daily for 5 days, followed by 40 mg daily for 5 days then 20 mg daily for the duration of anti-pneumocystis treatment (or equivalent dose of methylprednisolone) versus no adjuvant corticosteroid. After 31 days, those receiving corticosteroids had significantly lower mortality (13/123 [10.6%] with corticosteroids *v* 28/128 [21.9%] with no corticosteroids; RR 0.48, 95% CI 0.26 to 0.89; P = 0.02) and lower rates of respiratory failure (17/123 [13.8%] with corticosteroids *v* 38/128 [29.7%] with no corticosteroids; RR 0.47, 95% CI 0.28 to 0.78; P = 0.004). In people with mild PCP there was no significant difference in mortality (0/28 [0%] with corticosteroids *v* 1/34 [3.0%] with no corticosteroids; RR cannot be calculated as no events occurred with corticosteroids; P = 0.92) or respiratory failure (1/28 [3.6%] with corticosteroids *v* 3/34 [8.8%] with no corticosteroids; RR 0.40, 95% CI 0.04 to 3.68; P = 0.75).[19] The three remaining RCTs included in the review were small (23, 37, and 41 people with probable or confirmed PCP).[20–23] The first subsequent RCT (non-blinded, 59 people with PCP and either a $P_aO_2 < 67.5$ mm Hg or $P_aCO_2 < 30$ mm Hg on room air) compared intravenous methylprednisolone 0.5 mg/kg four times daily versus no adjuvant corticosteroid. The authors reported fewer deaths with methylprednisolone but this was not significant when the $2 \times 2\ \chi^2$ test with Yates' correction factor was used (3/30 [10.0%] with methylprednisolone *v* 9/29 [31.0%] with no corticosteroids; RR 0.32, 95% CI 0.10 to 1.07; P = 0.09).[24] Fewer people required mechanical ventilation with methylprednisolone (3/30 [10.0%] with methylprednisolone *v* 12/29 [41.4%] with no corticosteroid; RR 0.24, 95% CI 0.08 to 0.77; P = 0.01). The second subsequent RCT (78 people with HIV related PCP and either a $P_aO_2 < 70$ mm Hg breathing room air or an alveolar–arterial oxygen gradient > 40 mm Hg on oxygen) compared intravenous methylprednisolone 40 mg twice daily versus placebo. There was no significant difference in mortality (4/40 [10.0%] with methylprednisolone *v* 6/38 [15.8%] with placebo; RR 0.63, 95% CI 0.19 to 2.07; P = 0.67) or the need for mechanical ventilation (3/40 [7.5%] with methylprednisolone *v* 5/38 [13.2%] with placebo; RR 0.57, 95% CI 0.15 to 2.22; P = 0.65).[25]

Harms: The systematic review found a small increase in the rate of infection in people treated with corticosteroids. In the largest of the studies included in this review, the frequency of new herpetic lesions was higher in the corticosteroid group (32/123 [26.0%] with corticosteroid *v* 19/128 [14.8%] with no corticosteroid; RR 1.75, 95% CI 1.05 to 2.92; P = 0.04) and there was a non-significant increase in the occurrence of oral candida infections (65/123

[52.8%] with corticosteroid *v* 53/128 [41.4%] with no corticosteroid; RR 1.28, 95% CI 0.98 to 1.66; P = 0.09).[19] There was no significant difference in rates of serious opportunistic infections (cytomegalovirus disease, *Mycobacterium avium* bacteraemia, cryptococcosis, oesophageal candidosis, and Kaposi's sarcoma) (28/123 [22.8] with corticosteroid *v* 27/128 [21.1%] with no corticosteroid; RR 1.08, 95% CI 0.68 to 1.72; P = 0.87).[19] The smaller RCTs included in the review found no significant increase in the risk of infection with steroids, although one RCT reported a high overall rate of adverse events (3 opportunistic infections, 2 bacteraemias, 1 urinary tract infection, 1 upper gastrointestinal haemorrhage, and 2 acute psychoses among 19 people treated with methylprednisolone).[23] The first subsequent RCT found no significant difference in the number of participants with a complicating condition (5/30 [16.7%] with methylprednisolone *v* 4/29 [13.8%] with no corticosteroid; RR 1.21, 95% CI 0.36 to 4.06; P = 0.96).[24] The second subsequent RCT found more superinfections with corticosteroids but this was not significant (33 with methylprednisolone *v* 24 with placebo; P = 0.51).[25]

Comment: In one of the RCTs that showed no benefit from the use of adjuvant corticosteroids, the methylprednisolone was started later than the anti-pneumocystis drugs (more than 3 days for most participants).[23] This may explain the negative results of the study. We found no other RCTs on the use of corticosteroids after anti-pneumocystis drugs had failed and respiratory deterioration had already occurred.

25	120 people with suspected PCP and P_aO_2 < 70 mm Hg or alveolar–arterial oxygen gradient > 40 mm Hg. Only the 78 people in whom the diagnosis was confirmed were evaluated further	Intravenous methylprednisolone *v* placebo	40 *v* 38	0.63 (0.19–2.07)	0.57 (0.15–2.22)

*RR refers to the first treatment in comparison with the second. For reference 14 the RR refers to each treatment in comparison with TMP–SMX. For further details on the design, patient eligibility criteria, dose and duration of the treatments administered, length of follow up, and the definition of respiratory/treatment failure used in each study, please see the main text. Numbers analysed are smaller than those enrolled in some cases because the study authors did not perform an intent to treat analysis. Ref, reference.

Chickenpox

Search date July 2003

George Swingler

QUESTIONS

INTERVENTIONS

See glossary, p 957

Key Messages

Prevention

- **High dose aciclovir (> 3200 mg/day) in people with HIV infection** One systematic review has found that high dose aciclovir (at least 3200 mg/day) reduces the risk of clinical chickenpox and reduces all cause mortality over 22 months' treatment compared with placebo.
- **Live attenuated vaccine in healthy children** Two RCTs have found that live attenuated varicella vaccine reduces clinical chickenpox compared with placebo, with no significant increase in adverse effects.

Chickenpox

- **Zoster immune globulin versus human serum globulin in healthy children** One small RCT in children exposed to a sibling with chickenpox found that zoster immune globulin reduced the proportion of exposed children with clinical chickenpox at 20 days compared with human immune serum globulin.
- **Aciclovir in people with immunocompromise other than HIV** We found no RCTs on the effects of aciclovir in people with immunocompromise other than HIV.
- **Live attenuated vaccine in healthy adults** We found no RCTs in healthy adults on the effects of live attenuated varicella vaccine.
- **Live attenuated vaccine in immunocompromised people** We found no RCTs in immunocompromised people on the effects of live attenuated varicella vaccine.
- **Zoster immune globulin in immunocompromised adults** We found no RCTs on the effects of zoster immune globulin in immunocompromised adults.
- **Zoster immune globulin versus varicella zoster immune globulin in immunocompromised children** One RCT in immunocompromised children exposed to a sibling with chickenpox found no significant difference in clinical chickenpox with zoster immune globulin compared with varicella zoster immune globulin at 12 weeks.

Treatment

- **Oral aciclovir in healthy people (given < 24 hours of onset of rash)** Two systematic reviews have found that oral aciclovir compared with placebo reduces the symptoms of chickenpox in healthy people.
- **Intravenous aciclovir for treatment of chickenpox in children with malignancy** Two RCTs compared intravenous aciclovir versus placebo. One large RCT has found that aciclovir reduces clinical deterioration. The other smaller RCT found no significant difference in clinical deterioration.
- **Aciclovir in immunocompromised adults** We found no RCTs on the effects of aciclovir in immunocompromised adults.
- **Oral aciclovir in healthy people (given > 24 hours after onset of rash)** One systematic review and one additional RCT have found that oral aciclovir given beyond 24 hours after onset of rash does not significantly reduce the symptoms of chickenpox compared with placebo.

DEFINITION Chickenpox is due to primary infection with varicella zoster virus. In healthy people, it is usually a mild self limiting illness, characterised by low grade fever, malaise, and a generalised, itchy, vesicular rash.

INCIDENCE/ PREVALENCE Chickenpox is extremely contagious. Over 90% of unvaccinated people become infected, but infection occurs at different ages in different parts of the world: over 80% of people have been infected by the age of 10 years in the USA, the UK, and Japan, and by the age of 30 years in India, South East Asia, and the West Indies.[1,2]

AETIOLOGY/ RISK FACTORS Chickenpox is caused by exposure to varicella zoster virus.

PROGNOSIS **Infants and children:** In healthy children the illness is usually mild and self limiting. In the USA, death rates in infants and children (aged 1–14 years) with chickenpox are about 7/100 000 in infants and 1.4/100 000 in children.[3] In Australia, mortality in children aged between 1 and 11 years with chickenpox is about 0.5–0.6/100 000, and in infants with chickenpox it is about 1.2/100 000.[4]

Bacterial skin sepsis is the most common complication in children under 5 years of age, and acute cerebellar ataxia is the most common complication in older children; both cause hospital admission in 2–3/10 000 children.[5] **Adults:** Mortality in adults is higher, at about 31/100 000.[3] Varicella pneumonia is the most common complication, causing 20–30 hospital admissions/10 000 adults.[5] Activation of latent varicella zoster virus infection can cause herpes zoster, also known as shingles (see postherpetic neuralgia, p 1070). **Cancer chemotherapy:** One case series (77 children with cancer and chickenpox) found that more children receiving chemotherapy versus those in remission developed progressive chickenpox with multiple organ involvement (19/60 [32%] with children receiving chemotherapy *v* 0/17 [0%] with children in remission) and more children died (4/60 [7%] with children receiving chemotherapy *v* 0/17 [0%] with children in remission).[6] **HIV infection:** One retrospective case series (45 children with AIDS) found that one in four children with AIDS who acquired chickenpox in hospital developed pneumonia and 5% died.[7] In a retrospective cohort study (73 children with HIV and chickenpox; 83% with symptomatic HIV), infection beyond 2 months occurred in 10 children (14%) and recurrent varicella zoster virus infections occurred in 38 children (55%). There was a strong association between an increasing number of recurrences and low CD4 cell counts.[8] Half of recurrent infections involved generalised rashes and the other half had zoster. **Newborns:** We found no cohort studies of untreated children with perinatal exposure to chickenpox. One cohort study (281 neonates receiving varicella zoster immune globulin (see glossary, p 957) because their mothers had developed a chickenpox rash during the month before or after delivery) found that 134 (48%) developed a chickenpox rash and 19 (14%) developed severe chickenpox.[9] Severe chickenpox occurred in neonates of mothers whose rash had started during the 7 days before delivery.

AIMS OF INTERVENTION To prevent clinical chickenpox (characterised by a rash); to reduce the duration of illness and complications of chickenpox.

OUTCOMES Development of clinical chickenpox; duration of illness (time to no new lesions, disappearance of fever); complications of chickenpox; mortality.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of interventions to prevent chickenpox in healthy adults and children?

OPTION LIVE ATTENUATED VARICELLA VACCINE

Two RCTs identified by a systematic review have found that, live attenuated varicella vaccine reduces chickenpox in healthy children compared with placebo, with no significant increase in adverse effects. We found no RCTs in healthy adults.

Benefits: We found one systematic review (search date 2000, 2 RCTs).[10] **In healthy children:** The first RCT (914 healthy children aged 1–14 years) found that live attenuated varicella vaccine significantly

reduced clinical chickenpox at 9 months (0/468 [0%] with vaccine *v* 38/446 [8.5%] with placebo; ARR 8.5%, 95% CI 6.1% to 11.5%; protection level 100%)[11] and at 2 years (1/163 [1%] with vaccine *v* 21/161 [13%] with placebo; OR 0.05, 95% CI 0.01 to 0.35).[12] The second RCT (327 healthy children aged 10–30 months) also found that live attenuated varicella vaccine significantly reduced clinical chickenpox after a mean of 29 months (AR 5/166 [3%] with vaccine *v* 41/161 [25%] with placebo; RR 0.12, 95% CI 0.05 to 0.29).[13] **In healthy adults:** The review found no RCTs assessing clinical outcomes in healthy adults.

Harms: The systematic review found that the only reported adverse effect with varicella vaccine was a non-significant increase in varicella-like papules or vesicles (AR 5.4% with vaccine *v* 3.7% with placebo; RR 1.45, 95% CI 0.53 to 4.0).[10] No children had fever or constitutional symptoms. One postmarketing analysis of a database of 89 753 vaccinated adults and children found no associations with any rare serious adverse events.[14] Another analysis found that the rate of serious adverse events was 2.9/100 000 doses.[15]

Comment: A new systematic review of vaccines for preventing varicella in children and adults is underway.[16] Aciclovir, varicella zoster immune globulin and zoster immune globulin are of questionable clinical importance for prevention in healthy people. Data from both healthy and immunocompromised people are presented in question 2 (see aciclovir, p 954 and zoster immune globulin, p 955).

QUESTION What are the effects of interventions to prevent chickenpox in immunocompromised adults and children?

OPTION LIVE ATTENUATED VARICELLA VACCINE

We found no RCTs in immunocompromised adults or children.

Benefits: We found no RCTs assessing clinical outcomes in people receiving cancer chemotherapy or in people with HIV.

Harms: We found no RCTs.

Comment: A new systematic review of vaccines for preventing varicella in children and adults is underway.[16]

OPTION ACICLOVIR

One systematic review in people with HIV infection, has found that high dose aciclovir reduces the risk of clinical chickenpox and reduces all cause mortality over 22 months' treatment compared with placebo. We found no RCTs in people with other forms of immunocompromise.

Benefits: **In people with HIV:** We found one systematic review (search date not reported, 8 RCTs, 1792 people with different stages of HIV, median CD4 count 34–607/mm^3) comparing high dose aciclovir versus placebo.[17] Three of the RCTs were unpublished, including two pharmaceutical company trials. The review found that aciclovir (≥ 3200 mg/day for up to 22 months) significantly reduced clinical chickenpox (AR 14/895 [2%] with aciclovir *v* 54/897 [6%] with

placebo; OR 0.29, 95% CI 0.13 to 0.63; NNT 23, 95% CI 17 to 39). All cause mortality was also reduced (HR 0.78, 95% CI 0.65 to 0.93; OR 0.75, 95% CI 0.57 to 1.00). The treatment effect did not vary significantly with CD4 count. We found no RCTs of lower doses of aciclovir in people with HIV. **In other immunocompromised people:** We found no RCTs of aciclovir in adults or children with other forms of immunocompromise.

Harms: The systematic review did not assess adverse effects (see harms under aciclovir for treatment, p 957).

Comment: None.

OPTION ZOSTER IMMUNE GLOBULIN

We found insufficient evidence to assess zoster immune globulin in immunocompromised adults, although one small RCT in healthy children found that zoster immune globulin reduced the proportion of children with clinical chickenpox compared with immune serum globulin. One RCT in immunocompromised children exposed to a sibling with chickenpox found no significant difference in clinical chickenpox at 12 weeks with zoster immune globulin compared with varicella zoster immune globulin.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus immune serum globulin (ISG) in immunocompromised children:** See glossary, p 957. We found no RCTs. **Versus varicella zoster immune globulin (VZIG) in immunocompromised children:** We found one RCT (164 immunocompromised children, mostly with leukaemia, exposed to a sibling with chickenpox) comparing zoster immune globulin (ZIG) (1.25 mL/10 kg) versus VZIG (see glossary, p 957) (1.25 mL/10 kg).[18] It found no significant difference in the proportion of children with clinical chickenpox at 12 weeks (AR 31/88 [37%] with ZIG *v* 36/81 [44%] with VZIG; RR 0.84, 95% CI 0.58 to 1.22).

Harms: None of the RCTs assessed adverse effects.

Comment: **Versus ISG in healthy children:** We found one small RCT (12 healthy susceptible children exposed to a sibling with recent onset of chickenpox) comparing ZIG (2 mL/10 kg) versus ISG (2 mL/10 kg).[19] It found that ZIG significantly reduced the proportion of children with clinical chickenpox at 20 days (AR 0/6 [0%] with ISG *v* 6/6 [100%] with ZIG; OR 0, 95% CI 0 to 0.28). In the absence of evidence in immunocompromised people, data on effects in healthy people may be of some use, but the applicability of the findings to immunocompromised people is questionable. The imprecise estimates might not exclude clinically important differences.

Chickenpox

QUESTION **What are the effects of treatments for chickenpox in healthy adults and children?**

OPTION ACICLOVIR

Two systematic reviews have found that oral aciclovir compared with placebo reduces the symptoms of chickenpox in healthy people. One systematic review and an additional RCT found an effect when given within 24 hours of onset of the rash. It found no significant difference if started after 24 hours.

Benefits:

In healthy children: We found one systematic review in children and adolescents (search date 2002, 3 RCTs, 979 children)[20] and one additional RCT in both children and adults.[21] The systematic review compared aciclovir versus placebo given within 24 hours of onset of rash in otherwise healthy children aged 0–18 years.[20] It did not perform a meta-analysis because of differences in age among participants. Two of the three RCTs included in the review found that aciclovir (20 mg/kg or 800 mg 4 times daily) significantly reduced the time to no new lesions (WMD 1.2 days, 95% CI 1.0 day to 1.5 days in the first RCT; WMD 1.1 days, 95% CI 0.5 days to 1.8 days in the second RCT). The remaining RCT found no significant difference in the time to new lesions with aciclovir 10–20 mg/kg compared with placebo (WMD 0 days, 95% CI –0.5 days to +0.5 days). The number of days to no fever was significantly reduced by aciclovir in all three RCTs (first trial: WMD 1.1 days, 95% CI 0.9 days to 1.3 days; second trial: WMD 1.0 days, 95% CI 0.5 days to 1.5 days; third trial: WMD 1.3 days, 95% CI 0.6 days to 2.0 days).[20] We found one additional RCT that included children, adolescents, and adults (77 people).[21] It found that aciclovir started on the second day of the rash significantly reduced the time to no new lesions in children compared with starting on the third day (median 4 days when started on second day *v* 5 days when started on third day; $P < 0.04$) but found no significant difference in adolescents and adults. Earlier treatment significantly reduced the time to lowering of fever in adolescents (median 2–3 days when started on second day *v* 3–4 days when started on third day; $P < 0.02$) but not in children and adults. **In healthy adults:** We found one systematic review (search date 1997, 3 RCTs).[22] It did not perform a meta-analysis. The first RCT identified by the review (76 adults) compared early and late administration of aciclovir (800 mg 5 times daily) versus placebo. It found that aciclovir given within 24 hours of the rash significantly reduced the maximum number of lesions and the time to full crusting of lesions compared with placebo. It found no difference in time to full crusting of lesions if aciclovir was given 24–72 hours after the rash. The two remaining RCTs (total of 168 healthy adults) compared aciclovir given more than 24 hours after the onset of the rash versus placebo. Neither found a significant difference in the time to no new lesions, and did not provide numerical information on the time to lowering of fever. We found one additional RCT that included children, adolescents, and adults (see in healthy children above).[21]

Harms: The systematic review in children found no significant differences between treatment and control groups, or unfavourable trends in children taking aciclovir.[20]

Comment: The effect on the measured outcomes was small and of questionable clinical importance in healthy people who make an uneventful recovery without treatment.

QUESTION **What are the effects of treatments for chickenpox in immunocompromised adults and children?**

OPTION **ACICLOVIR**

Two RCTs compared intravenous aciclovir versus placebo in children with cancer; one large RCT found that aciclovir reduced clinical deterioration. The other smaller RCT found no significant difference in clinical deterioration.

Benefits: **In immunocompromised children:** We found two placebo controlled RCTs of intravenous aciclovir in children with cancer receiving chemotherapy.[23,24] The largest RCT (50 children aged 1–14 years with chickenpox, 60% of whom had a rash for > 24 hours) found that significantly fewer children receiving aciclovir 500 mg/m^2 deteriorated clinically and were transferred to open label aciclovir (1/25 [4%] with aciclovir *v* 12/25 [48%] with placebo; RR 0.08, 95% CI 0.01 to 0.59; NNT 3, 95% CI 2 to 4).[23] Analysis of the remaining children not moved to open label aciclovir found that aciclovir significantly reduced the time to full crusting of lesions (mean 5.7 days with aciclovir *v* 7.1 days with placebo; $P < 0.013$). It found no significant difference in lowering of fever. The second RCT (20 children, mean age 6.4 years) comparing aciclovir 500 mg/m^2 versus placebo found no significant difference in the proportion of children who deteriorated clinically and were moved to open label aciclovir (AR 1/8 [12.5%] with aciclovir *v* 5/12 [42%] with placebo; RR 0.30, 95% CI 0.04 to 2.1).[24] However, the RCT was too small to exclude a clinically important difference. **In immunocompromised adults:** We found no RCTs.

Harms: In the first RCT, two of 25 children on aciclovir developed transient elevated blood urea nitrogen levels, compared with two children with other transient minor adverse effects on placebo.[23] In the second RCT, no adverse events were observed in the eight children receiving aciclovir, except one child with a self limiting maculopapular rash lasting 1 day.[24]

Comment: In the first RCT in immunocompromised children the exclusion from the subsequent analysis of children taking placebo who deteriorated clinically means that the effect of placebo may have been overestimated.[23]

GLOSSARY

Immune serum globulin (ISG) Immunoglobulin prepared from pooled human plasma.

Varicella zoster immune globulin (VZIG) Prepared from units of donor plasma selected for high titres of antibodies to varicella zoster virus.

Zoster immune globulin (ZIG) Prepared from the plasma of donors convalescing from herpes zoster (sustainable supplies are difficult to obtain).

QUESTIONS

INTERVENTIONS

See glossary, p 962

Key Messages

- **Spiramycin and other antiparasitic drugs** Two systematic reviews of cohort studies in women who seroconvert during pregnancy found insufficient evidence on the effects of current antiparasitic treatment compared with no treatment on mother or baby.

Congenital toxoplasmosis

DEFINITION Toxoplasmosis is caused by the parasite *Toxoplasma gondii*. Infection is asymptomatic or unremarkable in immunocompetent individuals, but leads to a lifelong antibody response. During pregnancy, toxoplasmosis can be transmitted across the placenta and may cause intrauterine death, neonatal growth retardation, mental retardation, ocular defects, and blindness in later life. Congenital toxoplasmosis (confirmed infection of the fetus or newborn) can present at birth, either as subclinical disease, which may evolve with neurological or ophthalmological disease later in life, or as a disease of varying severity, ranging from mild ocular damage to severe mental retardation.

INCIDENCE/ PREVALENCE Reported rates of toxoplasma seroprevalence vary across and within countries, as well as over time. The risk of primary infection is highest in young people, including young women during pregnancy. We found no cohort studies describing annual seroconversion rates in women of childbearing age nor incidence of primary infection. One systematic review (search date 1996) identified 15 studies that reported rates of seroconversion in non-immune pregnant women ranging from 2.4–16/1000 in Europe and from 2–6/1000 in the USA.[1] France began screening for congenital toxoplasmosis in 1978, and during the period 1980–1995 the seroconversion rate during pregnancy in non-immune women was 4–5/1000.[2]

AETIOLOGY/ RISK FACTORS Toxoplasma infection is usually acquired by ingesting either sporocysts (from unwashed fruit or vegetables contaminated by cat faeces) or tissue cysts (from raw or undercooked meat). The risk of contracting toxoplasma infection varies with eating habits, contact with cats and other pets, and occupational exposure.

PROGNOSIS One systematic review of studies conducted from 1983–1996 found no population based prospective studies of the natural history of toxoplasma infection during pregnancy.[1] One systematic review (search date 1997) reported nine controlled, non-randomised studies, and found that untreated toxoplasmosis acquired during pregnancy was associated with infection rates in children of between 10–100%.[3] We found two European studies that correlated gestation at time of seroconversion with risk of transmission and severity of disease at birth.[4,5] Risk of transmission increased with gestational age at maternal seroconversion, reaching 70–90% for infections acquired after 30 weeks' gestation. In contrast, the risk of the infected infant developing clinical disease was highest when infection occurred early in pregnancy. The highest risk of early signs of disease (including chorioretinitis and hydrocephaly) was about 10%, and occurred with infection between 24 and 30 weeks' gestation.[5] Infants with untreated congenital toxoplasmosis and generalised neurological abnormalities at birth develop mental retardation, growth retardation, blindness or visual defects, seizures, and spasticity. Children with untreated subclinical infection at birth may have cognitive and motor deficits and visual defects or blindness, which may go undiagnosed for many years. One case control study (845 school children in Brazil) found mental retardation and retinochoroiditis to be significantly associated with positive toxoplasma serology (population attributable risk 6–9%).[6]

AIMS OF INTERVENTION To prevent transmission from mother to child, congenital infection, visual impairment, and neurological impairment in neonates and in later life, with minimum adverse effects.

OUTCOMES Incidence of spontaneous abortion, fetal infection, and overt neonatal disease (neurological and visual impairment); serological positivity in the newborn; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal November 2002.

QUESTION **What are the effects on mother and baby of antiparasitic treatment in women found to be seropositive for toxoplasma during pregnancy?**

OPTION **ANTIPARASITIC TREATMENT IN SEROPOSITIVE PREGNANT WOMEN**

We found no reliable evidence on the effects of treating women who seroconvert during pregnancy.

Benefits: We found two systematic reviews (search dates 1997).[3,7] The first identified no RCTs.[3] The second review identified nine small cohort studies comparing treatments (spiramycin alone, pyrimethamine-sulphonamides, or a combination of the 2 treatments) versus no treatment.[7] One study of case series of women treated with spiramycin or spiramycin plus pyrimethamine–sulphonamide found no evidence of difference in outcomes (fetal infection, overt neonatal disease).[8] Comparing data from these studies was difficult because of different follow up periods.

Harms: Spiramycin and pyrimethamine–sulphonamides are reportedly well tolerated and non-teratogenic.[9] Sulpha drugs are known to carry a risk of kernicterus (see glossary, p 962) in the newborn and should be avoided if possible in the third trimester; there is also a risk of bone marrow suppression, which can be reduced through concomitant use of folic acid.[9]

Comment: We found that the quality of evidence was poor. Studies included in the systematic review were small and did not account for differences in gestation. Only two studies provided information about the control group and congenital infection was common in the treatment groups.[7] One decision analysis on screening and treatment for intrauterine toxoplasma infection has suggested that treatment may save the pregnancy without preventing infection in the neonate. This may lead to an increase in congenital disease.[10] Drug regimens of co-trimoxazole (trimethoprim plus sulfamethoxazole [sulphamethoxazole]), atovaquone, or fluoroquinolones, which are either used or are being tested for secondary prophylaxis of toxoplasmosis in immunocompromised people (particularly those with HIV infection), have not been studied in pregnancy because their reproductive toxicity has not been properly documented. Finally, optimal duration of follow up is not established, although the longer the children are observed the higher the incidence of sequelae.

Congenital toxoplasmosis

GLOSSARY

Kernicterus Cerebral toxicity, caused by high levels of bilirubin in the neonate. Clinical effects include vomiting, lethargy, fever, and fits.

QUESTIONS

INTERVENTIONS

*Although we found no direct evidence to support their use, widespread consensus holds that intravenous fluid replacement with crystalloids should be used universally in children with dengue haemorrhagic fever or dengue shock syndrome because these conditions lead to an acute increase in vascular permeability that leads to plasma leakage, resulting in increased haematocrit and decreased blood pressure. Placebo controlled trials would be considered unethical.

See glossary, p 969

Key Messages

- **Intravenous fluids** We found no RCTs comparing intravenous fluids versus placebo or no treatment. It is widely accepted that immediate fluid replacement should be undertaken in a child who has dengue haemorrhagic fever or dengue shock syndrome; it would be considered unethical to test its role in a placebo controlled trial.
- **Colloids** Two RCTs found no significant difference in mortality between crystalloids and colloids for acute resuscitation in Vietnamese children with dengue shock syndrome, but they are likely to have been underpowered to detect a clinically important difference.
- **Adding corticosteroids to standard intravenous fluids** Two RCTs in Thai and Indonesian children with dengue shock syndrome found no significant difference in mortality between adding corticosteroids to standard fluid replacement and placebo. One open label RCT in Burmese children with dengue shock syndrome found that hydrocorticosone reduced mortality compared with other fluid replacements. An unpublished review of these RCTs and two uncontrolled studies found no significant difference between adding corticosteroids to standard intravenous fluids and standard intravenous fluids alone.

- **Adding intravenous immunoglobulin to standard intravenous fluids** We found no published RCTs on the effects of intravenous immunoglobulin in people with dengue haemorrhagic fever or dengue shock syndrome. One unpublished RCT in Filipino children with dengue shock syndrome found that intravenous immunoglobulin reduced mortality compared with placebo.

DEFINITION

Dengue infection is a mosquito borne arboviral infection. The spectrum of dengue virus infection ranges from asymptomatic or undifferentiated febrile illness to dengue fever and dengue haemorrhagic fever or dengue shock syndrome. An important epidemiologic criterion to consider in the diagnosis of dengue infection is history of travel or residence in a dengue endemic area within 2 weeks of onset of fever. **Dengue fever** is an acute febrile illness whose clinical presentation varies with age. Infants and young children may have an undifferentiated febrile disease with maculopapular rash. Children aged 15 years and older and adults may have either a mild febrile illness or the classic incapacitating disease also called "breakbone fever" presenting with high fever of sudden onset and non-specific signs and symptoms of severe headache; pain behind the eyes; muscle, bone, or joint pains; nausea; vomiting; and rash. **Dengue haemorrhagic fever** is characterised by four criteria: acute onset of high fever; haemorrhagic manifestations evidenced by positive tourniquet (see glossary, p 969) test, skin haemorrhages, mucosal, and gastrointestinal tract bleeding; thrombocytopenia; and evidence of plasma leakage manifested by a rise or drop in haematocrit, fluid in the lungs or abdomen, or hypoproteinaemia. Dengue haemorrhagic fever is classified into four grades of severity (see table 1, p 970).[1] Presence of thrombocytopenia and haemoconcentration differentiates dengue haemorrhagic fever grades I and II from dengue fever. Grades III and IV dengue haemorrhagic fever are considered **dengue shock syndrome**.[1] Plasma leakage is the major pathophysiological feature observed in dengue haemorrhagic fever.

INCIDENCE/ PREVALENCE

Dengue fever and dengue haemorrhagic fever are public health problems worldwide, particularly in low lying areas where *Aedes aegypti*, a domestic mosquito, is present. Cities near to the equator but high in the Andes are free of dengue because the *Aedes* mosquitoes do not survive at high altitudes. Worldwide, an estimated 50–100 million cases of dengue fever and hundreds of thousands of dengue haemorrhagic fever occur yearly.[2] Endemic regions are the Americas, South East Asia, western Pacific, Africa, and the eastern Mediterranean. Major global demographic changes, particularly increases in the density and geographic distribution of the vector, with declining vector control; unreliable water supply systems; increasing non-biodegradable container and poor solid waste disposal; increased geographic range of virus transmission owing to increased air travel; and increased population density in urban areas are responsible for the resurgence of dengue in the last century.[3,4] The World Health Organization estimates that global temperature rises of 1.0–3.5 °C can increase transmission by shortening the extrinsic incubation period of viruses within the mosquito, adding 20 000–30 000 more fatal cases annually.[5]

AETIOLOGY/ RISK FACTORS Dengue virus serotypes 1–4 (DEN 1, 2, 3, 4) belonging to the flavivirus genus are the main aetiologic agents. These serotypes are closely related but antigenically distinct and they provide specific lifetime immunity. *A aegypti* the principal vector, transmits the virus to man. Dengue haemorrhagic fever and dengue shock syndrome typically occur in children under the age of 15 years, although dengue fever primarily occurs in adults and older children. Important risk factors influencing the proportion of people who will develop dengue haemorrhagic fever or severe disease during epidemics include the virus strain and serotype, immune status of the host, and age and genetic predisposition. There is evidence that sequential infection or pre-existing antidengue antibodies increases the risk of dengue haemorrhagic fever through antibody dependent enhancement.[3,4,6–8]

PROGNOSIS Dengue fever is an incapacitating disease but prognosis is favourable in previously healthy adults, although dengue haemorrhagic fever and dengue shock syndrome are major causes of hospital admission and mortality in children. Dengue fever is generally self limiting, with less than 1% case fatality. The acute phase of the illness lasts for 2–7 days but the convalescent phase may be prolonged for weeks associated with fatigue and depression, especially in adults. Prognosis in dengue haemorrhagic fever and dengue shock syndrome depends on prevention or early recognition and treatment of shock. Case fatality ranges from 2.5% to 5.0%. Once shock sets in, fatality may be as high as 12–44%.[9] In centres with appropriate intensive supportive treatment, fatality can be less than 1%. There is no specific antiviral treatment. The standard of treatment is to give intravenous fluids to expand the plasma volume. People usually recover after prompt and adequate fluid and electrolyte supportive treatment. The optimal fluid regimen, however, remains unsettled. This is particularly important in dengue, wherein one of the management difficulties is to correct hypovolaemia rapidly without precipitating fluid overload.

AIMS OF INTERVENTION To prevent mortality and improve symptoms, with minimal adverse effects.

OUTCOMES Mortality; recurrence of shock; symptom relief; renal failure; length of hospital stay; time to recovery; time off work; need for blood transfusion; fluid requirements; adverse effects (bleeding, fluid overload, hypersensitivity reactions, and secondary infections).

METHODS *Clinical Evidence* search and appraisal March 2003. The author retrieved additional material through hand searches and personal contact with experts in the field.

QUESTION **What are the effects of supportive treatments for dengue haemorrhagic fever or dengue shock syndrome in children?** New

OPTION **INTRAVENOUS FLUIDS**

We found no RCTs comparing intravenous fluids versus placebo or no treatment. It is widely accepted that immediate fluid replacement should be undertaken in a child who has dengue haemorrhagic fever or dengue

shock syndrome; it would be considered unethical to test its role in a placebo controlled trial. Two RCTs found no significant difference in mortality between crystalloids and colloids for acute resuscitation in Vietnamese children with dengue shock syndrome, but it is likely that they were underpowered to detect a clinically important difference.

Benefits: **Versus placebo or no treatment:** We found no RCTs (see comment below). **Crystalloids versus colloids:** We found no systematic review but found two RCTs.[10,11] The first RCT (50 Vietnamese children aged 5–15 years with dengue shock syndrome) compared four intravenous fluid regimens for acute resuscitation: two crystalloid regimens (sodium chloride or Ringer's lactate solution, 25 children) and two colloid regimens (dextran 70 or gelafundin, 25 children).[10] Crystalloids or colloids were randomly infused at a rate of 20 mL/kg for the first hour followed by 10 mL/kg for the second hour. All children then received further intravenous infusions on an open basis at the discretion of the attending physician according to World Health Organization guidelines. All participants recovered with fluid resuscitation alone. The RCT found no significant difference among groups in recurrence of shock (median 1 episode in each group; P = 0.46) or requirement for further infusions of crystalloids (P = 0.16) or colloids (P = 0.70) between the 2 hour infusion and full recovery from shock. Recovery from shock was defined as a pulse pressure of 20 mm Hg or greater. The RCT also found no significant difference among groups in median duration in shock (mean 1.5 hours with sodium chloride *v* 5.0 hours with Ringer's *v* 2.8 hours with dextran 70 *v* 7.0 hours with gelafundin; P = 0.36).[10] The second RCT (222 Vietnamese children, aged 1–15 years with dengue shock syndrome) also compared four intravenous fluid regimens for acute resuscitation: two crystalloid regimens (sodium chloride or Ringer's lactate solution, 111 children) and two colloid regimens (dextran 70 or gelafundin, 111 children).[11] The fluids were infused at a rate of 20 mL/kg for the first hour followed by a bolus of 20 mL/kg for the second hour. All participants then received further infusions of Ringer's lactate solution according to World Health Organization guidelines. However, children who failed to improve or who deteriorated were given additional colloid (dextran 70) infusions at the discretion of the attending physician. All participants recovered with fluid resuscitation. The RCT found no significant difference between crystalloids and colloids in the proportion of children who had recurrence of shock (24/90 [27%] with colloids *v* 20/81 [25%] with crystalloids; RR 1.02, 95% CI 0.56 to 1.85). It also found no significant difference among groups in the total volume of fluid infused until full recovery from shock (P = 0.95) or in the proportion of children who required further infusions after the first hour (17/56 [30%] with sodium chloride *v* 20/55 [36%] with Ringer's *v* 17/55 [31%] with dextran 70 *v* 15/56 [27%] with gelafundin; P = 0.75).

Harms: The first RCT found no adverse effects attributable to colloids or crystalloids, but may have been underpowered to detect clinically important adverse effects.[10] In the second RCT, six children developed fever and chills after completing colloid treatment.[11] Two children receiving colloids had recurrence of shock, which

responded to treatment with crystalloids. One child in the gelafundin group had severe epistaxis requiring transfusion and another child in the dextran group developed a large haematoma at a site of minor trauma. Thirty five children equally distributed among the four groups required diuretic treatment for 1 or 2 days after recovery from shock.[11]

Comment: It would be considered unethical to test the role of intravenous fluids in children with dengue haemorrhagic fever or dengue shock syndrome in a placebo controlled trial. Widespread consensus holds that intravenous fluid replacement with crystalloids should be universally used in children with dengue haemorrhagic fever or dengue shock syndrome because these conditions lead to an acute increase in vascular permeability that leads to plasma leakage, resulting in increased haematocrit and decreased blood pressure. The RCTs comparing crystalloids versus colloids are likely to have been underpowered to detect a clinically important difference in outcomes.[10,11] The RCTs measured outcomes at 1 or 2 hours after fluid infusion so a clinically important effect within the first hour of fluid resuscitation may have been overlooked. Regardless of whether colloid or crystalloid is more effective, if equal volumes are infused, there is no difference between them with regard to fluid overload.[12]

OPTION ADDING CORTICOSTEROIDS TO STANDARD INTRAVENOUS FLUIDS

Two RCTs in Thai and Indonesian children with dengue shock syndrome receiving standard fluid replacement found no significant difference in mortality between adding corticosteroids and adding placebo. One open label RCT in Burmese children with dengue shock syndrome found limited evidence that adding hydrocortisone to intravenous fluids reduced mortality compared with intravenous fluids alone. An unpublished review of these RCTs and two uncontrolled studies found no significant difference between adding corticosteroids to standard intravenous fluids and standard intravenous fluids alone.

Benefits: We found no systematic review. We found three RCTs.[13–15] The first RCT (63 Thai children aged < 15 years with dengue shock syndrome receiving standard intravenous fluids) compared adding methylprednisolone sodium succinate (given as single bolus of 30 mg/kg) versus adding 5% dextrose in normal saline solution as placebo.[13] All children received crystalloids (either Ringer's lactate or 0.5% glucose in sodium chloride) given at a rate of 10–20 mL/kg adjusted to clinical and hydration status. Whole blood was given if there was a drop in haematocrit and platelet concentrate was given if bleeding was uncontrolled. Haematocrit was monitored every 2–4 hours depending on the severity of shock and bleeding. The RCT found no significant difference in mortality between adding methylprednisolone and adding placebo to intravenous fluids (4/32 [12.5%] with methylprednisolone *v* 4/31 [12.9%] with placebo; RR 0.97, 95% CI 0.27 to 3.54). It also found no significant difference in duration of hospital stay (mean 7.3 days with methylprednisolone *v* 6.2 days with placebo; P > 0.2) or in the proportion of children who needed blood transfusion (11/32 [34%] with methylprednisolone *v* 8/31 [26%] with placebo; RR 1.51, 95% CI 0.51 to

4.46).[13] The second RCT (97 Indonesian children aged 1–10 years with dengue shock syndrome confirmed by serologic, virologic, or both examinations receiving standard intravenous fluids) compared adding hydrocortisone hemisuccinate (given iv as single dose of 50 mg/kg) versus adding sodium chloride as placebo.[14] It also found no significant difference in mortality between adding hydrocortisone and adding placebo (8/47 [17%] with hydrocortisone *v* 9/50 [18%] with placebo; RR 0.95, 95% CI 0.40 to 2.25). It also found no significant difference in mean fluid requirements between hydrocortisone and placebo (mean 2.3 L with hydrocortisone *v* 2.4 L with placebo; $P > 0.05$).[14] The third RCT (98 Burmese children, aged 1–8 years with serologically proved dengue shock syndrome, open label) compared adding hydrocortisone hemisuccinate to intravenous fluid regimens including crystalloids (normal saline, modified Ringer's lactate solution), plasma, and blood products versus intravenous fluid regimens alone (see comment below). Hydrocortisone hemisuccinate was given intravenously in a single dose of 25 mg/kg on day 1, 15 mg/kg on day 2, and 10 mg/kg on day 3. It was unclear how many children received crystalloids and blood products alone or in combination.[15] It found that adding hydrocortisone significantly reduced mortality compared with intravenous fluids alone (9/48 [19%] with hydrocortisone *v* 22/50 [44%] with intravenous fluids alone; RR 0.43, 95% CI 0.22 to 0.83; see comment below).

Harms: In the first RCT, the frequency of episodes of infection (pneumonia, bacteraemia) and pulmonary haemorrhage were similar with methylprednisolone compared with placebo.[13] Three people taking methylprednisolone had convulsions. All survivors were followed up 2 weeks after treatment and sequelae rates, including haematomas, stiff joints, otitis media, abscesses, and gingivitis were similar between the two groups.[13] The other two RCTs gave no information on adverse effects.[14,15]

Comment: The third RCT is an open trial with unclear randomisation scheme and allocation concealment, which could have overestimated the effect of adding hydrocortisone.[15] Baseline characteristics of the two groups were not comparable with a greater proportion of children aged under 2 years and longer duration of shock in the children who did not receive steroids, which could have contributed to the higher mortality in these children. There is also a slight discrepancy between what is reported in the text of the article (see benefits above) and what is reported in the table about the number of children taking intravenous fluids alone who died; the figure reported in the table is 19/50, which gives a slightly different result (9/48 [19%] with hydrocortisone *v* 19/50 [38%] with intravenous fluids alone; RR 0.49, 95% CI 0.25 to 0.98). The other RCTs[13,14] did not find the mortality reduction found in the earlier RCT.[15] Differences in quality of methods in the RCTs and improvements in supportive care in the 1990s may account for the inconsistent results. A systematic review of corticosteroids in adults and children with dengue shock syndrome is in progress.[16] We found one unpublished systematic review (search date 1992,[17] 3 RCTs [described above],[13–15] 2 uncontrolled studies,[18,19] 334 children with dengue haemorrhagic fever or dengue shock syndrome) that

compared steroids versus placebo (personal communication, Thongpenyai Y, 2003).[17] The review found that trials were heterogeneous, but meta-analysis of the two RCTs (160 children with dengue shock syndrome) with adequate blinding and comparable groups at baseline found no significant difference in mortality between adding steroids to intravenous fluids and adding placebo (12/79 [15%] with steroids *v* 13/81 [16%] with placebo; OR 0.94, 95% CI 0.37 to 2.41). Meta-analysis of all five studies also found no significant difference in mortality between adding steroids to standard intravenous fluids and intravenous fluids alone (AR 27/152 [18%] with steroids *v* 36/160 [22%] with placebo; pooled OR 0.65, 95% CI 0.35 to 1.19).

OPTION ADDING INTRAVENOUS IMMUNOGLOBULIN TO STANDARD INTRAVENOUS FLUIDS

We found no RCTs on the effects of intravenous immunoglobulin in the treatment of dengue haemorrhagic fever or dengue shock syndrome. One unpublished RCT in Filipino children with dengue shock syndrome found that intravenous immunoglobulin reduced mortality compared with placebo.

Benefits: We found no published systematic review of RCTs (see comment below).

Harms: We found no published RCTs.

Comment: One unpublished, double blind RCT, conducted in a tertiary university teaching hospital in the Philippines (216 Filipino children, age 6 months to 14 years, 205 with serologically confirmed dengue shock syndrome) compared intravenous immunoglobulin (0.4 g/kg once daily for 3 days) versus placebo (personal communication, Frias MV, 2003).[20] All children received standard crystalloids as prescribed by World Health Organization guidelines. The RCT found that immunoglobulin significantly reduced mortality compared with placebo (18/108 [17%] with intravenous immunoglobulin *v* 31/108 [29%] with placebo; RR 0.58, 95% CI 0.35 to 0.97; NNT 8, 95% CI 4 to 102). It found similar duration of hospital stay between intravenous immunoglobulin and placebo. More children had rash with intravenous immunoglobulin than with placebo but the difference was not significant (RR 1.6, 95% CI 0.95 to 2.68).

GLOSSARY

Positive tourniquet A test that is performed by inflating the blood pressure cuff to a point midway between systolic and diastolic pressures for 5 minutes. It involves then deflating the cuff, waiting for the skin to return to its normal colour, and then counting the number of petechiae visible in a 2.5 cm square in the ventral surface of the forearm. Twenty or more petechiae in square patch (6.25 cm^2) constitutes a positive tourniquet test.

TABLE 1 **World Health Organization grading of severity of dengue haemorrhagic fever.[1]**

Grade	Description
Grade I	Fever accompanied by non-specific constitutional symptoms; the only haemorrhagic manifestation is a positive tourniquet test, easy bruising, or both
Grade II	Spontaneous bleeding in addition to the manifestations of Grade I, usually in the form of skin and other haemorrhages
Grade III	Circulatory failure manifested by a rapid, weak pulse and narrowing of pulse pressure or hypotension, with the presence of cold, clammy skin, and restlessness
Grade IV	Profound shock with undetectable blood pressure or pulse

Key Messages

- **Amino acid oral rehydration solution (ORS) in severe diarrhoea** One small RCT found that amino acid ORS reduced the total volume and duration of diarrhoea compared with standard ORS.
- **ORS in severe diarrhoea** ORS has not been compared in RCTs versus no treatment or intravenous rehydration. One small RCT found no difference in duration or volume of diarrhoea between intravenous rehydration and rehydration through a nasogastric tube, after both groups had received initial intravenous fluids.
- **Rice based ORS in severe diarrhoea** One systematic review has found that rice based ORS reduces the 24 hour stool volume compared with standard ORS.

Diarrhoea in adults (acute)

- **Bicarbonate ORS in severe diarrhoea** Two RCTs found no significant difference in the duration or volume of diarrhoea with bicarbonate ORS compared with standard ORS. One RCT found no significant difference in total stool output or duration of diarrhoea with bicarbonate ORS compared with an otherwise identical ORS in which the bicarbonate was replaced with chloride.
- **Reduced osmolarity ORS in severe diarrhoea** Three RCTs comparing reduced osmolarity ORS versus standard ORS found a small and inconsistent effect on total volume of stool and duration of diarrhoea.
- **Antibiotics used empirically in community acquired diarrhoea** RCTs have found that ciprofloxacin reduces the duration of community acquired diarrhoea by 1–2 days compared with placebo. RCTs found limited evidence that other antibiotics reduced duration of diarrhoea compared with placebo. Adverse effects varied by agent.
- **Antibiotics used empirically in travellers' diarrhoea** One systematic review and one additional RCT have found that empirical use of antibiotics increases cure rate at 3 and 6 days compared with placebo. Gastrointestinal symptoms (cramps, nausea, and anorexia), dermatological symptoms (rash), and respiratory symptoms (cough and sore throat) were reported with all antibiotics. Antibiotic treatment is associated in some people with prolonged presence of bacterial pathogens in the stool and development of resistant strains.
- **Antimotility agents in acute diarrhoea** RCTs have found that, in people with acute diarrhoea, loperamide hydrochloride and loperamide oxide reduce the time to relief of symptoms, but frequently cause constipation compared with placebo. We found insufficient evidence about the effects of other antimotility agents.

DEFINITION

Diarrhoea is watery or liquid stools, usually with an increase in stool weight above 200 g daily and an increase in daily stool frequency. This chapter covers empirical treatment of suspected infectious diarrhoea in adults.

INCIDENCE/ PREVALENCE

An estimated 4000 million cases of diarrhoea occurred worldwide in 1996, resulting in 2.5 million deaths.[1] In the USA, the estimated incidence for infectious intestinal disease is 0.44 episodes per person a year (1 episode per person every 2.3 years), resulting in about one consultation with a doctor per person every 28 years.[2] A recent community study in the UK reported an incidence of 19 cases per 100 person years, of which 3.3 cases per 100 person years resulted in consultation with a general practitioner.[3] Both estimates derive from population based studies including both adults and children. The epidemiology of travellers' diarrhoea (in people who have crossed a national boundary) is not well understood. Incidence is higher in travellers visiting developing countries, but it varies widely by location and season of travel.[4]

AETIOLOGY/ RISK FACTORS

The cause of diarrhoea depends on geographical location, standards of food hygiene, sanitation, water supply, and season. Commonly identified causes of sporadic diarrhoea in adults in developed countries include *Campylobacter*, *Salmonella*, *Shigella*, *Escherichia coli*, *Yersinia*, protozoa, and viruses. No pathogens are identified in more than half of people with diarrhoea. In returning travellers, about 50% of episodes are caused by bacteria such as enterotoxigenic *E coli*, *Salmonella*, *Shigella*, *Campylobacter*, *Vibrio*, enteroadherent *E coli*, *Yersinia*, and *Aeromonas*.[5]

PROGNOSIS In developing countries, diarrhoea is reported to cause more deaths in children under 5 years of age than any other condition.[1] Few studies have examined which factors predict poor outcome in adults. In developed countries, death from infectious diarrhoea is rare, although serious complications, including severe dehydration and renal failure, can occur and may necessitate admission to hospital. Elderly people and those in long term care have an increased risk of death.[6]

AIMS OF INTERVENTION To reduce the infectious period, length of illness, risk of dehydration, risk of transmission to others, and rates of severe illness; and to prevent complications and death.

OUTCOMES Time from start of treatment to last loose stool; number of loose stools a day; stool volume; time to first formed stool; duration of diarrhoea; duration of excretion of organisms; presence of bacterial resistance; relief of cramps, nausea and vomiting; incidence of vomiting; incidence of severe illness; and rate of hospital admission.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION What are the effects of empirical antibiotic treatment in travellers' diarrhoea?

OPTION EMPIRICAL TREATMENT WITH ANTIBIOTICS IN ADULTS WITH TRAVELLERS' DIARRHOEA

One systematic review and one additional RCT have found that empirical use of antibiotics increases the cure rate of travellers' diarrhoea compared with placebo. Gastrointestinal symptoms (cramps, nausea, and anorexia), dermatological symptoms (rash), and respiratory symptoms (cough and sore throat) were reported with all antibiotics. Antibiotic treatment is associated in some people with prolonged presence of bacterial pathogens in the stool and development of resistant strains.

Benefits: We found one systematic review[7] and one additional RCT.[8] The systematic review (search date 2000, 12 RCTs, 1474 people with travellers' diarrhoea, including students, package tourists, military personnel, and volunteers) compared empirical use of antibiotics versus placebo.[7] Antibiotics evaluated included aztreonam, bicozamycin, ciprofloxacin, co-trimoxazole (trimethoprim–sulfamethoxazole [sulphamethoxazole]), fleroxacin, norfloxacin, ofloxacin, and trimethoprim, which were given for durations varying from a single dose to 5 days. The review found that antibiotics significantly increased the cure rate at 72 hours compared with placebo (defined as cessation of unformed stools or > 1 unformed stool/24 hours without additional symptoms; OR 5.9, 95% CI 4.1 to 8.6). The additional RCT (598 people, 70% of whom had travelled recently) compared norfloxacin versus placebo. It found that norfloxacin significantly increased the number of people cured compared with placebo after 6 days (34/46 [74%] with norfloxacin *v* 18/48 [38%] with placebo; RR 1.97, 95% CI 1.32 to 2.95).[8]

Harms: The systematic review found that adverse effects varied with each antibiotic and ranged in frequency from 2–18%.[7] Gastrointestinal symptoms (cramps, nausea, and anorexia), dermatological symptoms (rash), and respiratory symptoms (cough and sore throat) were most frequently reported. One small RCT included in the review found that significantly more people taking ciprofloxacin developed resistant isolates at 48 hours (ciprofloxacin *v* placebo; ARI 50%, 95% CI 15% to 85%).[7] Another RCT (181 adults with acute diarrhoea) reported three cases of continued excretion of *Shigella* in people taking trimethoprim–sulfamethoxazole versus one person taking placebo.[9] Two of these isolates became resistant to the drug, although the participants were clinically well.[7] Other RCTs found no post-treatment resistance or did not report it.[7] The additional RCT found that people with *Salmonella* infection treated with norfloxacin had significantly prolonged excretion of *Salmonella* species compared with placebo (median time to clearance of *Salmonella* species from stools: 50 days with norfloxacin *v* 23 days with placebo; CI not reported).[8] In addition, 6/9 *Campylobacter* isolates obtained after treatment had developed resistance to norfloxacin.

Comment: Only 3/10 trials using the duration of diarrhoea as an outcome reported adequate statistical data for the duration of diarrhoea after initiation of treatment.[7] This limits the applicability of the results.

QUESTION What are the effects of empirical antibiotic treatment in community acquired diarrhoea?

OPTION EMPIRICAL TREATMENT WITH ANTIBIOTICS IN ADULTS WITH COMMUNITY ACQUIRED DIARRHOEA

RCTs have found that ciprofloxacin reduces the duration of community acquired diarrhoea by 1–2 days compared with placebo. RCTs found limited evidence that other antibiotics reduced duration of diarrhoea compared with placebo. Adverse effects varied by agent.

Benefits: We found no systematic review. We found six RCTs in five reports (1037 people)[10–14] comparing one or more antibiotics with placebo (antibiotics evaluated included ciprofloxacin, clioquinol, co-trimoxazole, enoxacin, nifuroxazide, and ofloxacin). Entry criteria varied among the RCTs, and treatment duration ranged from a single dose to 5 days. Three RCTs found that antibiotics significantly reduced illness duration or decreased the number of liquid stools at 48 hours,[11,13,14] two RCTs found a non-significant reduction in the duration of illness.[10,12] One RCT found reduced duration of diarrhoea for ciprofloxacin but not for trimethoprim–sulfamethoxazole.[11]

Harms: In the multicentre RCT (173 people with acute diarrhoea) of ciprofloxacin and trimethoprim–sulfamethoxazole, five people with *Campylobacter* isolated from stools (2 treated with ciprofloxacin, 3 treated with trimethoprim–sulfamethoxazole) developed isolates resistant to the treatment antibiotic.[13]

Comment: The main pathogenic organisms found in each study varied and may partly explain variations in effect. Reported outcomes varied between trials, which precludes direct comparisons or summaries of treatment effect.

QUESTION What are the effects of oral rehydration in severe diarrhoea?

OPTION ORAL REHYDRATION IN ADULTS WITH SEVERE DIARRHOEA

We found no RCTs of oral rehydration compared with placebo or no treatment. One small RCT comparing intravenous rehydration versus rehydration through a nasogastric tube found no difference in duration or volume of diarrhoea. One RCT found that amino acid oral rehydration solution (ORS) reduced the total volume and duration of diarrhoea compared with standard ORS. Both groups received initial treatment with intravenous fluids. One RCT found no significant difference in total stool output or duration of diarrhoea with bicarbonate ORS compared with chloride ORS. Two RCTs found no significant difference in the duration or volume of diarrhoea with bicarbonate ORS compared with standard ORS. Three RCTs found a small and inconsistent effect on total volume of stool and duration of diarrhoea with reduced osmolarity ORS compared with standard ORS. One systematic review has found that rice based ORS reduces the 24 hour stool volume compared with standard ORS.

Benefits: We found one systematic review and 10 additional RCTs of ORS in severe diarrhoea (see tables A and B on web extra).[15–25] **Versus no rehydration:** We found no systematic review or RCTs. RCTs of oral rehydration versus no rehydration would be considered unethical. **Versus intravenous rehydration:** We found no systematic review and no RCTs comparing intravenous rehydration versus oral rehydration solution alone. We found one small RCT (20 adults with cholera and severe dehydration) comparing enteral rehydration through a nasogastric tube versus intravenous rehydration.[15] Both groups received initial intravenous fluids for up to 90 minutes. The RCT found no significant difference in the total duration of diarrhoea (44 hours with iv fluids *v* 37 hours with nasogastric fluids; difference +7 hours, 95% CI −6 hours to +20 hours), total volume of stool passed (8.2 L *v* 11 L; difference −2.9 L), or duration of *Vibrio* excretion (1.1 days *v* 1.4 days; difference 0.3 days, 95% CI 0 days to 1 day). **Amino acid ORS:** We found no systematic review. We found two RCTs (97 men,[16] 108 men[17]) comparing amino acid ORS versus standard ORS (see glossary, p 977). In the RCT with intravenous rehydration, amino acid ORS was associated with a non-significant reduction in the total duration of diarrhoea and significantly reduced the total volume of stool compared with standard ORS.[16] The other RCT found that amino acid ORS improved weight gain, but not stool volume, compared with standard ORS in patients with cholera. For patients with non-cholera diarrhoea, amino acid ORS was associated with a reduction in stool volume, but not in weight gain.[17] **Bicarbonate ORS:** We found no systematic review. We found one small RCT (60 people with cholera and severe dehydration) comparing bicarbonate ORS versus an otherwise identical ORS, in which the bicarbonate was replaced with chloride.[18] The RCT found no significant difference in total stool output or duration of diarrhoea. We found three RCTs (367 people) comparing standard versus bicarbonate ORS.[19–21] Two of the RCTs found no significant difference between treatments in the duration or volume of diarrhoea.[19,21] One RCT did not report on significance, although duration

and volume of diarrhoea were worse with bicarbonate ORS.[20] **Reduced osmolarity ORS:** We found no systematic review. We found three RCTs, which found a small and inconsistent effect on total volume of stool and duration of diarrhoea with reduced osmolarity ORS versus standard ORS.[22–24] **Rice based ORS:** We found one systematic review (search date 1998, 4 RCTs) in people with cholera and non-cholera diarrhoea.[25] The review found that, in adults with cholera, rice based ORS significantly reduced the 24 hour stool volume compared with standard ORS (4 RCTs, WMD −51 mL/kg, 95% CI −66 mL/kg to −36 mL/kg). One RCT found that both rice based ORS and low sodium rice based ORS reduced stool output compared with standard ORS (4 L for rice based ORS *v* 5 L for standard ORS, $P < 0.02$; 3 L for low sodium rice based ORS *v* 5 L for standard ORS, $P < 0.05$).[24]

Harms: **Amino acid ORS:** One RCT (108 men) reported no episodes of hypernatraemia or hyponatraemia in people taking amino acid ORS or standard ORS.[17] **Bicarbonate ORS:** One RCT (130 people with cholera) reported that more people taking standard ORS had an unpleasant taste than those taking bicarbonate ORS (29% of people *v* 13% of people).[20] In another RCT, 2/115 people taking an effervescent standard ORS had an unpleasant taste (results not reported for bicarbonate ORS).[21] **Reduced osmolarity ORS:** Reduced osmolarity ORS significantly increased the risk of non-symptomatic hyponatraemia (OR 2.1, 95% CI 1.1 to 4.1).[22] In RCTs evaluating symptomatic hyponatraemia, no cases were reported.[22,23]

Comment: All people with cholera received antibiotic treatment in addition to fluid treatment. Oral tetracycline or doxycycline were widely used, and were initiated at varying intervals after the start of oral rehydration. Response to ORS in people with cholera may not be comparable with response in people with less severe forms of diarrhoea.

QUESTION What are the effects of antimotility agents in acute diarrhoea in adults?

OPTION ANTIMOTILITY AGENTS IN ADULTS WITH ACUTE DIARRHOEA

RCTs have found that, in people with acute diarrhoea, loperamide hydrochloride, and loperamide oxide reduce the time to relief of symptoms, but frequently cause constipation compared with placebo. Two RCTs found that lidamidine hydrochloride reduced stool weight and number of loose stools. We found insufficient evidence about the effects of other antimotility agents.

Benefits: We found no systematic review. **Difenoxin:** We found no RCTs of sufficient quality. **Diphenoxylate:** One RCT (152 adults with acute diarrhoea for < 24 hours) comparing diphenoxylate–atropine versus placebo found that diphenoxylate significantly reduced the rate of bowel actions in the 24 hours after treatment ($P = 0.05$).[26] The RCT found no significant difference in median time to last loose stool (25 hours *v* 30 hours; $P = 0.29$). **Lidamidine:** We found two RCTs comparing lidamidine versus placebo.[27,28] The first RCT (30 adults with acute diarrhoea) found that lidamidine reduced the stool weight after 29 hours (435 g with lidamidine 4 mg *v* 364 g with

lidamidine 2 mg *v* 576 g with placebo).[27] The second RCT (105 adults with acute diarrhoea) compared lidamidine versus loperamide versus placebo.[28] It found that lidamidine reduced the number of loose stools after 72 hours compared with placebo (8.5 stools *v* 3.9 stools; P values not reported). **Loperamide hydrochloride:** We found four RCTs comparing loperamide hydrochloride (loading dose of 4 mg, then 2 mg with each loose stool) versus placebo.[28–31] Two of the RCTs (409 people[29] and 261 people[30] with acute diarrhoea) found that loperamide significantly reduced the median time to complete relief of symptoms, which was defined as the time between taking the loading dose of loperamide and the time after which one pasty, watery, or loose stool was passed (189 people: 27 hours with loperamide *v* 45 hours with placebo, P = 0.006;[29] 123 people: 18 hours with loperamide *v* 37 hours with placebo, P = 0.007[30]). The third RCT (50 people) found that loperamide versus placebo significantly reduced the number of stools for the first 2 days, but subsequently the difference was not significant.[31] The fourth RCT (105 adults with acute diarrhoea) found no significant difference in the number of stools passed within 72 hours.[28] **Loperamide oxide:** We found five RCTs (409 people,[29] 261 people,[30] 230 people,[32] 242 people,[33] 258 people[34] with acute diarrhoea) comparing loperamide oxide (loading dose 1–8 mg, followed by 0.5–4 mg with each loose stool) versus placebo. All RCTs found that loperamide oxide significantly reduced the time to complete relief of symptoms.

Harms: **Lidamidine:** Constipation occurred in one person taking lidamidine compared with no people taking placebo (1/35 [3%] with lidamidine *v* 0/35 [0%] with placebo).[28] **Loperamide hydrochloride:** Two RCTs (409 people[29] and 261 people[30]) found that constipation was significantly more frequent in people taking loperamide versus placebo (25% with loperamide *v* 7% with placebo; ARI 18%, 95% CI 8% to 28%; NNH 5, 95% CI 3 to 12;[29] 22% *v* 10%; ARI 12%, 95% CI 5% to 29%; NNH 5, 95% CI 3 to 18[30]). **Loperamide oxide:** One RCT (409 people) found that significantly more people taking loperamide oxide had constipation (24% with loperamide oxide *v* 7% with placebo; ARI 17%, 95% CI 7% to 27%; NNH 5, 95% CI 3 to 14).[29] Another RCT (230 people) found that symptom scores for tiredness and sleepiness were significantly higher in people taking loperamide oxide 1 mg compared with placebo (P = 0.01).[32]

Comment: The RCTs used different outcome measures, making it difficult to summarise and compare results.

GLOSSARY

Standard ORS An oral rehydration solution that includes citrate 10 mmol/L and glucose 111 mmol/L, and has an osmolarity of 311 mmol/L.

Key Messages

In countries with high endemicity

- **Selective immunisation of high risk individuals (evidence only for children born to HBsAg positive mothers)** One non-systematic review of mainly observational studies with both plasma derived and recombinant vaccine, and three RCTs of plasma derived hepatitis B immunisation all found that immunisation prevented chronic carrier state compared with placebo or no treatment in children born to HBsAg positive mothers. One RCT found minor adverse events with immunisation; the other RCTs did not report on adverse events. We found no good evidence in other high risk groups. One cluster RCT found that selective immunisation in high risk individuals was less effective than universal immunisation of infants in preventing chronic carrier state and acute hepatitis events.
- **Universal immunisation of infants (limited evidence that it may be better than selective immunisation of high risk individuals)** One non-systematic review and four additional and subsequent RCTs provided evidence that universal (both recombinant and plasma derived) hepatitis B immunisation in infants in countries with high endemicity, compared with placebo, reduces

acute hepatitis and development of a chronic carrier state for at least 15 years. Observational studies and one RCT found only minor adverse reactions after recombinant hepatitis B immunisation. One cluster RCT found universal immunisation with first plasma and then recombinant vaccine reduced the development of chronic carrier state and acute hepatitis events compared with immunisation of high risk groups.

In countries with low endemicity

- **Selective immunisation of high risk individuals** One systematic review found that, in countries with low endemicity, plasma derived hepatitis B immunisation prevented acute hepatitis B and development of chronic carrier state in healthcare workers at high risk of exposure to bodily fluids. Three RCTs found that plasma derived hepatitis B immunisation prevented acute hepatitis B in homosexual men. One small RCT found no significant difference in hepatitis B events in heterosexual partners of infected people. Three RCTs of plasma derived immunisation in people on regular haemodialysis found potentially conflicting results. Two RCTs from France and Belgium found good protective efficacy against chronic carrier state. However, one large US based RCT found no good evidence of benefit. The systematic review of plasma derived vaccination found no significant difference between immunisation and placebo in the rate and severity of adverse events. One observational study showed a high prevalence of hepatitis B carrier state and low immunisation uptake in young homosexuals despite a national strategy to immunise high risk groups. Surveillance data from a national programme in Japan found that immunisation of neonates (with recombinant hepatitis B vaccine plus hepatitis B immunoglobulin [HBIG]) born to HBsAg positive mothers provided 95% protection against the development of a chronic carrier state. We found insufficient evidence to compare the effectiveness of selective immunisation in high risk individuals with other strategies.
- **Universal immunisation of infants** One historical cohort study found a reduction in the prevalence of hepatitis B chronic carrier state after universal immunisation. We found insufficient evidence to compare its effectiveness with other strategies. Two cohort studies and surveillance data did not report any links between hepatitis B immunisation and serious adverse events.
- **Comparative effectiveness of different strategies** We found no systematic reviews, RCTs, or observational studies comparing the effectiveness of different immunisation strategies in countries with low endemicity.
- **Universal immunisation of adolescents** We found insufficient evidence to assess the effects of universal adolescent immunisation, or to compare its effectiveness with other strategies. One observational study suggests minor adverse effects after hepatitis B immunisation in this group.

DEFINITION Hepatitis B is a viral infectious disease with an incubation period of 40–160 days. Acute hepatitis B infection is characterised by anorexia, vague abdominal discomfort, nausea and vomiting, jaundice, and occasional fever. Illness is associated with deranged liver function tests (especially raised alanine transaminases) and presence of serological markers of acute hepatitis B infection (e.g. hepatitis B surface antigen [HBsAg; see glossary, p 992], antiHBc IgM).[1]

INCIDENCE/ PREVALENCE The incidence of acute hepatitis B and prevalence of its chronic carrier state (see glossary, p 992) varies widely across the globe. In areas with high endemicity (see glossary, p 992) (HBsAg prevalence

≥ 8%, e.g. South East Asia and Africa), more than half of the population becomes infected at some point in their lives.[2] In countries with low endemicity (see glossary, p 992) (HBsAg prevalence < 2%, e.g. North America, western Europe, Australia), most of the population do not become infected.[2] Nearly a third of the world population has been infected by hepatitis B at some point, and at least 350 million people (5–6% of world population) are currently chronic carriers of hepatitis B infection.[3]

AETIOLOGY/ RISK FACTORS

In countries with high endemicity, most infections occur during childhood from an infected mother to her baby (vertical transmission) or from one family member to another (horizontal transmission).[4] Horizontal transmission is thought to be an important route of hepatitis B infection during early childhood, and probably occurs mainly through unnoticed contact with blood from infected family members.[5] In countries with high endemicity, the proportion of chronic HBsAg carriage attributable to vertical transmission has been estimated at 5–50%.[6–8] The proportion of chronic HBsAg carriage attributable to horizontal transmission is not known, although one survey in China found that 27.2% of families had one or more HBsAg positive members.[8] In developed countries, most hepatitis B infection occurs later, from sexual activity, injection drug use, or occupational exposure. Less frequent causes of infection include household contact, regular haemodialysis, transmission from a healthcare professional, and receipt of organs or blood products.[9] The vaccination policy of a country is a large determinant of the risk of developing hepatitis B. Since the development of plasma derived hepatitis B vaccine in the early 1980s, subsequently replaced by recombinant vaccine (see glossary, p 992), many countries have adopted a policy of universal immunisation of all infants. On the basis of disease burden, the World Health Organization recommended that hepatitis B vaccine be incorporated into routine infant and childhood immunisation programmes in countries with high endemicity by 1995 and in all countries by 1997.[10] However, in many countries with low endemicity, universal immunisation policy remains controversial and has still not been adopted.[11] Some of these countries have adopted a policy of selective immunisation of high risk individuals. Others have adopted a universal adolescent immunisation policy.

PROGNOSIS

Hepatitis B infection resolves after the acute infection in 90–95% of cases. In the remainder (5–10%), it may result in several serious sequelae. Massive hepatic necrosis occurs in 1% of people with acute viral hepatitis, leading to a serious and often fatal condition called acute fulminant hepatitis. Between 2% and 10% of those infected as adults become chronic carriers, indicated by HBsAg persistence for more than 6 months. Chronic carriage is more frequent in those infected as children, and reaches up to 90% in those infected during the perinatal period.[1] Between 20% and 25% of chronic carriers develop a progressive chronic liver disease. In about one quarter to one third of cases, this progresses to cirrhosis and hepatocellular carcinoma.[12] These complications usually arise in older adults and are major causes of mortality in populations with

high hepatitis B endemicity.[4] Observational studies suggest that in these countries almost 80% of chronic liver disease and cirrhosis is attributed to hepatitis B, and these complications lead to at least 1 million deaths every year worldwide.

AIMS OF INTERVENTION To reduce the risk of acquiring hepatitis B infection in susceptible people, while minimising adverse effects of interventions.

OUTCOMES Incidence of acute hepatitis B; prevalence of chronic carrier state; chronic liver disease; cirrhosis and hepatocellular carcinoma secondary to hepatitis B; mortality secondary to hepatitis B infection and its chronic sequelae; adverse events.

METHODS *Clinical Evidence* search and appraisal October 2003, including a search for observational studies. Where there were no good RCT data for a given comparison or outcome, we included the best available observational data. Both plasma derived and recombinant vaccines were included.

QUESTION What are the effects of immunisation in countries with high endemicity?

OPTION UNIVERSAL IMMUNISATION OF INFANTS

One non-systematic review and four additional and subsequent RCTs found that universal immunisation of infants (using either recombinant or plasma derived vaccines) reduces acute hepatitis and development of a chronic carrier state compared with placebo. The longest RCT found that universal immunisation protected at 15 years. Two historical cohort studies found reduced secondary mortality from hepatocellular carcinoma in children born after the introduction of a universal plasma derived hepatitis immunisation programme. One additional historical cohort study found a lower rate of related chronic liver disease, cirrhosis, and hepatocellular cancer after the introduction of a universal plasma derived immunisation programme. Three non-systematic reviews and one RCT found only minor adverse reactions after recombinant hepatitis B immunisation. One cluster RCT found universal immunisation with first plasma and then recombinant vaccine reduced the development of chronic carrier state and acute hepatitis events compared with immunisation of high risk groups.

Benefits: **Versus placebo or no immunisation:** We found one non-systematic review (search date 1989, 2 RCTs, 203 infants, aged less than 1 year),[13] three subsequent RCTs,[14–17] one additional RCT,[18] and three additional historical cohort studies,[19–21] comparing hepatitis B vaccine versus placebo or no vaccine. The review found that recombinant hepatitis B vaccine protected against development of the chronic carrier state (see glossary, p 992) at both 9 months after immunisation (protective efficacy [see glossary, p 992] 87%; 15/148 [10.1%] HBsAg [see glossary, p 992] positive in the intervention group) and 15 months (protective efficacy 96%; 2/55 [3.6%] HBsAg positive in the intervention group).[13] Confidence limits and numbers of people in control group not reported. The first subsequent RCT, conducted in the Gambia (1864 infants), compared four doses of hepatitis B vaccine (recombinant or plasma

derived) given along with the World Health Organization's recommended Expanded Program Immunisation (see glossary, p 992) versus Expanded Program Immunisation only.[14,15] It found that hepatitis B vaccine plus Expanded Program Immunisation significantly protected against development of the chronic carrier state at 4 years after immunisation (protective efficacy 94%, 95% CI 84% to 98%; 4/720 [0.6%] HBsAg positive with intervention *v* 103/816 [13%] with placebo). It found the results were still significant after 9 years (protective efficacy 90%, 95% CI 79% to 95%; 4/677 [0.5%] HBsAg positive with intervention *v* 99/823 [12%] with placebo). The second subsequent RCT, conducted in China (649 children aged 3–36 months, with no serological markers for previous infection), compared three doses of plasma derived hepatitis B vaccine versus placebo.[16] It found that hepatitis B vaccine significantly protected children against development of the chronic carrier state at 5, 12, and 15 years after immunisation (5 year protective efficacy 100.0%, 0/152 [0%] HBsAg positive with immunisation *v* 24/190 [12.6%] with placebo, $P < 0.001$; 12 year protective efficacy 82.2%, 3/171 [1.8%] HBsAg positive with immunisation *v* 18/179 [10.1%] with placebo, $P < 0.01$; 15 year protective efficacy 88.0%, 1/52 [1.9%] HBsAg positive with immunisation *v* 9/154 [16.7%] with placebo, $P < 0.01$; CI not reported). The third subsequent RCT, also in China (513 children aged 3–36 months, with no serological markers for previous infection), compared three doses of plasma derived hepatitis B vaccine versus placebo.[17] It found that hepatitis B vaccine significantly protected children against development of the chronic carrier state at 12 years after immunisation (protective efficacy 92%; 1/167 [0.6%] HBsAg positive with immunisation *v* 14/183 [7.6%] with placebo; $P < 0.0001$, CI not reported). One additional RCT from Burundi (480 infants) compared the protective efficacy of a plasma derived hepatitis vaccine (see glossary, p 992) versus placebo 1 year after immunisation.[18] It found that the vaccine significantly protected children from both acute hepatitis B events (see glossary, p 992) (efficacy 100%; event rates 0/59 [0%] with immunisation *v* 5/59 [8.5%] with placebo; $P = 0.046$) and development of chronic carrier state (efficacy 100%; carrier rates 0/59 [0%] with hepatitis B vaccine *v* 4/59 [6.8%] with placebo; statistics not reported). One additional historical cohort study in Taiwan estimated the incidence of hepatocellular carcinoma in three historical cohorts (children born during 1981–1986 [17 million], children born during 1987–1990 [14 million], and children born during 1991–1994 [14 million]) 5–13 years after immunisation with a plasma vaccine.[19] The average annual incidence of hepatocellular carcinoma was significantly reduced in children born after the introduction of universal immunisation in 1984 (0.70 per 100 000 [95% CI 0.65 per 100 000 to 0.78 per 100 000] in the 1981–1986 cohort, 0.57 per 100 000 [95% CI 0.48 per 100 000 to 0.62 per 100 000] in the 1987–1990 cohort, and 0.36 per 100 000 [95% CI 0.23 per 100 000 to 0.48 per 100 000] in the 1991–1994 cohort; $P < 0.01$ for comparison between before and after the 1990 cohorts). Mortality secondary to hepatocellular carcinoma was also reduced in the 1991–1994 cohort compared with the two other cohorts combined (incidence of hepatocellular deaths before July

1990 0.72 per 1000 000 and after July 1990 0.33 per 1000 000; RR 0.51; P < 0.001; see comment below). The second additional historical cohort study (children aged 1–9 years) in Taiwan also found a lower hepatocellular carcinoma standardised mortality ratio after the vaccination programme with a plasma derived vaccine (1.25 [95% CI 0.70 to 2.25] in 1983 *v* 0.34 [95% CI 0.14 to 0.89] in 1993, comparative statistical results not reported).[20] This contrasted with no change in the adult standardised mortality ratio secondary to hepatocellular carcinoma during this period. The third additional historical cohort study (children, adolescents, and young people) assessed the impact of universal immunisation (initially with plasma and then with recombinant vaccine [see glossary, p 992]) on related chronic liver disease, cirrhosis, and hepatocellular carcinoma in a town in southern Italy.[21] It found a decline in the prevalence of chronic carrier state 15 years after starting the immunisation programme (prevalence of HBsAg 8.3% during 1978–1983 *v* 1.0% in 1997, P < 0.001). It also reported a reduction in the prevalence of related chronic liver disease, cirrhosis, and hepatocellular carcinoma, but no numerical data were provided. **Versus selective immunisation in high risk individuals:** We found one cluster RCT in Italy (2 towns with a population of about 60 000 each), which compared a universal immunisation strategy (see glossary, p 992) (all infants and adolescents) versus immunisation of high risk groups only (people living with chronic carriers, homosexual men, intravenous drug abusers, infants born to infected mothers, healthcare workers, commercial sex workers, people receiving transfusion and other blood products, people exposed to needle stick injuries, and people with chronic eczema and psoriasis).[22] It used plasma derived vaccine until 1987 and then recombinant vaccine. It found universal immunisation was associated with a bigger reduction in the incidence of hepatitis B (with universal immunisation, mean annual incidence of hepatitis B 63/100 000 during 1963–1990 and 3/100 000 during 1991–1993; with high risk group immunisation, mean annual incidence of hepatitis B 55/100 000 during 1963–1990 and 15/100 000 in 1991–1993). It also found universal immunisation was associated with lower prevalence of HBsAg positivity (13.4% in 1978 to 3.0% in 1993 with universal immunisation *v* 13.6% in 1978 to 7.4% with selective immunisation; statistical significance not reported).

Harms:

Versus placebo or no treatment: The non-systematic review found that 10% of children (13 trials, 2096 enrolled) and 4% of neonates (11 trials, 1187 enrolled) had adverse reactions after hepatitis B recombinant immunisation. Sore arm (8.5%) in children and mild fever (2.5%) in neonates were the two most commonly reported symptoms.[13] It found no serious adverse reactions. We found two other non-systematic reviews that assessed connective tissue disorders (see glossary, p 992) and recombinant vaccine vaccine.[23,24] The first review found two uncontrolled population based studies.[23] The first study (166 757 children in New Zealand) of plasma derived vaccine found that arthritis or arthralgia occurred in less than 1 episode in 10 000 vaccines. The second study of plasma derived vaccine (43 618 people in Alaska) found that arthritis or arthralgia lasting more than 3 days occurred in less than

1 episode in 3000 vaccines. It found weak evidence (case reports and case series) of a link between hepatitis B vaccine and serious connective tissue disorders. The second non-systematic review (search date 2000, number of studies not reported) found no evidence (from case series and case reports) of a causal link between systematic lupus erythrematosis and recombinant vaccine.[24] One RCT in Egypt (590 infants) compared the addition of three doses of hepatitis B vaccine (recombinant) plus routine immunisation starting at birth (group A) versus immunisation at 2 months (group B) versus routine immunisation only (group C).[25] It found infants who started hepatitis B immunisation at 2 months had a significantly higher proportion of minor adverse reaction compared with children immunised at birth or with routine immunisation alone (group A 5/178 [2.8%] had local reaction and 10/178 [5.6%] had fever *v* group B 12/167 [7.2%] had local reaction and 12/167 [7.2%] had fever *v* group C 3/191 [1.6%] had local reaction and 4/191 [2.1%] had fever; $P < 0.05$ for group B *v* A and C) after the first dose. It found no serious adverse reactions in any group. One RCT found that infants immunised from birth onwards suffered less frequent adverse reactions than infants who received their first dose at the age of 2 months.[25] The RCT used strict inclusion criteria excluding underweight children and those with other disorders. The trial claimed to have lost only 10% of participants at follow up, with none because of adverse effects, but did not say how this was assessed. None of the reviews, RCTs, or cohort studies in the benefits section reported on harms.[14–21] **Versus selective immunisation of high risk individuals:** The RCT did not report any adverse effects with either intervention.[22]

Comment: **Versus placebo or no treatment:** All RCTs mentioned in the benefits section had above high loss to follow up.[13–21] This proportion was particularly high in one 15 year long study (83%) in China.[16] However, sensitivity analysis in the RCT conducted in the Gambia found immunisation reduced incidence of chronic carrier state after 9 years even after taking the 31% loss to follow up into account.[15] The study in Italy had possible misclassification bias as final diagnosis of hepatitis events were made only clinically by general practitioners and not validated.[21] **Versus selective immunisation of high risk individuals:** The cluster RCT in the two towns in southern Italy was possibly exposed to cross contamination and the effects of migration.[22] Despite these possible limitations, the difference between the declines in the incidences of hepatitis was overwhelmingly supportive toward universal immunisation strategy.

OPTION SELECTIVE IMMUNISATION OF HIGH RISK INDIVIDUALS

One non-systematic review of mainly observational studies with both plasma derived and recombinant vaccine, and three RCTs of plasma derived hepatitis B immunisation all found that immunisation prevented chronic carrier state compared with placebo or no treatment in children born to HBsAg positive mothers. One RCT found minor adverse events with immunisation; the other RCTs did not report on adverse events. We

found no good evidence in other high risk groups. One cluster RCT found that selective immunisation in high risk individuals was less effective than universal immunisation of infants in preventing chronic carrier state and acute hepatitis events.

Benefits: **Versus placebo or no treatment:** We found one non-systematic review[26] and two additional RCTs.[27–29] The review (24 studies in infants; mainly individual, clinical, and epidemiological surveillance studies) assessed the protective efficacy (see glossary, p 992) of both plasma derived and recombination vaccine in neonates born to mothers infected with hepatitis B.[26] The review did not do a meta-analysis owing to differences in study design. However, it found consistently high protective efficacy for both types of vaccines compared with placebo or historical controls in several studies. The first additional RCT, conducted in Taiwan, compared plasma derived vaccine with or without hepatitis B immunoglobulin (HBIG) versus no immunisation (group A vaccine alone, group B vaccine plus one dose of HBIG, group C vaccine plus two doses of HBIG, and group D no vaccine).[27] Infants receiving immunisation were more protected against HBsAg (see glossary, p 992) compared with non-immunised children at 6 months (HBsAg positives in group A 9/38 [23.7%], efficacy 73.7%; $P < 0.05$; group B 4/36 [11.1%], efficacy 87.7%; reported as non-significant, but P value not reported; group C 2/38 [5.3%], efficacy 94.1%; $P < 0.05$, and group D 26/29 [90%]). It also found that adding HBIG significantly increased protection compared with vaccine only.[27] The second additional RCT, in China (208 children born to HBsAg positive mothers), compared two different brands of plasma derived vaccine with or without HBIG versus placebo in preventing the development of chronic carrier state (see glossary, p 992) (group A placebo, group B vaccine produced by an international company, group C vaccine produced locally, and group D local vaccine plus HBIG).[28,29] It found that children receiving international vaccine brand were significantly less likely to develop the chronic carrier state than children who received placebo or the local brand after 6 months (prevalence of HBsAg: group A 24/55 [47%], group B 3/55 [5.4%], group C 12/56 [21%], and group D 2/27 [7%]; protective efficacy 87% [$P < 0.001$] in group B, 51% [$P < 0.03$] in group C, and 83% [$P < 0.003$] in group D), and at 5 years (prevalence of HBsAg: group A 19/31 [66%], group B 2/19 [11%]; protective efficacy 72%, group C 4/20 [22%] protective efficacy 38%; and group D 2/11 [12%]; P values not reported). It found similar protective efficacy in group B (international brand) and D (addition of HBIG to the local vaccine) in preventing hepatitis B carrier state (CI or P values not reported). **Versus universal immunisation of infants:** See benefits of universal immunisation of infants, p 982.[28,29]

Harms: **Versus placebo or no treatment:** In China, one RCT reported minor adverse reactions (5%, mainly irritability and rash) after immunisation of infants born to HBsAg positive mothers.[30] No further comparison with the control group was made. The other RCTs did not report on adverse events.[27–30] **Versus universal immunisation of infants:** See harms of universal immunisation of infants, p 984.

Comment: **Versus placebo or no treatment:** Two RCTs were conducted in China. Only 55% of women eligible for the trial agreed to take part in one RCT, which might make the results not representative of the population.[30] The other RCT, which lasted for 10 years, lost 56% of participants during follow up at 9 years.[28,29] Although groups were similar at baseline, this leads to attrition bias. One RCT in China (220 children born to HBsAg positive mothers) compared plasma derived vaccine against recombinant vaccine (see glossary, p 992) (group A plasma derived vaccine only, group B plasma derived vaccine plus HBIG, group C recombinant vaccine 20 μg, and group D recombinant vaccine 10 μg) in preventing the development of chronic carrier state.[30] It found that recombinant vaccine in either dose with or without HBIG provided more protection (group A protective efficacy 51%, prevalence of HBsAg 12/49 [24.5%]; group B protective efficacy 82.6%, prevalence of HBsAg 4/46 [8.7%]; group C protective efficacy 92%, prevalence of HBsAg 2/50 [4%]; and group D protective efficacy 87%, prevalence of HBsAg 3/49 [6.1%]; no P values reported) against plasma derived vaccine after 12 months. **Versus universal immunisation of infants:** See comment of universal immunisation of infants, p 985.

QUESTION What are the effects of immunisation in countries with low endemicity?

OPTION SELECTIVE IMMUNISATION OF HIGH RISK INDIVIDUALS

One systematic review found that, in countries with low endemicity, plasma derived hepatitis B immunisation prevented acute hepatitis B and development of chronic carrier state in healthcare workers at high risk of exposure to bodily fluids. Three RCTs found that plasma derived hepatitis B immunisation prevented acute hepatitis B in homosexual men. One small RCT found no significant difference in hepatitis B events in heterosexual partners of infected people. Three RCTs of plasma derived immunisation in people on regular haemodialysis found potentially conflicting results. Two RCTs from France and Belgium found good protective efficacy against chronic carrier state. However, one large US based RCT found no good evidence of benefit. The systematic review of plasma derived vaccination found no significant difference between immunisation and placebo in the rate and severity of adverse events. One observational study showed a high prevalence of hepatitis B carrier state and low immunisation uptake in young homosexuals despite a national strategy to immunise high risk groups. Surveillance data from a national programme in Japan found that immunisation of neonates (with recombinant hepatitis B vaccine plus hepatitis B immunoglobulin) born to HBsAg positive mothers provided 95% protection against the development of a chronic carrier state. We found insufficient evidence to compare the effectiveness of selective immunisation in high risk individuals with other strategies in countries with low endemicity.

Benefits: **Versus placebo or no immunisation:** We found one systematic review (search date not reported, 4 RCTs, 2701 people) of plasma derived vaccines in healthcare workers.[31] It found that vaccination significantly reduced hepatitis B compared with placebo (OR 0.33, 95% CI 0.21 to 0.53; NNT estimated between 7–145 depending on

the baseline incidence of hepatitis B). Mean length of follow up was 14.5 months. We found three RCTs in homosexual men.[32–34] The first RCT (800 homosexual men in the Netherlands) compared immunisation with plasma derived vaccine versus placebo for 21.5 months.[32] It found that immunisation significantly reduced the incidence of acute hepatitis infections compared with placebo (17/397 [4.3%] with immunisation *v* 56/403 [13.9%] with placebo; RR 0.31, 95% CI 0.18 to 0.52; NNT 11, 95% CI 8 to 18) among homosexual men. The second RCT (1083 homosexual men in the USA) compared hepatitis immunisation with plasma derived vaccine versus placebo.[33] It found that vaccine significantly protected against acute hepatitis B (acute hepatitis B: 13/448 [2.7%] with immunisation *v* 77/431 [21%] with placebo; $P < 0.0001$) and chronic carrier state (see glossary, p 992) at the end of 2 years (protective efficacy [see glossary, p 992] 87%; $P < 0.0001$; HBsAg [see glossary, p 992] positive 12/448 [2.7%] with immunisation *v* 90/448 [23.5%] with placebo; OR 71.6; CI and P value not reported). The third RCT (1402 homosexual men in the USA) compared hepatitis B immunisation with plasma derived vaccine versus placebo.[34] It found that immunisation significantly reduced the risk of hepatitis B events compared with placebo 2 years after immunisation (hepatitis events: 58/482 [9%] with immunisation *v* 110/443 [21%] with placebo; $P < 0.001$). We found one RCT (160 partners of infected people) that assessed the post-exposure prophylactic efficacy of hepatitis B immunisation versus placebo among regular heterosexual partners of infected people.[35] It found no significant difference in the incidence of acute hepatitis events at 9 months (12/75 [16%] with immunisation and 13/71 [18.3%] with placebo; $P > 0.5$). We found three RCTs comparing hepatitis B immunisation versus placebo in people on haemodialysis.[36–38] The first RCT (138 people in France) found that immunisation with plasma derived vaccine significantly reduced events 12 months after immunisation (15/72 [21%] with immunisation *v* 29/66 [45%] with placebo; $P < 0.02$).[36] The second RCT (401 people in Belgium) of plasma derived vaccine found a large and significant reduction in the hepatitis B attack rates with immunisation in the 435 days assessment (7/197 [4%] with immunisation *v* 30/191 [18%] with placebo; protective efficacy 78%; $P = 0.00016$).[37] However, one large RCT (1311 people in the USA) of plasma derived vaccine did not find any significant difference in the incidence of acute hepatitis B events (see glossary, p 992) between immunisation and placebo 2 years after immunisation (42/660 [6.4%] with immunisation *v* 35/651 [5.4%] with placebo; $P > 0.05$).[38] In Japan, where hepatitis B prevalence is about 1.4% and occurs mainly because of vertical transmission from infected mother to their neonates, a national immunisation programme (recombinant hepatitis B immunisation plus hepatitis B immunoglobulin) for neonates born to HBsAg positive mothers was introduced in 1986. Most expectant mothers (95.1%) were tested and this strategy protected most of the neonates born to infected mothers between 1986 and 1994 from developing a chronic carrier state (980/1030 [95.1%] of neonates born to infected mothers did not develop carrier state).[39] **Versus universal immunisation:** We found no systematic review, RCTs, or observational studies.

Harms: The systematic review of plasma derived hepatitis B immunisation in healthcare workers did not find any significant difference in incidence of adverse events (OR 1.13, 95% CI 0.95 to 1.35), severity of systemic adverse events (OR 1.60, 95% CI 0.64 to 4.04), or severity of local adverse events (OR 1.09, 95% CI 0.90 to 1.33) between vaccination and placebo.[31] The first RCT in homosexual men of plasma derived vaccine found no significant difference between the two groups (incidence of adverse events: 24.3% in the intervention group *v* 21.4% in the control group; difference not statistically significant; P value not reported).[33] The other two RCTs of plasma derived vaccine found a higher incidence of mild adverse reactions with immunisation compared with placebo.[32,34] One RCT found increased incidence of sore arm and dizziness after immunisation (sore arm: 8.9% with immunisation *v* 5.9% with placebo; dizziness: 2.6% with immunisation *v* 0.6% with placebo; $P < 0.001$) and the other RCT found a significant increase in sore arm (sore arm after first dose: 64% with immunisation *v* 45% with placebo; $P < 0.001$). One RCT in people receiving haemodialysis found a significantly higher incidence of adverse reactions with plasma derived vaccine immunisation compared with placebo (42% with immunisation *v* 22% with placebo; $P < 0.005$).[37] The other two RCTs in people receiving haemodialysis found no significant difference (3% with immunisation *v* 9% with placebo in the French RCT[36] and 13% with immunisation *v* 14% with placebo in the US RCT[38]). None of these RCTs found any serious adverse reactions. A retrospective study of post-marketing surveillance data in adults in the USA found that, compared with other vaccines, recombinant hepatitis B vaccine significantly increased risk of neuropathy (0.39 per million with recombinant hepatitis B vaccine *v* 0.12 per million with other vaccines; RR 3.3, 95% CI 1.4 to 8.0; $P < 0.01$), arthritis (0.88 per million with recombinant hepatitis B vaccine *v* 0.06 per million with other vaccines; RR 15, 95% CI 7 to 36; $P < 0.001$), multiple sclerosis (0.39 per million with recombinant hepatitis B vaccine *v* 0.01 per million with other vaccines; RR 19, 95% CI 7 to 442; $P < 0.001$), and other chronic adverse reactions.[40] However, such reactions are rare, and results should be interpreted with caution because of the retrospective nature of the study.

Comment: Both RCTs from the USA in homosexual men had high loss to follow up (19%[33] and 25%[34]) during 2 years, raising the possibility of bias. The RCT from the Netherlands lost 4.0–4.8% of participants during follow up.[32] All three RCTs had comparable groups in both intervention and control arms. However, one cross sectional study from the USA suggests poor uptake and high prevalence of chronic carrier state in this group despite a national high risk immunisation programme (see glossary, p 992).[41] This may be an underestimate of the actual problem, as only 62% were approached out of all eligible men, and only 62% of these agreed to take part in the study. One RCT found no advantage in providing post-exposure immunisation to the regular partners of people infected with hepatitis B identified during their hospital admission for recent jaundice.[35] The RCT was able to recruit only 75% of the eligible partners, which might make the results unrepresentative. One cohort study found that hepatitis B vaccine provides protection against the development of chronic carrier state in residents of mentally handicap

institutions up to 11 years. However, nearly 51% of participants did not complete follow up in this study. The US based RCT in people on haemodialysis lost 35% of participants during follow up as opposed to 15% in the French RCT, and less than 1% in the Belgian RCT. The US trial also had a low event rate in both placebo and intervention arms compared with the other two trials. This may be the reason for not detecting any significant difference between the two groups.

OPTION UNIVERSAL IMMUNISATION OF INFANTS

One historical cohort study found a reduction in the prevalence of hepatitis B chronic carrier state after universal immunisation in countries with low endemicity. We found insufficient evidence to compare its effectiveness with other strategies. Two cohort studies and surveillance data did not report any links between hepatitis B immunisation and serious adverse reactions.

Benefits: **Versus placebo or no immunisation:** We found no RCTs assessing the efficacy of universal immunisation in countries with low endemicity (see glossary, p 992) of hepatitis B. One historical cohort study in Alaska (7 villages, 533 children aged ≤ 10 years) found a marked decline in the prevalence of chronic carrier state (see glossary, p 992) after the adoption of universal immunisation strategy (prevalence of HBsAg [see glossary, p 992] 3.1% during 1982–1987 and 0% during 1993–1994, statistical significance not reported).[42] **Versus other immunisation strategies:** We found no systematic review, RCTs, or observational studies.

Harms: One retrospective cohort study in the USA (6515 children age < 6 years) of recombinant vaccine (see glossary, p 992) compared the incidence of adverse reactions in vaccinated versus unvaccinated children.[43] It found that children who received hepatitis B immunisation had higher rates of arthritis, acute ear infection, and pharyngitis compared with unvaccinated children (arthritis OR 5.91, 95% CI 1.05 to 33.14; acute ear infection OR 1.60, 95% CI 1.00 to 2.58; and pharyngitis OR 1.41, 95% CI 0.95 to 2.09). The results were adjusted for demographic differences, but absolute risk and exact number of events were not given. A second cohort study (conducted in the USA, 5655 children) of recombinant vaccine found no significant difference in the adverse events reported to health services in the first 21 days after birth between vaccinated and unvaccinated children (27/3302 [0.8%] with vaccinated *v* 26/2353 [1.1%] with unvaccinated, P = 0.28).[44] Fever, allergic reactions, seizures, or other neurological events were among the most common events in both groups. Post-marketing surveillance data of recombinant vaccine in USA during 1991–1995 found no unexpected adverse events in children given recombinant hepatitis B vaccine with or without other routine immunisation (no statistical analysis done).[45] It reported 18 neonatal deaths during 1991–1998 after hepatitis B immunisations,[46] but no causal link was established between these deaths and immunisation. Surveillance data from Italy (1991–2000) of recombinant vaccine

reported 19 serious post-immunisation adverse events, none of which was linked to multiple sclerosis or any other serious neurological disease.[47] Surveillance data from the USA did not suggest any link between hepatitis B immunisation and neurological or other serious adverse reactions.[45,46]

Comment: The Alaskan study was only able to recruit 49% of children approached, which might make results unrepresentative.[42] Two studies (one cohort[44] and one case control[43]), both with a large sample size, found conflicting results. However, none reported any serious adverse reactions. Both studies did not validate their data from other sources. The case control study had a potential for non-response bias, as the people who participated may not be representative of the general population. The cohort study analyzed adverse events reported only to hospitals and may, therefore, have underestimated the frequency of events.

OPTION UNIVERSAL IMMUNISATION OF ADOLESCENTS

We found insufficient evidence to assess the effects of universal adolescent immunisation, or to compare its effectiveness with other strategies. One observational study suggests minor adverse effects after hepatitis B immunisation in this group.

Benefits: We found no systematic review or RCTs.

Harms: One study from the routine post-marketing vaccine surveillance system in Canada (41 494 students aged 11 years) found 69 adverse events.[48] The major categories were injection site reactions (23%), fainting (20%), and rashes (17%). There were four cases of arthritis and one instance of anaphylaxis. The study had no control group, which makes establishing causality difficult.

Comment: We found a cross sectional survey of hepatitis B infection markers in a random sample of 1215 pregnant women aged 15–44 years in British Columbia, Canada. From this cohort, researchers assessed the prevalence of HBsAg (see glossary, p 992) among 15–19 year old girls, 7 years after the start of an adolescent vaccination programme (begun in 1992).[49] It reported no cases of HBsAg positivity in that age group. However, the prevalence of HBsAg among women aged 15–44 was 1.4% in the full cohort, which consisted mainly of people who had not been vaccinated under the programme.[49] The survey does not provide causal evidence on the efficacy of the adolescent immunisation strategy, but does suggest that the strategy may be protective against developing chronic carrier state.[49] We found no strong evidence on the effects of the adolescent immunisation strategy adopted in many parts of the USA and Canada. Evaluation of adolescent immunisation schemes in Canada did not include the primary outcome measures adopted in this review.[50] Surveillance data from the USA and Canada have reported few serious adverse reactions. The results are based on self reported events and had no control group.[48]

Hepatitis B (prevention)

GLOSSARY

Acute hepatitis B events Any acute illness with raised liver enzymes (alanine aminotransferase [ALT] levels) and serological signs of acute hepatitis (HBsAg, antiHBc IgM).[51]

Chronic carrier state A person is considered a chronic carrier if the HBsAg has been persistently positive for more than 6 months.[51]

Connective tissue disorders These are multisystemic conditions secondary to an inflammatory response in the body against its own tissues resulting in damage and long term disability.[51]

Countries with high hepatitis B endemicity HBsAg prevalence 8% or higher.[41]

Countries with low hepatitis B endemicity HBsAg prevalence less than 2%.[52]

Expanded Program Immunisation Was launched by the World Health Organization in 1974, to provide systematic immunisation to all infants on a global scale.

HBsAg Hepatitis B surface antigen is a serological marker on the surface of hepatitis B virus. It indicates acute or chronic hepatitis B infection.[52]

Hepatitis vaccine Both types of vaccines (plasma derived vaccine rarely used now and yeast derived recombinant vaccine most commonly used).[52]

High risk immunisation strategy In this strategy hepatitis B vaccine is recommended in individuals and groups who are at high risk of hepatitis B because of their lifestyle, occupation, and other factors. These include close contact of a case or a carrier, babies born to infected mothers, parenteral drug misusers, individuals who change sexual partners frequently, homosexual or bisexual men, people with haemophilia, people on haemodialysis, healthcare workers, and residents of institutions for individuals with severe learning disabilities.[52]

Protective efficacy $[(R_1 - R_2)/R_1] \times 100$ where R_1 is the incidence of event in control population and R_2 is the incidence of event in the immunised population.[30] This is the same as the relative risk reduction.

Recombinant vaccine It contains HBsAg absorbed on aluminium hydroxide adjuvant and is prepared from yeast cells using recombinant DNA technology.[1]

Universal immunisation strategy In this strategy, routine hepatitis B immunisation is carried out for either all infants or adolescents through a national programme.[52]

Substantive changes

Selective immunisation in low endemicity countries Two observational surveys added.[39,40] Benefits and harms data enhanced, but no change to categorisation.

QUESTIONS

INTERVENTIONS

Key Messages

- **Oral amantadine for early treatment of influenza A in adults (duration of symptoms reduced)** One systematic review and three additional RCTs have found that oral amantadine reduces the duration of influenza A symptoms by about 1 day compared with placebo. We found insufficient evidence about adverse effects in this setting. We found no good evidence of benefit if amantadine is started more than 2 days after symptom onset.
- **Orally inhaled zanamivir for early treatment of influenza A and B in adults (duration of symptoms reduced)** One systematic review has found that orally inhaled zanamivir reduces the duration of influenza symptoms by about 1 day compared with placebo. Adverse effects were similar in people taking zanamivir and in people taking placebo. We found no good evidence of benefit if zanamivir is started more than 2 days after symptom onset.
- **Oral oseltamivir for early treatment of influenza A and B in adults (duration of symptoms reduced)** Two RCTs have found that oral oseltamivir reduces the duration of influenza symptoms by about 1 day compared with placebo. Oral oseltamivir increases the incidence of nausea and vomiting compared with placebo. We found no good evidence of benefit if oseltamivir is started more than 1.5 days after symptom onset.
- **Oral rimantadine for early treatment of influenza A in adults (duration of symptoms reduced)** One systematic review has found that oral rimantadine reduces the duration of influenza A symptoms by about 1 day compared with placebo. We found insufficient evidence about adverse effects in this setting. We found no good evidence of benefit if rimantadine is started more than 2 days after symptom onset.

Influenza

- **All antivirals for preventing serious influenza complications** We found insufficient evidence about the effects of antiviral agents on reducing serious complications of influenza.

DEFINITION Influenza is caused by infection with influenza viruses. Uncomplicated influenza is characterised by the abrupt onset of fever, chills, non-productive cough, myalgias, headache, nasal congestion, sore throat, and fatigue.[1] Influenza is usually diagnosed clinically. Not all people infected with influenza viruses become symptomatic. People infected with other pathogens may have symptoms identical to those of influenza.[2] The percentage of infections resulting in clinical illness can vary from about 40–85%, depending on age and pre-existing immunity to the virus.[3] Influenza can be confirmed by viral culture, immunofluorescence staining, enzyme immunoassay, or rapid diagnostic testing of nasopharyngeal, nasal or throat swab specimens, or by serological testing of paired sera. Some rapid tests detect influenza A only, some detect and distinguish between influenza A and B, whereas others detect but do not distinguish between influenza A and B.

INCIDENCE/ PREVALENCE In temperate areas of the northern hemisphere, influenza activity typically peaks between late December and early March, whereas in temperate areas of the southern hemisphere influenza activity typically peaks between May and September. In tropical areas, influenza can occur throughout the year.[2] The annual incidence of influenza varies yearly, and depends partly on the underlying level of population immunity to circulating influenza viruses.[1] One localised study in the USA found that serological conversion with or without symptoms occurred in 10–20% a year, with the highest infection rates in people aged under 20 years.[4] Attack rates are higher in institutions and in areas of overcrowding.[5]

AETIOLOGY/ RISK FACTORS Influenza viruses are transmitted primarily from person to person through respiratory droplets disseminated during sneezing, coughing, and talking.[1,6]

PROGNOSIS The incubation period of influenza is 1–4 days and infected adults are usually contagious from the day before symptom onset until 5 days after symptom onset. The signs and symptoms of uncomplicated influenza usually resolve within a week, although cough and fatigue may persist.[1] Complications include otitis media, bacterial sinusitis, secondary bacterial pneumonia, and, less commonly, viral pneumonia and respiratory failure. Complications are also caused by exacerbation of underlying disease.[1,2] In the USA each year, over 110 000 admissions to hospital and about 20 000 deaths are related to influenza.[2] The risk of hospitalisation is highest in people 65 years or older, in very young children, and in those with chronic medical conditions.[1,7,8] Over 90% of influenza related deaths during recent seasonal epidemics in the USA have been in people 65 years or older.[1] During influenza pandemics, morbidity and mortality may be high in younger age groups.[1] Severe illness is more common with influenza A infections than with influenza B infections.[1]

AIMS OF INTERVENTION To reduce the duration and severity of influenza signs and symptoms, and the risk of complications, and to minimise adverse effects of treatment.

OUTCOMES Severity and duration of symptoms; frequency and severity of complications of influenza; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal November 2002. The authors searched Medline (1966–2001; major MeSH topics: amantadine and influenza, rimantadine and influenza; keywords: zanamivir, 4-guanidino-Neu5Ac2en, GG167, oseltamivir, GS4104, and Ro64-0796). Meeting abstracts were used to identify unpublished studies of zanamivir and oseltamivir. We included only systematic reviews and double blind RCTs of treatment versus placebo for naturally occurring influenza. We excluded RCTs and reviews of chemoprophylaxis of influenza, experimentally induced influenza, and reviews that combined RCTs of more than one agent. We only assessed people with laboratory confirmed influenza. For amantadine and rimantadine, we included only RCTs of influenza A. For zanamivir and oseltamivir, we included studies of influenza A or B. For zanamivir, we included only RCTs of orally inhaled drug and excluded intranasal drops plus oral inhalation unless oral inhalation results were reported separately. For amantadine, rimantadine, and oseltamivir we included only RCTs of oral administration. We excluded RCTs primarily on children younger than 18 years, those that used an antipyretic rather than a placebo as control, RCTs in which the delay from symptom onset to starting treatment was unclear, and RCTs without quantitative measures of clinical effectiveness.

QUESTION What are the effects of antiviral treatment of influenza in adults?

OPTION ORAL AMANTADINE

One systematic review and additional RCTs have found that oral amantadine reduces the duration of influenza A symptoms by about 1 day compared with placebo. We found insufficient evidence to assess adverse effects in this setting.

Benefits: We found one systematic review (search date 1997, 7 RCTs, 531 otherwise healthy people)[9] and three additional RCTs[10–12] of oral amantadine (usually started within 48 hours of symptom onset) versus placebo for the treatment of influenza A (see table A on web extra). The review found that amantadine significantly reduced the duration of fever (temperature > 37.0 °C reduced by 1 day, 95% CI 0.7 days to 1.3 days). We found no RCTs of the effect of amantadine in preventing serious complications of influenza, such as pneumonia or exacerbation of chronic diseases. We found no RCTs of amantadine for treatment of influenza A in pregnant women, those with chronic disease, or in immunised people.

Harms: The review found no significant difference in the frequency of adverse effects between amantadine and placebo groups. However, the included RCTs contained little information about the relative adverse effects of amantadine compared with placebo when used for treatment of influenza A (see table A on web extra).[13–15] More evidence is available about the harms of amantadine when used for prophylaxis of influenza A (see comment below).

Influenza

Comment: In vitro studies have found that amantadine has specific antiviral activity against influenza A but not influenza B viruses.[16] The RCTs used different outcome measures, and so summarising the results is difficult. Only one RCT examined amantadine in elderly people.[12] All RCTs considered only people with laboratory confirmed influenza A, and so the analyses were not by intention to treat. The proportion of influenza A isolates from the general population exhibiting resistance to amantadine has remained low.[17,18] Amantadine resistant influenza A viruses have not been found to be more virulent than non-resistant viruses.[2] The limited evidence from elderly and high risk groups makes it difficult to generalise results to these populations. A systematic review found that use of amantadine for prophylaxis of influenza A is associated with an increased incidence of gastrointestinal and central nervous system adverse effects compared with placebo.[9]

OPTION ORAL RIMANTADINE

One systematic review has found that oral rimantadine reduces the duration of influenza A symptoms by about 1 day compared with placebo. We found insufficient evidence about adverse effects in this setting.

Benefits: We found one systematic review (search date 1997, 3 RCTs, 104 otherwise healthy adults)[9] and one small additional RCT[19] of rimantadine (usually started within 48 hours of symptom onset) versus placebo for the treatment of influenza A (see table A on web extra). The review found that rimantadine significantly reduced the duration of fever compared with placebo (temperature > 37.0 °C reduced by 1.3 days, 95% CI 0.8 days to 1.8 days). We found no RCTs of rimantadine for treatment of influenza A in people over 65 years of age, in pregnant women, in those with chronic disease, or in immunised people. We found no RCTs of the effect of rimantadine in preventing serious complications of influenza, such as pneumonia or exacerbation of chronic diseases.

Harms: The review found insufficient evidence about the adverse effects of rimantadine compared with placebo in people with influenza A.[9] One non-systematic review (340 adults treated for influenza) of rimantadine versus placebo found that more people taking rimantadine had central nervous system symptoms, most commonly insomnia (10.8% *v* 8.6%; P value not provided); and gastrointestinal symptoms, most commonly abdominal pain and nausea (6.0% *v* 2.3%; P value not provided).[20] Additional evidence is available about adverse effects of rimantadine when used for prophylaxis of influenza A (see comment below).

Comment: In vitro studies have found that rimantadine has specific antiviral activity against influenza A but not influenza B viruses.[16] The RCTs used different outcome measures and so summarising results is difficult. Additional studies of rimantadine have been performed in Russia, but information in English is limited.[21] Viruses that are resistant to rimantadine show cross-resistance to amantadine, and *vice versa*.[17] Influenza A viruses resistant to rimantadine have not been found to be more virulent than non-resistant viruses.[2] The proportion of influenza A isolates from the general population exhibiting resistance to rimantadine (or amantadine)

has remained low.[17,18] The limited evidence from elderly and high risk groups makes it difficult to generalise results to these populations. A systematic review found that use of rimantadine for prophylaxis of influenza A is associated with an increased incidence of gastrointestinal adverse effects compared with placebo.[9]

OPTION ORALLY INHALED ZANAMIVIR

One systematic review has found that orally inhaled zanamivir reduces the duration of influenza symptoms by about 1 day compared with placebo. Adverse effects were similar in people taking zanamivir and placebo.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 1498 people with influenza)[22] and two additional RCTs (78 people with influenza)[23,24] that compared inhaled zanamivir (usually started within 48 hours of symptom onset) versus placebo (see table B on web extra). Some of the RCTs included small numbers of people aged 65 years or older, and people with chronic cardiac or respiratory illness.[24–27] **Symptoms in all people:** The review found that zanamivir significantly reduced the time to alleviation of symptoms (median time reduced by 1.4 days, 95% CI 0.8 days to 1.9 days) compared with placebo. One of the additional RCTs (27 people with influenza) found no significant difference between zanamivir and placebo in the time to alleviation of symptoms (median time reduced by 4.5 days, P = 0.3).[24] The other additional RCT (51 people with influenza) found that zanamivir reduced the time to alleviation of symptoms by 0.5 days (P value not provided) compared with placebo.[23] **Symptoms in high risk people:** The review performed a meta-analysis including one RCT (313 high risk people with influenza) and subgroups of people at high risk from four of the original RCTs (171 people).[28] It found no significant difference between zanamivir and placebo in the time to alleviation of symptoms (484 people; median time reduced by +1.67 days, 95% CI –0.02 to +3.37 days).[28] **Complications:** We found no fully published RCTs of the effect of zanamivir in preventing serious complications of influenza, such as pneumonia or exacerbation of chronic diseases.

Harms: Adverse effects were similar in people taking zanamivir compared with placebo (the inhaled lactose vehicle alone) (see table B on web extra).[22] Use of zanamivir has been associated with bronchospasm and worsening of underlying respiratory disease (see comment below).[29]

Comment: Zanamivir is administered as an orally inhaled powder. In vitro studies have found that zanamivir has antiviral activity against both influenza A and B viruses.[30] RCTs have predominantly included people with influenza A (≥ 85%). Because of the short period for which zanamivir has been available, and the lack of optimal assays to detect resistant strains, we found insufficient evidence to comment on the development of viral resistance to zanamivir.[2,31–36] We found one RCT (525 people with obstructive airways disease and influenza) published in abstract form only.[37] It found that zanamivir significantly reduced time to symptom resolution compared with placebo (median reduction with zanamivir *v* placebo 1.5 days; P = 0.009). We found some observational evidence that zanamivir is associated with bronchospasm and worsening of underlying respiratory disease.[29] However, the RCT published in abstract found a small but significant increase in morning and

evening peak expiratory flow rate with zanamivir compared with placebo (morning peak expiratory flow rate 12.9 L/minute higher with zanamivir *v* placebo, P = 0.011; evening peak expiratory flow rate 13.1 L/minute higher, P = 0.007).[37] It found a non-significant reduction between zanamivir and placebo in complications needing antibiotics or a change in respiratory medication (ARR 58% with zanamivir *v* placebo, P = 0.064).

OPTION ORAL OSELTAMIVIR

Two RCTs have found that oral oseltamivir reduces the duration of influenza symptoms by about 1 day compared with placebo, but increases the incidence of nausea and vomiting.

Benefits: We found no systematic review of oseltamivir used to treat influenza. We found two RCTs that compared oseltamivir with placebo.[38,39] People in both RCTs were selected with a temperature of 38.0 °C or greater. Both RCTs found that oseltamivir (started within 36 hours of symptom onset) significantly reduced the duration of influenza symptoms by about 1 day compared with placebo (see table B on web extra). We found no RCTs of oseltamivir for influenza in people 65 years or older, in pregnant women, in people with chronic disease, or in vaccinated people. We found no RCTs of the effect of oseltamivir in preventing serious complications of influenza, such as pneumonia, or exacerbation of chronic diseases.

Harms: Nausea and vomiting were significantly more common in people receiving oseltamivir compared with placebo.[38,39]

Comment: Studies in mice and ferrets have found that oseltamivir has *in vitro* activity against both influenza A and B viruses.[40] The RCTs predominantly included people with influenza A (97%).[38,39] Because of the short period for which oseltamivir has been available, and the lack of optimal assays to detect resistant strains, we found insufficient evidence about viral resistance to oseltamivir.[2,32,36,41]

Key Messages

Prevention

- **Bacillus Calmette Guerin (BCG) vaccine; BCG plus killed *Mycobacterium leprae*; *ICRC vaccine*; *Mycobacterium w* vaccine** One RCT evaluated four different vaccines and found that the largest effect was with ICRC vaccine and BCG plus killed *M leprae*, followed by BCG alone. The effectiveness of *Mycobacterium w* was only marginal. However, only for the vaccine BCG alone were the findings corroborated by large controlled clinical trials with long term follow up. Only one RCT reported on harms of vaccination; it found these to be minimal.

Treatment

- **Multidrug treatment for multibacillary leprosy** We found no reliable comparisons between multidrug treatment with rifampicin plus clofazimine plus dapsone versus dapsone alone, or versus dapsone plus rifampicin, in people with multibacillary leprosy. Observational studies found that multidrug treatment improved skin lesions and was associated with a low relapse rate. The evidence on the incidence of adverse effects is poor. Multidrug treatment was not compared with dapsone alone because rising dapsone resistance rates meant that it would have been unethical to do such a study. The same applies for multidrug treatment for paucibacillary leprosy below.

- **Multidrug treatment for paucibacillary leprosy** We found no reliable comparisons between multidrug treatment with dapsone plus rifampicin versus dapsone alone in people with paucibacillary leprosy. Observational studies found that multidrug treatment improved skin lesions and was associated with a low relapse rate. We found poor evidence on the incidence of adverse effects.
- **Multiple dose compared with single dose treatment for single skin lesion leprosy (both achieve high cure rates but multiple dose is likely to achieve higher)** One RCT found that multiple dose treatment with rifampicin monthly plus dapsone daily for 6 months achieved higher cure rates at 18 months than single dose treatment with rifampicin plus minocycline plus ofloxacin. Some improvement occurred in 99% of people in both groups. Adverse effects were similar with both regimens.

DEFINITION Leprosy is a chronic granulomatous disease caused by *Mycobacterium leprae*, primarily affecting the peripheral nerves and skin. The clinical picture depends on the individual's immune response to *M leprae*. At the tuberculoid end of the Ridley–Jopling scale, individuals have good cell mediated immunity and few skin lesions. At the lepromatous end of the scale, individuals have low reactivity for
M leprae, causing uncontrolled bacterial spread and skin and mucosal infiltration. Peripheral nerve damage occurs across the spectrum. Nerve damage may occur before, during, or after treatment. Some patients have no nerve damage, others develop anaesthesia of the hands and feet, which puts them at risk of developing neuropathic injury. Weakness and paralysis of the small muscles of the hands, feet, and eyes puts patients at risk of developing deformity and contractures. Loss of the fingers and toes is due to repeated injury in a weak, anaesthetic limb. These visible deformities cause stigmatisation the world over. Classification is based on clinical appearance and bacterial index of lesions (see glossary, p 1008). The World Health Organization field leprosy classification is based on the number of skin lesions: single lesion leprosy (1 lesion), paucibacillary leprosy (2–5 skin lesions), and multibacillary leprosy (see glossary, p 1009) (> 5 skin lesions).[1]

INCIDENCE/ PREVALENCE Worldwide, about 720 000 new cases of leprosy are reported each year,[2] and about 2 million people have leprosy related disabilities. Six major endemic countries (India, Brazil, Myanmar, Madagascar, Nepal, and Mozambique) account for 88% of all new cases. Cohort studies show a peak of disease presentation between 10–20 years of age.[3] After puberty, there are twice as many male as female cases.

AETIOLOGY/ RISK FACTORS *M leprae* is discharged from the nasal mucosa of people with untreated lepromatous leprosy, and spreads, via the recipient's nasal mucosa, to infect their skin and nerves. It is a hardy organism and has been shown to survive outside human hosts in India for many months.[4] Risk factors for infection include household contact with a person with leprosy. We found no good evidence of an association with HIV infection, nutrition, and socioeconomic status.[5]

PROGNOSIS Complications of leprosy include nerve damage, immunological reactions, and bacillary infiltration. Without treatment, tuberculoid

infection eventually resolves spontaneously. Most people with borderline tuberculoid and borderline lepromatous leprosy gradually develop lepromatous infection. Many people have peripheral nerve damage at the time of diagnosis, ranging from 15% in Bangladesh[6] to 55% in Ethiopia.[7] Immunological reactions can occur with or without antibiotic treatment. Further nerve damage occurs through immune mediated reactions (type 1) and neuritis (see glossary, p 1009). Erythema nodosum leprosum (see glossary, p 1009) (type 2 reaction) is an immune complex mediated reaction causing fever, malaise, and neuritis, which occurs in 20% of people with lepromatous leprosy and 5% with borderline lepromatous leprosy.[8] Secondary impairments (wounds, contractures, and digit resorption) occur in 33–56% of people with established nerve damage.[9] We found no recent information on mortality.

AIMS OF INTERVENTION **Prevention:** To prevent infection. **Treatment:** To treat infection and improve skin lesions; to prevent relapse and complications (nerve damage and erythema nodosum leprosum). Prevention of complications such as ulcers and deformity may improve the quality of life for the individual and help reduce the severe stigmatisation that still accompanies leprosy.

OUTCOMES **Prevention:** Incidence of leprosy **Treatment:** Clinical improvement, relapse rate, quality of life, adverse effects of treatment, and mortality.

METHODS *Clinical Evidence* search and appraisal March 2003, including a search for observational studies. The author identified additional references from hand searches of reference lists. RCTs of preventive interventions need a long follow up period as the incubation period can be 2–15 years, depending on disease type. We excluded trials with less than 2 years' follow up.

QUESTION What are the effects of interventions to prevent leprosy?

OPTION VACCINATION

One RCT evaluated four different vaccines and found that the largest effect was with ICRC vaccine and BCG plus killed *M leprae*, followed by BCG alone. The effectiveness of *Mycobacterium w* was only marginal. However, only for the BCG alone vaccine were the findings corroborated by large controlled clinical trials with long term follow up. Only one RCT reported on harms of vaccination; it found these to be minimal.

Benefits: We found no systematic review. **Different vaccines versus placebo:** We found one RCT carried out in a leprosy endemic area with clinical leprosy as the outcome measure (see table A on web extra).[10] The RCT (double blind, 171 400 healthy people in India aged 1–65 years, follow up for 6–7 years) compared four vaccines (ICRC vaccine [see glossary, p 1009], 22 541 people; *Mycobacterium w* vaccine, 33 720 people; BCG, 38 213 people; and BCG plus killed
M leprae, 38 229 people) versus normal saline (38 697 people). It included a statistical adjustment for the multiple comparisons against placebo. All four vaccines significantly reduced the incidence

of leprosy compared with placebo. The most effective vaccines were ICRC vaccine (RRR 65.5%, 95% CI 48.0% to 77.0%) and BCG plus killed *M leprae* (RRR 64.0%, 95% CI 50.4% to 73.9%). BCG alone was also effective (RRR 34.1%, 95% CI 13.5% to 49.8%), whereas the significance of the effect of *Mycobacterium w* was marginal (RRR 25.7%, 95% CI 1.9% to 43.8%). **BCG versus no treatment or placebo:** In addition to the RCT mentioned above,[10] we found three controlled clinical trials comparing BCG alone versus placebo, carried out in leprosy endemic areas, with clinical leprosy as the outcome measure (see table A on web extra).[11–13] The controlled trials (in a total of over 39 000 children in Uganda, Myanmar, and Papua New Guinea) were quasi or non-randomised, but had longer follow up than the RCT (13–16 years). They found that BCG significantly reduced the incidence of leprosy. The degree of protection against leprosy varied between countries, with higher protection in Uganda than Myanmar. One of the trials also looked at mortality and found a significant reduction (442/2707 [16.3%] deaths from all causes with BCG *v* 489/2649 [18.5%] with saline; RR 0.89, 95% CI 0.79 to 0.99; NNT 47, 95% CI 24 to 997).[10,12] **BCG plus killed *M leprae* versus placebo:** In addition to the RCT mentioned above,[10] we found one further RCT carried out in leprosy endemic areas, with clinical leprosy as the outcome measure (see table A on web extra).[14] The RCT stratified people according to the presence of a BCG scar. Those with a scar or a possible scar (54 865 people) received either BCG, BCG plus killed *M leprae*, or placebo. This RCT (double blind, 121 020 healthy people in Malawi without history of previous leprosy or tuberculosis, severe malnutrition, or other severe illness, aged ≥ 3 months, follow up for 5–9 years) found that combined results for BCG and BCG plus killed *M leprae* significantly reduced the incidence of leprosy compared with placebo (combined analysis for BCG or BCG plus killed *M leprae* versus placebo; RR 0.51, 95% CI 0.26 to 0.99).[14] Those without a scar (66 155 people) received BCG or BCG plus killed *M leprae*. **ICRC vaccine versus placebo:** We found one RCT (see different vaccines *v* placebo above).[10] **Mycobacterium w versus placebo:** We found one RCT (see different vaccines *v* placebo above).[10] **Dose of vaccine:** The controlled trial performed in Myanmar compared two different concentrations of BCG vaccine versus no treatment.[13] The vaccine with the higher concentration of bacilli significantly reduced the incidence of leprosy over 14 years (3.8/1000 person years [see glossary, p 1009] with BCG *v* 5.4/1000 person years for controls; RRR 30%, 95% CI 9–40%). The vaccine with the lower concentration of bacilli had no significant protective effect (5.0/1000 person years with BCG *v* 5.6/1000 person years; RRR +11%, 95% CI −3% to +23%). The RCT performed in Malawi found no significant differences between a higher and a standard dose of killed *M leprae*.[14]

Harms: The RCT conducted in India found that "fluctuant lymphadenitis" was minimal with all four vaccines used, and no other adverse effects were observed (numbers not reported).[10] The other trials did not report on harms.[11–14]

Leprosy

Comment: In the trial in Malawi, 7/82 people (9%) tested positive for HIV.[14] Eleven different batches of BCG were used. The number of people lost to follow up was high (26%), and the sample size may have been insufficient to rule out clinically important effects, given that there were multiple comparisons against placebo.[14]

QUESTION What are the effects of treatments for leprosy?

OPTION MULTIDRUG TREATMENT FOR PAUCIBACILLARY LEPROSY

We found no reliable comparison between multidrug treatment with dapsone plus rifampicin versus dapsone alone in people with paucibacillary leprosy, and RCTs would probably be unethical. Observational studies found that multidrug treatment improved skin lesions and was associated with a low relapse rate. The evidence on the incidence of adverse effects is poor.

Benefits: We found no systematic review or RCT (see comment below). We found seven observational studies assessing the affects of multidrug treatment (dapsone 100 mg/day plus rifampicin 600 mg monthly for 6 months), with follow up ranging from 6 months to 10 years (see table 1, p 1011 and table 2, p 1012).[15–22] The studies used different methods of assessment making it difficult to compare results. **Skin lesions:** Three cohort studies reported rates of resolution of skin lesions (see comment below) (see table 1, p 1011).[15–17,19] One study (499 people) found that resolution of lesions occurred in 38% of people after 1 year;[16] another (50 people) found that resolution occurred in 8% of people after 6 months.[15] The number of people with lesions that were clinically active after treatment ranged from 2–44%.[15–17] **Nerve impairment:** Two studies reported rates of new or worsening nerve impairment (see table 1, p 1011).[17,19] One (499 people) found that new disabilities occurred in 2.5% of people, and worsening of existing disabilities occurred in 3.3% after 4 years.[19] The other study (130 people) found that the visible disabilities (World Health Organization grade II — see glossary, p 1009) increased from 4% at enrolment to 7% after 8–10 years' follow up.[17] **Relapse:** Six studies reported relapse rates over a 3–8 year follow up period (see table 2, p 1012).[17–22] Rates ranged from 0% in Ethiopia[18] to 2.5% over 4 years in Malawi (see table 2, p 1012).[19] The risk of relapse ranged from 0.66/1000 person years in China[22] to 6.5/1000 person years in Malawi.[19] (It is clinically difficult to differentiate relapse from reaction in paucibacillary leprosy — see glossary, p 1009.)

Harms: None of the studies formally monitored adverse effects. In one study, hepatitis due to rifampicin occurred in 1/130 people (0.8%), but the method of diagnosis was not stated.[17] In another study 1/503 people (0.2%) suffered an "allergic reaction" to rifampicin and dapsone (details not reported).[16]

Comment: Because studies had shown that 30% of *M leprae* isolates were resistant to dapsone,[23] the World Health Organization introduced the combination of dapsone plus rifampicin urgently in 1982, without formal trials comparing it against dapsone.

OPTION MULTIDRUG TREATMENT FOR MULTIBACILLARY LEPROSY

We found no reliable comparisons between multidrug treatment with rifampicin plus clofazimine plus dapsone versus dapsone alone, or versus dapsone plus rifampicin, in people with multibacillary leprosy. Observational studies found that multidrug treatment improved skin lesions and was associated with a low relapse rate. The evidence on the incidence of adverse effects is poor.

Benefits: We found no systematic review or RCTs. We found six observational studies assessing the effects of multidrug treatment (monthly supervised rifampicin 600 mg and clofazimine 300 mg, plus daily unsupervised dapsone 100 mg and clofazimine 500 mg) for 24 months.[17,18,20,22,24,25] **Skin lesions:** One study in Thailand (53 people) found that 29% lesions were still active at 3 years (see table 3, p 1012).[17] **Nerve impairment:** The study in Thailand found that the proportion of people with visible deformity (World Health Organization grade II — see glossary, p 1009) increased from 8% at enrolment to 13% at 8–10 years' follow up.[17] **Relapse:** Six observational studies reported relapse rates (see table 4, p 1013),[17,18,20,22,24,25] which varied from 0% (per 100 person years — see glossary, p 1009) in Ethiopia to 20.4% in India. In the study conducted in India, the overall relapse rate was 20/260 (7.7%) over about 8 years (2.04/1000 person years), and 18/20 (90%) relapses were in people with a bacterial index (see glossary, p 1008) greater than 4 at the start of treatment.[24]

Harms: Most studies did not report on adverse effects. Skin pigmentation may occur with clofazimine, which may be especially problematic in people with fair skin.

Comment: Only one study[24] stratified its results according to bacterial index. The World Health Organization study group on chemotherapy recommended that treatment be given for 24 months.[26] In 1998, the 7th Expert committee gave the option of reducing the length of treatment from 24 months to 12 months.[1] We found no controlled trial to support this recommendation. We found one RCT (93 people with untreated lepromatous leprosy), which compared dapsone 50 mg/day plus daily rifampicin 450 mg versus dapsone 50 mg/day plus monthly rifampicin 1200 mg for the first 6 months of treatment.[27] It found no significant difference in clinical improvement between daily versus monthly rifampicin (40/47 [85%] with daily rifampicin *v* 43/46 [91%]; RR 0.91, 95% CI 0.62 to 1.03). Adverse effects were more common with daily than with monthly rifampicin, causing discontinuation in 8.5% of people with daily rifampicin compared with 0% with monthly rifampicin.[27]

OPTION MULTIPLE DOSE VERSUS SINGLE DOSE TREATMENT FOR SINGLE SKIN LESIONS

One RCT found that multiple dose treatment with rifampicin monthly plus dapsone daily for 6 months achieved higher cure rates at 18 months than single dose treatment with rifampicin plus minocycline plus ofloxacin. Some improvement occurred in 99% of people in both groups. Adverse effects were similar with both regimens.

Leprosy

Benefits: We found no systematic review. We found one RCT (1483 people with single skin lesions typical of paucibacillary leprosy — see glossary, p 1009; see comment below) comparing single dose treatment with rifampicin 600 mg plus ofloxacin 400 mg plus minocycline 100 mg versus multiple dose treatment with dapsone 100 mg /daily plus rifampicin 600 mg monthly for 6 months.[28] Outcomes measured at 18 months were based on a scoring system involving five measurements: disappearance of the lesion, reduction in hypopigmentation, reduction in the degree of infiltration, reduction in the size of the lesion, and improvement in sensation in the lesion. Treatment failure was defined as no change or an increase of the clinical score, and marked improvement was defined as a difference of 13 between the baseline and 18 month scores. The RCT found that multiple dose treatment significantly increased the proportion of people with marked improvement compared with single dose treatment (392/684 [57.3%] with multiple dose *v* 361/697 [51.8%] with single dose; P = 0.04), and with complete cure (374/684 [54.7%] *v* 327/697 [46.9%]; RR 1.17, 95% CI 1.05 to 1.28; NNT 13, 95% CI 8 to 40). There were 12 treatment failures (6 in each group), and 99.1% of people in both groups had some improvement by the end of the study.[28]

Harms: Allergic reactions (which were not specified) occurred in seven people (6 taking multiple dose *v* 1 taking single dose treatment), and gastrointestinal effects occurred in five people (2 taking multiple dose *v* 3 taking single dose treatment). There was no significant difference in the number of type 1 reactions (see glossary, p 1009) (7/697 [1.0%] with single dose treatment *v* 3/684 [0.4%] with multiple dose; ARI +0.6%, 95% CI –0.2% to +3.4%).

Comment: The RCT did not specify its diagnostic criteria and did not confirm the clinical diagnosis. The follow up of only 18 months for people in the single dose group is short for detection of relapse. Some infections in this group would have resolved spontaneously, and the absence of a placebo control group means that the treatment effect cannot be estimated.[28] Single dose treatment has previously been assessed in people with paucibacillary leprosy. One RCT (622 people in Zaïre) compared two single dose regimens: rifampicin 40 mg/kg plus clofazimine 1200 mg versus rifampicin 40 mg/kg plus clofazimine 100 mg plus dapsone 100 mg plus ethionamide 500 mg. It found that the overall relapse rate was 20.4/1000 person years (see glossary, p 1009), which was substantially higher than the relapse rate found for 6 months' treatment with dapsone plus rifampicin (see dapsone plus rifampicin, p 1006), or rifampicin plus dapsone plus clofazimine (see rifampicin plus dapsone plus clofazimine, p 1007). However, single dose treatment has operational advantages in the field, particularly when people live in remote areas and are unable to attend a clinic for several months.[29]

GLOSSARY

Bacteriological index A measure of the density of *M leprae* in the skin. Slit skin smears are made at several sites, the smears are stained and examined microscopically. The number of bacteria per high power field is scored on a logarithmic scale (0–6), and the index calculated by dividing the total score by the numbers of sites sampled.

Heaf grade 0 = 0–4 mm induration; 1 = 5–9; 2 = 10–14; 3 = 15–19; 4 = ≥ 20. A grade 3 or 4 test generally indicates infection with *M tuberculosis*, although the cut off point varies between countries.
ICRC vaccine A vaccine developed at the Indian Cancer Research Centre.
Multibacillary leprosy More than five skin lesions (WHO 1998, WHO expert committee on leprosy seventh report 874).
Neuritis Inflammation of a nerve presenting with any of the following: spontaneous nerve pain, paraesthesia, tenderness, sensory, motor, or autonomic impairment.
Paucibacillary leprosy Between two and five skin lesions.
Person years at risk The number of new cases of disease in a specified time period divided by the number of person years at risk during that period (average number at risk of relapse multiplied by the length of observation)
Single lesion leprosy One skin lesion.
Type 1 (reversal) reaction A delayed type hypersensitivity reaction occurring at sites of *M leprae* antigen. It presents with acutely inflamed skin lesions and acute neuritis (nerve tenderness with loss of function).
Type 2 reaction or Erythema Nodosum Leprosum (ENL) An immunological complication of multibacillary leprosy presenting with short lived and recurrent crops of tender erythematous subcutaneous nodules that may ulcerate. There may be signs of systemic involvement with fever, inflammation in lymph nodes, nerves, eyes, joints, testes, fingers, toes, or other organs.
World Health Organization disability grading These are simple gradings for use in the field, mainly for collection of general data regarding disabilities.[1] Grade 0 = no anaesthesia, no visible deformity or damage; Grade 1 = anaesthesia present, but no visible deformity or damage; Grade 2 = visible deformity or damage present.

QUESTIONS

INTERVENTIONS

*Based on subgroup analysis of RCTs

See glossary, p 1022

Key Messages

Administration of Lyme disease vaccine

- **Lyme disease vaccine in people exposed to North American strains of *Borrelia burgdorferi*** One RCT has found that, compared with placebo, three doses of a vaccine (consisting of recombinant outer surface protein A [Osp–A] of *B burgdorferi* combined with adjuvant) reduces the incidence of Lyme disease in immunocompetent aged 15–70 years in Lyme disease endemic areas in North America.
- **Lyme disease vaccine in Europe or Asia** We found no RCTs about the effects of recombinant Osp–A vaccine in European or Asian populations. There is heterogeneity of the species that cause Lyme disease in Europe and Asia. The vaccine may not be as effective in European or Asian populations as it is in North American populations.

Prophylactic treatment of tick bite

- **Prophylactic antibiotics after *Ixodes scapularis* tick bites in Lyme disease endemic areas in North America** One systematic review in people with recognised *I scapularis* tick bites in the preceding 72 hours found that antibiotics reduced the risk of developing clinical Lyme disease compared with placebo, but the difference was not significant. One subsequent large RCT in people who had removed an attached *I scapularis* tick in the preceding 72 hours found that doxycycline reduced the proportion of people with erythema migrans at the site of the tick bite compared with placebo.

Treatment of Lyme arthritis

- **Cefotaxime (more effective than penicillin for Lyme arthritis)** One RCT found weak evidence from a small subgroup analysis of people with Lyme arthritis that cefotaxime increased the proportion of people with full recovery compared with penicillin.
- **Ceftriaxone (more effective than penicillin for Lyme arthritis)** One RCT found weak evidence from a small subgroup analysis of people with Lyme arthritis that ceftriaxone improved symptoms compared with penicillin.
- **Doxycycline (as effective as amoxicillin plus probenecid for Lyme arthritis)** One RCT in people with Lyme arthritis found no significant difference between doxycycline and amoxicillin plus probenecid in resolution of Lyme arthritis.
- **Penicillin (better than placebo for Lyme arthritis)** One RCT in people with Lyme arthritis has found that penicillin increases resolution of Lyme arthritis compared with placebo.

Treatment of late neurological Lyme disease

- **Cefotaxime (more effective than penicillin for late neurological Lyme disease)** One RCT found weak evidence from a small subgroup analysis of people with late Lyme disease that cefotaxime improved symptoms of neuropathy compared with penicillin.
- **Ceftriaxone (in late neurological Lyme disease)** One RCT found insufficient evidence from a small subgroup analysis in people with late neurological Lyme disease about effects of ceftriaxone and cefotaxime.
- **Ceftriaxone plus doxycycline (in people with late neurological Lyme disease who had been previously treated)** One RCT comparing ceftriaxone plus doxycycline versus placebo in people with previously treated Lyme disease and persistent neurological symptoms found no significant difference in health related quality of life at interim analysis at 180 days; therefore the RCT was terminated.

DEFINITION Lyme disease is an inflammatory illness resulting from infection with spirochetes of the *Borrelia burgdorferi* genospecies transmitted to humans by ticks. Some infected people have no symptoms. The characteristic manifestation of early Lyme disease is erythema migrans: a circular rash at the site of the infectious tick attachment that expands over a period of days to weeks in 80–90% of people with Lyme disease. Early disseminated infection may cause secondary erythema migrans, disease of the nervous system (facial palsy or other cranial neuropathies, meningitis, and radiculoneuritis), musculoskeletal disease (arthralgia), and, rarely, cardiac disease

(myocarditis or transient atrioventricular block). Untreated or inadequately treated Lyme disease can cause late disseminated manifestations weeks to months after infection. These late manifestations include arthritis, polyneuropathy, and encephalopathy. Diagnosis of Lyme disease is based primarily on clinical findings and a high likelihood of exposure to infected ticks. Serological testing may be helpful in people with endemic exposure who have clinical findings consistent with later stage disseminated Lyme disease.

INCIDENCE/ PREVALENCE

Lyme disease occurs in temperate regions of North America, Europe, and Asia. It is the most commonly reported vector borne disease in the USA, with over 16 000 cases reported a year.[1] Most cases occur in the north-eastern and north-central states, with a reported annual incidence in endemic states as high as 67.9/100 000 people.[1] In highly endemic communities, the incidence of Lyme disease may exceed 1000/100 000 people a year.[2] In some countries of Europe, the incidence of Lyme disease has been estimated to be over 100/100 000 people a year.[3] Foci of Lyme disease have been described in northern forested regions of Russia, in China, and in Japan.[4] Transmission cycles of *B burgdorferi* have not been described in tropical areas or in the southern hemisphere.[4]

AETIOLOGY/ RISK FACTORS

Lyme disease is caused by infection with any of the *B burgdorferi* sensu lato genospecies. Virtually all cases of Lyme disease in North America are the result of infection with *B burgdorferi*. In Europe, Lyme disease may be caused by *B burgdorferi*, *B garinii*, or *B afzelii*. The infectious spirochetes are transmitted to humans through the bite of certain *Ixodes* ticks.[4] Humans who have frequent or prolonged exposure to the habitats of infected *Ixodes* ticks are at highest risk of acquiring Lyme disease. Individual risk depends on the likelihood of being bitten by infected tick vectors, which varies with the density of vector ticks in the environment, the prevalence of infection in ticks, and the extent of a person's contact with infected ticks. The risk of Lyme disease is often concentrated in focal areas. In the USA, risk is highest in certain counties within north-eastern and north-central states during the months of April to July.[2] People become infected when they engage in activities in wooded or bushy areas that are favourable habitats for ticks, and deer and rodent hosts.

PROGNOSIS

Lyme disease is rarely fatal. Untreated Lyme arthritis resolves at a rate of 10–20% a year; over 90% of facial palsies due to Lyme disease resolve spontaneously, and most cases of Lyme carditis resolve without sequelae.[5] However, untreated Lyme disease can result in arthritis (50% of untreated people), meningitis or neuropathies (15% of untreated people), carditis (5–10% of untreated people with erythema migrans), and, rarely, encephalopathy.

AIMS OF INTERVENTION

To prevent Lyme disease; to ameliorate or eliminate the symptoms of established Lyme disease; to reduce sequelae, with minimal adverse effects.

OUTCOMES

For prophylaxis: incidence of Lyme disease, adverse events. **For treatment:** incidence, prevalence, or severity of symptoms and signs of short term manifestations; long term sequelae of infection; quality of life.

METHODS *Clinical Evidence* search and appraisal January 2003. Additional searches of author's files.

QUESTION **What are the effects of measures to prevent Lyme disease?**

OPTION **LYME DISEASE VACCINE**

One RCT has found that, compared with placebo, a vaccine (consisting of recombinant outer surface lipoprotein A of *B burgdorferi* combined with adjuvant) reduces the incidence of Lyme disease in immunocompetent adults aged 15–70 years in North America who are at high risk of Lyme disease. We found no RCTs about the effects of recombinant outer surface protein A vaccine in European or Asian populations. There is heterogeneity of the species that cause Lyme disease in Europe and Asia. The vaccine may not be as effective in European or Asian populations as it is in North American.

Benefits: We found no systematic review but found one RCT (10 936 people, aged 15–70 years, living in Lyme disease endemic areas in the USA) that compared a vaccine made of recombinant outer surface lipoprotein A (Osp–A) plus adjuvant (see glossary, p 1022) versus placebo.[6] People in the RCT were self selected and were at high risk of Lyme disease. The RCT found that, compared with placebo, the vaccine significantly reduced laboratory confirmed Lyme disease after two doses in the first year (AR of developing Lyme disease 22/5469 [0.4%] with vaccine *v* 43/5467 [0.8%] with placebo; RR 0.51, 95% CI 0.31 to 0.85; NNT 260, 95% CI 146 to 1046). After a third dose 1 year later, it found a greater reduction of the incidence of laboratory confirmed Lyme disease (16/5469 [0.3%] with vaccine *v* 66/5467 [1.2%] with placebo; RR 0.24, 95% CI 0.14 to 0.42; NNT 110, 95% CI 80 to 167); asymptomatic infection was prevented completely (0/5469 [0%] with vaccine *v* 15/5467 [0.3%] with placebo; NNT 365, 95% CI 222 to 687).[6]

Harms: We found nine RCTs evaluating adverse effects of Osp–A vaccines.[6–14] No serious adverse events were found to be causally related to the vaccine in any of these trials. The results are summarised in table 1, p 1024.

Comment: The rOsp–A vaccine is no longer commercially available. **Applicability of the evidence:** The absolute benefit of vaccination in the RCT was high (1 case of Lyme disease prevented for every 110 people vaccinated), which was partly because the people recruited into the RCT were self selected and had a very high incidence of Lyme disease in the untreated group.[6] If the risk of Lyme disease in the unvaccinated population was 100/100 000 people a year (comparable to the reported Lyme disease incidence in many endemic areas),[1,3] then about 1316 people would need to be vaccinated to prevent one case of Lyme disease. We found no evidence about the effects of this vaccine in Europe or Asia where a greater variety of *B burgdorferi* genospecies cause Lyme disease, and no clinical evidence of efficacy in children. The vaccine may not be as effective in European or Asian populations as it is in North

American. **Other RCTs:** One RCT evaluated the efficacy of recombinant Osp–A vaccine without adjuvant.[7] It found that the vaccine reduced the incidence of Lyme disease by 68% (95% CI 36% to 85%) after two doses in the first year. However, the criteria for confirming the diagnosis of Lyme disease were not defined clearly. Of 1734 suspected cases of Lyme disease in 2 years, only 499 were reviewed "in depth" by the Data and Safety Monitoring Board. The RCT reported an estimate of vaccine efficacy after a third dose of vaccine, but this dose was not part of the original RCT protocol, was given only to a subset of participants, and the criteria for selection of the subset who received the third dose were not specified. This RCT found that the efficacy of vaccine was highest in people aged less than 60 years, but results for this subgroup were not provided.[7]

OPTION PROPHYLACTIC TREATMENT OF TICK BITE

One systematic review in people with recognised *I scapularis* tick bites in the preceding 72 hours found that antibiotics reduced the risk of developing clinical Lyme disease compared with placebo, but the difference was not significant. One subsequent large RCT in people who had removed an attached *I scapularis* tick in the preceding 72 hours found that doxycycline reduced the proportion of people with erythema migrans at the site of the tick bite compared with placebo.

Benefits: We found one systematic review[15] and one subsequent RCT[16] comparing prophylactic antibiotics versus placebo for the treatment of tick bite (see table 2, p 1026). The review (search date 1995, 3 RCTs,[17–19] 639 adults and children with recognised *I scapularis* tick bites in the preceding 72 hours; see comment below) found that prophylactic treatment with antibiotics (penicillin, amoxicillin [amoxycillin], and tetracycline were studied in the individual trials) reduced the risk of developing clinical Lyme disease (erythema migrans) compared with placebo, but the difference was not significant (0/308 [0%] with antibiotics *v* 4/292 [1.4%] with placebo; ARR 1.4%, 95% CI 0% to 3%; OR 0.0, 95% CI 0.0 to 1.5; P = 0.12).[15] The subsequent large RCT (482 people ≥ 12 years old who had removed an attached *I scapularis* tick in the preceding 72 hours; see comment below) compared doxycycline (200 mg as a single dose) versus placebo with 6 weeks' follow up.[16] It found that doxycycline significantly reduced the proportion of people with erythema migrans at the site of the tick bite compared with placebo (1/235 [0.4%] with doxycycline *v* 8/247 [3.2%] with placebo; ARR 2.8%, 95% CI 0.4% to 5.2%; NNT 36, 95% CI 20 to 250), and the proportion of people with any evidence of Lyme disease (erythema migrans at the site of the tick bite, or at other sites, or a viral-like illness with laboratory evidence of Lyme disease, 3/235 [1.3%] with doxycycline *v* 11/247 [4.5%] with placebo; ARR 3.2%, 95% CI 0.2% to 6.2%; NNT 31, 95% CI 16 to 500). Of 431 people who had serum samples tested at study entry and 3 and 6 weeks later, none had asymptomatic seroconversion for antibody to *B burgdorferi*. Erythema migrans at the site of the tick bite only occurred after the removed tick was in the nymph stage, was partially engorged, and was estimated to be attached for more than 72 hours. A subgroup analysis found that in people who removed

partially engorged nymphal ticks, doxycycline significantly reduced erythema migrans at the site of the tick bite compared with placebo (AR 1/78 [1.3%] with doxycycline *v* 8/81 [9.9%] with placebo; ARR 8.6%, 95% CI 1.4% to 15.8%; NNT 12, 95% CI 7 to 71).[16]

Harms: One RCT in the review reported a rash with penicillin (AR 1/27 [4%] with penicillin *v* 0/29 [0%] with placebo), and another RCT reported a rash with amoxicillin (AR 2/205 [1%] with amoxicillin *v* 0/182 [0%] with placebo) (see table 2, p 1026). The third RCT in the review reported no adverse effects among persons who had been treated with antibiotics. The RCT conducted after the review found that of the 309 people who recorded data on adverse events, significantly more people taking doxycycline had nausea or vomiting compared with placebo (33/156 [21.0%] with doxycycline *v* 6/153 [3.9%] with placebo; ARI 17.2%, 95% CI 9.8% to 24.6%; NNH 6, 95% CI 4 to 10).[16] It also reported abdominal discomfort (11/156 [7.1%] with doxycycline *v* 6/153 [3.9%] with placebo; P = 0.34), diarrhoea (6/156 [3.8%] with doxycycline *v* 6/153 [3.9%] with placebo; P = 0.79), and dizziness (4/156 [2.6%] with doxycycline *v* 1/153 [0.7%] with placebo; P = 0.37).[16]

Comment: The three RCTs included in the systematic review and the subsequent RCT were all conducted in Lyme disease endemic areas in North America.[15,16] There is a possibility that people treated with antibiotics for tick bite may not develop erythema migrans but could progress to late stages of Lyme disease. However, none of the people who were treated with antibiotics in the RCTs had asymptomatic infection with *B burgdorferi*, or developed late manifestations of Lyme disease during follow up (ranging from 6 weeks to up to 3 years). The most recent and largest RCT found that for a baseline risk of 1% for contracting Lyme disease in the control group, the number needed to treat for a single dose of doxycycline (200 mg) to prevent Lyme disease was 31.[16] The same RCT found that the number needed to harm for nausea or vomiting from this treatment was six; therefore, about five people would develop nausea or vomiting for every person in whom Lyme disease was prevented. People in the RCT with adult and/or non-engorged ticks did not develop Lyme disease, although Lyme disease can occur after the bite of an engorged adult tick. If treatment was limited to people with engorged nymphal ticks (NNT 12), then two people would develop nausea and less than one person would develop vomiting for every person in whom Lyme disease was prevented.

QUESTION What are the effects of antibiotic treatment for Lyme disease arthritis?

OPTION ANTIBIOTICS FOR LYME DISEASE ARTHRITIS

One RCT in people with Lyme arthritis has found that penicillin increases resolution of Lyme arthritis compared with placebo. Another RCT in people with Lyme arthritis found no significant difference between doxycycline and amoxicillin plus probenecid in resolution of Lyme arthritis. One RCT found weak evidence from a small subgroup analysis of people with Lyme arthritis that ceftriaxone improved symptoms compared with penicillin. One RCT found weak evidence from a small subgroup

analysis of people with Lyme arthritis that cefotaxime increased the proportion of people with full recovery compared with penicillin. Some people have developed symptoms of neuroborreliosis after oral antibiotic treatment of Lyme arthritis with concurrent neuroborreliosis.

Benefits: We found no systematic review. **People with Lyme arthritis:** We found two RCTs that selected people with Lyme disease arthritis and randomised them to different treatments.[20,21] The first RCT (40 people with Lyme disease arthritis) compared intramuscular benzathine penicillin versus saline placebo.[20] It found that penicillin significantly increased the proportion of people having complete resolution of the arthritis compared with placebo (AR 7/20 [35%] with penicillin *v* 0/20 [0%] with placebo; $P < 0.02$).[20] The second RCT (48 people with Lyme arthritis) compared oral doxycycline (100 mg twice daily for 30 days) versus oral amoxicillin (500 mg) plus probenecid (4 times daily for 30 days).[21] After 3 months, an intention to treat analysis found no significant difference in rates of arthritis resolution in both groups (AR 18/25 [72%] with doxycycline *v* 16/23 [70%] with amoxicillin plus probenecid; RR 1.04, 95% CI 0.72 to 1.49). In the doxycycline group, one person had recurrence of arthritis and another developed polyneuropathy after treatment. In the amoxicillin plus probenecid group, one person had recurrent arthritis, two developed polyneuropathy, and two developed encephalopathy. **Subgroup analyses of people with Lyme arthritis:** We found three other RCTs that recruited people with a variety of forms of late Lyme disease (including Lyme arthritis).[22–24] The first RCT (23 people with late Lyme disease, 70% with arthritis) compared ceftriaxone (2 g iv every 12 hours for 14 days) versus penicillin (4 MU iv every 4 hours for 10 days).[22] Ceftriaxone seemed to be more effective than penicillin, but the differences in rates of clinical improvement after 3 months were not significant (AR of improvement 12/13 [92%] with ceftriaxone *v* 5/10 [50%] with penicillin; RR 1.85, 95% CI 0.97 to 3.50). More of the subgroup of people with arthritis improved with ceftriaxone (AR 9/9 [100%] with ceftriaxone *v* 2/7 [29%] with penicillin; NNT 2, 95% CI 1 to 4). The second RCT (135 people with late Lyme disease, 73 with arthritis) compared cefotaxime (6 g/day for 8–10 days) versus penicillin G (20 MU/day for 8–19 days).[23] Two years after treatment, full recovery was significantly more frequent with cefotaxime compared with penicillin (AR 44/69 [64%] with cefotaxime *v* 25/66 [38%] with penicillin; RR 1.68, 95% CI 1.18 to 2.41; NNT 3, 95% CI 2 to 11). In the subgroup of people with arthritis, full recovery was also significantly increased by cefotaxime compared with penicillin (17/39 [44%] with cefotaxime *v* 4/34 [12%] with penicillin; RR 3.7, 95% CI 1.4 to 9.9; NNT 4, 95% CI 2 to 10). The third RCT (62 people with disseminated Lyme disease, 13 people with Lyme arthritis) did not report separate results for the subgroup with arthritis. It compared intravenous ceftriaxone followed by oral amoxicillin plus probenecid versus oral cefixime plus probenecid.[24]

Harms: Some people have developed symptoms of neuroborreliosis (see glossary, p 1023) after oral antibiotic treatment of arthritis.[21] Jarisch-Herxheimer reactions (see glossary, p 1022) have been described in people treated for late Lyme disease. One RCT reported symptoms suggestive of a mild Jarisch-Herxheimer reaction in

12/44 (27%) of people treated with ceftriaxone and 1/10 (10%) of people with penicillin,[22] and one RCT reported "Herxheimer-like" reactions in 20% of people treated with penicillin and 40.5% of people treated with cefotaxime.[23] Possible "Herxheimer-like" reactions, including fever, transient rash, and worsening of symptoms or cardiac arrhythmia, were reported in an unspecified number of people treated with cefixime and probenecid, and with ceftriaxone followed by amoxicillin.[24] No significant differences were found in the risk of developing a prolonged form of such reactions for people receiving ceftriaxone plus amoxicillin versus cefixime plus probenecid (18/30 [60%] with ceftriaxone plus amoxicillin treatment *v* 12/30 [40%] with cefixime plus probenecid; RR 1.50, 95% CI 0.88 to 2.54).[24] Other harms include those expected from the antibiotics. In RCTs including people with Lyme arthritis, the following adverse effects were reported: diarrhoea and skin rash with ceftriaxone;[22] shock and colitis with penicillin; anaphylaxis and colitis with cefotaxime;[23] rash and gastrointestinal effects with amoxicillin and probenecid;[21] diarrhoea and rash with cefixime; and nausea, diarrhoea, and rash with ceftriaxone followed by amoxicillin.[24]

Comment: Results of the RCTs that presented results for subgroups of people with Lyme arthritis should be interpreted with caution as people with arthritis were not randomly assigned to treatment groups. The RCTs were small, and the type, dose, and regimen of antibiotics used varied between trials. The enrolment criteria also varied between trials. Only one RCT had a placebo control.[20] The proportion of people who respond in comparative RCTs is difficult to interpret because, without a placebo comparison, it is unclear how many people would have improved without treatment.

QUESTION What are the effects of antibiotic treatments for late neurological Lyme disease?

OPTION ANTIBIOTICS FOR LATE NEUROLOGICAL LYME DISEASE

One RCT comparing ceftriaxone plus doxycycline versus placebo in people with previously treated Lyme disease and persistent late neurological symptoms found no significant difference in health related quality of life at interim analysis at 180 days; therefore, the RCT was terminated. One RCT found weak evidence from a small subgroup analysis of people with late Lyme disease that cefotaxime improved symptoms of neuropathy compared with penicillin. One RCT found weak evidence from a small subgroup analysis in people with late neurological Lyme disease that there was no significant difference between ceftriaxone and cefotaxime in the proportion of people who were asymptomatic.

Benefits: We found no systematic review. **People with late neurological Lyme disease:** We found one RCT (129 people, 78 people seropositive for *B burgdorferi*, 51 people who were seronegative) comparing antibiotics (iv ceftriaxone 2 g/day for 30 days followed by oral doxycycline 100 mg twice daily for 60 days) versus placebo.[25] All participants had been previously treated for Lyme disease but had persistent symptoms including arthralgia, myalgia, neurocognitive changes, altered sensation, malaise, headache, and sleep disturbance. At 180 days, a planned interim analysis of 107 people found

that the probability of finding a significant difference in health related quality of life (measured on the medical outcomes survey short form general health survey; SF-36) after full study enrolment was less than 5%, and the study was therefore terminated.[25]

Subgroup analyses in people with late neurological Lyme disease: We found two comparative RCTs that reported results for people with late neurological Lyme disease.[23,26] The first RCT (135 people with late Lyme disease, 93 with neuropathy) compared cefotaxime (6 g/day for 8–10 days) versus penicillin G (20 MU/day for 8–19 days).[23] Two years after treatment, cefotaxime significantly increased complete recovery compared with penicillin (44/69 [64%] with cefotaxime *v* 25/66 [38%] with penicillin; RR 1.68, 95% CI 1.18 to 2.41). Similar results were reported for the subgroup with neuropathy (35/49 [71%] with cefotaxime *v* 20/44 [46%] with penicillin; RR 1.57, 95% CI 1.09 to 2.27). The second RCT (33 people with Lyme neuroborreliosis [see glossary, p 1023] of varying duration) compared ceftriaxone (2 g iv/day for 10 days) versus cefotaxime (2 g iv every 8 hours for 10 days).[26] Some of the people treated with ceftriaxone were asymptomatic before treatment, and so were excluded from analysis (3/17). Of the remaining people, most (17/30) had disease duration of over 30 days at study entry, and some (8/30) had a duration over 60 days. The RCT found no significant difference between ceftriaxone and cefotaxime in the proportion of people who were asymptomatic after 8 months (8/14 [57%] with ceftriaxone *v* 9/16 [56%] with cefotaxime; RR 1.02, 95% CI 0.54 to 1.90).

Harms: See harms under antibiotics for Lyme disease arthritis, p 0. The RCT in people with previously treated Lyme disease found no significant difference in the overall rate of adverse events between the antibiotic and placebo groups. In the other clinical trials involving people with late neurological Lyme disease reported above, the following adverse effects were reported: shock and colitis with penicillin, and anaphylaxis and colitis with cefotaxime;[22] rash with cefotaxime, and fever, diarrhoea, and elevated liver enzymes with ceftriaxone.[26] One case control study found an association between biliary disease and ceftriaxone treatment of suspected late Lyme disease.[27]

Comment: The RCTs of previously untreated people either recruited people with late Lyme disease, some of whom had neurological manifestations, or people with Lyme neuroborreliosis, some of whom had late disease. Results presented for these subsets of study participants may be subject to undetected biases, because people with late neurological disease were not randomly assigned to treatment groups. None of these RCTs had a placebo treated control group. The antibiotics used in RCTs, as well as doses and schedules, varied between trials. The enrolment criteria also varied between trials.

GLOSSARY

Adjuvant A substance such as aluminium hydroxide included in a vaccine to enhance its effectiveness.

Jarisch-Herxheimer reaction An inflammatory reaction in tissues induced by antibiotic treatment of spirochetal diseases, and believed to be caused by an immunological reaction to the release of spirochetal antigens.

Neuroborreliosis Central or peripheral neuropathy resulting from infection with *Borrelia* sp spirochetes.

QUESTIONS

INTERVENTIONS

Key Messages

- **Insecticide treated nets** We found no RCTs in travellers. One systematic review in adult and child residents of malaria endemic settings found that insecticide treated nets reduced the number of mild episodes of malaria and reduce child mortality.

Malaria: prevention in travellers

- **Atovaquone plus proguanil in adults** One RCT in migrants with limited immunity found that atovaquone plus proguanil reduced the proportion of people with malaria compared with placebo. One RCT found no significant difference between atovaquone plus proguanil and chloroquine plus proguanil in preventing malaria. One RCT of atovaquone plus proguanil versus mefloquine found no cases of clinical malaria throughout the trial, but found a higher rate of neuropsychiatric harm with mefloquine compared with atovaquone plus proguanil.
- **Doxycycline in adults** One RCT in soldiers and one RCT in migrants with limited immunity found that doxycycline reduced the risk of malaria compared with placebo. One of the RCTs found that doxycycline was associated with nausea and vomiting, diarrhoea, cough, headache, and unspecified dermatological symptoms over 13 weeks. We found no evidence on long term safety.
- **Insecticide treated clothing in adults** Two RCTs in soldiers and refugee householders found that permethrin treated fabric (clothing or sheets) reduced the incidence of malaria.
- **Mefloquine in adults** One systematic review of one RCT in soldiers found that, compared with placebo, mefloquine had 100% protective efficacy. One RCT of mefloquine versus atovaquone plus proguanil found no cases of clinical malaria throughout the trial, but found a higher rate of neuropsychiatric harm with mefloquine compared with atovaquone plus proguanil.
- **Aerosol insecticides in adults** We found no RCTs on the effects of aerosol insecticides in preventing malaria in travellers. One large questionnaire survey in travellers found insufficient evidence on the effects of aerosol insecticides in preventing malaria. Two community RCTs in residents of malaria endemic areas found that indoor spraying of aerosol insecticides reduced clinical malaria.
- **Air conditioning and electric fans in adults** We found no RCTs on the effects of air conditioning or electric fans in preventing malaria in travellers. One large questionnaire survey found that air conditioning reduced the incidence of malaria. One small observational study found that electric ceiling fans reduced total catches of culicine mosquitos in indoor spaces but did not significantly reduce total catches of anopheline mosquitoes.
- **Chloroquine in adults** We found no RCTs on the effects of chloroquine in travellers. One RCT in Austrian workers residing in Nigeria found no significant difference between chloroquine and sulfadoxine plus pyrimethamine in the incidence of malaria after 6–22 months. *Plasmodium falciparum* resistance to chloroquine is now established in most malaria endemic regions of the world.
- **Chloroquine plus proguanil in adults** One RCT found no significant difference between chloroquine plus proguanil and chloroquine plus sulfadoxine plus pyrimethamine in the incidence of *P falciparum* malaria. One RCT found no significant difference between chloroquine plus proguanil and proguanil alone in the incidence of *P falciparum* malaria. One RCT found no significant difference between chloroquine plus proguanil and atovaquone plus proguanil in preventing malaria.
- **Full length clothing in adults** We found no RCTs on the effects of full length clothing in preventing malaria in travellers. One large questionnaire survey in travellers found that wearing trousers and long sleeved shirts reduced the incidence of malaria.

- **Insecticide treated nets in pregnant travellers** We found no RCTs on the effects of insecticide treated nets in preventing malaria in pregnant travellers. One RCT of pregnant long term residents of a malaria endemic area found insufficient evidence on the effects of permethrin treated nets in preventing malaria.
- **Mosquito coils and vaporising mats in adults** We found no RCTs on the effects of coils and vaporising mats in preventing malaria in travellers. One RCT of coils and one observational study of pyrethroid vaporising mats found that these devices reduced numbers of culicine mosquitoes in indoor spaces.
- **Pyrimethamine plus dapsone in adults** We found no RCTs in travellers. One RCT in Thai soldiers found insufficient evidence to compare pyrimethamine plus dapsone versus proguanil plus dapsone. We found limited observational evidence that pyrimethamine plus dapsone may cause agranulocytosis.
- **Smoke** We found no RCTs on the effects of smoke in preventing malaria. One controlled clinical trial found that smoke repelled mosquitoes during the evening.
- **Topical (skin applied) insect repellents in adults** We found no RCTs on the effects of topical (skin applied) insect repellents in preventing malaria in travellers. One small crossover RCT found that diethyltoluamide (DEET) preparations protected against mosquito bites. DEET has been reported to cause systemic and skin adverse reactions, particularly with prolonged use.
- **Vaccines** We found no RCTs in travellers. One systematic review of antimalaria vaccines in residents of malaria endemic areas has found that the SPf66 vaccine reduces first attacks of malaria compared with placebo.
- **Amodiaquine in adults** We found no RCTs on the effects of amodiaquine in preventing malaria in travellers. We found limited observational evidence that amodiaquine may cause neutropenia, liver damage, and hepatitis.
- **Sulfadoxine plus pyrimethamine in adults** One RCT found no significant difference between chloroquine plus proguanil and chloroquine plus sulfadoxine plus pyrimethamine in the incidence of *P falciparum* malaria. One retrospective observational study suggested that sulfadoxine plus pyrimethamine was associated with severe cutaneous reactions.
- **Topical (skin applied) insect repellents containing DEET in children** We found no RCTs on the effects of DEET in preventing malaria in child travellers. Case reports in young children found serious adverse effects with DEET.
- **Antimalaria drugs in airline pilots and aircrew; antimalaria drugs in pregnant travellers; biological control measures; insect electrocuters and ultrasonic buzzers; insecticide treated clothing in pregnant travellers; mefloquine in children; topical (skin applied) insect repellents in pregnant travellers** We found no RCTs on the effects of these interventions.

DEFINITION Malaria is caused by a protozoan infection of red blood cells with one of four species of the genus *Plasmodium*: *P falciparum*, *P vivax*, *P ovale*, and *P malariae*.[1] Clinically, malaria may present in different ways but it is usually characterised by fever (which may be swinging), tachycardia, rigors, and sweating. Anaemia, hepatosplenomegaly, cerebral involvement, renal failure, and shock may occur; see chapter on malaria: severe, life threatening), p 1047.[2,3] Travellers are defined here as visitors from a malaria free area to a malaria endemic area, who stay in the endemic area for less than 1 year. This definition includes refugees and migrants.

Malaria: prevention in travellers

INCIDENCE/ PREVALENCE Each year there are 300–500 million clinical cases of malaria. About 40% of the world's population is at risk of acquiring the disease.[2,3] Each year 25–30 million people from non-tropical countries visit malaria endemic areas, of whom 10 000–30 000 contract malaria.[4,5] Most RCTs of malaria prevention in travellers have been conducted in soldiers and travellers. The results of these trials may not be applicable to people such as refugees and migrants, who are likely to differ in their health status and in their susceptibility to disease and adverse drug effects.

AETIOLOGY/ RISK FACTORS Malaria is mainly a rural disease, requiring nearby standing water. It is transmitted by bites of infected female anopheline mosquitoes, mainly at dusk and during the night.[1,6–8] In cities, mosquito bites are usually from female culicine mosquitoes, which are not vectors of malaria.[9] Malaria is resurgent in most tropical countries and risk to travellers is increasing.[10] The sickle cell trait has been shown to convey some protection against malaria in non-immune carriers of that trait. Non-immune adults with the sickle cell trait who develop severe malaria have lower parasite densities, fewer complications (e.g. cerebral malaria), and a reduced mortality compared with adults without the trait.[11] There is little good evidence on the degree of protection afforded by the sickle cell trait.[12]

PROGNOSIS Ninety per cent of tourists and business travellers who contract malaria do not become ill until after they return home.[5] "Imported malaria" is easily treated if diagnosed promptly, and follows a serious course in only about 12% of people.[13,14] The most severe form is cerebral malaria, with a case fatality rate in adult travellers of 2–6%, mainly because of delays in diagnosis.[3,15]

AIMS OF INTERVENTION To reduce the risk of infection; to prevent illness and death, with minimal adverse effects of treatment.

OUTCOMES Rates of clinical malaria and death, and adverse effects of treatment. Proxy measures include numbers of mosquito bites and rates of mosquito catches in indoor areas. We found limited evidence linking numbers of mosquito bites and risk of malaria.[16]

METHODS *Clinical Evidence* search and appraisal September 2003. Additional hand searches by the author of his own files. Observational (non-RCT) data have been included in some sections where appropriate control studies are lacking or may be considered unethical.

QUESTION What are the effects of non-drug preventive interventions in adult travellers?

OPTION AEROSOL INSECTICIDES IN ADULTS

We found no RCTs on the effects of aerosol insecticides in preventing malaria in travellers. One large questionnaire survey in travellers found insufficient evidence on the effects of aerosol insecticides in preventing malaria. Two community RCTs in residents of malaria endemic areas found that indoor spraying of aerosol insecticides reduced clinical malaria.

Benefits: We found no systematic review or RCTs in travellers (see comment below). Two community RCTs found that indoor residual spraying of synthetic pyrethroids reduced clinical malaria in lifelong residents of malaria endemic areas.[17,18]

Harms: We found no reports of adverse effects.

Comment: One large questionnaire survey (89 617 European tourists returning from East Africa) found that commercially available personal aerosol insecticides did not significantly reduce the incidence of malaria ($P = 0.55$).[19] Historically, indoor residual spraying has not been recommended for short stay travellers, but we found no evidence to support this.

OPTION BIOLOGICAL CONTROL MEASURES

We found no RCTs on the effects of biological control measures in preventing malaria in travellers.

Benefits: We found no systematic review or RCTs of biological control measures (see glossary, p 1044) in preventing malaria in travellers (see comment below).

Harms: We found no evidence of harms.

Comment: One systematic review (search date 1997) identified two cohort studies based on mosquito counts.[20] It found no evidence that growing the citrosa plant and encouraging natural predation of insects by erecting bird or bat houses reduced bites to humans from infected anopheline mosquitoes. The only known way to reduce mosquito populations naturally is to eliminate sources of standing water, such as blocked gutters, tree stump holes, and discarded tyres, cans, and bottles.[20]

OPTION AIR CONDITIONING AND ELECTRIC FANS IN ADULTS

We found no RCTs on the effects of air conditioning or electric fans in preventing malaria in travellers. One large questionnaire survey in travellers found that air conditioning reduced the incidence of malaria. One small observational study found that electric ceiling fans reduced total catches of culicine mosquitoes but did not significantly reduce total catches of anopheline mosquitoes in indoor spaces.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: We found no evidence of harms.

Comment: One questionnaire survey of 89 617 European tourists returning from East Africa found that sleeping in an air conditioned room significantly reduced the incidence of malaria ($P = 0.04$).[19] One cohort study (6 experimental huts in villages in Pakistan) of various antimosquito interventions found that an electric ceiling fan run at high speed significantly reduced total catches of blood fed culicine mosquitoes ($P < 0.05$), but did not significantly reduce total catches of blood fed anopheline mosquitoes.[21] These studies support the finding that mosquitoes are reluctant to fly in windy conditions,[22] but suggest that anopheline mosquitoes are more tolerant of air turbulence than culicine mosquitoes.

OPTION INSECT ELECTROCUTERS AND ULTRASONIC BUZZERS

We found no RCTs on the effects of insect electrocuters and ultrasonic buzzers in preventing malaria.

Benefits: We found no systematic review and no RCTs with clinical malaria as an outcome.

Harms: We found no RCTs.

Comment: We found one non-randomised controlled trial (18 houses in Gabon) of a commercially available ultrasound emitting device. The trial lasted 6 weeks and used total mosquito catches as an outcome.[23] Most mosquitoes were culicine. It found no significant difference in mosquito catches between the ultrasound emitting device and a sham device (P = 0.48).[23]

OPTION MOSQUITO COILS AND VAPORISING MATS IN ADULTS

We found no RCTs on the effects of coils and vaporising mats in preventing malaria in travellers. One RCT of coils and one observational study of pyrethroid vaporising mats found that these devices reduced numbers of culicine mosquitoes in indoor spaces.

Benefits: We found no systematic review and no RCTs that used clinical malaria as an outcome. We found one RCT (18 houses in Malaysia) of various mosquito coil formulations versus no treatment.[24] It found that treated coils reduced populations of mosquitoes by 75% but 85% of the mosquitoes collected were culicine.[24]

Harms: We found no evidence of harms.

Comment: One observational study of pyrethroid vaporising mats in six experimental huts in a Pakistan village setting found that the mats reduced total catches of blood fed mosquitoes by 56%.[21]

OPTION SMOKE

We found no RCTs on the effects of smoke in preventing malaria in travellers. One controlled clinical trial found that smoke repelled mosquitoes during the evening.

Benefits: We found no systematic review and no RCTs of smoke in preventing malaria. We found one controlled clinical trial (see comment below).[25]

Harms: There may be an irritant and toxic effect of smoke on the eyes and respiratory system, but this effect was not quantified in the controlled clinical trial.[25]

Comment: One controlled clinical trial, in which five small fires were tended on five successive evenings in a village in Papua New Guinea, found a smoke specific and species specific effect from different types of smoke.[25] Catches of one anopheline species were reduced by 84% by burning betelnut (95% CI 62% to 94%), 69% by burning ginger (95% CI 25% to 87%), and 66% by burning coconut husks (95% CI 17% to 86%).

OPTION INSECTICIDE TREATED NETS

We found no RCTs in travellers. One systematic review in adult and child residents of malaria endemic settings found that insecticide treated nets reduced the number of mild episodes of malaria and reduced child mortality.

Benefits: We found no systematic review and no RCTs in travellers. We found one systematic review (search date not reported) that identified 18 RCTs in malaria endemic settings (non-traveller children and adults).[26] It found that nets sprayed or impregnated with a pyrethroid insecticide such as permethrin reduced the number of mild episodes of malaria compared with no nets or untreated nets (stable transmission area > 1 infective bite per person per year: insecticide treated nets *v* no nets: 2 RCTs, RRR 48%, 95% CI 41% to 54%; insecticide treated nets *v* untreated nets: 3 RCTs, RRR 39%, 95% CI 27% to 48%; see comment below) and child mortality (impregnated nets *v* no nets: 3 RCTs, RR 0.83, CI not reported; impregnated nets *v* untreated nets: 1 RCT, RR 0.77, CI not reported).[26] The review reported a summary risk difference of 5.6 deaths averted per 1000 children protected per year (4 RCTs, CI not reported).[26]

Harms: We found no evidence of harms.

Comment: In 7 RCTs included in the review, randomisation and allocation were done by individual (or household), whereas in 11 RCTs it was done by group (household, zones within 1 village, hamlets, villages, or blocks of villages).[26] Reported CIs for protective efficacy are not corrected for cluster randomisation.[26] Permethrin remains active for about 4 months.[6] Although the analysis of insecticide treated nets was undertaken in non-traveller children and adults, the results may be generalisable to other groups such as travellers.

OPTION INSECTICIDE TREATED CLOTHING IN ADULTS

Two RCTs in soldiers and refugee householders found that permethrin treated fabric (clothing or sheets) reduced the incidence of malaria.

Benefits: We found no systematic review but found two RCTs.[27,28] The first RCT (172 male Colombian soldiers patrolling a malaria endemic area for a mean of 4.2 weeks) found that permethrin impregnated uniforms significantly reduced the incidence of malaria compared with non-impregnated uniforms (3/86 [3%] *v* 12/86 [13%]; RR 0.25, 95% CI 0.07 to 0.85).[27] The second RCT (102 refugee households in northwestern Pakistan) found that permethrin treated wraps and top sheets significantly reduced the risk of falciparum malaria compared with placebo (RR 0.56, 95% CI 0.41 to 0.78).[28]

Harms: The first RCT also included an analysis of permethrin impregnated uniforms versus non-impregnated uniforms in 286 soldiers patrolling a leishmaniasis endemic area for a mean 6.6 weeks.[27] It found that 2/229 (0.9%) participants wearing permethrin impregnated uniforms experienced irritation and itching. No comparative information was given for soldiers wearing non-impregnated uniforms.

Comment: In the first RCT, the entire uniform (hat, shirt, undershirt, trousers, socks) was treated with a single application of permethrin. All participants were instructed to wear the uniform continuously, day and night, with the sleeves rolled down. Each participant washed his own uniform two to three times during the study, using soap and water, but uniforms were not reimpregnated with permethrin. Topical (skin applied) insect repellents were not used. Trials in soldiers may not be generalisable to other travellers.

OPTION FULL LENGTH CLOTHING IN ADULTS

We found no RCTs on the effects of full length clothing in preventing malaria in travellers. One large questionnaire survey in travellers found that wearing trousers and long sleeved shirts reduced the incidence of malaria.

Benefits: We found no systematic review or RCTs (see comment below). **Other lifestyle changes:** We found no studies (see comment below).

Harms: None.

Comment: We found one large questionnaire survey (89 617 European tourists returning from East Africa), which found that wearing long sleeved shirts and trousers significantly reduced the incidence of malaria ($P = 0.02$).[19] **Other lifestyle changes:** These include not travelling to malaria endemic regions during the rainy season (when most malaria transmission occurs) and not going outdoors in the evening or at night. Travellers who take day trips from a malaria free city to a malaria endemic region may be at minimal risk if they return to the city before dusk.[29] Some authors suggest wearing long sleeved shirts and trousers at dusk and wearing light rather than dark colours, as insects prefer landing on dark surfaces.[9,29]

OPTION TOPICAL (SKIN APPLIED) INSECT REPELLENTS IN ADULTS

We found no RCTs on the effects of topical (skin applied) insect repellents in preventing malaria in travellers. One small crossover RCT found that diethyltoluamide (DEET) preparations protected against mosquito bites. DEET has been reported to cause systemic and skin adverse reactions, particularly with prolonged use.

Benefits: We found no systematic review and no RCTs (see comment below).

Harms: We found a case series of systemic toxic reactions (confusion, irritability, insomnia) in US national park employees after repeated and prolonged use of DEET.[31] We found 14 case reports of contact urticaria and irritant contact dermatitis (mostly in soldiers) as a result of DEET.[19] The risk of absorption is especially high if DEET is left in the antecubital fossa overnight.[32] DEET also degrades certain plastics, such as in spectacle frames.[33]

Comment: One small crossover RCT (4 people), involving successive random exposure to female culicine mosquitoes, compared six different controlled release preparations of DEET.[30] It found that all gave at least 95% protection against mosquito bites.[30] DEET is a broad

spectrum repellent effective against mosquitoes, biting flies, chiggers, fleas, and ticks, and has been used for over 40 years.[20] Although most authorities would recommend the use of topical (skin applied) repellents in malaria endemic areas, the only evidence comes from small RCTs with non-clinical outcomes. Larger RCTs are needed to compare DEET with other topical (skin applied) repellents and placebo in preventing malaria.

QUESTION What are the effects of drug prophylaxis in adult travellers?

OPTION CHLOROQUINE IN ADULTS

We found no RCTs in travellers on the effects of chloroquine. One RCT in Austrian workers residing in Nigeria found no significant difference between chloroquine and sulfadoxine plus pyrimethamine in the incidence of malaria after 6–22 months. *P falciparum* resistance to chloroquine is now established in most malaria endemic regions of the world.

Benefits: We found no systematic review or RCTs in travellers. One RCT (173 Austrian industrial workers residing in Nigeria) found no significant difference between chloroquine and sulfadoxine plus pyrimethamine in the incidence of malaria after 6–22 months.[34]

Harms: The RCT found that chloroquine was associated with insomnia in 3/87 (3%) people.[35] Two people withdrew from the study because of adverse effects: one with skin rash and the other with visual disturbance. Retrospective questionnaire surveys have suggested that severe adverse effects are rare at prophylactic dosages.[35]

Comment: Alcohol consumption, other medication, and comorbidities can modify the effects of antimalaria drugs.[36,37] *P falciparum* resistance to chloroquine is now established in almost all malaria endemic regions of the world, although there are countries (principally in Central America and the Near East) where there has been no reported resistance as yet.

OPTION CHLOROQUINE PLUS PROGUANIL IN ADULTS

One RCT found no significant difference between chloroquine plus proguanil and chloroquine plus sulfadoxine plus pyrimethamine in the incidence of *P falciparum* malaria. One RCT found no significant difference between chloroquine plus proguanil and proguanil alone in the incidence of *P falciparum* malaria. One RCT found no significant difference between chloroquine plus proguanil and atovaquone plus proguanil in preventing malaria.

Benefits: We found no systematic review but found two RCTs. **Versus chloroquine plus sulfadoxine plus pyrimethamine:** One open label RCT (767 Scandinavian travellers to East Africa) comparing chloroquine plus proguanil versus chloroquine plus sulfadoxine plus pyrimethamine found no significant difference in rates of *P falciparum* malaria (4/384 [1%] *v* 3/383 [0.7%] travellers; RR 1.3, 95% CI 0.3 to 5.9).[38] **Versus proguanil alone:** One RCT in Dutch travellers to Africa found no significant difference between chloroquine 300 mg weekly plus proguanil 200 mg daily and proguanil

alone in incidence of *P falciparum* malaria (risk per 100 person months: chloroquine plus proguanil 2.8, 95% CI 0.9 to 10.1 *v* proguanil alone 6.0, 95% CI 2.6 to 14.0).[39] **Versus atovaquone plus proguanil:** See benefits of atovaquone plus proguanil in adults, p 1038.

Harms: In the RCT conducted in Scandinavian travellers, adverse effects associated with chloroquine plus proguanil were nausea (3%), diarrhoea (2%), and dizziness (1%).[38] One cohort study (470 British soldiers in Belize) found that the risk of mouth ulcers almost doubled with chloroquine plus proguanil compared with proguanil alone (P = 0.025).[40]

Comment: The incidence of confirmed *P falciparum* malaria in both trials was so low that a clinically important effect cannot be excluded.

OPTION DOXYCYCLINE IN ADULTS

One RCT in soldiers and one RCT in migrants with limited immunity found that doxycycline reduced the risk of malaria compared with placebo. One of the RCTs found that doxycycline was associated with nausea and vomiting, diarrhoea, cough, headache, and unspecified dermatological symptoms over 13 weeks. We found no evidence on long term safety.

Benefits: We found no systematic review but found two RCTs.[41,42] The first RCT (136 Indonesian soldiers) compared doxycycline versus mefloquine versus placebo in a malaria endemic setting (see comment below).[41] It found that, in an area of drug resistance, doxycycline significantly reduced the risk of malaria compared with placebo (AR 1/67 [2%] with doxycycline *v* 53/69 [77%] with placebo; RR 0.02, 95% CI 0.003 to 0.14; NNT 2, 95% CI 2 to 2). The second RCT (300 Indonesian migrants with limited immunity) comparing azithromycin versus doxycycline versus placebo found that doxycycline significantly reduced the incidence of malaria compared with placebo (2/75 [3%] cases of *P falciparum* malaria with doxycycline *v* 29/77 [38%] with placebo; RR 0.07, 95% CI 0.02 to 0.29; NNT 3, 95% CI 2 to 4; 1/75 [2%] cases of *P vivax* malaria with doxycycline *v* 27/77 [35%] with placebo; RR 0.04, 95% CI 0.01 to 0.28).[42]

Harms: The first RCT found that doxycycline was associated with gastrointestinal symptoms (including nausea and vomiting, abdominal pain, and diarrhoea) in 16/67 (24%) soldiers, unspecified dermatological problems in 22/67 (33%), cough in 21/67 (31%), and headache in 11/67 (16%) over 13 weeks.[41] One questionnaire survey (383 returned Australian travellers taking doxycycline) found that 40% reported nausea or vomiting, 12% reported diarrhoea, and 9% of female travellers reported vaginitis.[43] Evidence from case reports suggests that, in sunny conditions, up to 50% of travellers using doxycycline may experience photoallergic skin rash.[44]

Comment: Most drug trials in travellers have been in soldiers, and the results may not be generalisable to tourists or business travellers.[45,46] Both RCTs were three arm parallel studies. Only the doxycycline versus placebo comparisons are reported here.[41,42]

OPTION MEFLOQUINE IN ADULTS

One systematic review of one RCT in soldiers found that, compared with placebo, mefloquine had a protective efficacy of 100%. One RCT of mefloquine versus atovaquone plus proguanil found no cases of clinical malaria throughout the trial, but found a higher rate of neuropsychiatric harm with mefloquine compared with atovaquone plus proguanil.

Benefits: **Versus placebo:** We found one systematic review (search date 2000), which identified one RCT (203 Indonesian soldiers) comparing mefloquine versus doxycycline versus placebo in a malaria endemic setting that assessed malaria incidence (see comment below).[46] It found that, compared with placebo, mefloquine had a protective efficacy of 100% (95% CI 93% to 100%; malaria cases: 0 in 202 person-months of exposure with mefloquine *v* 53 in 109 person-months of exposure with placebo). **Versus atovaquone plus proguanil:** The subsequent RCT (976 people) compared mefloquine plus placebo versus atovaquone plus proguanil. It found no clinical cases of malaria among people included in the trial.[47]

Harms: The systematic review identified 10 RCTs (275 people) of mefloquine.[46] It found no significant difference between mefloquine and alternative antimalaria prophylaxis (chloroquine or doxycycline) in withdrawal (29/863 [3%] with mefloquine *v* 20/798 [2%] with alternative prophylaxis; RR 1.32, 95% CI 0.75 to 2.31).[46] Commonly reported adverse effects associated with mefloquine were headache (16%), insomnia (15%), and fatigue (8%).[46] The review found over 500 case reports of mefloquine adverse effects, including four reports of death. These reports suggest that mefloquine is a potentially harmful drug for tourists and business travellers and requires more careful evaluation through an RCT in these groups.[46] The subsequent RCT (976 non-immune tourists and business travellers) found no significant difference in the risk of adverse events between mefloquine plus placebo and atovaquone plus proguanil (313/493 [63.5%] with atovaquone plus proguanil *v* 324/483 [67.1%] with mefloquine; ARR +2.6%, 95% CI –3.4% to +8.5%).[47] However, when adverse effects specifically attributable to the study drug were analysed, there were significantly more adverse effects caused by mefloquine than by atovaquone plus proguanil (204/483 [42%] with mefloquine *v* 149/493 [30%] with atovaquone plus proguanil; RR 1.40, 95% CI 1.18 to 1.66; NNH 9, 95% CI 6 to 17; see comment below). Specifically, mefloquine increased the incidence of "strange or vivid dreams" compared with atovaquone plus proguanil (66/483 [14%] *v* 33/493 [7%]), insomnia (65/483 [13%] *v* 15/493 [3%]), dizziness or vertigo (43/483 [9%] *v* 11/493 [2%]), anxiety (18/483 [4%] *v* 3/493 [1%]), depression (17/483 [4%] *v* 3/493 [1%]), visual difficulties (16/483 [3%] *v* 8/493 [2%]), and headache (19/493 [4%] *v* 32/483 [7%]).[47] Retrospective questionnaire surveys in tourists and business travellers found that sleep disturbance and psychosis were common.[48] One review of 74 dermatological case reports found that up to 30% of mefloquine users developed a maculopapular rash and 4–10% had pruritus.[49] Ten cohort studies in tourists found that more women than men experienced adverse effects (including dizziness, sleep disturbance, headache, diarrhoea, and nausea) with

mefloquine.[43,48,50–57] One retrospective questionnaire survey of 93 668 European travellers to East Africa found that elderly travellers experienced fewer adverse reactions (not specified) with mefloquine than younger travellers ($P < 0.05$).[58] A review of 516 published case reports suggested that many of mefloquine's adverse effects could be explained as a posthepatic syndrome due to mefloquine use combined with concurrent insults to the liver (such as from alcohol, dehydration, an oral contraceptive pill, recreational drugs, and other liver damaging drugs), and that in some users mefloquine may also cause a symptomatic thyroid disturbance.[59]

Comment: Trials in soldiers may not be generalisable to other travellers. The RCT in Indonesian soldiers was a three arm parallel RCT. It compared mefloquine (68 people) versus doxycycline (67 people) versus placebo (69 people). Only the comparison of mefloquine versus placebo is included here.[46] The subsequent RCT of mefloquine versus atovaquone plus proguanil suggested a higher rate of adverse effects with mefloquine than in previous studies, but this RCT only reported adverse events that occurred after starting active treatment, which was 3 weeks earlier in the mefloquine group than in the atovaquone plus proguanil group.

OPTION ATOVAQUONE PLUS PROGUANIL IN ADULTS

One RCT in migrants with limited immunity found that atovaquone plus proguanil reduced the proportion of people with malaria compared with placebo. One RCT found no significant difference between atovaquone plus proguanil and chloroquine plus proguanil in preventing malaria in travellers. One RCT of mefloquine versus atovaquone plus proguanil found no cases of clinical malaria throughout the trial, but found a higher rate of neuropsychiatric harm with mefloquine compared with atovaquone plus proguanil.

Benefits: We found no systematic review, but found three RCTs.[47,60,61] **Versus placebo:** One RCT (299 Indonesian migrants with limited immunity) found that atovaquone plus proguanil significantly decreased the proportion of people with malaria compared with placebo (AR 3/150 [2%] with atovaquone plus proguanil *v* 37/149 [25%] with placebo; $P < 0.001$).[60] **Versus chloroquine plus proguanil:** One multicentre RCT (1083 travellers) comparing atovaquone plus proguanil versus chloroquine plus proguanil found no significant difference in the incidence of malaria (1/511 [0.2%] cases of *P ovale* malaria with atovaquone plus proguanil *v* 3/511 [0.6%] cases of *P falciparum* malaria with chloroquine plus proguanil; ARR 0.4%; RR 0.33, 95% CI 0.03 to 3.16).[61] **Versus mefloquine:** See benefits of mefloquine in adults, p 1037.

Harms: **Versus placebo:** The RCT found that stomatitis ($P < 0.001$) and back pain ($P = 0.009$) occurred significantly more frequently in the atovaquone plus proguanil group, whereas abdominal pain ($P = 0.02$) and malaise ($P = 0.01$) occurred significantly more frequently with placebo (absolute numbers not given).[60] Most adverse events were described as mild or moderate. Four subjects had severe events that were possibly drug related (3 people with abdominal pain and 1 with skin rash).[60] **Versus chloroquine plus**

proguanil: The multicentre RCT in travellers found no significant difference between atovaquone plus proguanil versus chloroquine plus proguanil in one or more adverse events (311/511 [61%] with atovaquone plus proguanil *v* 329/511 [64%] with chloroquine plus proguanil; RR 0.95, 95% CI 0.85 to 1.04).[61] Common adverse effects were mainly gastrointestinal (atovaquone plus proguanil *v* chloroquine plus proguanil: diarrhoea 5% *v* 7%, mouth ulcers 4% *v* 5%, abdominal pain 3% *v* 6%, nausea 2% *v* 7%), neuropsychiatric (atovaquone plus proguanil *v* chloroquine plus proguanil: strange/vivid dreams 4% *v* 3%, dizziness 3% *v* 4%, insomnia 2% *v* 2%), and visual difficulties (2% *v* 2%).[61] **Versus mefloquine:** See harms of mefloquine in adults, p 1037.

Comment: None.

OPTION AMODIAQUINE IN ADULTS

We found no RCTs on the effects of amodiaquine in preventing malaria in travellers. We found limited observational evidence that amodiaquine may cause neutropenia, liver damage, and hepatitis.

Benefits: We found no systematic review and no RCTs in travellers.

Harms: One retrospective cohort study in 10 000 British travellers taking prophylactic amodiaquine reported severe neutropenia in about 1/2000 users.[62] We found 28 case reports describing liver damage or hepatitis in travellers who had taken amodiaquine to treat or prevent malaria.[63–68]

Comment: Amodiaquine use is now restricted to treatment of malaria because of adverse effects.

OPTION PYRIMETHAMINE PLUS DAPSONE IN ADULTS

We found no systematic review and no RCTs in travellers. One RCT in Thai soldiers found insufficient evidence to compare pyrimethamine plus dapsone versus proguanil plus dapsone. We found limited observational evidence that pyrimethamine plus dapsone may cause agranulocytosis.

Benefits: We found no systematic review and no RCTs in travellers. One RCT in Thai soldiers comparing pyrimethamine plus dapsone versus proguanil plus dapsone found no significant difference in *P falciparum* infection rates over 40 days (10.3% with proguanil plus dapsone *v* 11.3% with pyrimethamine plus dapsone; results presented graphically, P value not reported) but found a significantly lower *P vivax* infection rate with proguanil plus dapsone compared with pyrimethamine plus dapsone (1.6% *v* 12.4%; results presented graphically, $P < 0.001$).[69]

Harms: The RCT in Thai soldiers found that fewer than 2% reported any drug related symptoms from pyrimethamine plus dapsone.[69] One retrospective cohort study in 15 000 Swedish travellers taking pyrimethamine plus dapsone reported agranulocytosis in about 1/2000 users.[70]

Comment: None.

OPTION SULFADOXINE PLUS PYRIMETHAMINE IN ADULTS

One RCT found no significant difference between chloroquine plus proguanil and chloroquine plus sulfadoxine plus pyrimethamine in the incidence of *P falciparum* malaria. One retrospective observational study suggested that sulfadoxine plus pyrimethamine was associated with severe cutaneous reactions.

Benefits: We found no systematic review and no RCTs of sulfadoxine plus pyrimethamine alone. We found one RCT of sulfadoxine plus pyrimethamine plus chloroquine versus chloroquine plus proguanil (see benefits of chloroquine plus proguanil in adults, p 1035).

Harms: One retrospective observational study in 182 300 US travellers taking prophylactic sulfadoxine plus pyrimethamine reported severe cutaneous reactions (erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis) in 1/5000–8000 users, with a mortality of about 1/11 000–25 000 users.[70]

Comment: None.

QUESTION What are the effects of antimalaria vaccines in travellers?

OPTION VACCINES

We found no RCTs in travellers of the effects of antimalaria vaccines. One systematic review of antimalaria vaccines in residents of malaria endemic areas has found that the SPf66 vaccine reduces first attacks of malaria compared with placebo.

Benefits: We found no systematic review or RCTs of antimalaria vaccines in travellers. One systematic review (search date 1999, 13 RCTs) of antimalaria vaccines in residents of malaria endemic areas found that the SPf66 vaccine significantly reduced the incidence of first attacks of *P falciparum* malaria compared with placebo (1039/3718 [28%] with SPf66 *v* 1108/3681 [30%] with placebo; RR 0.90, 95% CI 0.84 to 0.96).[71]

Harms: The systematic review found that, in all but one of the RCTs of the SPf66 vaccine, fewer than 10% of recipients reported a systemic reaction (fever, headache, gastric symptoms, muscle pain, dizziness), and fewer than 35% reported a local reaction (inflammation, nodules, pain, erythema, pruritus, induration, injection site warmth).[71] The remaining RCT found a larger proportion of local cutaneous reactions, although these resolved within 24 hours with symptomatic treatment. It also reported higher systemic reaction rates after vaccination (11–16%), although rates after placebo were also higher (10–13%). Surveillance was also more intense than in the other RCTs.

Comment: None.

QUESTION **What are the effects of antimalaria interventions in child travellers?**

OPTION **TOPICAL (SKIN APPLIED) INSECT REPELLENTS CONTAINING DEET IN CHILDREN**

We found no RCTs on the effects of DEET in preventing malaria in child travellers. Case reports in young children found serious adverse effects with DEET.

Benefits: We found no systematic review or RCTs.

Harms: We found 13 case reports of encephalopathic toxicity in children aged under 8 years after excessive use (not clearly defined) of topical (skin applied) insect repellents containing diethyltoluamide (DEET).[72,73]

Comment: Infants and young children have thinner skin and greater surface area to mass ratio.[74] Some authors advise that ethylhexanediol should be issued as a topical (skin applied) insect repellent in preference to DEET in children aged 1–8 years;[75] however, we found insufficient evidence.

OPTION **MEFLOQUINE IN CHILDREN**

We found no RCTs of the effects of mefloquine in preventing malaria in child travellers.

Benefits: We found no systematic review or RCTs.

Harms: Three RCTs in children and adults with symptomatic *P falciparum* malaria found that mefloquine was associated with less vomiting, nausea, anorexia, diarrhoea, and dizziness in children than in adults.[76–78]

Comment: None.

QUESTION **What are the effects of antimalaria interventions in pregnant travellers?**

OPTION **INSECTICIDE TREATED NETS IN PREGNANT TRAVELLERS**

We found no RCTs on the effects of insecticide treated nets in preventing malaria in pregnant travellers. One RCT of pregnant residents of a malaria endemic area found insufficient evidence on the effects of permethrin treated nets in preventing malaria.

Benefits: We found no systematic review or RCTs in pregnant travellers. We found one RCT (341 pregnant women living in Thailand, 3 sites in a malaria endemic area), which compared permethrin treated nets versus non-treated nets versus usual practice.[79] Two sites found no significant difference in the incidence of malaria with treated nets, whereas the third site found that treated nets significantly reduced the incidence of malaria.

Harms: We found no evidence relating to pregnant travellers. The RCT of permethrin treated nets in Thailand found no evidence of toxic effects to mother or fetus.[79]

Comment: Pregnant women are relatively immunosuppressed and are at greater risk of malaria than non-pregnant women.[80] Contracting malaria significantly increases the likelihood of losing the fetus.[81]

OPTION INSECTICIDE TREATED CLOTHING IN PREGNANT TRAVELLERS

We found no RCTs in pregnant travellers of the effects of impregnated clothing.

Benefits: We found no systematic review or RCTs.

Harms: We found little evidence relating to pregnant travellers. **Permethrin:** One RCT (341 pregnant women living in Thailand) of permethrin treated nets found no evidence of toxic effects to mother or fetus.[79] **Diethyltoluamide (DEET):** See harms of topical (skin applied) insect repellents in pregnant travellers, p 1042.

Comment: Pregnant women are relatively immunosuppressed and are at greater risk of malaria than non-pregnant women.[80] Contracting malaria significantly increases the likelihood of losing the fetus.[81]

OPTION TOPICAL (SKIN APPLIED) INSECT REPELLENTS IN PREGNANT TRAVELLERS

We found no RCTs in pregnant travellers. It is unclear which topical (skin applied) insect repellents are safe in pregnancy.

Benefits: We found no systematic review or RCTs.

Harms: We found little evidence in pregnant travellers. **Diethyltoluamide (DEET):** We found one case report indicating an adverse fetal outcome (mental retardation, impaired sensorimotor coordination, craniofacial dysmorphology) in a child whose mother had applied DEET daily throughout her pregnancy.[82] One RCT in pregnant women (897 refugees in a Thai forest area of low malaria endemicity) comparing DEET (median dose 214.2 g per pregnancy) versus a cosmetic cream found no differences in weekly reporting of headache, dizziness, or nausea and vomiting.[83] It also found no adverse effects on infant survival, growth, or development at either birth or 1 year (survival 95.2% with DEET *v* 94.0% without DEET, P = 0.57; mean weight at 1 year 7983 g with DEET *v* 7984 g without DEET). Some animal studies have found that DEET crosses the placental barrier.[84] Animal studies of reproductive effects of DEET are inconclusive.[81,85]

Comment: The RCT in refugees reported that DEET significantly increased the number of women reporting skin warmth (359/449 [80%] with DEET *v* 258/448 [58%] with cosmetic cream; RR 1.39, 95% CI 1.27 to 1.52), although the clinical significance of this is unclear.[83] Pregnant women are relatively immunosuppressed and

are at greater risk of malaria than non-pregnant women.[80] Contracting malaria significantly increases the likelihood of losing the fetus.[81] Some authors advise that only plant derived skin applied insect repellents are safe in pregnancy because of a potential risk of mutagenicity from DEET.[75] However, we found no evidence on the effects of other repellents.

OPTION ANTIMALARIA DRUGS IN PREGNANT TRAVELLERS

We found no RCTs on the effects of antimalaria drugs in pregnant travellers. We found insufficient evidence on the safety of chloroquine, doxycycline, and mefloquine in pregnancy.

Benefits: We found one systematic review (search date 2000), which identified no RCTs in pregnant travellers.[86] It identified 15 RCTs of antimalaria drugs in pregnancy, all in residents of malaria endemic settings. It found that antimalaria prophylaxis significantly reduced the number of women infected at least once compared with no prophylaxis (5/167 [3%] *v* 37/170 [22%]; RR 0.14, 95% CI 0.06 to 0.34) and significantly reduced the number of episodes of fever (22/119 [18%] with prophylaxis *v* 45/108 [42%] with no prophylaxis; RR 0.42, 95% CI 0.27 to 0.66). It found no significant difference between antimalaria prophylaxis and no prophylaxis in the number of perinatal deaths (66/1494 [4%] *v* 64/1426 [4%]; RR 1.02, 95% CI 0.73 to 1.43) or preterm births (17/182 [9%] with prophylaxis *v* 22/175 [12%] with no prophylaxis; RR 0.75, 95% CI 0.42 to 1.35), but found that antimalaria prophylaxis resulted in significantly higher birth weight in the infant compared with no prophylaxis (OR 0.53, 95% CI 0.32 to 0.81).[86]

Harms: **Chloroquine:** One RCT (1464 pregnant long term residents of Burkina Faso) gave no information on adverse effects.[87] **Doxycycline:** Case reports have found that doxycycline taken in pregnancy or while breast feeding may damage fetal or infant bones or teeth.[35] **Mefloquine:** One RCT (339 long term Thai residents) found that mefloquine versus placebo significantly increased the number of women reporting dizziness (28% with mefloquine *v* 14% with placebo; $P < 0.005$), but found no other significant adverse effects on the mother, the pregnancy, or on infant survival or development over 2 years' follow up.[88]

Comment: Pregnant women are relatively immunosuppressed and are at greater risk of malaria than non-pregnant women.[80] Contracting malaria significantly increases the likelihood of losing the fetus.[81] Mefloquine is secreted in small quantities in breast milk, but it is believed that levels are too low to harm infants.[35]

QUESTION What are the effects of antimalaria interventions in airline pilots?

OPTION ANTIMALARIA DRUGS IN AIRLINE PILOTS AND AIRCREW

We found no RCTs on the effects of antimalaria drugs in airline pilots.

Benefits: We found no systematic review or RCTs (see comment below).

Malaria: prevention in travellers

Harms: **Doxycycline:** One retrospective questionnaire survey (28 Israeli pilots) found that 39% experienced adverse effects from doxycycline (abdominal pain 7/28, fatigue 5/28; see comment below).[89] **Mefloquine:** One placebo controlled RCT of adverse effects (23 trainee commercial pilots) found no evidence that mefloquine significantly affected flying performance (mean total number of errors recorded by the instrument coordination analyser 12.6 with mefloquine *v* 11.7 with placebo).[90] One retrospective questionnaire survey (15 Israeli non-aviator aircrew) found that 13% experienced adverse effects from mefloquine (dizziness, nausea, and abdominal pain in 2/15, abdominal discomfort in 1/15; see comment below).[89]

Comment: One retrospective questionnaire survey (28 Israeli pilots taking doxycycline and 15 non-aviator crew taking mefloquine) found no cases of malaria at 4 weeks.[89]

GLOSSARY

Biological control measures Antimosquito interventions based on modifying the local flora or fauna.

QUESTIONS

INTERVENTIONS

ANTIMALARIAL TREATMENTS

Likely to be beneficial

Artemether (as effective as quinine) 1051

High initial dose quinine 1050

Quinine* 1049

Rectal artemisinin (as effective as quinine) 1053

Unknown effectiveness

Intramuscular versus intravenous quinine 1050

ADJUNCTIVE TREATMENTS

Unknown effectiveness

Desferrioxamine mesylate . . .1053

Exchange blood transfusion . .1055

Initial blood transfusion 1055

Likely to be ineffective or harmful

Dexamethasone 1054

To be covered in future updates

Anticonvulsants

Artemotil

Treatment in pregnancy

Covered elsewhere in *Clinical Evidence*

Malaria: prevention in travellers, p 1027

See glossary, p 1056

*Based on consensus. RCTs would be considered unethical.

Key Messages

Antimalarial treatment for complicated falciparum malaria

- **Artemether** Two systematic reviews and three subsequent RCTs found no significant difference in death rates between artemether and quinine in people with severe malaria.
- **High initial dose quinine** One systematic review (3 small RCTs) and one additional RCT found no significant difference in mortality between quinine regimens with high initial quinine dose and those with no loading dose. The systematic review found that high initial dose quinine reduced parasite and fever clearance times compared with no loading dose.
- **Quinine** We found no RCTs comparing quinine versus either placebo or no treatment, but international consensus recommends quinine for the treatment of severe falciparum malaria.
- **Rectal artemisinin** One systematic review found no significant difference in mortality between rectal artemisinin and quinine in people with severe malaria.
- **Intramuscular versus intravenous quinine** One RCT in children found no significant difference between intramuscular and intravenous quinine in recovery times or death. However, the study may have lacked power to detect clinically important differences between treatments.

Malaria: severe, life threatening

Adjunctive treatment for complicated falciparum malaria

- **Desferrioxamine mesylate** One systematic review found weak evidence that the risk of persistent seizures in children with cerebral malaria was reduced with desferrioxamine mesylate compared with placebo.
- **Exchange blood transfusion** One systematic review found no suitable RCTs. A systematic review of case control studies found no significant difference in mortality between exchange transfusion plus antimalarial drugs and antimalarial drugs alone.
- **Initial blood transfusion** One systematic review found no significant difference in mortality between initial and expectant blood transfusion among clinically stable children with malarial anaemia, but found that adverse events were more common with initial blood transfusion. We found no RCTs examining the effects of transfusion in adults with malaria.
- **Dexamethasone** One systematic review found no significant difference in mortality between dexamethasone and placebo, but gastrointestinal bleeding and seizures were more common with dexamethasone.

DEFINITION

Severe malaria is caused by protozoan infection of red blood cells with *Plasmodium falciparum* and comprises a variety of syndromes, which require hospitalisation. Clinically complicated malaria presents with life threatening conditions, which include coma, severe anaemia, renal failure, respiratory distress syndrome, hypoglycaemia, shock, spontaneous haemorrhage, and convulsions. The diagnosis of cerebral malaria should be considered where there is encephalopathy in the presence of malaria parasites. A strict definition of cerebral malaria requires the presence of unrousable coma, and no other cause of encephalopathy (e.g. hypoglycaemia, sedative drugs), in the presence of *P falciparum* infection.[1] This review does not currently cover the treatment of malaria in pregnancy.

INCIDENCE/ PREVALENCE

Malaria is a major health problem in the tropics with 300–500 million clinical cases occurring annually, and an estimated 1.1–2.7 million deaths each year as a result of severe malaria.[2] Over 90% of deaths occur in children under 5 years of age, mainly from cerebral malaria and anaemia.[2] In areas where the rate of malaria transmission is stable (endemic), those most at risk of acquiring severe malaria are children under 5 years old, because adults and older children have partial immunity that offers some protection. In areas where the rate of malaria transmission is unstable (non-endemic), severe malaria affects both adults and children. Non-immune travellers and migrants are also at risk of developing severe malaria.

AETIOLOGY/ RISK FACTORS

Malaria is transmitted by the bite of infected female anopheline mosquitoes. Certain genes are associated with resistance to severe malaria. The human leukocyte antigens HLA-Bw53 and HLA-DRB1*1302 protect against severe malaria. However, associations of HLA antigens with severe malaria are limited to specific populations.[3,4] Haemoglobin S[3] and haemoglobin C[5] are also protective against severe malaria. Genes such as the tumour necrosis factor gene have also been associated with increased susceptibility to severe malaria (see aetiology under malaria: prevention in travellers, p 1027).[6]

PROGNOSIS In children under 5 years of age with cerebral malaria, the estimated case fatality of treated malaria is 19%, although reported hospital case fatality may be as high as 40%.[1,7] Neurological sequelae persisting for more than 6 months occur in more than 2% of survivors, and include ataxia, hemiplegia, speech disorders, behavioural disorders, epilepsy, and blindness. Severe malarial anaemia has a case fatality rate higher than 13%.[7] In adults the mortality of cerebral malaria is 20%; this rises to 50% in pregnancy, and neurological sequelae occur in about 3% of survivors.[8]

AIMS OF INTERVENTION To prevent death and cure the infection; to prevent long term disability; to minimise neurological sequelae resulting from cerebral malaria, with minimal adverse effects of treatment.

OUTCOMES Death; parasite clearance at day 7 or 14; parasite clearance time, p 1056; fever clearance time, p 1056; time to walking and drinking; coma recovery time; neurological sequelae at follow up; adverse events.

METHODS *Clinical Evidence* search and appraisal June 2003. We applied the World Health Organization criteria for severe malaria when deciding which RCTs to include.[1]

QUESTION **What are the effects of antimalarial treatments for complicated falciparum malaria in non-pregnant people?**

OPTION QUININE VERSUS PLACEBO OR NO TREATMENT

We found no RCTs comparing quinine versus either placebo or no treatment, but international consensus recommends quinine for the treatment of severe falciparum malaria.

Benefits: Placebo controlled RCTs would be inappropriate in severe malaria (see comment below).

Harms: We found two observational studies on hypoglycaemia associated with quinine. One study in people with severe malaria treated with quinine in Thailand found a correlation between plasma quinine and insulin levels during hypoglycaemic episodes ($P = 0.007$).[9] One prospective cohort study in Zaire (9 children and 19 adults) treated severe malaria with intravenous quinine (average dose 8.5 mg base/kg over 1 hour every 8 hours).[10] Nine people developed significant hypoglycaemia (glucose < 2.8 mmol/L), which was associated with high plasma insulin levels. It is not clear from these studies whether hypoglycaemia was caused by malaria or by quinine administration.

Comment: The use of quinine to treat severe malaria was established before modern trial methods were developed. In a case series in Singapore (1944–1945), 15 adults with acute severe malaria were treated with continuous intravenous quinine.[11] Thirteen recovered and two comatose people died. In a non-comparative study conducted in Zaire (1987), intravenous quinine (10 mg/kg 8 hourly for 3 days) was given to 34 children (aged 7 months to 13 years) with severe or moderate falciparum malaria.[12] One child who was comatose on admission died. The mean parasite clearance time (see glossary,

p 1056) was 59.6 hours. The mean fever clearance time (see glossary, p 1056) was 44.1 hours. Thirty three children were clinically well and had negative blood slides on day 7. Reviews[13,14] and consensus statements[1,15,16] recommend quinine for treatment of severe falciparum malaria, particularly in chloroquine resistant areas.

OPTION INTRAMUSCULAR VERSUS INTRAVENOUS QUININE

One RCT in children found no significant difference between intramuscular and intravenous quinine in recovery times or death. However, the study may have lacked power to detect clinically important differences between treatments.

Benefits: We found no systematic review. We found one RCT (59 Kenyan children < 12 years old in 1989–1990), which compared intramuscular versus intravenous quinine (20 mg salt/kg loading immediately followed by 10 mg salt/kg 12 hourly) versus standard dose intravenous quinine in severe falciparum malaria.[17] The RCT found no significant difference in mortality (3/20 [15%] deaths with im quinine *v* 1/18 [5.6%] with iv quinine; RR 2.7, 95% CI 0.3 to 23.7), in mean parasite clearance time (see glossary, p 1056) (57 hours with im quinine *v* 58 hours with iv quinine; WMD –1.0 hours, 95% CI –12.2 hours to +10.2 hours), in mean recovery times to drinking (47 hours with im quinine *v* 32 hours with iv quinine; WMD +15 hours, 95% CI –5.6 hours to +35.6 hours), or in mean recovery times to walking (98 hours with im quinine *v* 96 hours with iv quinine; WMD +2.0 hours, 95% CI –24.5 hours to +28.5 hours).

Harms: Neurological sequelae were reported in two children in the intramuscular group, and one child in the intravenous group had transient neurological sequelae that were not specified (2/20 [10%] with im quinine *v* 1/18 [5.6%] with iv quinine; RR 1.8, 95% CI 0.2 to 18.2).[17]

Comment: Quinine concentration profiles were similar with both routes of administration, and peak concentrations were achieved soon after intramuscular injection. The sample size might have been insufficient to rule out important clinical differences.[17]

OPTION HIGH INITIAL DOSE QUININE VERSUS NO LOADING DOSE

One systematic review (3 small RCTs) and one additional RCT found no significant difference in mortality between quinine regimens with high initial quinine dose and those with no loading dose. The systematic review found that high initial dose quinine reduced parasite and fever clearance times compared with no loading dose.

Benefits: We found one systematic review (search date 2002, 3 RCTs, 92 people)[18] and one additional RCT.[19] The systematic review found no significant difference in mortality between high initial dose of quinine (20 mg salt/kg or 16 mg base/kg given im or iv) and no loading dose, followed in both groups by standard dose quinine (2 RCTs; 2/35 [5.7%] died with high initial dose *v* 5/37 [13.5%] with no loading dose; RR 0.43, 95% CI 0.09 to 2.15).[18] One of the included RCTs (39 children) found no significant difference between

high initial dose and no loading dose in mean time to recover consciousness (14 hours with high initial dose *v* 13 hours with no loading dose; WMD +1.0 hours, 95% CI −8.8 hours to +10.8 hours).[17] Parasite clearance time and fever clearance time (see glossary, p 1056) were shorter for the high initial dose quinine group than for the group with no loading dose (parasite clearance time: 2 RCTs, 67 people; WMD −7.4 hours, 95% CI −13.2 hours to −1.6 hours; fever clearance time: 2 RCTs, 68 people; WMD −11.1 hours, 95% CI −20.0 hours to −2.2 hours). The additional RCT (72 children aged 8 months to 15 years in Togo [1999–2000]) found no significant difference between high initial dose intravenous quinine regimen (20 mg quinine salt/kg over 4 hours, then 10 mg quinine salt/kg 12 hourly) and no loading dose (15 mg salt/kg 12 hourly) in mortality (2/35 [6%] with high initial dose *v* 2/37 [5%] with no loading dose; RR 1.06, 95% CI 0.16 to 7.1).[19] It found no significant difference between high initial dose and no loading dose for recovery of consciousness or parasite clearance time (recovery of consciousness: 35.5 hours with high initial dose *v* 28.6 hours with no loading dose; WMD +6.9 hours, 95% CI −0.6 hours to +14.4 hours; time to 100% parasite clearance: 48 hours with high initial dose *v* 60 hours with no loading dose; P value not reported).

Harms: The systematic review found no significant difference between high initial dose of quinine and no loading dose in rate of hypoglycaemia (2 RCTs; 4/35 [11%] hypoglycaemia with high initial dose *v* 3/37 [8%] with no loading dose; RR 1.39, 95% CI 0.32 to 6.00).[18] One RCT (33 people) included in the review found that high initial dose quinine significantly increased transient partial hearing loss compared with no loading dose (10/17 [59%] *v* 3/16 [19%]; RR 3.14, 95% CI 1.05 to 9.38).[20] One RCT (39 children) included in the review found no significant difference between high initial dose of quinine and no loading dose in neurological sequelae (1/18 [6%] high initial dose *v* 2/21 [10%] no loading dose; RR 0.58, 95% CI 0.06 to 5.91).[17]

Comment: The RCTs may have been too small to detect a clinically important difference.[17,19,20]

OPTION ARTEMETHER VERSUS QUININE

Two systematic reviews and three subsequent RCTs found no significant difference in death rates between artemether and quinine in people with severe malaria.

Benefits: We found two systematic reviews[21,22] and three subsequent RCTs.[23–25] The first review (search date not reported, 7 RCTs, 1919 adults and children) analysed individual participant data.[21] It found no significant difference in mortality between intramuscular artemether and either intravenous or intramuscular quinine (im quinine in 1 RCT only) in severe falciparum malaria (mortality 136/961 [14%] with artemether *v* 164/958 [17%] with quinine; OR 0.80, 95% CI 0.62 to 1.02). Parasite clearance was faster with artemether than with quinine (HR 0.62, 95% CI 0.56 to 0.69). The review found no significant difference in the speed of coma recovery, fever clearance time (see glossary, p 1056), or neurological

sequelae between artemether and quinine (coma recovery time with quinine: HR 1.09, 95% CI 0.97 to 1.22; fever clearance time with quinine: HR 1.01, 95% CI 0.90 to 1.15; neurological sequelae: 81/807 [10%] with artemether *v* 91/765 [12%] with quinine; OR 0.82, 95% CI 0.59 to 1.15). The second review (search date 1999, 11 RCTs, 2142 people) found a small significant reduction in mortality for intramuscular artemether compared with intravenous quinine (OR 0.72, 95% CI 0.57 to 0.91).[22] However, more rigorous analysis excluding three poorer quality RCTs found no significant difference in mortality (OR 0.79, 95% CI 0.59 to 1.05). The review found no significant difference in neurological sequelae at recovery between artemether and quinine (OR 0.8, 95% CI 0.52 to 1.25). The first subsequent RCT (105 people aged 15–40 years with cerebral malaria in Bangladesh) compared intramuscular artemether (160 mg initially, then 80 mg/kg once daily) versus intravenous quinine (loading dose 20 mg/kg, then 10 mg/kg 8 hourly).[23] It found no significant difference in death rates between artemether and quinine (9/51 [18%] with artemether *v* 10/54 [19%] with quinine; OR 0.94, 95% CI 0.35 to 2.55). Mean fever clearance time and coma recovery time were significantly longer for artemether than for quinine (fever clearance time: 58 hours with artemether *v* 47 hours with quinine; WMD 11.0 hours, 95% CI 1.6 hours to 20.4 hours; coma recovery time: 74 hours with artemether *v* 53 hours with quinine; WMD 20.8 hours, 95% CI 3.6 hours to 38.0 hours). There was no significant difference in mean parasite clearance time (see glossary, p 1056) between artemether and quinine (52 hours with artemether *v* 61 hours with quinine; WMD −8.6 hours, 95% CI −22.5 hours to +5.3 hours). The second subsequent RCT (41 children with severe malaria in Sudan, 40 analysed) compared intramuscular artemether (3.2 mg/kg loading dose, then 1.6 mg/kg daily) versus intravenous quinine (loading dose 20 mg/kg, then 10 mg/kg 8 hourly).[24] It found that artemether significantly increased fever clearance time but found no significant difference between artemether and quinine in time to parasite clearance (mean fever clearance time: 30.5 hours with artemether *v* 18 hours with quinine; $P = 0.02$; mean parasite clearance time: 16 hours with artemether *v* 22.4 hours with quinine; $P > 0.05$). It found that one child died with quinine compared with no deaths with artemether (0/20 [0%] with artemether *v* 1/21 [5%] with quinine; P value not reported). The third subsequent RCT (77 comatosed children aged 3 months to 15 years with cerebral malaria) compared intramuscular artemether (1.6 mg/kg 12 hourly) versus intravenous quinine (10 mg/kg 8 hourly).[25] It found no significant difference in death rates between artemether and quinine (3/38 [8%] with artemether *v* 2/39 [5%]; P value not reported). There was no significant difference in mean fever clearance time, coma recovery time, and parasite clearance time (fever clearance time: 31 hours with artemether *v* 36 hours with quinine; coma recovery time: 21 hours with artemether *v* 26 hours with quinine; parasite clearance time: 36 hours with artemether *v* 41 hours with quinine; P value not reported for any comparison).

Harms: The two systematic reviews[21,22] and one of the subsequent RCTs[23] found no significant difference in neurological sequelae between artemether and quinine (systematic reviews: see benefits above;

additional RCT: 3/51 [6%] with artemether *v* 1/54 [2%] with quinine; RR 3.18, 95% CI 0.34 to 29.56). However, in the first review, rates for the combined outcome of death or neurological sequelae were lower for artemether than for quinine (OR 0.77, 95% CI 0.62 to 0.96; P = 0.02).[21] The second subsequent RCT found that one child treated with quinine developed hypoglycaemia (0/20 [0%] with artemether *v* 1/21 [5%] with quinine; P value not reported).[24] It reported no neurological problems in either treatment group after 28 days of follow up. The third subsequent RCT found no significant difference in transient neurological sequelae between artemether and quinine (2/38 [5%] with artemether *v* 1/39 [3%] with quinine; P value not reported).[25]

Comment: We found a fourth subsequent RCT (52 people).[26] However, it was not clear whether participants had severe malaria, and outcomes were poorly reported. The third subsequent RCT did not use loading doses of either artemether or quinine at the beginning of treatment.[25]

OPTION RECTAL ARTEMISININ DERIVATIVES (ARTEMISININ OR ARTESUNATE) VERSUS QUININE

One systematic review found no significant difference in mortality between rectal artemisinin and quinine in people with severe malaria.

Benefits: We found one systematic review (search date 1999, 3 RCTs) comparing rectal artemisinin versus quinine in severe malaria.[22] Two RCTs were conducted in Vietnam and one in Ethiopia (1996–1997). Meta-analysis found lower mortality with artemisinin and quicker coma recovery time, but the difference was not significant (mortality, 3 RCTs: 9/87 [10%] with artemisinin *v* 16/98 [16%] with quinine; RR 0.73, 95% CI 0.35 to 1.50; coma recovery, 2 RCTs, 59 people: WMD –9.0 hours, 95% CI –19.7 hours to +1.7 hours). Fever clearance time (see glossary, p 1056) was not significantly different (no figures provided). We found no RCTs comparing rectal artesunate versus quinine.

Harms: One RCT found that artemisinin significantly reduced the risk of hypoglycaemia compared with quinine (3/30 [10%] with artemisinin *v* 19/30 [63%] with quinine; RR 0.16, 95% CI 0.05 to 0.48).[27]

Comment: The World Health Organization is currently conducting a trial of prompt administration of rectal artesunate for severe malaria by paramedical staff before referral to hospital (Olliaro P, personal communication, 2002).

QUESTION What are the effects of adjunctive treatment for complicated falciparum malaria in non-pregnant people?

OPTION DESFERRIOXAMINE MESYLATE

One systematic review found weak evidence that the risk of persistent seizures in children with cerebral malaria was reduced with desferrioxamine mesylate compared with placebo.

Malaria: severe, life threatening

Benefits: **Versus placebo:** We found one systematic review (search date 2003, 2 RCTs, 435 children > 6 years of age with cerebral malaria treated with quinine) of desferrioxamine mesylate (100 mg/kg daily iv for 72 hours) versus placebo.[28] Both RCTs were conducted in Zambia (1990–1991). The review found no difference in overall mortality but results were heterogeneous (39/217 [18%] with desferrioxamine *v* 28/218 [13%] with placebo; RR 1.40, 95% CI 0.89 to 2.18). The review found that desferrioxamine mesylate significantly reduced the risk of persistent seizures (93/168 [55.4%] with desferrioxamine *v* 115/166 [69.3%] with placebo; RR 0.80, 95% CI 0.67 to 0.95).

Harms: One RCT included in the review found no significant difference between desferrioxamine mesylate and placebo for phlebitis or recurrent hypoglycaemia (phlebitis: 26/172 [15%] with desferrioxamine *v* 20/172 [12%] with placebo; RR 1.30, 95% CI 0.76 to 2.24; recurrent hypoglycaemia: 43/172 [25%] with desferrioxamine *v* 29/172 [17%] with placebo; RR 1.48, 95% CI 0.97 to 2.26).[29]

Comment: The trials were probably underpowered to detect a clinically important difference in adverse events.

OPTION DEXAMETHASONE

One systematic review found no significant difference in mortality between dexamethasone and placebo, but gastrointestinal bleeding and seizures were more common with dexamethasone.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 2 RCTs, 143 people with severe/cerebral malaria treated with quinine) that compared dexamethasone versus placebo over 48 hours.[30] One RCT was conducted in Indonesia and the other in Thailand. The review found no significant difference in mortality (14/71 [20%] with dexamethasone *v* 16/72 [25%] with placebo; RR 0.89, 95% CI 0.47 to 1.68). One RCT found a longer mean time between start of treatment and coma resolution with dexamethasone (76 hours with dexamethasone *v* 57 hours with placebo; $P < 0.02$),[31] but the other RCT found no significant difference (83.4 hours with dexamethasone *v* 80.0 hours with placebo; WMD +3.4 hours, 95% CI –31.3 hours to +38.1 hours).[32]

Harms: The review found that dexamethasone significantly increased gastrointestinal bleeding and seizures compared with placebo (gastrointestinal bleeding: 7/71 [10%] with dexamethasone *v* 0/72 [0%] with placebo; RR 8.17, 95% CI 1.05 to 63.6; seizures: 1/71 [15.5%] with dexamethasone *v* 3/72 [4%] with placebo; RR 3.32, 95% CI 1.05 to 10.47).[30]

Comment: No effect of steroids on mortality was shown but the trials were small. The effect of steroids on disability was not reported.

OPTION INITIAL BLOOD TRANSFUSION FOR TREATING MALARIAL ANAEMIA

One systematic review found no significant difference in mortality between initial and expectant blood transfusion among clinically stable children with malarial anaemia, but found that adverse events were more common with initial blood transfusion. We found no RCTs examining the effects of transfusion in adults with malaria.

Benefits: We found one systematic review (search date 1999, 2 RCTs, 230 children with malarial anaemia; packed cell volume range 12% to 17%).[33] The first RCT (116 children) compared initial blood transfusion versus conservative treatment in children from Tanzania, and the second RCT (114 children) compared blood transfusion versus iron supplements in children from the Gambia. Both trials excluded children who were clinically unstable with respiratory distress or signs of cardiac failure. Meta-analysis found fewer deaths in the transfused children but the difference was not significant (1/118 [1%] with transfusion *v* 3/112 [3%] with control; RR 0.41, 95% CI 0.06 to 2.70). We found no RCTs examining the effects of transfusion in adults with malaria.

Harms: Coma and convulsions occurred more often after transfusion (8/118 [6.8%] with transfusion *v* 0/112 [0%] without transfusion; RR 8.6, 95% CI 1.1 to 66.0).[33] Seven of the eight adverse events occurred in one RCT. Meta-analysis combining deaths and severe adverse events found no significant difference between transfused and non-transfused people (8/118 [7%] with transfusion *v* 3/112 [3%] without transfusion; RR 2.5, 95% CI 0.7 to 9.3). Transmission of hepatitis B or HIV was not reported.

Comment: Studies were small and loss to follow up was greater than 10%, both of which are potential sources of bias. In the first RCT one child in the transfusion group and one child in the conservative treatment group required an additional transfusion after clinical assessment. In the second RCT 10 children allocated to receive iron supplements later required transfusion when packed cell volume fell below 12% or they showed signs of respiratory distress.

OPTION EXCHANGE BLOOD TRANSFUSION

One systematic review found no suitable RCTs. A systematic review of case control studies found no significant difference in mortality between exchange transfusion plus antimalarial drugs and antimalarial drugs alone.

Benefits: We found one systematic review (search date 2001).[34] It found no suitable RCTs in people with malaria. We found no additional RCTs that met our inclusion criteria (see comment below).

Harms: We found no good evidence.

Comment: We found one systematic review of case control studies[34] and one small RCT.[35] The review (search date 2001, 8 studies, 279 people) found no significant difference in mortality between exchange transfusion plus antimalarial drugs and antimalarial drugs only (8 studies; OR for death 1.2, 95% CI 0.7 to 2.1).[34] Admission criteria

for exchange transfusion varied in the included studies but generally parasitaemia was greater than 10%, and most people had failed to improve after 24 hours of antimalarial treatment. The methods and volumes used for exchange transfusion also varied. Those who received exchange blood transfusions had higher mean levels of parasitaemia before treatment began (26% with exchange transfusion *v* 11% with no exchange transfusion; $P < 0.05$) and fulfilled more World Health Organization criteria for the diagnosis of severe malaria (mean 3.6 with exchange transfusion *v* 2.8 with no exchange transfusion; $P = 0.03$). The RCT compared exchange transfusion plus antimalarial drugs versus antimalarial drugs, but it included only eight people.[35]

GLOSSARY

Fever clearance time The time between commencing treatment and the temperature returning back to normal.

Parasite clearance time (PCT) The time between commencing treatment and the first negative blood test. PCT 50 is the time taken for parasites to be reduced to 50% of the first test value and PCT 90 is the time taken for parasites to be reduced to 10% of the first test value.

Substantive changes

Artemether versus quinine Two RCTs added;[24,25] conclusions unchanged.

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Antibiotics for throat carriage (reduce carriage but unknown effect on risk of disease) . .1060

Pre-admission parenteral penicillin in suspected cases*. 1061

Prophylactic antibiotics in contacts* 1060

To be covered in future updates

Hospital treatment of meningococcal disease

Vaccines (monovalent/multivalent, polysaccharide alone, or conjugate)

*Based on observational evidence. RCTs unlikely to be conducted

See glossary, p 1062

Key Messages

- **Antibiotics for throat carriage (reduce carriage but unknown effect on risk of disease)** RCTs have found that antibiotics reduce throat carriage of meningococci compared with placebo. We found no evidence that eradicating throat carriage reduces the risk of meningococcal disease.
- **Pre-admission parenteral penicillin in suspected cases** We found no RCTs on the effects of pre-admission antibiotics in suspected cases. It is unlikely that RCTs will be performed because of the unpredictably rapid course of meningococcal disease in some people, the likely risks involved in delaying treatment, and the low risk of causing harm. Most observational studies suggest benefit with antibiotics, but at least one did not.
- **Prophylactic antibiotics in contacts** We found no RCTs on the effects of prophylactic antibiotics on the incidence of meningococcal disease among contacts. RCTs are unlikely to be performed because the intervention has few associated risks whereas meningococcal disease has high associated risks. Observational evidence suggests that antibiotics reduce the risk of meningococcal disease. We found no evidence regarding which contacts should be treated.

DEFINITION Meningococcal disease is any clinical condition caused by *Neisseria meningitidis* (the meningococcus) groups A, B, C, W135, or other serogroups. These conditions include purulent conjunctivitis, septic arthritis, meningitis, and septicaemia (see glossary, p 1063) with or without meningitis.

INCIDENCE/ PREVALENCE Meningococcal disease is sporadic in temperate countries, and is most commonly caused by group B or C meningococci. Annual incidence in Europe varies from fewer than 1 case/100 000 people in France, up to 4–5 cases/100 000 people in the UK and Spain, and in the USA it is 0.6–1.5/100 000 people.[1,2] Occasional outbreaks occur among close family contacts (see glossary, p 1062), secondary school pupils, military recruits, and students living in halls of residence. Sub-Saharan Africa has regular epidemics in countries lying in the expanded "meningitis belt", reaching 500/100 000 people during epidemics, which are usually due to serogroup A, although recent outbreaks of serogroup W135 cause concern.[3–5]

AETIOLOGY/ RISK FACTORS The meningococcus colonises and infects healthy people and is transmitted by close contact, probably by exchange of upper respiratory tract secretions (see table 1, p 1065).[6–14] Risk of transmission is greatest during the first week of contact.[9] Risk factors include crowding and exposure to cigarette smoke.[15] In the UK, children younger than 2 years have the highest incidence, with a second peak between ages 15–24 years. There is currently an increased incidence of meningococcal disease among university students, especially among those in their first term and living in catered accommodation,[16] although we found no accurate numerical estimate of risk from close contact in, for example, halls of residence. Close contacts of an index case have a much higher risk of infection than do people in the general population.[9,12,13] The risk of epidemic spread is higher with groups A and C meningococci than with group B meningococci.[6–8,10] It is not known what makes a meningococcus virulent. Certain clones tend to predominate at different times and in different groups. Carriage of meningococcus in the throat has been reported in 10–15% of people; recent acquisition of a virulent meningococcus is more likely to be associated with invasive disease.

PROGNOSIS Mortality is highest in infants and adolescents, and is related to disease presentation and availability of therapeutic resources. In developed countries case fatality rates have been around 19–25% for septicaemia, 10–12% for meningitis plus septicaemia, and less than 1% in meningitis alone, but an overall reduction in mortality was observed in recent years in people admitted to paediatric intensive care units.[17–21]

AIMS OF INTERVENTION To prevent disease in contacts; to prevent development of meningococcal disease and its complications.

OUTCOMES Rates of infection; rates of eradication of throat carriage; adverse effects of treatment; case–fatality; sequelae.

METHODS *Clinical Evidence* search and appraisal March 2003, including a search for observational studies. In addition, the authors drew from a collection of references from the pre-electronic data era and cross-references from relevant papers.

QUESTION **What are the effects of interventions to prevent meningococcal disease in contacts and carriers?**

OPTION PROPHYLACTIC ANTIBIOTICS IN CONTACTS

We found no RCTs on the effects of prophylactic antibiotics on the incidence of meningococcal disease among contacts. One observational study suggested that sulfadiazine reduced the risk of meningococcal disease over 8 weeks. We found no good evidence regarding which contacts should be treated.

Benefits: We found no systematic review and no RCTs examining the effect of prophylactic antibiotics in people in contact (see glossary, p 1062) with someone with meningococcal disease (see comment below). **Rifampicin:** We found only anecdotal data. **Phenoxymethylpenicillin:** We found one retrospective study, but the results of that study cannot be generalised beyond the sample tested.[22] **Sulfadiazine:** One cohort study of soldiers in temporary troop camps in the 1940s compared the incidence of meningococcal disease in camps where sulfadiazine (sulphadiazine) was given to everyone after a meningococcal outbreak versus the incidence in camps where no prophylaxis was given.[23] The study reported a higher incidence of meningococcal disease in soldiers not given prophylaxis (approximate figures 17/9500 [0.18%] *v* 2/7000 [0.03%] over 8 weeks).

Harms: **Rifampicin:** No excess adverse effects compared with placebo were found in RCTs on eradicating throat carriage of meningococcal disease.[24,25] However, rifampicin is known to cause various adverse effects, including turning urine and contact lenses orange, and inducing hepatic microsomal enzymes, potentially rendering oral contraception ineffective. Rifampicin prophylaxis may be associated with emergence of resistant strains.[26] **Sulfadiazine:** One in 10 soldiers experienced minor adverse events, including headache, dizziness, tinnitus, and nausea.[23]

Comment: RCTs addressing this question are unlikely to be performed because the intervention has few associated risks whereas meningococcal disease has high associated risks. RCTs would also need to be large to find a difference in incidence of meningococcal disease. In the sulfadiazine cohort study, the two infected people in the treatment group only became infected after leaving the camp.[23]

OPTION ANTIBIOTICS FOR THROAT CARRIAGE

RCTs have found that antibiotics reduce throat carriage of meningococci compared with placebo. We found no evidence that eradicating throat carriage reduces the risk of meningococcal disease.

Benefits: We found no systematic review. **Incidence of disease:** We found no RCTs or observational studies that examined whether eradicating throat carriage (see glossary, p 1062) of meningococcus reduces the risk of meningococcal disease. **Throat carriage:** We found five placebo controlled RCTs that examined the effect of antibiotics on carriage of meningococcus in the throat (see table 2, p 1066).[24,25,27–29] All trials found that antibiotics (rifampicin, minocycline, or ciprofloxacin) achieved high rates of eradication (ranging from 90–97%), except one trial of rifampicin in students with heavy growth on culture, in which the rate of eradication was 73%.[24] Eradication rates on placebo ranged from 9–29%. We found seven RCTs that compared different antibiotic regimens (see table 3, p 1067).[30–36] Three RCTs found no significant difference between rifampicin and minocycline, ciprofloxacin, or intramuscular ceftriaxone.[31,34,36] A fourth RCT randomised households to different treatments and found that intramuscular ceftriaxone increased eradication rates compared with rifampicin.[33] However, that trial used cluster randomisation, and therefore the results should be interpreted with caution. Another trial found no significant difference between oral azithromycin and rifampicin in eradicating meningococcal throat carriage.[35]

Harms: **Minocycline:** One RCT reported adverse effects (1 or more of nausea, anorexia, dizziness, and abdominal cramps) in 36% of participants.[31] **Rifampicin:** See harms of postexposure antibiotic prophylaxis, p 1060. **Ciprofloxacin:** Trials of single dose prophylactic regimens reported no more adverse effects than with comparators or placebo.[28,29,34] Ciprofloxacin is contraindicated in pregnancy and in children because animal studies have indicated a possibility of articular cartilage damage in developing joints.[37] **Ceftriaxone:** Two trials of ceftriaxone found no significant adverse effects.[33,34] In one trial, 12% of participants complained of headache.[35] Ceftriaxone is given as a single intramuscular injection. **Azithromycin:** No serious or moderate adverse effects were reported, but nausea, abdominal pain, and headache of short duration were reported equally in the azithromycin and rifampicin treated groups.[35]

Comment: Eradicating meningococcal throat carriage is a well accepted surrogate for preventing meningococcal disease. It is unlikely that any RCT will be conducted on the efficacy of prophylactic antibiotics in preventing secondary community acquired meningococcal disease in household contacts because the number of participants required would be large.

QUESTION What are the effects of interventions to treat suspected cases before admission to hospital?

OPTION PRE-ADMISSION PARENTERAL PENICILLIN

We found no RCTs on the effects of pre-admission parenteral penicillin in meningococcal disease. Most observational studies we found suggest benefit with antibiotics, but at least one found no benefit.

Meningococcal disease

Benefits: We found seven observational studies on the effect of pre-admission parenteral penicillin in people of all ages with meningococcal disease (see table 4, p 1068).[38–44] We also found two reports of pooled data from six of the observational studies.[47,48] The first report (3 English observational studies,[38–40] 487 people) found that antibiotics significantly reduced mortality (OR 2.61, 95% CI 1.04 to 7.18).[47] However, the second report (664 people; the same people in the English studies[38–40] plus partial data from a Danish cohort[45]) found no significant benefit with antibiotics (outcomes not specified; OR 0.82, 95% CI 0.43 to 1.56).[48]

Harms: It is difficult to differentiate people with early features of meningococcal disease from those with self limiting illnesses. According to more or less strict criteria for suspicion, between 28% and 89% of individuals receive parenteral penicillin unnecessarily.[49–52] One study of the harms of penicillin found that anaphylaxis occurred in about 0.04% of cases and that fatal anaphylaxis occurred in about 0.002% of cases.[53]

Comment: We found no studies about the relationship between early treatment with antibiotics and development of subsequent antibiotic resistance. Retrospective observational studies usually provide limited evidence for treatment interventions. In the case of pre-admission penicillin, no study was able to adjust adequately for clinical severity, stage of disease progression, or cointerventions such as earlier suspicion and referral (following media coverage and official recommendation). However, it is unlikely that RCTs on pre-admission antibiotics will be performed because of the unpredictably rapid course of disease in some people and the likely risks involved in delaying treatment, combined with a low risk of causing harm.

GLOSSARY

Carrier Individual in whom *N meningitidis* can be retrieved from nasopharynx by swabbing. Most carriers are asymptomatic and unaware of their carriage status.

Confirmed case Clinical diagnosis of meningitis, septicaemia or other invasive disease plus the finding of *N meningitidis* (culture, polymerase chain reaction, Gram staining) in normally sterile site or the presence of meningococcal antigen in blood, cerebrospinal fluid or urine.[54]

Contact Those recently exposed to an index case of meningococcal disease and who have a higher risk of developing the disease when compared with the general population (usually close, prolonged contact in the same household or direct contact with respiratory secretions). [54]

Meningitis (meningococcal) A case with clinical signs of meningitis (i.e. fever, headache, vomiting, nuchal rigidity) plus laboratory evidence of meningococcal infection, such as a positive blood or cerebrospinal fluid culture or polymerase chain reaction.[55]

Possible case Clinical diagnosis of meningitis or septicaemia or other invasive disease where the public health physician, in consultation with the physician and microbiologist, considers that diagnoses other than meningococcal disease are at least as likely.[54]

Probable case Clinical diagnosis of meningitis or septicaemia or other invasive disease where the public health physician, in consultation with the physician and microbiologist, considers that meningococcal infection is the most likely diagnosis.[54]

Septicaemia (meningococcal) A case with systemic signs and symptoms of infection (i.e. fever, malaise, patient "unwell") plus a skin rash, which can be purpuric (petechial, ecchymotic) or, less often, maculopapular. Laboratory provides evidence of meningococcal infection in the blood.

Suspected case Cases with early clinical signs of meningitis, septicaemia or both, where the health care worker (usually GP) suspects meningococcal aetiology.

TABLE 1 **Risk of infection among contacts (see text, p 1059).**

Group of meningococcus	Setting	Risk
A	Household contacts in Milwaukee, USA[6]	AR 1100/100 000; RR not possible to estimate
	General population in Santiago province, Chile	Attack rate in general population 23–262/100 000 (1941 and 1942)
	Household contacts in Chile[7]	Attack rate in household contacts 250/100 000 (0.25%) over both years
	General population in Indianapolis, USA[8]	AR 4500/100 000; RR not possible to estimate
B	Household contacts in Belgium[9]	RR 1245*
	Nursery schools[9]	RR 23*
	Day care centres[9]	RR 76*
C	Household contacts from two lower socioeconomic groups Dade County, Florida, USA[10]	Attack rate in two communities 13/100 000 population. Attack rate in household contacts 5/85 (582/100 000)
Unspecified	School based clusters in USA. Predominant meningococcal types: 13 clusters of Gp C, 7 Gp B, 1 Gp Y, 1 GpC/W135 (impossible to distinguish)[11]	RR 2.3*
	Household contacts from several states in USA, meningococcus types B and C predominantly[12]	RR 500–800*
	Household contact in Norway. Meningococcus types A, B, and C predominantly[13]	RR up to 4000*
	Schools in Vermont. Predominant meningococcus type C[14]	OR 14.1 (95% CI 1.6 to 127)

*Compared with the risk in the general population.

TABLE 2 **Effect of antibiotics on throat carriage: results of placebo controlled RCTs (see text, p 1061).**

Antibiotic	Group of meningococcus	Participants	Eradication		RR (95% CI)
			Treatment (%)	Placebo (%)	
Rifampicin (oral)[24]	B, X, Z	30 students with heavy growth on culture	11/15 (73)	2/15 (13)	5.5 (1.5 to 21)
Rifampicin (oral)[25]	B, C, Y, Z29 E, W 135, NT	76 airforce recruits	36/38* (95)	3/22‡ (14)	7.0 (5.8 to 8.1)
Minocycline (oral)[27]	Predominantly Y (63%)	149 naval recruits	37/41 (90)†	14/48 (29)§	3.1 (2.6 to 3.6)

Postherpetic neuralgia

Search date May 2003

David Wareham

QUESTIONS

INTERVENTIONS

Key Messages

Preventing postherpetic neuralgia

- **Aciclovir, famciclovir, valaciclovir, netivudine** One systematic review has found limited evidence from RCTs that aciclovir given for 7–10 days reduced pain at 1–3 months. One systematic review found that famciclovir reduces mean pain duration after acute herpes zoster compared with placebo. One RCT found that valaciclovir reduced the prevalence of postherpetic neuralgia at 6 months compared with aciclovir. One RCT found no significant difference in effectiveness between netivudine and aciclovir. One RCT found no significant difference between valaciclovir and famciclovir in the resolution of postherpetic neuralgia or in adverse effects over 7 days.
- **Amitriptyline** One small RCT found no significant difference between amitriptyline and placebo started within 48 hours of rash onset in the prevalence of postherpetic neuralgia at 6 months. The RCT may have lacked power to detect a clinically important difference.
- **Topical antiviral agents (idoxuridine) for pain at 6 months** One systematic review has found that idoxuridine increases short term pain relief in acute herpes zoster compared with placebo or oral aciclovir, but found no significant difference at 6 months.

- **Corticosteroids** Systematic reviews found conflicting evidence from RCTs about the effects of corticosteroids alone on postherpetic neuralgia. We found insufficient evidence from two RCTs about effects of high dose steroids plus antiviral agents. There is concern that corticosteroids may cause dissemination of herpes zoster.
- **Adenosine phosphate; amantadine; cimetidine; inosine pranobex; levodopa** RCTs found insufficient evidence on the effects of these interventions.

Treating established postherpetic neuralgia

- **Gabapentin** One systematic review has found that gabapentin reduces pain at 8 weeks compared with placebo.
- **Tricyclic antidepressants** One systematic review has found that tricyclic antidepressants increase pain relief in postherpetic neuralgia after 2–6 weeks compared with placebo.
- **Oral opioids (oxycodone, morphine, methadone)** We found no RCTs examining effects of morphine or methadone in people with postherpetic neuralgia. One small RCT found that oral oxycodone reduced pain after 4 weeks compared with placebo, but was associated with more adverse effects.
- **Topical counterirritants** Two systematic reviews and one small subsequent RCT found limited evidence that the topical counterirritant capsaicin improved pain relief in postherpetic neuralgia compared with placebo, but found that capsaicin may cause painful skin reactions.
- **Topical anaesthesia** We found insufficient evidence from three RCTs about the effects of lidocaine (lignocaine).
- **Tramadol** One small RCT found that tramadol reduced pain more than clomipramine after 6 weeks. However, we were unable to draw reliable conclusions from this small study.
- **Dextromethorphan** One systematic review and one subsequent RCT found no evidence that dextromethorphan was more effective than placebo or lorazepam after 3–6 weeks, but found that dextromethorphan was associated with sedation and ataxia at high doses.
- **Epidural morphine** One small RCT found that epidural morphine reduced pain by more than 50% compared with placebo but the reduction was not maintained beyond 36 hours. Epidural morphine caused intolerable opioid effects in 75% of people.

DEFINITION Postherpetic neuralgia is pain that sometimes follows resolution of acute herpes zoster and healing of the zoster rash. It can be severe, accompanied by itching, and follows the distribution of the original infection. Herpes zoster is an acute infection caused by activation of latent varicella zoster virus (human herpes virus 3) in people who have been rendered partially immune by a previous attack of chickenpox. Herpes zoster infects the sensory ganglia and their areas of innervation. It is characterised by pain along the distribution of the affected nerve, and crops of clustered vesicles over the area.

INCIDENCE/ PREVALENCE In a UK general practice survey of 3600–3800 people, the annual incidence of herpes zoster was 3.4/1000.[1] Incidence varied with age. Herpes zoster was relatively uncommon in people under the age of 50 years (< 2/1000 a year), but rose to 5–7/1000 a year in people aged 50–79 years, and 11/1000 in people aged 80 years or older. In a population based study of 590 cases in Rochester,

Postherpetic neuralgia

Minnesota, USA, the overall incidence was lower (1.5/1000) but there were similar increases in incidence with age.[2] Prevalence of postherpetic neuralgia depends on when it is measured after acute infection. There is no agreed time point for diagnosis.

AETIOLOGY/RISK FACTORS

The main risk factor for postherpetic neuralgia is increasing age. In a UK general practice study (involving 3600–3800 people, 321 cases of acute herpes zoster) there was little risk in those under the age of 50 years, but postherpetic neuralgia developed in over 20% of people who had had acute herpes zoster aged 60–65 years and in 34% aged over 80 years.[1] No other risk factor has been found to predict consistently which people with herpes zoster will experience continued pain. In a general practice study in Iceland (421 people followed for up to 7 years after an initial episode of herpes zoster), the risk of postherpetic neuralgia was 1.8% (95% CI 0.6% to 4.2%) for people under 60 years of age and the pain was mild in all cases.[2] The risk of severe pain after 3 months in people aged over 60 years was 1.7% (95% CI 0% to 6.2%).

PROGNOSIS

About 2% of people with acute herpes zoster in the UK general practice survey had pain for more than 5 years.[1] Prevalence of pain falls as time elapses after the initial episode. Among 183 people aged over 60 years in the placebo arm of a UK trial, the prevalence of pain was 61% at 1 month, 24% at 3 months, and 13% at 6 months after acute infection.[3] In a more recent RCT, the prevalence of postherpetic pain in the placebo arm at 6 months was 35% in 72 people over 60 years of age.[4]

AIMS OF INTERVENTION

To prevent or reduce postherpetic neuralgia by intervention during acute attack; to reduce the severity and duration of established postherpetic neuralgia, with minimal adverse effects of treatment.

OUTCOMES

Prevalence of persistent pain 6 months after resolution of acute infection and healing of rash. We did not consider short term outcomes such as rash healing or pain reduction during the acute episode. It is difficult to assess the clinical significance of reported changes in "average pain"; therefore, we present data as dichotomous outcomes where possible (pain absent or greatly reduced, or pain persistent).

METHODS

Our initial search was part of two systematic reviews of treatments for acute herpes zoster and postherpetic neuralgia on the basis of comprehensive searches of published and unpublished studies to 1993.[5,6] The details of the searches are described in the published reports. This search was updated by a *Clinical Evidence* search and appraisal in May 2003. Where reliable meta-analyses from systematic reviews were available, they were taken to be the most accurate estimates of treatment effectiveness. In trials, the most common time point chosen for assessing the prevalence of persistent pain was 6 months, which we use in this review unless otherwise specified.

QUESTION **What are the effects of interventions during an acute attack of herpes zoster aimed at preventing postherpetic neuralgia?**

OPTION **ORAL ANTIVIRAL AGENTS (ACICLOVIR, FAMCICLOVIR, VALACICLOVIR, NETIVUDINE)**

One systematic review has found limited evidence from RCTs that aciclovir given for 7–10 days reduced pain at 1–3 months. One systematic review has found that famciclovir reduces mean pain duration after acute herpes zoster compared with placebo. One RCT found that valaciclovir reduced the prevalence of postherpetic neuralgia at 6 months compared with aciclovir. One RCT found no significant difference in effectiveness between netivudine and aciclovir. One RCT found no significant difference between valaciclovir and famciclovir in the resolution of postherpetic neuralgia or in adverse effects over 7 days.

Benefits:

Aciclovir versus placebo: We found one systematic review (search date 1998).[7] It included results from 6 RCTs comparing aciclovir alone versus placebo. It found important heterogeneity among studies making it difficult to summarise results. Meta-analysis was not conducted. The first RCT (376 people) compared aciclovir (4 g/day for 7 days) versus placebo. It found no significant difference between aciclovir and placebo for pain at 3 or 6 months (at 3 months AR for pain 24% in both groups; at 6 months AR 14% with aciclovir *v* 13% placebo; CI not reported in the review). The second RCT (187 people; aciclovir 4 g/day for 10 days) found that aciclovir significantly reduced pain compared with placebo at 1–3 months (AR for pain 4.2% with aciclovir *v* 16.7% with placebo; P = 0.012). However, it found no significant difference at 4–6 months (3.9% *v* 6.3%, CI not reported in the review). The third included RCT (83 people; aciclovir 4 g/day for 7 days) found that aciclovir significantly reduced pain at 3 months (AR 10% *v* 40%; P = 0.0082). The fourth RCT (46 people; aciclovir 4 g/day for 10 days) found that aciclovir significantly reduced pain at 3 months (7% *v* 38%; P = 0.05), but the difference was not significant at 6 months (5% with aciclovir *v* 26% with placebo; P = 0.07). The fifth RCT (65 people; aciclovir 2 g/day for 10 days) found no significant difference in pain between aciclovir and placebo (time to outcome and AR not stated in the review). The final included RCT (86 people; aciclovir 4 g/day for 7 or 14 days) found no significant difference between aciclovir and placebo for pain at 6 months (13% in both groups). **Famciclovir versus placebo:** We found one systematic review (search date 1998, 1 RCT, 419 people).[7] The multicentre RCT in the review compared two different doses of famciclovir in immunocompetent adults (age > 18 years) and defined duration of postherpetic neuralgia as time to pain resolution. It found that both doses of famciclovir significantly reduced the duration of pain after acute herpes zoster compared with placebo (median duration of pain with 500 mg [138 people] 63 days, with 750 mg [135 people] 61 days, with placebo [146 people] 119 days; CI not reported). **Aciclovir versus other antiviral agents:** We found one systematic review (search date 1998, 1 RCT, 1141 people).[7] The RCT in the review compared valaciclovir (a precursor of aciclovir) given three times daily for 7 or 14 days versus 7 days of aciclovir. When the results

from the two valaciclovir regimens were combined, those treated with valaciclovir had a lower prevalence of pain at 6 months (AR 19.3% *v* 25.3%; RR 0.92; NNT 16, 95% CI 9 to 100). We found one double blind RCT comparing netivudine versus aciclovir (511 people), which found no significant difference in effectiveness between treatments.[8] **Addition of amitriptyline:** We found no systematic review or RCTs. **Valaciclovir versus famciclovir:** We found no systematic review. One RCT (597 immunocompetent people aged ≥ 50 years) compared valaciclovir (1 g 3 times daily) versus famciclovir (500 mg 3 times daily) started within 72 hours of appearance of the rash and given for 7 days.[9] It found no significant difference in postherpetic neuralgia (HR 1.01, 95% CI 0.82 to 1.24).

Harms: One previous systematic review (search date 1993) found that the most common adverse events reported with aciclovir were headache and nausea.[5] In placebo controlled trials, these effects occurred with similar frequency with treatment and placebo (headache 37% *v* 43%, nausea 13% *v* 14%). There were no major adverse events reported in the RCTs included in the systematic review.[5] In the RCTs, famciclovir, valaciclovir, and netivudine had similar safety profiles to aciclovir.[8,10,11] In the RCT comparing valaciclovir versus famciclovir the two drugs had similar safety profiles.[9]

Comment: We found no evidence on adherence, but it has been suggested that adherence to treatment may be better with the newer antiviral drugs because they are given one to three times daily compared with five times daily for aciclovir.

OPTION TOPICAL ANTIVIRAL AGENTS (IDOXURIDINE)

One systematic review has found that idoxuridine increases short term pain relief in acute herpes zoster compared with placebo or oral aciclovir, but found no significant difference at 6 months.

Benefits: We found one systematic review (search date 1993, 4 RCTs, 431 people).[5] **Versus placebo:** Three RCTs (242 people) compared topical idoxuridine versus placebo. Pooled results were not reported because of heterogeneity and poor quality of the trials. Two of the RCTs found that treatment during an acute attack significantly increased pain relief at 1 month, but none of the three RCTs found any significant difference at 6 months. **Versus aciclovir:** One RCT found that topical idoxuridine significantly increased pain relief at 1 month compared with oral aciclovir (OR 0.41, 95% CI 0.15 to 1.11), but found no significant difference in prevalence of pain at 6 months (RR 0.38, 95% CI 0.13 to 1.00).[12]

Harms: We found no reports of important adverse effects from idoxuridine. Application beneath dressings may be cumbersome.

Comment: None.

OPTION CORTICOSTEROIDS

Systematic reviews found conflicting evidence from RCTs about the effects of corticosteroids alone on postherpetic neuralgia. We found insufficient evidence from two RCTs about effects of high dose steroids plus antiviral agents. There is concern that corticosteroids may cause dissemination of herpes zoster.

Benefits: **Corticosteroids alone:** We found two systematic reviews (search dates 1993[5] and 1998[7]). The earlier review (search date 1993) included RCTs of corticosteroids with conflicting results and concluded that it was not possible to assess the effect of corticosteroids.[5] The more recent review (search date 1998) found similar results but identified one RCT (201 people) subsequent to the earlier review.[7] The RCT found no significant differences in pain at 3 or 6 months. **Corticosteroids plus aciclovir:** We found one systematic review (search date 1998, 2 RCTs, 608 people).[7] The first identified RCT (400 people) randomised people into four active treatment groups: 7 days of aciclovir (101 people); 7 days of aciclovir plus 21 days of prednisone (99 people); 21 days of aciclovir (101 people); or 21 days of aciclovir plus prednisone (99 people).[13] It found no significant differences in relief of postherpetic neuralgia. The second RCT (208 people) had a factorial design, randomising people to 21 days of aciclovir plus prednisone (60 mg initially, tapered over 3 weeks), prednisone plus placebo, aciclovir plus placebo, or two placebos.[14] Although there was evidence of short term benefit from prednisone, there was no significant effect on pain prevalence at 6 months after disease onset.

Harms: It is feared that corticosteroids might cause dissemination of herpes zoster. This effect was not reported in an RCT of prednisone in the earlier systematic review.[5] In the RCT of aciclovir plus prednisone, two people receiving prednisone plus aciclovir placebo and one receiving aciclovir plus prednisone placebo developed cutaneous dissemination of lesions (see harms of corticosteroids under rheumatoid arthritis, p 000).[14]

Comment: None.

OPTION TRICYCLIC ANTIDEPRESSANTS (AMITRIPTYLINE)

One small RCT found no significant difference between amitriptyline and placebo started within 48 hours of rash onset in the prevalence of postherpetic neuralgia at 6 months. The RCT may have lacked power to detect a clinically important difference.

Benefits: We found one systematic review (search date 1998, 1 RCT, 90 people).[7] The RCT in the review (72 people aged > 60 years) found that amitriptyline 25 mg taken within 48 hours of rash onset (prescribed with or without antiviral agents, at the practitioner's discretion) and continued for 90 days reduced the prevalence of postherpetic neuralgia at 6 months compared with placebo, but the result did not reach significance (AR 16% *v* AR 35%; RR 0.45; ARR +0.19%, 95% CI –0.003% to +0.39%).[4]

Harms: The RCT did not report adverse effects.[4] In another RCT, amitriptyline was associated with adverse anticholinergic effects such as dry mouth, sedation, and urinary difficulties.[5]

Comment: Interpretation of the RCT is complicated because practitioners were allowed to decide whether an antiviral agent was prescribed as well as amitriptyline.[4] Blinding may also have been inadequate.

OPTION OTHER DRUG TREATMENTS

RCTs found insufficient evidence on the effects of other drug treatments in acute herpes zoster.

Benefits: We found one systematic review (search date 1993), which identified small, single RCTs of adenosine phosphate, amantadine, and levodopa.[5] The RCTs found limited evidence of short term benefit in treating herpes zoster. No benefit was found in small studies of cimetidine and inosine pranobex.[5]

Harms: We found no evidence.

Comment: None.

QUESTION What are the effects of interventions to relieve established postherpetic neuralgia after the rash has healed?

OPTION TRICYCLIC ANTIDEPRESSANTS

One systematic review has found that tricyclic antidepressants increase pain relief in postherpetic neuralgia after 2–6 weeks compared with placebo.

Benefits: We found two systematic reviews (search dates 1993[6] and 2000[15]). Three RCTs (216 people) comparing tricyclic antidepressants versus placebo were common to both reviews. Two of these RCTs compared amitriptyline versus placebo. The other RCT compared desipramine versus placebo. The first review pooled results and found that tricyclic antidepressants taken for 3–6 weeks significantly improved pain relief from postherpetic neuralgia at the end of the treatment period compared with placebo (OR for complete or large reduction in pain at end of treatment period 0.15, 95% CI 0.08 to 0.27).[6] The more recent review found one subsequent RCT that compared amitriptyline alone; amitriptyline plus fluphenazine; fluphenazine alone; and placebo.[15] However, it did not report results for amitriptyline alone compared with placebo.

Harms: Tricyclic antidepressants are associated with anticholinergic adverse effects. In one RCT, amitriptyline increased the following adverse effects compared with placebo: dry mouth (AR 62% *v* 40%), sedation (AR 62% *v* 40%), and urinary difficulties (AR 12% *v* < 5%).[16] Syncope and heart block occurred in one person in a trial of desipramine in people with postherpetic neuralgia.[17]

Comment: The adverse effects of tricyclic antidepressants are dose related. Adverse effects may be less pronounced when treating postherpetic neuralgia rather than depression because lower doses are used. Treatments were not assessed for more than 8 weeks.

OPTION TOPICAL COUNTERIRRITANTS

Two systematic reviews and one small subsequent RCT found limited evidence that the topical counterirritant capsaicin improved pain relief in postherpetic neuralgia compared with placebo, but found that capsaicin may cause painful skin reactions.

Benefits: We found two systematic reviews (search date 1993[5] and 2000[15]) and one subsequent RCT.[18] Both reviews identified the same two placebo controlled RCTs. The first review (205 people) found that capsaicin significantly improved pain relief compared with placebo (OR for complete or greatly reduced pain 0.29, 95% CI 0.16 to 0.54).[5] The second review did not pool results, but reached the same conclusion. The subsequent RCT (31 people) found that capsaicin 0.025% was not effective.[18]

Harms: Reported local skin reactions included burning, stinging, and erythema. These effects tended to subside with time and frequency of use.[19]

Comment: The difficulty in blinding studies with capsaicin because of skin burning could have caused overestimation of benefit.

OPTION TOPICAL ANAESTHESIA

We found insufficient evidence from three RCTs about the effects of lidocaine (lignocaine).

Benefits: We found one systematic review (search date 2000, 2 RCTs with evaluation period > 24 hours, 204 people)[15] and one additional RCT.[20] The first trial included in the review (unpublished, 171 people) found no significant difference for pain relief between lidocaine patches and placebo after 3–4 weeks (pain score on 0–5 pain scale 2.6 for lidocaine *v* 2.1 for placebo).[15] The second RCT only recruited people who had responded to lidocaine patches (see comment below).[15] The additional RCT (35 people) found that lidocaine patches reduced average pain scores on a visual analogue scale over 12 hours compared with placebo.[20]

Harms: No systemic adverse effects were noted with lidocaine patches, and systemic absorption as determined by blood concentrations was minimal.[20]

Comment: One RCT included in the review only recruited people who had responded to lidocaine.[15] Results are therefore likely to be biased in favour of lidocaine. It found that lidocaine patches were more effective for pain relief than placebo.

OPTION GABAPENTIN

One systematic review has found that gabapentin reduces pain in postherpetic neuralgia at 8 weeks compared with placebo.

Postherpetic neuralgia

Benefits: We found one systematic review (search date not stated,[21] 2 multicentre RCTs[22,23]). Both RCTs assessed pain using an 11 point Likert scale. The first RCT identified by the review (229 people who remained on tricyclic antidepressants or opiates during the trial) found that gabapentin significantly reduced the proportion of people reporting pain after 8 weeks of treatment (no pain: 16% with gabapentin *v* 8% with placebo; pain much or moderately reduced: 43% with gabapentin *v* 12% with placebo; $P < 0.001$).[23] The second RCT identified by the review (334 people) found that gabapentin (1800 mg/day or 2400 mg/day in 3 divided doses) significantly reduced mean daily pain scores at 7 weeks compared with placebo (pain reduction with gabapentin 1800 mg *v* placebo: –18.8%, 95% CI –10.9% to –26.8%; pain reduction with gabapentin 2400 mg *v* placebo: – 18.7%, 95% CI –10.7% to –26.7%).[22]

Harms: The first RCT in the review[21] found that gabapentin increased adverse effects compared with placebo (somnolence: 7% *v* 5%; dizziness: 24% *v* 5%; ataxia: 7% *v* 0%; peripheral oedema: 10% *v* 3%; infection: 8% *v* 3%).[23] It found no significant difference in withdrawal rates due to adverse effects between gabapentin and placebo (13.3% with gabapentin *v* 9.5% with placebo). The second RCT in the review also found that gabapentin increased adverse effects compared with placebo (somnolence: 17% with 1800 mg *v* 20% with 2400 mg *v* 6% with placebo; dizziness: 31% *v* 33% *v* 10%; peripheral oedema: 5% *v* 11% *v* 0%).[22] This RCT found that gabapentin increased withdrawal rates due to adverse effect (13% with 1800 mg *v* 18% with 2400 mg *v* 6% with placebo).

Comment: None.

OPTION NARCOTIC ANALGESICS

We found no RCTs examining effects of morphine or methadone in people with postherpetic neuralgia. One small RCT found that oral oxycodone reduced pain after 4 weeks compared with placebo but was associated with more adverse effects. The review and one subsequent RCT found no evidence that dextromethorphan was more effective than placebo or lorazepam after 3–6 weeks, but found that dextromethorphan was associated with sedation and ataxia at high doses. One additional RCT found that epidural morphine reduced pain more than placebo over 36 hours, but was poorly tolerated because of adverse effects. The review found limited evidence from one RCT that tramadol reduced pain more than clomipramine after 6 weeks. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found no RCTs examining effects of morphine or methadone. We found one systematic review (search date 2000, 3 RCTs, 103 people), one subsequent RCT, and one additional RCT not identified by the review.[15,24,25] The first RCT included in the review (a blinded crossover RCT; 50 people, 4 weeks on each treatment; comparing oxycodone *v* placebo) found that oxycodone significantly improved pain on a visual analogue scale after 4 weeks, but the data were not converted into a dichotomous outcome. However, it found that a greater proportion of people preferred oxycodone to placebo (67% *v* 11%).[15] A second, small, double blind, crossover RCT (18 people)

found no evidence of pain relief from 6 weeks' treatment with dextromethorphan (a codeine analogue) compared with placebo.[15] The third included RCT (35 people) compared tramadol versus clomipramine with or without levomepromazine.[15] It found that tramadol improved pain relief compared with other treatments (after 6 weeks, AR for "good or excellent" pain relief 60% with tramadol *v* 45% with control; RR, CI and P values not reported in the review). The first subsequent crossover RCT (22 people) compared three treatments: dextromethorphan, memantine, and lorazepam.[24] It found no significant difference between dextromethorphan and lorazepam for pain score at 3 weeks (20 point pain Gracely score; mean difference between dextromethorphan and lorazepam –0.9, 95% CI –2.3 to +0.5). The additional, small, single blind, placebo controlled RCT found that epidural morphine reduced pain by more than 50% in a significantly greater proportion of people than placebo, but this was not sustained beyond 36 hours.[25]

Harms: The review found that oxycodone produced adverse effects such as constipation, nausea, and sedation with greater frequency than placebo (76% *v* 49%; RR 1.4, 95% CI 0.5 to 3.4).[15] High dose dextromethorphan produced sedation and ataxia, causing 5/18 (28%) people to stop treatment.[15] Epidural morphine produced intolerable opioid effects in 6/8 (75%) people treated.[25]

Comment: The studies were small and in the tramadol study, results may have been biased by the co-intervention (levomepromazine).

Tuberculosis

Key Messages

Preventing tuberculosis in high risk people without HIV infection

- **Isoniazid** One systematic review, in people without HIV infection at high risk of tuberculosis, found that, isoniazid prophylaxis for 6–12 months reduced the risk of active tuberculosis or extra-pulmonary tuberculosis compared with placebo. It also found that a short 6 month course was as effective as a 12 month course. One large RCT found that treatment with isoniazid significantly increased the risk of hepatotoxicity compared with placebo.

Treating newly diagnosed tuberculosis

- **Short course chemotherapy (as good as longer courses)** One RCT found that a 6 month regimen of rifampicin plus isoniazid improved relapse rate compared with isoniazid alone. One RCT found no evidence of a difference in relapse rates between short course regimens containing isoniazid (6 months) and longer term (8–9 months) chemotherapy in people with pulmonary tuberculosis. Three RCTs suggested that treatment with pyrazinamide speeds up sputum clearance after 2 months and improves risk of relapse compared with treatment without pyrazinamide.
- **Intermittent short course chemotherapy (as good as daily treatment)** Two RCTs in people with newly diagnosed tuberculosis found no significant difference in cure rates between daily and two or three times weekly short course chemotherapy regimens. However, the RCTs may have lacked power to exclude a clinically important difference.
- **Pyrazinamide** RCTs found that, in people with newly diagnosed tuberculosis, chemotherapy regimens containing pyrazinamide speed up sputum clearance in the first 2 months compared with other regimens, but have found limited evidence about effects on relapse rates.
- **Regimens containing quinolones** We found insufficient evidence about effects of regimens containing quinolones.
- **Chemotherapy for less than 6 months** One systematic review found limited evidence that reducing duration of treatment to less than 6 months significantly increased relapse rates compared with 12 months treatment.

Treating multidrug resistant tuberculosis

- **Comparative benefits of different regimens in multidrug resistant tuberculosis** We found no good evidence comparing different drug regimens for multidrug resistant tuberculosis.

Effects of low level laser therapy

- **Laser therapy** One systematic review found insufficient evidence about effects of low level laser therapy in people with tuberculosis.

Improving adherence and reattendance

- **Cash incentives** One systematic review has found that cash incentives improve attendance among people living in deprived circumstances compared with usual care. One subsequent RCT found that cash incentives improved treatment completion in intravenous drug users. Another subsequent RCT found no significant difference in treatment completion with immediate compared with deferred cash incentives.
- **Community health advisors** One RCT found that consultation with health advisors recruited from the community significantly increased the rate of treatment attendance compared with no consultation.

- **Defaulter actions** RCTs have found that intensive action (repeated home visits and reminder letters) improves completion of treatment compared with routine action (single reminder letter and home visit) for defaulters.
- **Health education by a nurse** One RCT found that health education by a nurse improved treatment completion compared with provision of an educational leaflet.
- **Direct observation treatment** One systematic review found no significant difference in cure rates between any direct observation treatment compared with self treatment. One large RCT, which allowed participants to choose their therapy supervisor, found that direct observative therapy significantly improved both cure rates and cure plus treatment completion rates combined, compared with self treatment. However, cointerventions factors may have contributed to better treatment adherence in this study.
- **Prompts and contracts to improve reattendance for Mantoux test reading** One RCT in healthy people found that telephone prompts to return for Mantoux test reading slightly increased the number of people who reattended compared with no prompts, but the difference was not significant. One RCT found that healthy people were more likely to reattend for Mantoux test reading after providing either a verbal or written commitment compared with no such commitment.
- **Health education by a doctor; prompts to adhere to treatment; sanctions for non-adherence; staff training** We found insufficient evidence on the effects of these interventions.

DEFINITION Tuberculosis is caused by *Mycobacterium tuberculosis* and can affect many organs. Specific symptoms relate to site of infection and are generally accompanied by fever, sweats, and weight loss.

INCIDENCE/ PREVALENCE About a third of the world's population is infected with *M tuberculosis*. The organism kills more people than any other infectious agent. The World Health Organization estimates that 95% of cases are in developing countries, and that 25% of avoidable deaths in developing countries are caused by tuberculosis.[1]

AETIOLOGY/ RISK FACTORS Social factors include poverty, overcrowding, homelessness, and inadequate health services. Medical factors include HIV and immunosuppression.

PROGNOSIS Prognosis varies widely and depends on treatment.[2]

AIMS OF INTERVENTION To cure tuberculosis; eliminate risk of relapse; reduce infectivity; avoid emergence of drug resistance; and prevent death.

OUTCOMES *M tuberculosis* in sputum (smear examination and culture), symptoms, weight, cure, relapse rates, attendance, completion of treatment.

METHODS *Clinical Evidence* search and appraisal August 2003. Key words: tuberculosis, pulmonary, isoniazid, pyrazinamide, and rifampicin. We included all Cochrane systematic reviews and studies that were randomised or used alternate allocation, and had at least 1 year follow up after completion of treatment.

QUESTION **What are the effects of interventions to prevent tuberculosis in high risk people without HIV infection?**

New

OPTION **ISONIAZID**

One systematic review, in people without HIV infection at high risk of tuberculosis, found that, isoniazid prophylaxis for 6–12 months reduced the risk of active tuberculosis or extra-pulmonary tuberculosis compared with placebo. It also found that a short 6 month course was as effective as a 12 month course. One large RCT found that treatment with isoniazid increased the risk of hepatotoxicity compared with placebo.

Benefits: We found one systematic review (search date 2003; 11 RCTs: 73 375 people without HIV infection).[3] The review compared 6 to 12 month courses of isoniazid versus placebo in HIV negative people at increased risk of developing tuberculosis (people with previous pulmonary tuberculosis or positive skin tests; people with recent or remote contact with an active case of pulmonary tuberculosis; or people living in an area with a high incidence and prevalence of disease). It found that isoniazid significantly reduced the risk of active tuberculosis or extra-pulmonary tuberculosis compared with placebo (AR for active tuberculosis; 11 RCTs: 239/40 262 [0.6%] with isoniazid *v* 557/33 113 [1.7%] with placebo; RR 0.40, 95% CI 0.31 to 0.52; AR for extra-pulmonary tuberculosis; 4 RCTs: 9/22 379 [0.04%] with isoniazid *v* 28/22 257 [1.3%] with placebo). The review found no significant difference in active tuberculosis or extra-pulmonary tuberculosis between a 6 month and a 12 month course of isoniazid (AR for active tuberculosis; 1 RCT: 34/6965 [0.5%] with 6 months of isoniazid *v* 24/6919 [0.3%] with 12 months of isoniazid; RR 1.41, 95% CI 0.84 to 2.37). Isoniazid did not significantly reduce deaths from tuberculosis compared with placebo (2 RCTs: 3/16 318 [0.02%] with isoniazid *v* 10/9396 [0.1%]; RR 0.29, 95% CI 0.07 to 1.18).

Harms: The review found that hepatotoxicity was significantly more common in people receiving isoniazid compared with placebo (AR for hepatitis; 1 RCT: 77/13 884 [0.6%] with isoniazid *v* 7/6990 [0.1%] with placebo; RR 5.54, 95% CI 2.56 to 12.00). Other reported adverse effects of isoniazid therapy include mild and transient headache, nausea, and dizziness.

Comment: Even in the isoniazid group, the absolute risk of hepatotoxicity is still small.

QUESTION **What are the effects of different drug regimens in people with newly diagnosed pulmonary tuberculosis?**

OPTION **SHORT COURSE CHEMOTHERAPY**

One RCT found that a 6 month regimen of rifampicin plus isoniazid improved relapse rate compared with isoniazid alone. One RCT found no evidence of a difference in relapse rates between short course regimens containing isoniazid (6 months) and longer term (8–9 months)

chemotherapy in people with pulmonary tuberculosis. Three RCTs suggested that treatment with pyrazinamide speeds up sputum clearance after 2 months and improves risk of relapse compared with treatment without pyrazinamide.

Benefits: We found no systematic review, but found four RCTs.[4–7] **Rifampicin in continuation phase:** We found one RCT (851 people).[4] It compared four daily short course chemotherapy regimens (three 6 months and one 8 months in duration). All four treatment arms had the same initial 2 month phase of streptomycin, isoniazid, rifampicin, and pyrazinamide. The continuation phase of the 6 month regimens was: isoniazid plus rifampicin; isoniazid plus pyrazinamide; or isoniazid alone. The continuation phase of the 8 month regimen was isoniazid alone. It found that bacteriological relapse was significantly reduced with isoniazid plus rifampicin compared with isoniazid alone at 6 months (relapse rate: 2% with rifampicin plus isoniazid *v* 9% with isoniazid alone; $P < 0.01$).[4] **Long versus short rifampicin regimens**: We found two RCTs (1295 people with untreated, culture/smear positive pulmonary tuberculosis), which compared 6 versus 8–9 months of chemotherapy.[4,5] Participants were followed up for at least 1 year after treatment was completed. The trials were performed in the UK and in east and central Africa, and used different combinations of isoniazid, rifampicin, ethambutol, streptomycin, and pyrazinamide for initial (first 2 months) and continuation treatment. Both RCTs found no significant difference in relapse rates between short and longer course chemotherapy regimens ($P > 0.1$). The first RCT (described above)[4] found no significant difference in relapse rate between 6 and 8 months continuation with isoniazid alone (relapse rate: 9% with isoniazid alone for 6 months *v* 3% with isoniazid alone for 8 months; $P > 0.1$). The second RCT compared an initial regimen of isoniazid, rifampicin, pyrazinamide plus either ethambutol or streptomycin for 6 months.[5] It found no difference in relapse rates between ethambutol and streptomycin (relapse rate: 4/127 [3.1%] with ethambutol *v* 2/119 [1.7%] with streptomycin). **Adding pyrazinamide:** We found 3 RCTs that compared chemotherapy regimens with or without pyrazinamide.[5–7] The first RCT (444 people) found that sputum conversion was faster with regimens containing pyrazinamide at 2 months (AR for negative cultures: 77% with pyrazinamide *v* 64% without pyrazinamide; $P < 0.01$).[5] The second RCT (833 people) compared four different 6 month regimens and found that bacterial relapse was significantly higher for those not receiving pyrazinamide in the 12 months after chemotherapy (12/160 [7.5%] *v* 8/625 [1.3%]; $P < 0.001$).[6] The third RCT (497 people) compared ongoing pyrazinamide versus no treatment.[7] It found that relapse at 18 months was more likely in those not receiving pyrazinamide, but the difference was not significant (3.1% with pyrazinamide *v* 1.0% with no pyrazinamide).

Harms: In the largest RCT, possible adverse reactions were reported in 24/851 people (3%), with six requiring modification of treatment.[4] Two people in the trial developed jaundice, one of whom died. **Pyrazinamide:** Adding pyrazinamide did not increase the risk of hepatitis (4% with pyrazinamide *v* 4% with no pyrazinamide).[5] However, mild adverse effects were more common, including

arthralgia, skin rashes, flu-like symptoms, mild gastrointestinal disturbance, vestibular disturbance, peripheral neuropathy, and confusion. Arthralgia was the most common adverse effect, reported in about 1% of people on pyrazinamide, but was mild and never required modification of treatment.[4,5]

Comment: Short course chemotherapy may not be effective in people treated previously, because the organisms may have acquired drug resistance.

OPTION INTERMITTENT SHORT COURSE CHEMOTHERAPY

Two RCTs in people with newly diagnosed tuberculosis found no significant difference in cure rates between daily and two or three times weekly short course chemotherapy regimens. However, the RCTs may have lacked power to exclude a clinically important difference.

Benefits: We found one systematic review (search date 2001)[8] and one subsequent RCT (206 children).[9] The review found one RCT (399 people) that compared three times weekly versus daily chemotherapy for 6 months in people with newly diagnosed pulmonary tuberculosis. It found no significant difference in bacteriological cure rates (defined as negative sputum culture) or relapse rates between three times weekly versus daily chemotherapy 1 month after treatment was completed (bacteriological cure rate: 99.9% with 3 times weekly *v* 100% with daily; relapse rate: 5/186 [2.7%] with 3 times weekly *v* 1/192 [0.5%] with daily; RR 4.0, 95% CI 0.7 to 24.1).[8] The subsequent RCT compared twice weekly versus daily chemotherapy. It found no significant difference in cure rates between the two regimens (85/89 [95%] people with twice weekly *v* 114/117 [97%] people with daily; RR 0.98, 95% CI 0.84 to 1.02).[9]

Harms: Intermittent treatment has the potential to contribute to drug resistance, but this was not found in the studies.[8]

Comment: The RCTs had low event rates and were too small to exclude a clinically important effect difference between the dosing regimens. At least 12 cohort studies have found cure rates of 80–100% with three times weekly regimens taken over 6–9 months.[8]

OPTION CHEMOTHERAPY FOR LESS THAN 6 MONTHS

One systematic review found limited evidence that reducing duration of treatment to less than 6 months significantly increased relapse rates compared with 12 months treatment.

Benefits: We found one systematic review (search date 1999, 7 RCTs, 2248 outpatients with newly diagnosed pulmonary tuberculosis), which compared a variety of shorter (minimum 2 months) and longer (maximum 12 months) drug regimens.[10] The trials included people in India, Hong Kong, Singapore, and Germany. The review found that a 3 month regimen significantly increased relapse rates compared with a 12 month regimen (5 RCTs: RR 3.03, 95% CI 2.08 to 4.40). One of the RCTs found that people given a 2 month regimen were significantly less likely to change or discontinue drugs than those given a 12 month regimen (6/299 [2.0%] *v* 17/299 [5.7%]; RR 0.35; 95% CI 0.14 to 0.88).[10]

Harms: The review found similar rates of adverse events or toxicity with both shorter and longer regimens.

Comment: The treatments were given under optimal conditions. In clinical practice adherence is likely to be lower, so relapse rates associated with the shorter regimens are likely to be higher than those in clinical trials.

OPTION REGIMENS CONTAINING QUINOLONES

We found insufficient evidence about effects of regimens containing quinolones.

Benefits: We found no systematic review, but found two RCTs.[11,12] One RCT in Tanzania (200 people) compared a regimen containing a low dose of quinolone (750 mg/day ciprofloxacin) versus a regimen without a quinolone. It found that the quinolone regimen increased relapse rate, but the difference was not significant (RR of relapse at 6 months: 16.0, 95% CI 0.9 to 278.0).[11] The second RCT (160 people) compared a regimen containing ciprofloxacin versus a regimen without, and focused only on adverse effects (see harms below).[12]

Harms: Adverse effects, which were mild and responsive to symptomatic treatment, were similar in people taking quinolone regimens versus controls.[12]

Comment: Quinolones have good mycobactericidal activity *in vitro*. Some of the newer quinolones have greater antimycobacterial activity than ciprofloxacin.

QUESTION What are the effects of different drug regimens in people with multidrug resistant tuberculosis?

OPTION COMPARATIVE BENEFITS OF DIFFERENT REGIMENS IN MULTIDRUG RESISTANT TUBERCULOSIS

We found no RCTs comparing different drug regimens for multidrug resistant tuberculosis.

Benefits: We found no systematic review and no RCTs comparing different regimens in people with multidrug resistant tuberculosis.

Harms: We found no evidence.

Comment: Current clinical practice in multidrug resistant tuberculosis is to include at least three drugs to which the particular strain of tuberculosis is sensitive, using as many bactericidal agents as possible. People are observed directly and managed by a specialised clinician.

QUESTION What are the effects of low level laser therapy in people with tuberculosis? New

OPTION LASER THERAPY

One systematic review found insufficient evidence about effects of low level laser therapy in people with tuberculosis.

Tuberculosis

Benefits: We found one systematic review (search date 2001, no RCTs; see comment below) and no subsequent RCTs.[13]

Harms: The systematic review did not provide reliable data on harms.

Comment: The systematic review found 29 observational studies, mainly from Russia and India.[13] It found no reliable evidence for a beneficial effect of low level laser therapy for people with tuberculosis, although a "range of positive effects" was reported.[13]

QUESTION Which interventions improve adherence to treatment?

OPTION STAFF TRAINING

We found insufficient evidence on the effects of staff training on adherence to treatment.

Benefits: We found one systematic review (search date 2000, 1 poorly randomised RCT; see comment below) comparing intensive staff supervision versus routine supervision at centres in Korea performing tuberculosis extension activities.[14] Centres were paired and randomised, and supervision was carried out by senior doctors. The review found that higher completion rates were achieved with intensive supervision (RR 1.2; CI not estimated because of cluster design).

Harms: None reported.

Comment: The trial used cluster randomisation, but the unit of analysis was the individual.

OPTION PROMPTS TO ADHERE TO TREATMENTS

We found no RCTs about the effects of prompts on adherence to treatment.

Benefits: We found one systematic review (search date 2000), which found no RCTs of prompts to return for treatment.[14]

Harms: None.

Comment: None.

OPTION DEFAULTER ACTIONS

One systematic review has found that intensive action (repeated home visits and reminder letters) improves completion of treatment compared with routine action (single reminder letter and home visit) for defaulters.

Benefits: We found one systematic review (search date 2000, 2 RCTs conducted in India).[14] The first included RCT (170 people randomised; 150 followed up) found that up to four home visits to defaulters (see glossary, p 1092) significantly improved completion

of treatment compared with the routine policy of a reminder letter followed by one home visit (RR 1.32, 95% CI 1.02 to 1.71). The second RCT (200 people) found that up to two reminder letters significantly improved completion of treatment (RR 1.21, 95% CI 1.05 to 1.39), even in people who were illiterate.

Harms: None reported.

Comment: None.

OPTION CASH INCENTIVES

One systematic review has found that cash incentives improve attendance among people living in deprived circumstances compared with usual care. One subsequent RCT found that cash incentives improved treatment completion in intravenous drug users. Another subsequent RCT found no significant difference in treatment completion with immediate compared with deferred cash incentives.

Benefits: **Versus no cash incentive:** We found one systematic review (search date 2000, 2 RCTs conducted in the USA)[14] and one subsequent RCT.[15] The first included RCT (244 homeless men) found that a cash incentive ($5 [1992 US$]) significantly improved attendance at the first appointment compared with usual care (RR 1.6, 95% CI 1.3 to 2.0). The second RCT (248 migrants; 205 followed up) found that a cash incentive ($10 [1985 US$]) combined with health education significantly improved attendance in people on tuberculosis preventive therapy compared with usual care, but did not improve attendance in individuals with clinical disease (preventative therapy: RR 2.4, 95% CI 1.5 to 3.7; treatment: RR 1.07, 95% CI 0.97 to 1.19).[14] The subsequent RCT (163 drug users with positive tuberculin skin test) compared three groups: direct observation at a participant chosen site plus a cash incentive ($5 [1994–1997 US$]) per visit; direct observation at a designated site plus $5 a visit; and direct observation at a participant chosen site without a cash incentive. It found that both groups given cash incentives were significantly more likely to complete treatment compared with the group given no cash incentive (AR for treatment completion: 28/53 [53%] with chosen site plus cash *v* 2/55 [4%] with no cash incentive; OR 29.7, 95% CI 6.5 to 134.5; 33/55 [60%] with designated site plus cash *v* 2/55 [4%] with no cash incentive; OR 39.7, 95% CI 8.7 to 134.5).[15] **Immediate versus deferred cash incentive:** We found one RCT (300 intravenous drug users with latent tuberculosis), which compared three interventions: treatment with direct observation (see direct patient observation, p 1091) by a nurse; treatment with self administration plus peer counselling and education; and routine care. Participants in each group were further randomised to receive either an immediate versus a deferred cash incentive ($10 [1995–1997 US$]).[16] The immediate payment was given at the end of each month when people completed a routine assessment for adherence and drug toxicity. The deferred payment was given either after the 6 months' treatment period or when the person withdrew from the study. The RCT found no difference in treatment completion between immediate versus deferred payments (125/150 [83%] *v* 112/150 [75%]; $P = 0.09$).[16]

Harms: The RCTs did not assess adverse effects.

Comment: None.

OPTION HEALTH EDUCATION

One RCT found that health education by a nurse improved treatment completion compared with an educational leaflet alone, but found no evidence of benefit from health education by a doctor. One RCT in drug users found no significant effect of 5–10 minutes of health education on attendance rates for scheduled follow up.

Benefits: We found one systematic review (search date 2000, 2 RCTs conducted in the USA).[14] The first RCT (1004 people) identified by the review compared four methods of health education: telephoning by a nurse; visiting by a nurse; consultation by a clinic doctor; and provision of an educational leaflet. It found that nurse telephone call and nurse visit both significantly increased treatment completion compared with the leaflet alone (75/80 [94%] with nurse telephone call *v* 55/77 [71%] with leaflet; RR 1.30, 95% CI 1.18 to 1.37; 75/79 [95%] with nurse visit *v* 55/77 [71%] with leaflet; RR 1.33, 95% CI 1.20 to 1.38). However, it found no significant difference in treatment completion between consultation by the clinic doctor and the education leaflet alone (64/82 [78%] *v* 55/77 [71%]; RR 1.09, 95% CI 0.89 to 1.23). The second RCT (403 drug users) found that 5–10 minutes of health education had no significant effect on whether people kept a scheduled appointment compared with no targeted health education (RR 1.04, 95% CI 0.70 to 1.54).[14]

Harms: None measured.

Comment: Education is often part of a package of care that includes prompts and incentives, which makes it difficult to evaluate the independent effects of education.

OPTION SANCTIONS FOR NON-ADHERENCE

We found no RCTs on the effect of sanctions.

Benefits: We found one systematic review (search date 2000), which identified no RCTs of sanctions.[14]

Harms: The use of sanctions may be ethically dubious.

Comment: In New York (USA), incarcerating people who did not comply with treatment was thought to increase compliance with the Department of Health's community tuberculosis treatment programme.[17]

OPTION COMMUNITY HEALTH ADVISORS

One RCT found that consultation with health advisors recruited from the community significantly increased the rate of attendance for treatment compared with no consultation.

Benefits: We found one systematic review (search date 2000, 1 RCT).[14] The RCT (200 homeless people) found that consultation with health advisors recruited from the community significantly increased the rate of attendance for treatment compared with no consultation (62/83 [75%] *v* 42/79 [53%]; RR 1.4, 95% CI 1.1 to 1.8).

Harms: None reported.

Comment: None.

OPTION DIRECT OBSERVATION TREATMENT

One systematic review found no significant difference in cure rates between any direct observation treatment compared with self treatment. One large RCT, which allowed participants to choose their therapy observer, found that direct observation therapy significantly improved both cure rates and cure plus treatment completion rates combined, compared with self administration. However confounding factors may have contributed to better treatment adherence in this study.

Benefits: We found one systematic review (search date 2002, 6 RCTs, 1910 people).[18] **Versus self administered treatment**: The review found four RCTs that compared direct observation of people as they took their drugs (by a health professional, lay health worker, or family member) versus self administered treatment. Treatment for all studies was for 6 months, and cure was measured at the end of treatment (3 RCTs) or 1–2 months (1 RCT). The review found no significant difference in cure between any direct observation treatment compared with self treatment (4 RCTs; RR 1.06, 95% CI 0.98 to 1.14). When analysed by the person observing the treatment, there was no significant difference in cure and treatment completion rates combined between self administered treatment and treatment observed by either a health professional, lay health worker, or family member. However, one RCT (836 people), which allowed participants to choose their therapy observer, found that direct observation therapy significantly improved both cure rates and cure plus treatment completion rates combined, compared with self administration (cure: RR 1.13, 95% CI 1.04 to 1.24; cure and treatment completion combined: RR 1.11, 95% CI 1.03 to 1.18). However, cointerventions may have contributed to better treatment adherence in this study (see comments below).[18] The fifth RCT found no significant difference in treatment completion rate between direct observation at a participant chosen site compared with direct observation at a designated site, with or without cash incentives (see cash incentives, p 1089) at 12 months (RR 0.88; 95% CI 0.63 to 1.23).[15] The sixth RCT (300 intravenous drug users with latent tuberculosis) compared three interventions: treatment with direct observation by a nurse; treatment with self administration plus peer counselling and education; and routine care. Participants in each group were further randomised to receive either an immediate versus a deferred cash incentive ($10 [1995–1997 US$]) (see cash incentives, p 1089).[16] It found no significant difference between any direct observation therapy, with or without cash incentives, compared with self administration alone at 6 months (direct observation *v* self administration alone; RR 1.02, 95% CI 0.89 to 1.18).[18]

Harms: Potential harms include reduced cooperation between patient and doctor, removal of individual responsibility, detriment to long term sustainability of antituberculosis programmes, and increased burden on health services to the detriment of care for other diseases. None of these has been adequately investigated.

Comment: In the RCT in which people where given a choice of supervisor, cointerventions may have contributed to the positive findings.[18] Allocation concealment was inadequate, raising the possibility of selection bias. Furthermore, participants receiving direct observation therapy also received twice weekly home visits by health workers as part of the monitoring process which included tablet counting and urine testing for rifampicin. These cointerventions may have contributed to better adherence rates in this study. Numerous observational studies have evaluated interventions described as direct observation treatment, but all were packages of interventions that included specific investment in antituberculosis programmes, such as strengthened drug supplies; improved microscopy services; and numerous incentives, sanctions, and other co-interventions that were likely to influence adherence.[19,20]

QUESTION **Which interventions improve reattendance for Mantoux test reading?**

OPTION **PROMPTS AND CONTRACTS TO IMPROVE REATTENDANCE FOR MANTOUX TEST READING**

One RCT in healthy people found insufficient evidence on the effects of telephone prompts to return for Mantoux test reading. One RCT found that healthy people were more likely to return for Mantoux test reading after providing either a verbal or written commitment compared with no such commitment.

Benefits: **Prompts:** We found one systematic review (search date 2000, 1 RCT).[14] The RCT (701 healthy people) compared an automatic telephone message prompt to return for Mantoux reading versus no prompt. It found that people were slightly more likely to return for testing after prompting, but the difference was not significant (93% with prompting *v* 88% with no prompting; RR 1.05, 95% CI 1.00 to 1.10).[14] **Contracts:** We found no systematic review. One RCT (2053 healthy students in the USA) found that reattendance for Mantoux reading was significantly improved both by verbal and written commitments compared with no commitment (reattendance with verbal commitment: RR 1.10, 95% CI 1.03 to 1.18; reattendance with written commitment: RR 1.12, 95% CI 1.05 to 1.19).[21]

Harms: None reported.

Comment: None.

GLOSSARY

Defaulter actions Actions taken by health workers when people fail to attend for treatment of their tuberculosis.

Substantive changes

Direct observation treatment Evidence reassessed and option categorised as Unknown effectiveness.

QUESTIONS

INTERVENTIONS

See glossary, p 1114

Key Messages

Preventing acute renal failure

- **Low osmolality contrast media (better than standard)** One systematic review found that low osmolality contrast media reduced nephrotoxicity in people with underlying renal failure needing contrast investigation compared with standard osmolality contrast media. One subsequent RCT found that non-ionic iso-osmolar contrast medium (iodixanol) reduced contrast media induced nephropathy compared with low osmolar non-ionic contrast medium (iohexol) in people with diabetes.
- **Acetylcysteine** One systematic review found that N-acetylcysteine plus hydration reduced contrast induced renal failure compared with hydration alone in people with chronic renal insufficiency who were undergoing contrast nephrography.
- **Fluids** One RCT of people undergoing non-emergency cardiac catheterisation found that intravenous saline hydration reduced acute renal failure compared with unrestricted fluids 48 hours after catheterisation. One RCT found that hydration with 0.9% sodium chloride infusion reduced radiocontrast induced nephropathy compared with 0.45% sodium chloride. This effect was greater in women, people with diabetes, and individuals who received more than 250 mL of contrast. One RCT found inconclusive evidence on the effects of inpatient hydration regimens compared with outpatient hydration regimens.
- **Single dose aminoglycosides (as effective as multiple doses for treating infection, but with reduced nephrotoxicity)** One systematic review and one additional RCT compared single and multiple doses of aminoglycosides and found different results for nephrotoxicity. The systematic review, in people with fever and neutropenia receiving antibiotic therapy including aminoglycosides, found no significant differences in cure rates or nephrotoxicity between once daily compared with three times daily administration of the aminoglycoside. The RCT, however, found that single doses of aminoglycosides reduced nephrotoxicity compared with multiple doses in people with fever and receiving antibiotic therapy including an aminoglycoside.
- **Lipid formulations of amphotericin B (better than standard formulations)** We found no RCTs. Lipid formulations of amphotericin B seem to cause less nephrotoxicity compared with standard formulations, but direct comparisons of long term safety are lacking.
- **Fenoldopam** We found limited evidence from three small RCTs suggesting that fenoldopam may be of some benefit in maintaining renal perfusion and creatinine clearance, but found no evidence that it is effective in the prevention of acute renal failure. Fenoldopam may induce hypotension.
- **Mannitol** Small RCTs in people with traumatic rhabdomyolysis, or in people who had undergone coronary artery bypass, vascular, or biliary tract surgery, found that mannitol plus hydration did not reduce acute renal failure compared with hydration alone. One RCT found that mannitol increased the risk of acute renal failure compared with 0.45% sodium chloride infusion, but the difference was not significant.
- **Theophylline** One RCT found that in people with adequate intravenous hydration who require radiocontrast investigations, theophylline did not prevent acute renal failure induced by contrast media compared with placebo. One RCT also found that theophylline did not prevent acute renal failure after coronary artery bypass surgery compared with hydration alone.

Acute renal failure

- **Calcium channel blockers for early allograft dysfunction** One RCT found no significant difference between isradipine and placebo in preventing early allograft dysfunction in renal transplantation. We found no RCTs assessing the effects of calcium channel blockers in preventing other forms of acute renal failure. Calcium channel blockers are associated with hypotension and bradycardia.
- **Dopamine** Two systematic reviews and one subsequent RCT found no significant difference between dopamine and placebo in the development of acute renal failure, the need for dialysis, or death. One RCT found insufficient evidence on the effects of combined dopamine and diltiazem in people undergoing cardiac surgery. Dopamine is associated with serious adverse effects, such as extravasation necrosis, gangrene, and conduction abnormalities.
- **Loop diuretics** One systematic review has found that loop diuretics plus fluids are not effective and may be harmful in preventing acute renal failure compared with fluids alone in people at high risk of acute renal failure. Two RCTs found that diuretics seem to worsen outcome in acute tubular necrosis induced by contrast media and after cardiac surgery compared with 0.9% sodium chloride infusion.
- **Natriuretic peptides** One large RCT found no significant difference in the prevention of acute renal failure induced by contrast media between natriuretic peptides and placebo. Subgroup analysis in another RCT found that atrial natriuretic peptide reduced dialysis free survival in non-oliguric people compared with placebo.

Treating acute renal failure in critically ill people

- **High dose continuous renal replacement therapy (better than low dose)** One RCT has found that high dose continuous renal replacement therapy (haemofiltration) significantly reduces mortality compared with standard dose continuous therapy. A small prospective study found that intensive (daily) intermittent haemodialysis reduced mortality in people with acute renal failure compared with conventional alternate day haemodialysis. A subsequent small three arm RCT found no significant difference in survival at 28 days between early, low dose haemofiltration; early, high dose haemofiltration; and late, low dose haemofiltration.
- **Continuous renal replacement therapy** One systematic review found insufficient evidence to compare continuous versus intermittent renal replacement therapy in mortality, renal death, or dialysis dependence in critically ill adults with acute renal failure.
- **Synthetic dialysis membranes (better than cellulose based membranes)** Two systematic reviews found insufficient evidence on the effects of synthetic membranes on mortality in critically ill people with acute renal failure compared with cellulose based membranes.
- **Combined diuretics and albumin; continuous infusion versus bolus diuretics** We found insufficient evidence on the effects of these interventions.
- **Loop diuretics** Underpowered RCTs in people with oliguric renal failure found no significant difference between loop diuretics and placebo on renal recovery, the number of days spent on dialysis, or mortality. Loop diuretics have been associated with toxicity and low renal perfusion.

- **Dopamine** One systematic review found no significant difference in mortality or need for dialysis between dopamine and control. One additional RCT found that low dose dopamine did not reduce renal dysfunction compared with placebo. Dopamine has been associated with important adverse effects, including extravasation necrosis, gangrene, tachycardia, and conduction abnormalities.
- **Natriuretic peptides** RCTs found no significant difference between atrial natriuretic peptide, ularitide (urodilatin), and placebo in dialysis free survival in oliguric and non-oliguric people with acute renal failure. One of the RCTs found that atrial natriuretic peptide may reduce survival in non-oliguric people.

DEFINITION

Acute renal failure is characterised by abrupt and sustained decline in glomerular filtration rate (see glossary, p 1114),[1] which leads to accumulation of urea and other chemicals in the blood. There is no clear consensus on a biochemical definition,[2] but most studies define it as a serum creatinine of 2–3 mg/dL (200–250 μmol/L), an elevation of more than 0.5 mg/dL (45 μmol/L) over a baseline creatinine below 2 mg/dL (170 μmol/L), or a twofold increase of baseline creatinine. A recent international, interdisciplinary, consensus panel has classified acute renal failure according to a change from baseline serum creatinine or urine output. The three level classification begins with "Risk", defined by either a 50% increase in serum creatinine or a urine output of less than 0.5 mL/kg/hour for at least 6 hours, and concludes with "Failure", defined by a threefold increase in serum creatinine or a urine output of less than 0.3 mL/kg/hour for 24 hours.[3] Acute renal failure is usually additionally classified according to the location of the predominant primary pathology (prerenal, intrarenal, and postrenal failure). Critically ill people are unstable and at imminent risk of death, which usually implies that they need to be in, or have been admitted to, the intensive care unit.

INCIDENCE/ PREVALENCE

Two prospective observational studies (2576 people) have found that established acute renal failure affects nearly 5% of people in hospital and as many as 15% of critically ill people, depending on the definitions used.[4,5]

AETIOLOGY/ RISK FACTORS

General risk factors: Risk factors for acute renal failure that are consistent across multiple causes include hypovolaemia; hypotension; sepsis; pre-existing renal, hepatic, or cardiac dysfunction; diabetes mellitus; and exposure to nephrotoxins (e.g. aminoglycosides, amphotericin, immunosuppressive agents, non-steroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, iv contrast media) (see table 1, p 1118). **Risk factors/aetiology in critically ill people:** Isolated episodes of acute renal failure are rarely seen in critically ill people, but are usually part of multiple organ dysfunction syndromes (see glossary, p 1114). Acute renal failure requiring dialysis is rarely seen in isolation (< 5% of people). The kidneys are often the first organs to fail.[10] In the perioperative setting, acute renal failure risk factors include prolonged aortic clamping, emergency rather than elective surgery, and use of higher volumes (> 100 mL) of intravenous contrast media. One study (3695 people) using multiple logistic regression identified the following independent risk factors: baseline creatinine clearance below 47 mL/minute (OR 1.20, 95% CI 1.12 to 1.30); diabetes (OR 5.5, 95% CI 1.4 to 21.0), and a marginal effect for doses of

contrast media above 100 mL (OR 1.01, 95% CI 1.00 to 1.01). Mortality of people with acute renal failure requiring dialysis was 36% during hospitalisation.[6] Prerenal acute renal failure is caused by reduced blood flow to the kidney from renal artery disease, systematic hypotension, or maldistribution of blood flow. Intrarenal acute renal failure is caused by parenchymal injury (acute tubular necrosis, interstitial nephritis, embolic disease, glomerulonephritis, vasculitis, or small vessel disease). Postrenal acute renal failure is caused by urinary tract obstruction. Observational studies (in several hundred people from Europe, North America, and west Africa with acute renal failure) found a prerenal cause in 40–80%, an intrarenal cause in 10–50%, and a postrenal cause in the remaining 10%.[8,9,11–14] Prerenal acute renal failure is the most common type of acute renal failure in people who are critically ill,[8,15] but acute renal failure in this context is usually part of multisystem failure, and most frequently because of acute tubular necrosis resulting from ischaemic or nephrotoxic injury, or both.[16,17]

PROGNOSIS One retrospective study (1347 people with acute renal failure) found that mortality was less than 15% in people with isolated acute renal failure.[18] One recent prospective study (> 700 people) found that, in people with acute renal failure, overall mortality and the need for dialysis were higher in an intensive care unit (ICU) than in a non-ICU setting, despite no significant difference between the groups in mean maximal serum creatinine (need for dialysis 71% in ICU *v* 18% in non-ICU; $P < 0.001$; mortality 72% in the ICU *v* 32% in non-ICU settings; $P = 0.001$).[19] One large study (> 17 000 people admitted to Austrian ICUs) found that acute renal failure was associated with a greater than fourfold increase in mortality.[20] Even after controlling for underlying severity of illness, mortality was still significantly higher in people with acute renal failure (62.8% *v* 38.5%), suggesting that acute renal failure is independently responsible for increased mortality, even if dialysis is used. However, the exact mechanism that leads to increased risk of death is uncertain.

AIMS OF INTERVENTION **Prevention:** To preserve renal function. **Critically ill people:** To prevent death; to prevent complications of acute renal failure (volume overload, acid–base disturbance, and electrolyte abnormalities); and to prevent the need for chronic dialysis, with minimum adverse effects.

OUTCOMES **Prevention:** Rates of acute renal failure, nephrotoxicity (see glossary, p 1115), or both. Surrogate outcomes were limited to measurements of biochemical evidence of organ function (serum creatinine or creatinine clearance) after the intervention. Surrogate markers such as urine output or renal blood flow were not considered as evidence of effectiveness. **Critically ill people:** Rate of death; rate of renal recovery; adverse effects of treatment. Extent of natriuresis is a proxy outcome.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION **What are the effects of interventions to prevent acute renal failure in people at high risk?**

OPTION FLUIDS

One RCT of people undergoing non-emergency cardiac catheterisation found that intravenous saline hydration reduced acute renal failure compared with unrestricted fluids 48 hours after catheterisation. One RCT found that hydration with 0.9% sodium chloride infusion reduced radiocontrast induced nephropathy compared with 0.45% sodium chloride. This effect was greater in women, people with diabetes, and individuals who received more than 250 mL of contrast. One RCT found inconclusive evidence on the effects of inpatient hydration regimens compared with outpatient hydration regimens.

Benefits:

Versus no treatment: We found one RCT (53 people undergoing non-emergency cardiac catheterisation with an iodine containing contrast agent) that compared intravenous saline hydration (0.9% saline for 24 hours at a rate of 1 mL/kg/hour begun 12 hours before catheterisation) versus unrestricted oral fluids.[21] It found that saline hydration significantly reduced acute renal failure compared with unrestricted oral fluids within 48 hours (acute renal failure defined as increase in serum creatinine by at least 44.2 μmol/L [0.5 mg/dL]: 1/27 [3.7%] with saline hydration *v* 9/26 [34.6%] with unrestricted fluids; RR 0.11, 95% CI 0.015 to 0.79). Older RCTs compared combinations of fluids (especially 0.45% sodium chloride infusion) versus other active treatments. Comparisons between outcomes in these trials and historical untreated controls are difficult to evaluate but suggest benefit from fluids.[22] In certain settings, such as traumatic rhabdomyolysis, early and aggressive fluid resuscitation has had dramatic benefits compared with historical controls.[7]

Versus other fluids: We found one RCT (1620 people who had a coronary angiography), which compared 0.9% sodium chloride infusion versus 0.45% sodium chloride in dextrose infusion in radiocontrast induced nephropathy.[23] Radiocontrast induced nephropathy was defined as an increase in serum creatinine of more than 0.5 mg/dL (45 μmol/L) within 48 hours. The RCT found that hydration with 0.9% sodium chloride infusion significantly reduced radiocontrast induced nephropathy compared with 0.45% sodium chloride in dextrose infusion (0.7% with 0.9% sodium chloride infusion *v* 2% with 0.45% sodium chloride infusion; P = 0.04). Three predefined subsets of people (women, people with diabetes, and individuals receiving > 250 mL of the contrast) benefited the most from 0.9% sodium chloride infusion hydration.

Inpatient versus outpatient hydration regimens: We found one RCT (36 people), which compared an inpatient hydration regimen (0.45% sodium chloride solution at 75 mL/hour intravenously for 12 hours before and after cardiac catheterisation) with an outpatient hydration regimen (1 L of clear liquids over 10 hours followed by 6 hours of iv hydration beginning just before contrast exposure) for the prevention of radiocontrast induced renal dysfunction.[24] The predefined primary end point was maximal change in creatinine up to 48 hours after cardiac catheterisation. No significant differences were found in the maximal changes in serum creatinine between

groups (0.21 ± 0.38 mg/dL for inpatients *v* 0.12 ± 0.23 mg/dL for outpatients; P > 0.05, no additional data available). However, this study may be underpowered to rule out clinically important differences. The outpatient group also received more fluid volume.

Harms: The volumes of fluids recommended (e.g. 1 L) and the rates of infusion (generally < 500 mL/hour) have little potential for harm in most people. The RCT (53 people undergoing non-emergency cardiac catheterisation) comparing saline hydration versus unrestricted oral fluids found no adverse effects with saline hydration.[21] No significant differences were found in cardiac or peripheral vascular complications between hydration with 0.9% sodium chloride and 0.45% sodium chloride plus dextrose (cardiac complications: 5.3% with 0.9% sodium chloride *v* 6.4% with 0.45% sodium chloride plus dextrose; P = 0.59; peripheral vascular complications: 1.6% *v* 1.5%; P = 0.93).[23] The RCT comparing inpatient and outpatient hydration regimens did not report harms data.[24]

Comment: Hypovolaemia is a significant risk factor for acute renal failure. The provision of adequate maintenance fluids is considered important in preventing acute renal failure. Additional fluid loading may be useful because it assures adequate intravascular volume. It also stimulates urine output, theoretically limiting renal exposure time to higher concentrations of nephrotoxins.

OPTION LOOP DIURETICS

One systematic review has found that loop diuretics plus fluids are not effective and may be harmful in preventing acute renal failure compared with fluids alone in people at high risk of acute renal failure. Two RCTs found that diuretics seem to worsen outcome in acute tubular necrosis induced by contrast media and after cardiac surgery compared with 0.9% sodium chloride infusion.

Benefits: We found one systematic review (search date 1997, 7 RCTs), which compared fluids alone versus diuretics plus fluids in people at risk of acute renal failure from various causes.[25] It found no evidence of improved survival, decreased incidence of acute renal failure, or need for dialysis associated with diuretics. The systematic review also assessed the efficacy of loop diuretics in the prevention of acute tubular necrosis (1 RCT, 121 people randomised to receive 1 mg/hour of furosemide or placebo immediately after major thoraco-abdominal or vascular surgery, and maintained during stay in the intensive care unit). It found no significant difference between furosemide and placebo in creatinine clearance. Both groups had significant reductions in creatinine clearance compared with baseline, but no differences were found between groups (reduction compared with baseline values: 83% with furosemide *v* 81% with placebo). The study did not address the use of loop diuretics given during the procedure.[26]

Harms: We found two RCTs addressing harms.[22,27] The first RCT (78 people with chronic renal insufficiency who had a cardiac angiography, mean serum creatinine 2.1 ± 0.6 mg/dL or 186 ± 53 μmol/L) found that acute renal failure (defined as an increase in serum creatinine ≥ 0.5 mg/dL or 44 μmol/L at 48 hours) was significantly more likely

to occur when people were treated with furosemide (frusemide) plus fluid compared with fluid alone (10/25 [40%] with furosemide plus 0.45% sodium chloride infusion *v* 3/28 [11%] with 0.45% sodium chloride infusion alone; RR 3.73, 95% CI 1.16 to 12.10; NNH 4, 95% CI 2 to 17).[22] The second RCT found that furosemide plus fluid compared with 0.9% sodium chloride alone was associated with the development of post-cardiac surgery acute renal failure (6/41 [15%] with furosemide *v* 0/40 [0%] with sodium chloride; NNH 6, 95% CI 3 to 34).[27]

Comment: The trials addressing harms[22,27] provided a three way comparison showing significant differences among the three groups ($P < 0.05$). Although they seem to have used the same control group for both comparisons, no adjustment or multiple comparisons were made.

OPTION MANNITOL

Small RCTs in people with traumatic rhabdomyolysis, or in people who had undergone coronary artery bypass, vascular, or biliary tract surgery, found that mannitol plus hydration did not reduce acute renal failure compared with hydration alone. One RCT found that mannitol increased the risk of acute renal failure, compared with 0.45% sodium chloride infusion, but the difference was not significant.

Benefits: We found no systematic review. Several small RCTs did not find a reduction in the incidence of acute renal failure with mannitol plus hydration over hydration alone in a variety of conditions, including coronary artery bypass surgery,[28] traumatic rhabdomyolysis,[29] and vascular,[30] and biliary tract surgery.[31] One trial comparing 0.45% sodium chloride, furosemide, and mannitol (78 people with chronic renal insufficiency who had a cardiac angiography, mean serum creatinine 2.1 ± 0.6 mg/dL or 186 ± 53 μmol/L) found that mannitol plus 0.45% sodium chloride increased acute renal failure (defined as an increase in serum creatinine ≥ 0.5 mg/dL or 44 μmol/L at 48 hours) compared with 0.45% sodium chloride alone, although the difference was not statistically significant (AR 7/25 [28%] with mannitol *v* 3/28 [11%] with 0.45% sodium chloride; RR 2.61, 95% CI 0.76 to 9.03).[22]

Harms: The RCT did not report harms.

Comment: Mannitol is an intravascular volume expander and may also function as a free radical scavenger, as well as an osmotic diuretic. A trial addressing the effect of mannitol on renal function[22] provided a three way comparison showing significant differences among the three groups ($P < 0.05$). Although the same control group seems to have been used to compare both interventions, no adjustment was made for multiple comparisons.

OPTION DOPAMINE

Two systematic reviews and one subsequent RCT found no significant difference between dopamine and placebo in the development of acute renal failure, need for dialysis, or mortality in people at high risk of acute renal failure. One RCT found insufficient evidence on the effects of

combined dopamine and diltiazem in people undergoing cardiac surgery. Dopamine is associated with serious adverse effects, such as extravasation necrosis, gangrene, and conduction abnormalities.

Benefits: We found two systematic reviews[32,33] and one subsequent large RCT.[34] The first systematic review (search date 1999, 17 RCTs, 854 people) examined the effects of any dose of dopamine.[32] It was adequately powered and found no significant difference between dopamine and placebo in mortality, onset of acute renal failure, or need for dialysis (mortality: 11 RCTs, 508 people; 4.7% with dopamine *v* 5.6% with placebo; RR 0.83, 95% CI 0.39 to 1.77; onset of acute renal failure: 11 RCTs, 511 people; 15.3% with dopamine *v* 19.5% with placebo; RR 0.79, 95% CI 0.54 to 1.13; need for dialysis: 10 RCTs, 618 people; 13.9% with dopamine *v* 16.5% with placebo; RR 0.89, 95% CI 0.66 to 1.21). The second systematic review (search date 2000, 15 RCTs, 970 adults either with or at risk of acute renal insufficiency, see comments) assessed the effects of low dose dopamine.[33] It was also adequately powered and found no significant difference between low dose dopamine (2–5 μg/kg/minute) and placebo in acute deterioration in renal function (defined as an increase in serum creatinine of > 25% from baseline; AR 31% *v* 33%; RR 1.01, 95% CI 0.79 to 1.28). The subsequent RCT (328 critically ill people with signs of sepsis) evaluated dopamine in early renal dysfunction (see glossary, p 1114).[34] It found no significant difference between dopamine and placebo on the development of acute renal failure, the requirement for dialysis, intensive care unit length of stay, hospital length of stay, or mortality (acute renal failure: peak serum creatinine concentration during treatment was 2.7 ± 1.6 mg/dL [245 ± 144 μmol/L] in the dopamine group *v* 2.8 ± 1.6 mg/dL [249 ± 147 μmol/L] in the placebo group; P = 0.93; the requirement for dialysis: 35/161 [22%] with dopamine *v* 40/163 [25%] with placebo; RR 0.89, 95% CI 0.58 to 1.30; intensive care unit length of stay: 13 ± 14 days with dopamine *v* 14 ± 15 days with placebo; P = 0.67; hospital length of stay: 29 ± 27 days with dopamine *v* 33 ± 39 days with placebo; P = 0.29; mortality: 69/161 [43%] with dopamine *v* 66/163 [40%] with placebo; RR 1.06, 95% CI 0.8 to 1.33).

Harms: Two systematic reviews (search date 1999[32,33]) and one large RCT in people with sepsis[34] did not report on harms. Dopamine has known adverse effects, including extravasation necrosis, gangrene, tachycardia, headache, conduction abnormalities, and effects on prolactin.

Comment: One RCT (60 people undergoing coronary artery bypass grafting) compared four interventions: dopamine, diltiazem, dopamine plus diltiazem versus control (not specified). Drug administration (iv infusion rates 2 μg/kg/minute of diltiazem and 2 μg/kg/minute dopamine) was initiated 24 hours before surgery and continued for 72 hours after surgery.[35] Creatinine clearance (primary end point) was significantly higher in the combined diltiazem and dopamine group compared with the dopamine only, diltiazem only, and control groups 24 hours after surgery. However, this study was underpowered, and the hydration status of the people was not controlled. The increase in urine output associated with dopamine is often thought

to be caused exclusively by the increase in renal blood flow and, therefore, it may be confused with evidence of benefit. However, dopamine also has a significant diuretic effect. The review comparing low dose dopamine versus placebo included people with normal renal function who were undergoing elective vascular surgery, cardiac surgery, and liver transplantation, people with obstructive jaundice, diabetics, people receiving nephrotoxic drugs or undergoing radiocontrast investigations, and people with renal insufficiency undergoing cardiac surgery or receiving radiocontrast agents.[33]

OPTION DOPAMINE 1 RECEPTOR AGONISTS (FENOLDOPAM)

We found limited evidence from three small RCTs suggesting that fenoldopam may be of some benefit in maintaining renal perfusion and creatinine clearance, but found no evidence that it is effective in the prevention of acute renal failure. Fenoldopam may induce hypotension.

Benefits: We found three RCTs.[36–38] The first RCT (31 people undergoing elective coronary revascularisation) compared intravenous 0.1 μg/kg/minute fenoldopam versus placebo (not described, presumably 0.9% sodium chloride). Mean creatinine clearance decreased in the placebo group from 107 ± 36 mL/minute to 71 ± 22 mL/minute ($P < 0.01$) and from 107 ± 36 to 79 ± 26 mL/minute ($P < 0.01$) for the 0–4 hour and 4–8 hour intervals, respectively, but not the fenoldopam group after separation from cardiopulmonary bypass. However, the clinical significance of this end point is not clear, comparisons were made within groups, and this study was underpowered to assess relevant clinical outcomes, such as need for dialysis. The second RCT[37] evaluated the role of fenoldopam in preventing acute renal failure after aortic surgery in 28 people undergoing elective aortic surgery requiring infrarenal aortic cross-clamping. People were randomised to intravenous 0.1 μg/kg/minute fenoldopam or placebo (not described) before skin incision and until release of the aortic clamp. On application of the aortic cross-clamp, creatinine clearance decreased significantly in the placebo group (83 ± 20 mL/minute to 42 ± 29 mL/minute; $P < 0.01$) but not in the fenoldopam group. No comparisons were made between groups. This decrease persisted for at least 8 hours after release of the cross-clamp. Plasma creatinine concentration increased significantly from baseline on the first day after surgery in the placebo group (87 ± 12 mmol/L to 103 ± 28 mmol/L; $P < 0.01$) but not in the fenoldopam group. However, this study is small and the clinical significance of end point studied is unclear. The third RCT[38] randomised 45 people with chronic renal insufficiency (defined as creatinine level 2.0–5.0 mg/dL) and undergoing contrast angiography to hydration plus 0.1 μg/kg/minute fenoldopam mesylate or hydration with 0.45% sodium chloride. The primary end point was change in renal plasma flow 1 hour after contrast infusion. The secondary end point was incidence of radiocontrast induced nephropathy, defined as a 0.5 mg/dL or a 25% rise in serum creatinine level at 48 hours. Fenoldopam plus hydration significantly increased renal plasma flow 1 hour after angiography compared with hydration alone (+15.8% with fenoldopam plus hydration *v* –33.2% with hydration alone; $P < 0.05$). Fenoldopam also produced a non-significant reduction in radiocontrast induced

nephropathy. Renal plasma flow is a surrogate outcome, and the RCT was underpowered to find any significant difference in clinical outcomes. Drugs that have been shown to improve renal plasma flow may not improve clinical outcomes (e.g. dopamine).

Harms: Only one of these three RCTs reported data on potential harm from fenoldopam. The RCT found that fenoldopam significantly lowered the mean arterial pressure within 30 minutes of the infusion and for the entire 4 hour infusion after angiography compared with sodium chloride.[38]

Comment: There is conflicting evidence on the efficacy of fenoldopam in the prevention of radiocontrast induced nephropathy. Although small RCTs and one systematic review (search date 2000)[39] have shown that fenoldopam increases renal blood flow,[40] renal plasma flow,[38] and creatinine clearance,[36] we found no evidence from RCTs that clinical outcomes are improved. Fenoldopam may cause hypotension and therefore it can potentially predispose to renal failure by reducing renal perfusion pressure.[40]

OPTION NATRIURETIC PEPTIDES

One large RCT found no significant difference in the prevention of acute renal failure induced by contrast media between natriuretic peptides and placebo. Subgroup analysis in another RCT found that atrial natriuretic peptide reduced dialysis free survival in non-oliguric people compared with placebo.

Benefits: We found no systematic review, but found one large RCT (247 people) comparing three different doses of atrial natriuretic peptide (0.01, 0.05, and 0.10 μg/kg/minute) versus placebo for preventing acute renal failure induced by contrast media.[41] It found no difference in the incidence of acute renal failure between groups (19% with placebo *v* 23 % with 0.01 μg/kg/minute anaritide *v* 23% with 0.05 μg/kg/minute anaritide *v* 25% with 0.10 μg/kg/minute anaritide).

Harms: We found one RCT (504 people with early acute renal failure).[42] It found that atrial natriuretic peptide reduced rates of dialysis free survival in a subgroup of people (378 non-oliguric people) compared with placebo (dialysis free survival: 88/183 [48%] with atrial natriuretic peptide *v* 116/195 [59%] with placebo; RR 1.24, 95% CI 1.02 to 1.50; NNH 8, 95% CI 4 to 36).

Comment: Natriuretic peptides (atrial natriuretic peptide and urodilatin) have also been evaluated in the treatment of acute renal failure (see benefits of natriuretic peptides, p 1113).

OPTION THEOPHYLLINE

One RCT found that in people with adequate intravenous hydration who required radiocontrast investigations, theophylline did not prevent radiocontrast induced nephropathy compared with placebo. One RCT found no significant reduction in renal impairment after elective coronary artery bypass surgery with theophylline compared with hydration alone.

Benefits: We found no systematic review. **Radiocontrast induced nephropathy:** We found three RCTs.[43–45] The first RCT (39 people receiving 100 mL of non-ionic low osmolar contrast medium) found that glomerular filtration rates were unchanged with a pretreatment dose of 5 mg/kg of intravenous theophylline (75 ± 26 mL/minute/1.72 m^2 *v* 78 ± 33 mL/minute/1.72 m^2) but decreased modestly without pretreatment (88 ± 40 mL/minute/1.72 m^2 *v* 75 ± 32 mL/minute/1.72 m^2; $P < 0.01$).[43] The second RCT (58 people receiving 40 mL of high osmolar contrast medium) found that pretreatment with 165 mg theophylline abolished the decline in glomerular filtration rates seen with placebo (107.5 ± 3.6 *v* 85.4 ± 3.8 mL/minute; $P < 0.001$). In people receiving placebo, radiocontrast agent induced a significant increase in plasma creatinine compared with baseline values (88.1 ± 2.7 *v* 113.4 ± 4.7 μmol/L; $P < 0.001$). Theophylline prevented this increase (89.2 ± 3.1 *v* 89.3 ± 3.5 μmol/L). In both of the above RCTs, the hydration status of people receiving the radiocontrast agent was unclear. However, in the third RCT (80 people with pre-existent mild to moderate renal insufficiency) the glomerular filtration rate was preserved with hydration alone. It found that serum creatinine concentration and creatinine clearance did not change significantly with additional theophylline or with placebo. Two people in the theophylline group and one in the placebo group (5.7% *v* 3.4%) developed acute renal failure, defined as an increase in serum creatinine of at least 0.5 mg/dL.[45] **After coronary artery bypass grafting:** We found one small RCT (56 people with normal renal function), which compared theophylline (a bolus of 4 mg/kg and a subsequent continuous infusion of 0.25 mg/kg/hour for up to 96 hours) versus 0.9% sodium chloride for prevention of renal impairment after elective coronary artery bypass surgery.[46] It found no significant difference between theophylline and saline in rates of renal impairment, but the RCT may have been underpowered to rule out clinically important differences (renal impairment, defined as an increase in serum creatinine of ≥ 0.4 mg/dL from the baseline at day 5 after surgery, 5/28 [18%] with theophylline *v* 4/28 [14%] with sodium chloride; $P > 0.05$).

Harms: Theophylline has a narrow therapeutic index and known adverse effects (see harms of theophyllines under chronic obstructive pulmonary disease, p 2003). Harms were not reported in the above RCTs.[43–45]

Comment: We found no evidence of benefit from the use of theophylline in the prevention of renal failure in any setting.

OPTION CALCIUM CHANNEL BLOCKERS

One RCT found no significant difference between isradipine and placebo in preventing early allograft dysfunction (see glossary, p 0) in renal transplantation. We found no RCTs assessing the effects of calcium channel blockers in preventing other forms of acute renal failure. Calcium channel blockers are associated with hypotension and bradycardia.

Benefits: We found one RCT (210 people) comparing isradipine for renal allograft function after transplantation with placebo.[47] It found that isradipine significantly improved median serum creatinine levels at

3 months compared with placebo at 3 and 12 months (3 months: 185 μmol/L with isradipine *v* 220 μmol/L with placebo; P = 0.002; 12 months: 141 μmol/L with isradipine *v* 158 μmol/L with placebo; P = 0.021). However, there was no significant difference in the incidence or duration of graft dysfunction (graft dysfunction: 34/98 [35%] with isradipine *v* 44/112 [39%] with placebo; RR 1.13, 95% CI 0.79 to 1.62; duration of dysfunction: isradipine 9.1 days *v* placebo 9.3 days).

Harms: As a class, calcium channel blockers are associated with hypotension and bradycardia, as well as a number of less serious adverse effects. The incidence and nature of adverse effects varies between individual drugs (see harms of antihypertensive drug treatment, p 098).

Comment: None.

OPTION ACETYLCYSTEINE

One systematic review found that N-acetylcysteine plus hydration reduced contrast induced renal failure compared with hydration alone in people with chronic renal insufficiency who were undergoing contrast nephrography.

Benefits: We found one systematic review (search date 2003, 7 RCTs, 805 people with chronic renal insufficiency, serum creatinine from 14 to 28 mg/L, proportion of diabetics from 21% to 64%) that compared N-acetylcysteine plus hydration versus hydration alone in people undergoing contrast nephrography.[48] It found that acetylcysteine plus hydration significantly reduced contrast induced renal failure compared with hydration alone (RR 0.44, 95% CI 0.22 to 0.88). Significant statistical heterogeneity was found among studies. Four of the included RCTs found that acetylcysteine plus hydration significantly reduced contrast nephropathy compared with hydration alone, and the other three RCTs found no significant difference. The overall incidence of contrast nephropathy varied between 2% and 26% with acetylcysteine compared with 11% to 45% with control.

Harms: Acetylcysteine has been widely used to treat people with paracetamol (acetaminophen) overdose, and has virtually no toxicity at therapeutic levels (see harms of paracetamol poisoning, p 1826). No data on harms were reported in the systematic review.[48]

Comment: The primary outcome assessed in the RCTs included in the systematic review was radiocontrast induced nephropathy at 48 hours (defined as an increase in serum creatinine of 0.5 mg/dL or > 25% from baseline after 48 hours).[48] The timing of administration of N-acetylcysteine differed among RCTs. Five of the seven included RCTs initiated acetylcysteine treatment on the day before contrast administration, one RCT initiated treatment 1 hour before, and one RCT did not report the timing.[48] In the RCTs, further doses of acetylcysteine were given up to 12 hours after the procedure.

OPTION SINGLE DOSE AMINOGLYCOSIDES

One systematic review and one additional RCT compared single and multiple doses of aminoglycosides and found different results for nephrotoxicity. The systematic review, in people with fever and neutropenia receiving antibiotic therapy including aminoglycosides, found no significant differences in cure rates or nephrotoxicity between once daily compared with three times daily administration of the aminoglycoside. The RCT however, found that single doses of aminoglycosides reduced nephrotoxicity compared with multiple doses in people with fever and receiving antibiotic therapy including an aminoglycoside.

Benefits: We found one systematic review[49] and one additional RCT.[50] The systematic review (search date 1995, 4 RCTs, 803 people with fever and neutropenia, not limited to people in intensive care units) found no significant difference between single and multiple doses of aminoglycosides in antimicrobial efficacy, clinical cure rates, and nephrotoxicity (see glossary, p 1115) (antimicrobial efficacy, 2 RCTs, 57 people: RR 1.00, 95% CI 0.86 to 1.16; clinical cure, 4 RCTs, 961 episodes: RR 0.97, 95% CI 0.91 to 1.05; nephrotoxicity, defined as increase in serum creatinine by > 35–45 μmol, 3 RCTs, 718 episodes: RR 0.78, 95% CI 0.31 to 1.94; see comment below).[49] The additional RCT (85 people with fever) compared a once daily dose of gentamicin versus three times daily doses of gentamicin. It found that single dosing significantly reduced nephrotoxicity compared with multiple dosing (2/40 [5%] with single dosing *v* 11/45 [24%]; RR 0.21, 95% CI 0.05 to 0.87; NNT 5, 95% CI 2 to 24).[50] Nephrotoxicity was defined as an increase in serum creatinine of 0.5 mg/dL (45 μmol/L) or more.

Harms: The review found no evidence of greater harm from once daily aminoglycoside dosing (see RR of nephrotoxicity in benefits section above).

Comment: The systematic review defined clinical cure according to the definitions used by investigators in the primary studies, which may have varied among studies.[49] The risk from aminoglycosides is highest in people with volume depletion; underlying renal, cardiac, or hepatic disease; or when combined with diuretics or other nephrotoxic agents (see glossary, p 1115). Two studies included in the systematic review randomised episodes of infection, allowing for people to be included in more than one option in the study.[51]

OPTION LIPID FORMULATIONS OF AMPHOTERICIN B

We found no RCTs. Lipid formulations of amphotericin B seem to cause less nephrotoxicity compared with standard formulations, but direct comparisons of long term safety are lacking.

Benefits: We found no systematic review and no RCTs.

Harms: We found no evidence of greater harms from lipid formulations of amphotericin B (see glossary, p 1114). However, these formulations are still nephrotoxic and should be used with care.

Comment: A phase II trial of a lipid formulation of amphotericin B (556 people) found an incidence of renal toxicity (defined by any increase in serum creatinine) of 24% (*v* 60–80% with standard formulation of amphotericin B). People with baseline serum creatinine in excess of 2.5 mg/dL (221 μmol/L) on standard amphotericin B showed a significant decrease in serum creatinine when transferred to the lipid formulation ($P < 0.001$).[52] One trial found that simply infusing amphotericin B in a lipid solution designed for parenteral nutrition did not result in any benefit and may be associated with pulmonary adverse effects.[53] Fluid loading can be useful in reducing the risk of acute renal failure from all nephrotoxins. Considerable variability may exist between individual lipid formulations of amphotericin B in terms of efficacy and safety.

OPTION LOW OSMOLALITY CONTRAST MEDIA

One systematic review found that low osmolality contrast media reduced nephrotoxicity compared with standard osmolality contrast media in people with underlying renal failure needing contrast investigation. One subsequent RCT found that non-ionic iso-osmolar contrast medium reduced nephropathy compared with non-ionic low osmolar contrast medium (iohexol) in people with diabetes who needed contrast investigation.

Benefits: We found one systematic review (search date 1991, 31 RCTs, 5146 people)[51] comparing low osmolality contrast media versus standard contrast media and one subsequent RCT that compared iso-osmolar contrast media (see glossary, p 1114) versus low osmolar contrast media.[54] The systematic review found no significant difference between low osmolality and standard contrast media in the development of acute renal failure or need for dialysis (these are rare events), but there was less nephrotoxicity (see glossary, p 1115) with low osmolality contrast media, measured by serum creatinine. Subgroup analysis found that low osmolality contrast media significantly reduced the proportion of people with a rise in serum creatinine > 44 μg/L compared with standard contrast media in people with underlying renal failure but found no significant difference between treatments for people without prior renal failure (prior underlying renal impairment, 8 RCTs, 1418 people: OR 0.50, 95% CI 0.36 to 0.68; no underlying renal impairment: 20 RCTs, 2865 people: OR 0.75, 95% CI 0.52 to 1.10). The subsequent RCT (129 people with diabetes mellitus treated with insulin or antidiabetic drugs and serum creatinine concentrations between 1.5–3.5 mg/dL) compared non-ionic iso-osmolar contrast media (iodixanol) versus low osmolar (iohexol) contrast media in people undergoing coronary or aortofemoral angiography.[54] It found that iso-osmolar contrast medium significantly reduced contrast medium induced nephropathy compared with low osmolar contrast medium (nephropathy, defined as an increase in serum creatinine > 0.5 mg/dL: 2/64 [3%] with iso-osmolar *v* 17/56 [26%] with low osmolar contrast medium; OR 0.09, 95% CI 0.02 to 0.4; see comment below). In the RCT, although both treatment groups received similar volumes of contrast media, both the volume of contrast media and the hydration regimens were not standardised.

Harms: The subsequent RCT found that iso-osmolar contrast medium reduced adverse events compared with low osmolar contrast media (13/67 [19%] with iso-osmolar *v* 29/67 [43%] with low osmolar contrast media, P value not reported).[54]

Comment: Acute renal failure induced by contrast media usually occurs in people with diabetic nephropathy (incidence nearly 50%, varies with the degree of baseline renal function). In the RCT comparing iso-osmolar versus low osmolar contrast media, the incidence of nephropathy with low osmolar contrast media (26%) was exceptionally high.[54]

QUESTION What are the effects of treatments for critically ill people with acute renal failure?

OPTION CONTINUOUS RENAL REPLACEMENT THERAPY

One systematic review found insufficient evidence to compare continuous versus intermittent renal replacement therapy in mortality, renal death, or dialysis dependence in critically ill adults with acute renal failure.

Benefits: We found one systematic review (search date 2002, 6 RCTs, 624 critically ill adults with acute renal failure) comparing continuous with intermittent renal haemodialysis.[55] It found no significant difference between continuous and intermittent renal replacement therapy in mortality, renal death, or dialysis dependence among survivors (mortality: RR 0.96, 95% CI 0.85 to 1.08; renal death, 4 RCTs: RR 1.02, 95% CI 0.89 to 1.17; dialysis dependence, 4 RCTs: RR 1.19, 95% CI 0.62 to 2.27).

Harms: Harms were not reported in the systematic review.[55] Heparin is often used with intermittent and continuous renal replacement therapy, and may have adverse effects (see thromboembolism, p 284).[56] Hypotension is common with intermittent haemodialysis, whereas haemodynamic stability is better preserved with continuous renal replacement therapy.[57]

Comment: The evidence from the systematic review is insufficient to draw conclusions regarding the preferred mode of renal replacement for critically ill people with acute renal failure.[55] A prospective multicentre survey (587 people in 28 intensive care units) found no significant difference in survival between continuous and intermittent renal replacement therapy.[58] Similarly, one RCT (1846 people with chronic rather than acute renal failure receiving chronic treatment with thrice weekly sessions) found no survival benefit from increasing the dose of dialysis or from using a high flux membrane.[59] However, we found one earlier systematic review (search date 1998, 13 studies, 3 RCTs, 1400 critically ill people with acute renal failure),[60] which performed subgroup analysis, adjusting by baseline severity of illness, and found a survival benefit with continuous renal replacement therapy (mortality; RR 0.48, 95% CI 0.34 to 0.69). A secondary analysis in the review, including all studies and adjusting for study quality, found that continuous modalities significantly reduced mortality (RR 0.72, 95% CI 0.60 to 0.87).[60]

OPTION HIGH DOSE CONTINUOUS RENAL REPLACEMENT THERAPY

One RCT has found that high dose continuous renal replacement therapy (haemofiltration) reduces mortality compared with standard dose continuous renal replacement therapy. A small prospective study found that intensive (daily) intermittent haemodialysis reduced mortality in people with acute renal failure compared with conventional alternate day haemodialysis. A subsequent small three arm RCT found no significant difference in survival at 28 days between early, low dose haemofiltration; early, high dose haemofiltration; and late, low dose haemofiltration.

Benefits: We found no systematic review but found two RCTs.[61,62] The first RCT (425 people) compared three doses of continuous replacement renal therapy (20, 35, and 45 mL/kg/hour of haemofiltration in post-dilution).[61] Mortality was similar for the two high dose arms (60/139 [43%] with 35 mL/kg/hour *v* 59/140 [42%] with 45 mL/kg/hour), but was significantly higher in the low dose arm (86/146 [59%] with 20 mL/kg/hour). Survival time analysis was adjusted for three way comparison (combined RR 1.38, 95% CI 1.14 to 1.67; NNT 7, 95% CI 4 to 16). The second, three arm RCT (106 severely ill people with oliguric acute renal failure recruited from two different centres) compared early, high dose haemofiltration (72–96 L/day); early, low dose haemofiltration (24–36 L/day); or late, low dose haemofiltration (24–36 L/day).[62] It found no significant difference in survival at 28 days between groups, but the study had low power to detect differences. Haemofiltration was started at a mean of 7 hours after inclusion in the "early" groups and 42 hours after inclusion in the "late" group. No significant differences were found in survival at day 28 (26/35 [74%] with early, high dose; 24/35 [69%] with early, low dose; and 27/37 [73%] with late, low dose groups; $P > 0.05$ for two way and three way comparisons).

Harms: We found no evidence that the higher dialysis dose is associated with increased adverse effects (such as haemodynamic instability, intolerance, or bleeding). In a prospective study on daily intermittent haemodialysis,[63] there was no evidence of increased morbidity compared with alternate day dialysis. In particular, hypotension was less common with daily treatment. No data on harms were found in the above RCTs.[49,62]

Comment: There is no standard method to compare dialysis dosage between continuous and intermittent renal replacement therapies (see glossary, p 1114), but urea kinetic modelling predicts that the doses used in this study would be impossible to achieve without continuous renal replacement therapy (see glossary, p 1114).[64] In addition, the underlying mechanisms for solute removal are different, based on the type of treatment applied (convection with haemofiltration compared with diffusion with haemodialysis). This makes comparisons of elimination of diverse solutes difficult. However, a recent, small, prospective study (160 people) has found that a higher dose of dialysis delivered as daily intermittent haemodialysis compared with alternate day haemodialysis sessions is associated with improved survival in people with acute renal failure (RR 0.59, 95% CI 0.39 to 91).[63] Although this study may have had low power

to detect important differences and did not deliver the prescribed dialysis dose, it does support the concept that a dose–response relationship exists for dialysis in acute renal failure, and suggests that the traditional, end stage renal disease based dose recommendation may be too low.

OPTION SYNTHETIC DIALYSIS MEMBRANES

Two systematic reviews found insufficient evidence of the effects of synthetic membranes on mortality in critically ill people with acute renal failure compared with cellulose based membranes.

Benefits: We found two systematic reviews comparing synthetic and cellulose based (see glossary, p 1114) dialysis membranes in critically ill people with all cause acute renal failure.[65,66] The first systematic review (search date 2000, 7 RCTs and controlled clinical trials, 722 people) found that synthetic membranes had similar effects on mortality among people with acute renal failure requiring in-centre haemodialysis as cellulose based membranes (RR 0.92, 95% CI 0.76 to 1.13).[65] Subgroup analysis revealed that synthetic membranes fared best against unsubstituted cellulose (RR 0.82, 95% CI 0.62 to 1.08), although the result was still not significant.[67] The second systematic review (search date 2000, 8 prospective trials providing survival data, data on recovery of renal function, or both, 867 people) found that synthetic membranes significantly increased survival rates (OR 1.37, 95% CI 1.02 to 1.83; P = 0.03) and showed a non-significant trend toward improved renal recovery (OR 1.23, 95% CI 0.90 to 1.68; P = 0.18).[66] A sensitivity analysis performed by stratifying studies according to the type of membrane used in the control group found that the mortality reduction observed with synthetic membranes was evident when compared with unsubstituted cellulose, but not when compared with modified cellulose.

Harms: Severe anaphylactoid reactions in people taking angiotensin converting enzyme inhibitors have been reported occasionally with certain synthetic biocompatible (see glossary, p 1114) membranes (exact frequency unknown).[67]

Comment: Many of the RCTs included in both systematic reviews had methodological limitations, and all studies were underpowered. Differences in effect on outcomes seem most easily demonstrable when synthetic membranes are compared with unsubstituted cellulose. Whether synthetic membranes are superior to modified cellulose (e.g. cellulose triacetate) remains controversial. However, no study has shown an advantage with any cellulose based membrane over synthetic membranes, except that the former are generally less expensive.

OPTION DOPAMINE

One systematic review found no significant difference in mortality or need for dialysis between dopamine and control. One additional RCT found that low dose dopamine did not reduce renal dysfunction compared with placebo. Dopamine has been associated with important adverse effects, including extravasation necrosis, gangrene, tachycardia, and conduction abnormalities.

Acute renal failure

Benefits: We found one systematic review[32] and one additional RCT.[34] The systematic review (search date 1999, 58 trials, of which 17 were RCTs, 2149 people) found no significant difference between dopamine and placebo in mortality or need for dialysis (mortality, 11 trials, 508 people: 4.7% with dopamine *v* 5.6% with control; RR 0.83, 95% CI 0.39 to 1.77; need for dialysis, 10 trials, 618 people: 13.9% with dopamine *v* 16.5% with control; RR 0.89, 95% CI 0.66 to 1.21).[32] The additional RCT (multicentre, double blind, placebo controlled, 328 people with early renal dysfunction defined as oliguria [see glossary, p 1114] or increase in serum creatinine) found no significant difference between low dose dopamine and placebo in mortality at discharge (69/161 [43%] with dopamine *v* 66/163 [41%] with placebo; RR 1.06, 95% CI 0.82 to 1.37).[34]

Harms: Dopamine has recognised adverse effects, including extravasation necrosis, gangrene, tachycardia, headache, conduction abnormalities, and effects on prolactin. The systematic review and the RCT provided no data on harms.[32,34]

Comment: Studies using dopamine to prevent renal failure or to ameliorate progression have found no benefit (see prevention of acute renal failure, p 1099). Studies evaluating the effectiveness of dopamine for the treatment of acute renal failure have focused on early renal dysfunction and have often included people with normal renal function who were at risk of acute renal failure.

OPTION LOOP DIURETICS

Underpowered RCTs in people with oliguric renal failure found no significant difference between loop diuretics and placebo on renal recovery, the number of days spent on dialysis, or mortality. Loop diuretics have been associated with toxicity and low renal perfusion.

Benefits: We found no systematic review. We found two RCTs (66 and 58 people, respectively; some in intensive care units, proportion unknown) comparing intravenous furosemide versus placebo in people with oliguric acute renal failure of various causes.[68,69] In the second RCT, all people received one dose of furosemide 1 g and were then randomised to continued treatment or placebo. Neither RCT found significant differences in renal recovery (first RCT 19/33 [58%] with furosemide *v* 22/33 [67%] with placebo; RR 0.86, 95% CI 0.50 to 1.20;[68] second RCT 10/28 [36%] with furosemide *v* 12/28 [43%] with placebo; RR 0.83, 95% CI 0.37 to 1.45)[69] or mortality. The RCTs lacked power to exclude a clinically important effect of loop diuretics on these outcomes.

Harms: Ototoxicity can occur with high doses of loop diuretics. No adverse effects were reported in the first trial.[68] Deafness occurred in two people in the second trial; both were randomised to furosemide. Hearing loss was permanent in one of these people.[69] Diuretics may reduce renal perfusion and add a prerenal component to the renal failure, but the frequency of this event is uncertain.[70] See harms of loop diuretics to prevent acute renal failure in people at high risk, p 1100.

Comment: None.

OPTION CONTINUOUS INFUSION OF LOOP DIURETICS

We found no RCTs comparing continuous infusion with bolus injection of loop diuretics in critically ill people with acute renal failure.

Benefits: We found no systematic review and no RCTs in critically ill people with acute renal failure.

Harms: One small crossover RCT (8 people with acute deterioration of chronic renal failure, mean creatinine clearance 0.28 mL/second) found that fewer people experienced myalgia when treated with continuous infusion than with bolus dosing of bumetanide (3/8 [38%] people with bolus dosing *v* 0/8 [0%] with continuous infusion).[71]

Comment: The small crossover trial found that continuous infusion resulted in a net increase in sodium excretion over 24 hours (mean increase in sodium excretion 48 mmol/day, 95% CI 16 mmol/day to 60 mmol/day; P = 0.01).

OPTION INTRAVENOUS ALBUMIN SUPPLEMENTATION PLUS LOOP DIURETICS

We found no RCTs on the effects of adding intravenous albumin to loop diuretic treatment in critically ill people with acute renal failure.

Benefits: We found no systematic review and no RCTs evaluating clinical outcomes in critically ill people with acute renal failure.

Harms: We found insufficient evidence in people with acute renal failure.

Comment: One systematic review (search date 2002, 30 RCTs, 1419 people, most without acute renal failure) found that albumin increased the risk of death in unselected critically ill people (mortality 98/704 [14%] with albumin *v* 58/715 [8%] with control; RR 1.68, CI 1.26 to 2.23). All of the included trials were small and combined highly heterogeneous populations.[72] One crossover RCT (9 people with nephrotic syndrome) compared three interventions: furosemide alone, furosemide plus albumin, and albumin alone.[73] It found that furosemide was superior to albumin alone, and furosemide plus albumin resulted in the greatest urine and sodium excretion. The clinical significance of this finding is unclear.

OPTION NATRIURETIC PEPTIDES

RCTs found no significant difference between atrial natriuretic peptide, ularitide (urodilatin), and placebo in dialysis free survival in oliguric and non-oliguric people with acute renal failure. One of the RCTs found that atrial natriuretic peptide may reduce survival in non-oliguric people.

Benefits: We found no systematic review but found three RCTs.[42,74,75] One large RCT (504 people) found no overall difference in dialysis free survival with atrial natriuretic peptide compared with placebo in people with acute renal failure.[42] Preplanned subgroup analysis suggested a possible benefit to people with oliguria (see glossary, p 1115), and lower survival rates in non-oliguric people. However, a recent RCT (220 people)[74] in people with oliguric acute renal failure

found no improvement in dialysis free survival with a 24 hour infusion of atrial natriuretic peptide compared with placebo. A third RCT compared ularitide ([urodilatin], a natriuretic peptide with fewer systemic haemodynamic effects) in a dose finding (5, 20, 40, or 80 ng/kg/minute ularitide), placebo controlled RCT (176 people). Ularitide did not reduce the requirement for dialysis (people who needed dialysis: 35% with 5 ng/kg/minute ularitide *v* 36% with 20 ng/kg/minute ularitide *v* 28% with 40 ng/kg/minute ularitide *v* 41% with 80 ng/kg/minute ularitide *v* 36% with placebo; P = NS).[75]

Harms: One RCT found that natriuretic peptide caused significant hypotension compared with placebo (95% with natriuretic peptide *v* 55% with placebo; $P < 0.01$). Also, atrial natriuretic peptide may be associated with a worse outcome in people with non-oliguric renal failure (dialysis free survival in 378 non-oliguric people was 48% with anaritide *v* 59% with placebo; $P = 0.03$).[74] See harms of natriuretic peptides, p 1104.

Comment: We found no evidence of significant improvement of acute renal failure with atrial natriuretic peptide.

GLOSSARY

Biocompatible Artificial materials can induce an inflammatory response. This response can be humoral (including complement) or cellular. Synthetic dialysis membranes seem to produce less of an inflammatory response *in vitro* and are classified as more "biocompatible". By contrast, cellulose based membranes (see below) seem to be less biocompatible (cause more inflammation). When cellulose based membranes are rendered semi-synthetic by modifications or substitution of materials like acetate, they may be become more biocompatible. We found no standards by which this comparison can be made.

Cellulose based Dialysis membranes may be made from cellulose. "Unsubstituted" cellulose has not undergone modification to attempt to improve biocompatibility. Synthetic membranes do not use cellulose.

Continuous renal replacement therapy Any extracorporeal blood purification treatment intended to substitute for impaired renal function over an extended period of time and applied for, or aimed at being applied for, 24 hours a day.

Early allograft dysfunction Renal dysfunction that occurs after renal transplantation, and which is usually secondary to ischaemic injury.

Early renal dysfunction An acute derangement in renal function that is still evolving.

Glomerular filtration rate The rate of elaboration of protein free plasma filtrate (ultrafiltration) across the walls of the glomerular capillaries.

Intermittent renal replacement therapy Renal support that is not, nor intended to be, continuous; usually prescribed for a period of 12 hours or less.

Iso-osmolar contrast media Contrast media that are iso-osmolar compared with plasma, and therefore of lower osmolality than "low osmolality contrast media" (see below).

Lipid formulations of amphotericin B Complexes of amphotericin B and phospholipids or sterols. This reduces the toxicity of amphotericin B while preserving its antifungal activity.

Low osmolality contrast media Contrast media with osmolality between 600–800 mOsm/L.

Multiple organ dysfunction syndrome A syndrome of progressive organ failure, affecting one organ after another and believed to be the result of persistent or recurrent infection or inflammation.

Nephrotoxic agents Any agent that has the potential to produce nephrotoxicity.
Nephrotoxicity Renal parenchymal damage manifested by a decline in glomerular filtration rate, tubular dysfunction, or both.
Oliguria Urine output of less than 5 mL/kg daily.

Substantive changes

Fluids One RCT added;[20] categorisation unchanged.
Dopamine One systematic review added;[33] categorisation unchanged.
Acetylcysteine One systematic review found that acetylcysteine reduced contrast induced renal failure compared with placebo.[48] Acetylcysteine recategorised as Likely to be beneficial.
Low osmolality versus standard contrast media One RCT added;[54] categorisation unchanged.
Continuous versus intermittent renal replacement therapy One systematic review added;[55] categorisation unchanged.

TABLE 1 **Selected risk factors for acute renal failure (ARF) (see text, p 1097).**

Risk factor	Incidence of ARF	Comments
Sepsis	Unknown	Sepsis seems to be a contributing factor in as many as 43% of ARF cases[5]
Aortic clamping	Approaches 100% when > 60 minutes[6]	Refers to cross-clamping (no flow) above the renal arteries
Rhabdomyolysis	16.5%[7]	None
Aminoglycosides	8–26%[8]	None
Amphotericin	88% with > 5 g total dose[9]	60% overall incidence of nephrotoxicity

Key Messages

- **α Blockers** Systematic reviews have found that α blockers improve lower urinary tract symptom scores compared with placebo. Systematic reviews found limited evidence that different α blockers have similar effects. RCTs found limited evidence that α blockers improved symptom scores compared with the 5α reductase inhibitor finasteride. One RCT found no significant difference between tamsulosin and saw palmetto plant extracts in symptom scores or maximum flow rate after 1 year. Another RCT found limited evidence suggesting that α blockers were less effective than transurethral microwave thermotherapy in improving symptoms over 18 months. We found no RCTs comparing α blockers versus surgical treatment.
- **5α Reductase inhibitors** One systematic review and additional RCTs have found that 5α reductase inhibitors improve symptom scores and reduce complications compared with placebo. The review found that 5α reductase inhibitors were associated with more adverse events than placebo, including decreased libido, impotence, and ejaculatory dysfunction. RCTs found limited evidence that the 5α reductase inhibitor finasteride was less effective at improving symptom scores than α blockers. One systematic review found no significant difference in symptom scores between finasteride and saw palmetto plant extracts. We found no RCTs comparing 5α reductase inhibitors versus surgical treatment.

Benign prostatic hyperplasia

- **Saw palmetto plant extracts** One systematic review has found that saw palmetto plant extracts improve symptom scores compared with placebo. It found no significant difference in symptom scores between saw palmetto plant extracts and the α blocker tamsulosin or the 5α reductase inhibitor finasteride. One RCT found no significant difference in symptom scores between tamsulosin and tamsulosin plus saw palmetto plant extracts.
- **Transurethral microwave thermotherapy** RCTs found that transurethral microwave thermotherapy reduced symptom scores compared with sham treatment. We found limited evidence that thermotherapy was less effective in relieving short term symptoms than transurethral resection. One RCT found that transurethral microwave thermotherapy improved symptom scores over 18 months compared with α blockers.
- **Transurethral resection versus no surgery** RCTs found that transurethral resection reduced symptom scores more than watchful waiting, and did not increase the risk of erectile dysfunction or incontinence.
- **β-Sitosterol plant extract** One systematic review has found that β-sitosterol plant extract improves lower urinary tract symptom scores compared with placebo in the short term. We found no RCTs comparing β-sitosterol plant extract versus other treatments.
- ***Pygeum africanum*** One systematic review found limited evidence that *Pygeum africanum* increased peak urinary flow and reduced residual urine volume at 4–16 weeks compared with placebo. We found no RCTs comparing Pygeum africanum versus other treatments.
- **Rye grass pollen extract** One systematic review found limited evidence that rye grass pollen extract increased self rated improvement and reduced nocturia at 12–24 weeks compared with placebo. However, the review identified only two small RCTs, from which we were unable to draw reliable conclusions. We found no RCTs comparing rye grass pollen extract versus other treatments.
- **Transurethral resection versus less invasive surgical techniques** RCTs found no significant difference in symptom scores between transurethral resection and transurethral incision or between transurethral resection and electrical vaporisation. RCTs found limited evidence that transurethral resection improved symptom scores more than visual laser ablation but that transurethral resection may be associated with a higher risk of blood transfusion.
- **Transurethral resection versus transurethral needle ablation** One RCT found that transurethral resection reduced symptom scores compared with transurethral needle ablation after 1 year, although transurethral needle ablation caused fewer adverse effects.

DEFINITION Benign prostatic hyperplasia is defined histologically. Clinically, it is characterised by lower urinary tract symptoms (urinary frequency, urgency, a weak and intermittent stream, needing to strain, a sense of incomplete emptying, and nocturia) and can lead to complications, including acute urinary retention.

INCIDENCE/ PREVALENCE Estimates of the prevalence of symptomatic benign prostatic hyperplasia range from 10–30% for men in their early 70s, depending on how benign prostatic hyperplasia is defined.[1]

AETIOLOGY/ RISK FACTORS The mechanisms by which benign prostatic hyperplasia causes symptoms and complications are unclear, although bladder outlet obstruction is an important factor.[2] The best documented risk factors are increasing age and normal testicular function.[3]

PROGNOSIS Community and practice based studies suggest that men with lower urinary tract symptoms can expect slow progression of the symptoms.[4,5] However, symptoms can wax and wane without treatment. In men with symptoms of benign prostatic hyperplasia, rates of acute urinary retention range from 1–2% a year.[5–7]

AIMS OF INTERVENTION To reduce or alleviate lower urinary tract symptoms; to prevent complications; and to minimise adverse effects of treatment.

OUTCOMES Burden of lower urinary tract symptoms including peak urinary flow rate; residual urine volume, and rates of acute urinary retention and prostatectomy, self rated improvement; and adverse effects of treatment. Symptoms are measured using the validated International Prostate Symptom Score (IPSS), which includes seven questions measuring symptoms on an overall scale from 0–35, with higher scores representing more frequent symptoms.[8] RCTs reported in this chapter used a variety of symptom based assessment instruments, including the Boyarsky Symptom Score (see glossary, p 1136) and the American Urological Association Symptom Index (AUASI) (see glossary, p 1136).

METHODS This review was originally based on ongoing Medline searches and prospective journal hand searches by the Patient Outcomes Research Team for Prostatic Diseases (Agency for Health Care Policy and Research grant number HS0839). *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of medical treatments?

OPTION α BLOCKERS

Systematic reviews have found that α blockers improve lower urinary tract symptom scores compared with placebo. Systematic reviews found limited evidence that different α blockers have similar effects. RCTs found limited evidence that α blockers improved symptom scores compared with the 5α reductase inhibitor finasteride. One RCT found no significant difference between tamsulosin and saw palmetto plant extracts in symptom scores or maximum flow rate after 1 year. Another RCT found limited evidence suggesting that α blockers were less effective than transurethral microwave thermotherapy in improving symptoms over 18 months. We found no RCTs comparing α blockers versus surgical treatment.

Benefits: **Versus placebo:** We found four systematic reviews[9–12] and three subsequent RCTs.[13–15] Two systematic reviews assessed any α blocker (search dates 1998, 21 RCTs;[9] and 1999, 24 RCTs[10]), one systematic review assessed tamsulosin (search date 2000, 6 RCTs[11]), and one systematic review assessed terazosin (search date 2001, 10 RCTs[12]). Most RCTs included in the first two reviews found a greater improvement in symptom scores with α blockers than with placebo, but overall results were not reported (results presented graphically or in tabular form).[9,10] The largest RCT (2084 men) identified by the reviews[11,12] compared terazosin at doses of up to 10 mg daily for 1 year versus placebo.[16] It found that terazosin significantly improved International Prostate Symptom Score (IPSS)

compared with placebo (mean −7.6 points from baseline with terazosin *v* −3.7 with placebo; mean change, terazosin *v* placebo −3.9 points, 95% CI −5.5 points to −3.3 points).[16] One RCT (81 men) included in the first review[11] found that sustained release alfuzosin (5 mg twice daily) for 48 hours significantly increased the proportion of men who were able to pass urine after catheter removal in men catheterised for acute retention compared with placebo (22/40 [55%] with alfuzosin *v* 12/41 [29%] with placebo; OR 2.95, 95% CI 1.08 to 8.21).[17] The third review found that tamsulosin (0.4 or 0.8 mg/day) significantly improved symptom scores and peak urine flow compared with placebo (WMD for mean change in Boyarsky Symptom Score [see glossary, p 1136] for 0.4 mg tamsulosin *v* placebo −1.1 points, 95% CI −1.49 points to −0.72 points; for 0.8 mg tamsulosin *v* placebo −1.6 points, 95% CI −2.3 points to −1.0 points; WMD for change in peak urine flow from baseline for 0.4 mg tamsulosin 1.1 mL/second, 95% CI 0.59 mL/second to 1.51 mL/second; for 0.8 mg tamsulosin 1.1 mL/second, 95% CI 0.65 mL/second to 1.48 mL/second).[11] The fourth review found that terazosin improved the Boyarsky Symptom Score and the American Urological Association Symptom Index (AUASI — see glossary, p 1136) at 4–52 weeks compared with placebo, but it did not assess the significance of the difference between groups (mean improvement in Boyarsky Symptom Score in 4 RCTs 37% with terazosin *v* 15% with placebo, P value not reported; mean improvement in AUASI in 2 RCTs 38% for terazosin *v* 17% for placebo, P value not reported).[12] It also found that terazosin improved peak urinary flow rates compared with placebo (improvement 23% with terazosin *v* 11% with placebo, P value not reported). The first subsequent RCT (795 men) compared three interventions: standard doxazosin, controlled released doxazosin, and placebo.[13] It found that more men had a reduction from baseline in IPSS of at least 30% with either formulation of doxazosin compared with placebo, but it did not report the significance of the difference between groups (74.7% with standard doxazosin *v* 73.5% with controlled release doxazosin *v* 53.5% with placebo; absolute figures and P value not reported). The second subsequent RCT (536 men) compared prolonged release alfuzosin 10 mg versus placebo, and prolonged release alfuzosin 15 mg versus placebo.[14] It found that alfuzosin 10 and 15 mg significantly improved symptom scores compared with placebo (mean change in IPSS from baseline at end point −3.6 points with alfuzosin 10 mg *v* −3.4 points with alfuzosin 15 mg *v* −1.6 points with placebo; alfuzosin 10 mg *v* placebo, $P = 0.001$; alfuzosin 15 mg *v* placebo, $P = 0.004$). It found no significant difference in symptom scores between 10 and 15 mg alfuzosin. The third subsequent RCT (1095 men) compared four interventions: standard doxazosin, finasteride, doxazosin plus finasteride, and placebo.[15] It found that doxazosin significantly improved total IPSS scores from baseline over 1 year compared with placebo (503 men: mean change −8.4 with doxazosin *v* −5.4 with placebo; $P < 0.001$). It also found that doxazosin significantly improved peak urinary flow rate (mean change +3.6 mL/second with doxazosin *v* +1.3 mL/second for placebo; $P < 0.001$).[15]

Versus each other: We found two systematic reviews, one comparing tamsulosin versus other α blockers (search date 2000, 5

RCTs)[11] and one comparing terazosin versus other α blockers (search date 2001, 6 RCTs),[12] one additional RCT,[18] and two subsequent RCTs (reported in the same paper).[19] The first review did not pool results for comparisons between tamsulosin and all other α blockers combined.[11] It found no significant difference between tamsulosin 0.2 mg daily and terazosin 2–5 mg daily in IPSS and urine flow (4 RCTs; WMD for change in IPSS –0.72 points, 95% CI –2.54 points to +1.51 points; WMD for change in peak urine flow –0.26 mL/second, 95% CI –1.12 mL/second to +0.60 mL/second). It found no significant difference in symptoms between tamsulosin and alfuzosin or between tamsulosin and prazosin (tamsulosin *v* alfuzosin: 1 RCT; improvement in Boyarsky Symptom Score about 40% in each group; increase in peak urine flow about 16% in each group; tamsulosin *v* prazosin: 1 RCT; improvement in IPSS 26% with tamsulosin *v* 38% with prazosin; improvement in peak urine flow 15% with tamsulosin *v* 27% with prazosin, P values reported as non-significant, CI not reported). The second review found no significant difference between terazosin and tamsulosin in IPSS scores or peak urinary flow rates (3 RCTs; improvement in IPSS score 40% with terazosin *v* 41% with tamsulosin; WMD of IPSS score +0.72 points, 95% CI –1.51 points to +2.93 points; increase in peak flow 25% with terazosin *v* 29% with tamsulosin; WMD +0.26%, 95% CI –0.60% to +1.12%).[12] It found similar Boyarsky Symptom Scores for terazosin compared with doxazosin, and similar IPSS scores for terazosin and prazosin (terazosin *v* doxazosin: 1 RCT; improvement in Boyarsky Symptom Score 38–47% with terazosin *v* 42% with doxazosin, P value not reported; terazosin *v* prazosin: 1 RCT; improvement in IPPS score 39% with terazosin *v* 38% with prazosin; P value not reported). The additional RCT (103 people) found no significant difference in Boyarsky Symptom Score at 21 days between alfuzosin and prazosin (change in score: –2.6 with alfuzosin *v* – 2.8 with prazosin; P value not reported).[18] The results of the two subsequent RCTs (total 1475 men) were combined in a meta-analysis.[19] It found no significant difference between standard and controlled release doxazosin in IPSS improvement from baseline (–7.9 points with controlled release *v* –8.0 points with standard; adjusted mean difference –0.1 points, 95% CI –0.5 points to +0.3 points).[19]

Versus 5α reductase inhibitors: We found one systematic review (search date 2001, 1 RCT, 1229 men)[12], and one additional[20] and two subsequent RCTs.[15,21] The RCT identified by the review[12] was poor quality (see comment below). It compared three interventions: terazosin, finasteride, and terazosin plus finasteride.[22] It found that terazosin significantly reduced AUASI score compared with finasteride (mean change in AUASI score –6.1 points with terazosin *v* –3.2 points with finasteride; WMD –2.80 points, 95% CI –3.88 points to –1.72 points; $P < 0.001$). There was no significant difference between finasteride plus terazosin and terazosin alone. The additional RCT (1051 men) compared alfuzosin versus finasteride versus both drugs combined over 6 months.[20] It found that alfuzosin significantly decreased the mean IPSS score from baseline compared with finasteride, and it found no significant difference between alfuzosin alone and alfuzosin plus finasteride.[20] The second subsequent RCT (1095 men) compared four interventions:

standard doxazosin, finasteride, doxazosin plus finasteride, and placebo.[15] It found that both doxazosin and doxazosin plus finasteride significantly improved total IPSS and peak urinary flow rate over 1 year compared with finasteride alone (759 men; $P < 0.05$). The second subsequent RCT (205 men) compared tamsulosin versus finasteride.[21] It found that tamsulosin was significantly more effective than finasteride in improving IPSS score and mean peak urinary flow at 4 weeks (mean change in IPSS –3.5 with tamsulosin *v* –1.9 with finasteride; mean peak flow 1.0 mL/second with tamsulosin *v* +0.3 mL/second with finasteride; $P < 0.05$ for both outcomes) but found no significant difference in scores at 24 weeks (mean change in IPSS –6.9 with tamsulosin *v* –5.8 with finasteride; mean peak flow: +2.2 mL/second with tamsulosin *v* +2.2 mL/second with finasteride; P reported as non-significant, CI not reported for either outcome). **Versus transurethral microwave thermotherapy:** See benefits of transurethral microwave thermotherapy, p 1132. **Versus saw palmetto plant extracts:** See benefits of saw palmetto plant extracts, p 1133.

Harms:

Versus placebo: The first systematic review found that withdrawals because of adverse events were similar with alfuzosin, tamsulosin (0.4 mg dose), and placebo (results presented graphically; CI not reported).[9] There was little observable difference in rates of dizziness between either alfuzosin or tamsulosin compared with placebo (results presented graphically; CI not reported). However, terazosin and doxazosin increased dizziness compared with placebo (results presented graphically; CI not reported). One non-systematic review of RCTs (3 RCTs, 830 people) suggested that both selective and less selective α blockers may be associated with abnormal ejaculation; the risk of abnormal ejaculation was significantly higher with tamsulosin than with placebo (4.5% with tamsulosin *v* 1.0% with placebo; $P = 0.042$).[23] Another systematic review found no significant difference between tamsulosin and placebo in withdrawal because of adverse events (4 RCTs; RR 1.08, 95% CI 0.72 to 1.62).[11] However, it found that tamsulosin significantly increased abnormal ejaculation, rhinitis, and dizziness compared with placebo (abnormal ejaculation: 4 RCTs; AR 10.8% with tamsulosin *v* < 1% with placebo; RR 17.0, 95% CI 2.5 to 114.0; rhinitis: 4 RCTs; AR 11.2% with tamsulosin *v* 6% with placebo; RR 1.84, 95% CI 1.24 to 2.72; dizziness: 5 RCTs; AR 11.9% with tamsulosin *v* 7.8% with placebo; RR 1.50, 95% CI 1.13 to 1.98). Another systematic review found that terazosin significantly increased dizziness, asthenia, and postural hypotension compared with placebo (dizziness: 6 RCTs; RR 2.43, 95% CI 1.82 to 3.25; asthenia: 5 RCTs; RR 2.24, 95% CI 1.68 to 3.00; postural hypotension: 4 RCTs; RR 5.27, 95% CI 5.27 to 10.72).[12] It found no significant difference in discontinuation rates between terazosin and placebo (10 RCTs: 27% with terazosin *v* 34% with placebo; RR 0.94, 95% CI 0.76 to 1.17). Discontinuations because of adverse events were significantly higher with terazosin compared with placebo (6 RCTs: 229/1817 [12.6%] with terazosin *v* 140/1607 [8.7%] with placebo; RR 1.50, 95% CI 1.23 to 1.83). **Versus each other:** We found three systematic reviews assessing harms.[9,11,12] The first review found no significant difference between tamsulosin and a less selective α blocker, alfuzosin (1 RCT; dizziness 7%, asthenia

2%, and postural hypotension 2% of men in each group).[9] The second review comparing tamsulosin versus other α blockers found that discontinuation of treatment due to adverse effects was less likely with tamsulosin 0.2 mg daily than with terazosin (4 RCTs; RR 0.15, 95% CI 0.04 to 0.57).[11] However, tamsulosin 0.4 or 0.2 mg daily was associated with greater all cause withdrawal from treatment than alfuzosin or prazosin, although the differences were not significant (tamsulosin *v* alfuzosin: 1 RCT; RR for withdrawal 1.46, 95% CI 0.66 to 3.25; tamsulosin *v* prazosin: 1 RCT; RR for withdrawal 2.87, 95% CI 0.65 to 12.65). The review found no significant difference between tamsulosin and alfuzosin in dizziness (1 RCT: AR 6.8% with tamsulosin *v* 7.3% with alfuzosin; RR 0.94, 95% CI 0.39 to 2.29), asthenia (1 RCT: AR 3% with tamsulosin *v* 1.6% with alfuzosin; RR 1.88, 95% CI 0.35 to 10.08), headache (1 RCT: AR 7.6% with tamsulosin *v* 3.2% with alfuzosin; RR 2.35, 95% CI 0.76 to 7.29). The review also found that risk of abnormal ejaculation increased with increasing dose of tamsulosin (0% with 0.2 mg/day; 18% with 0.8 mg/day; CI not reported). The third review found no significant difference in discontinuation rates between terazosin and either prazosin or doxazosin (terazosin *v* prazosin: 1 RCT; RR 3.93, CI 95% 0.92 to 16.72; terazosin *v* doxazosin: 1 RCT; RR 1.75, 95% CI 0.48 to 6.41).[12] The review found no significant difference between terazosin and alfuzosin in dizziness (1 RCT; 5.1% with terazosin *v* 0% with alfuzosin; RR 4.50, 95% CI 0.22 to 90.64). It found no significant difference in dizziness or headache between terazosin and doxazosin (dizziness: 1 RCT; 14.3% with terazosin *v* 4.5% with doxazosin; RR 3.14, 95% CI 0.35 to 27.88; headache: 1 RCT; 4.8% with terazosin *v* 4.5% with doxazosin; RR 1.05, 95% CI 0.07 to 15.69) but it may have lacked power to exclude a clinically important effect. **Versus 5α reductase inhibitors:** In the RCT identified by the review comparing terazosin versus finasteride, dizziness, generalised weakness, rhinitis, and postural hypotension were more common with terazosin than with finasteride (dizziness: 26% with terazosin *v* 8% with finasteride; generalised weakness: 14% with terazosin *v* 7% with finasteride; rhinitis: 7% with terazosin *v* 3% with finasteride; postural hypotension: 8% with terazosin *v* 2% with finasteride; significance not reported for any comparison), whereas sexual dysfunction was more common in men taking finasteride (impotence: 9% with finasteride *v* 6% with terazosin; significance not reported).[22] The other RCTs gave no information on adverse effects.[15,20,21] **Versus transurethral microwave thermotherapy:** See harms of transurethral microwave thermotherapy, p 1132. **Versus saw palmetto plant extracts:** See harms of saw palmetto plant extracts, p 1134.

Comment: Men with severe symptoms can expect the largest absolute fall in their symptom scores with medical treatment.[16,24] Prazosin, terazosin, and doxazosin lower blood pressure and may be used to treat both hypertension and benign prostatic hyperplasia.[25] The RCT included in the review that compared α blockers versus 5α reductase inhibitors is limited by its small sample size, low drug doses, and unclear methods of randomisation and blinding.[12]

OPTION 5α REDUCTASE INHIBITORS

One systematic review and additional RCTs have found that 5α reductase inhibitors improve symptom scores and reduce complications compared with placebo. The review found that 5α reductase inhibitors were associated with more adverse events than placebo, including decreased libido, impotence, and ejaculatory dysfunction. RCTs found limited evidence that the 5α reductase inhibitor finasteride was less effective at improving symptom scores than α blockers. One systematic review found no significant difference in symptom scores between finasteride and saw palmetto plant extracts. We found no RCTs comparing 5α reductase inhibitors versus surgical treatment.

Benefits:

Versus placebo: We found one systematic review (search date 1999, 12 RCTs, 11 338 men),[10] one subsequent RCT (generating numerous publications)[7,26–29] and two additional RCTs.[15,30] Ten of the 12 RCTs included in the systematic review found that finasteride significantly reduced symptom scores compared with placebo.[10] The first RCT in the review (2902 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 24 months (change in Boyarsky Symptom Score [see glossary, p 1136]: –20% with finasteride *v* –13% with placebo; $P < 0.001$). The second RCT in the review (2112 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 12 months (change in American Urological Association Symptom Index [AUASI — see glossary, p 1136] score: –26% with finasteride *v* –20% with placebo; $P < 0.01$). The third RCT in the review (496 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 12 months (change in Boyarsky Symptom Score: –20% with finasteride *v* –14% with placebo; $P < 0.05$). The fourth RCT in the review (472 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 24 months (change in Boyarsky Symptom Score: –13% with finasteride *v* –4% with placebo; $P < 0.01$). The fifth RCT in the review (707 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 24 months (change in Boyarsky Symptom Score: –15% with finasteride *v* +2% with placebo; $P < 0.01$). The sixth RCT in the review (895 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 12 months (change in Boyarsky Symptom Score: –26% with finasteride *v* –10% with placebo; $P < 0.05$). The seventh RCT in the review (46 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 6 months (change in AUASI score: –30% with finasteride *v* –12% with placebo; $P < 0.05$). The eighth RCT in the review (2760 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo (change in AUASI scores: –17% with finasteride *v* –7% with placebo; $P < 0.001$). The ninth RCT in the review (99 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 12 months (change in AUASI score: –30% with finasteride *v* –10% with placebo; $P < 0.05$). The 10th RCT in the review (182 men) found that 5 mg finasteride significantly improved symptom scores compared with placebo at 6 months (change in Boyarsky Symptom Score: –23% with finasteride *v* –9% with placebo;

P = 0.05). The 11th RCT in the review (615 men) found no significant difference in symptom scores between 1–10 mg finasteride and placebo at 12 months (change in AUASI score: –20% with finasteride *v* –16% with placebo; P = 0.63). The 12th RCT in the review (52 men) found that finasteride improved symptom scores at 3 months compared with placebo but the significance of the difference between groups was not reported in the review (change in AUASI score: –21% with finasteride *v* –19% with placebo). The first subsequent RCT (3040 men) compared finasteride 5 mg daily versus placebo.[7] After 4 years, finasteride significantly reduced symptom scores compared with placebo (difference in symptom score –1.6 points, 95% CI –2.5 points to –0.7 points [range of score 0–34 points]). It also found that finasteride significantly reduced the risk of acute urinary retention and prostatectomy compared with placebo (urinary retention 6.6% with finasteride *v* 2.8% with placebo; NNT 26, 95% CI 22 to 38; prostatectomy 8.3% with finasteride *v* 4.2% with placebo; NNT 24, 95% CI 19 to 37). There was a greater effect among men with higher concentrations of prostate specific antigen at baseline (3.3–12.0 ng/mL), reflecting larger prostates (risk of either acute urinary retention or needing prostatectomy: 19.9% with placebo *v* 8.3% with finasteride; NNT 8, 95% CI 7 to 11).[27] The RCT also found that, after 4 years, finasteride produced a larger fall in International Prostate Symptom Score compared with placebo. The fall was greater for men with prostate specific antigen levels greater than 1.3 ng/mL than for men with prostate specific antigen levels equal to or lower than 1.3 ng/mL.[26] The second subsequent RCT (1095 men) compared four interventions: finasteride, standard doxazosin, doxazosin plus finasteride, and placebo.[15] It found no significant difference between finasteride and placebo in International Prostate Symptom Score or peak urinary flow rate over 1 year (492 men; P reported as non-significant, CI not reported).[15] The third subsequent RCT (4325 men) compared dutasteride versus placebo.[30] It found that, compared with placebo, dutasteride significantly improved AUASI scores (–4.5 with dutasteride *v* –2.3 with placebo; P < 0.001), and peak urinary flow rate after 24 months (+2.2 mL/second with dutasteride *v* +0.6 mL/second with placebo; P < 0.001).[30] **Versus α blockers:** See benefits of α blockers, p 1121. **Versus saw palmetto plant extracts:** See benefits of saw palmetto plant extracts, p 1133.

Harms:

Versus placebo: The systematic review found that finasteride increased adverse events in the first year compared with placebo.[10] The most common adverse events with finasteride in the first year were decreased libido, impotence, and ejaculatory dysfunction. The largest RCT (3168 men) found decreased libido, increased impotence, and increased ejaculatory dysfunction compared with placebo (decreased libido 4.0% *v* 2.8%; reported as non-significant; increased impotence 6.6% *v* 4.7%; reported as significant; ejaculatory dysfunction 2.1% *v* 0.6%; reported as significant; none of the P values reported). Another large RCT (2342 men) found decreased libido, increased impotence, and increased ejaculatory dysfunction compared with placebo (decreased libido 3.1% *v* 1.2%; reported as significant; impotence 6.8% *v* 3.2%; reported as significant;

increased ejaculatory dysfunction 2.3% *v* 0.5%; reported as significant; none of the P values reported). The large subsequent 4 year RCT (3040 men) found that, after the first year of treatment, there was no significant difference in decreased libido (2.6% *v* 2.6%) or impotence (5.1% *v* 5.1%) between finasteride and placebo, but there was still a slightly greater rate of ejaculation disorder (0.2% *v* 0.1%; significance not tested).[7] Although finasteride reduced concentrations of prostate specific antigen by a mean of 50% (individual responses were highly variable), its use for up to 4 years did not change the rate of detection of prostate cancer compared with placebo.[7] The additional RCTs did not address harms. **Versus α blockers:** See harms of α blockers, p 1124. **Versus saw palmetto plant extracts:** See harms of saw palmetto plant extracts, p 1134.

Comment: We found two non-systematic reviews comparing finasteride versus placebo.[31,32] One of the non-systematic reviews (6 RCTs) found that finasteride significantly decreased symptom scores compared with placebo (difference in symptom score –0.9 points, 95% CI –1.2 points to –0.6 points [range of score 0–30 points]).[32] The benefit over placebo was greatest in men with larger prostates (≥ 40 g). The other non-systematic review (meta-analysis of 3 RCTs) found that finasteride reduced acute urinary retention requiring catheterisation after 2 years from 2.7% to 1.1%.[31] The meta-analysis also found that finasteride was significantly more effective than placebo in men with larger prostates at 1–2 years. However, the absolute difference in mean decrease of symptom score from baseline between men with the smallest and largest prostates was only about 1 point. The relative effectiveness of finasteride compared with placebo also seemed higher in men with slightly raised prostate specific antigen levels, and it is assumed that the higher prostate specific antigen is a proxy for a larger prostate.[26]

QUESTION What are the effects of surgical treatments?

OPTION TRANSURETHRAL RESECTION OF THE PROSTATE

RCTs found that transurethral resection of the prostate reduced symptom scores more than watchful waiting, and did not increase the risk of erectile dysfunction or incontinence. RCTs found no significant difference in symptom scores between transurethral resection and transurethral incision or between transurethral resection and electrical vaporisation. RCTs found limited evidence that transurethral resection improved symptom scores more than visual laser ablation but may be associated with a higher risk of blood transfusion.

Benefits: **Versus watchful waiting:** We found no systematic review. We found two RCTs comparing transurethral resection of the prostate (TURP) versus watchful waiting.[33,34] The first RCT (556 men with moderate symptoms of benign prostatic hyperplasia) found that TURP significantly improved symptom scores compared with watchful waiting (90% with TURP *v* 39% with watchful waiting; $P < 0.001$). After 5 years, the treatment failure rate was 10% with TURP compared with 21% with watchful waiting (NNT 9, 95% CI 7 to 17), and 36% of men assigned to watchful waiting had crossed over

to surgery.[35] Treatment failure was defined as death, acute urinary retention, high residual urine volume, renal azotaemia, bladder stones, persistent incontinence, or a high symptom score. The major categories of treatment failure reduced by TURP were acute urinary retention, development of a large bladder residual (> 350 mL), and deterioration to a severe symptom level. The second RCT (223 men) had a shorter duration of follow up (7.5 months).[34] It found that TURP significantly improved the International Prostate Symptom Score (IPSS) compared with watchful waiting (difference in IPSS 10.4 points, 95% CI 8.5 points to 12.3 points). **Versus less invasive techniques:** We found four systematic reviews[36–39] and four subsequent RCTs.[40–43] The first systematic review (search date 1999, 9 RCTs) compared TURP versus transurethral incision.[36] Four of the included RCTs (243 men) examined symptom scores at 12 months and found no significant difference between TURP and transurethral incision (WMD +0.2 points, 95% CI –0.8 points to +1.1 points). The review found little good, long term evidence. The second systematic review (search date 1999, 5 RCTs) compared TURP versus visual laser ablation (4 RCTs, 331 men) or laser contact vaporisation (1 RCT, 28 men).[37] The review did not perform a meta-analysis. It found that TURP was more effective at reducing symptom score than visual laser ablation but increased the length of hospital stay. The largest RCT (151 men) identified by the second review found that TURP significantly improved symptom scores compared with ablation at 52 weeks (American Urological Association Symptom Index [see glossary, p 1136] mean score reduced from 18.2 to 5.1 with TURP *v* from 18.1 to 7.7 with laser ablation). The review found no significant difference between TURP and laser contact vaporisation in symptom scores or quality of life at 12 months' follow up. The third systematic review (search date 1999, 5 RCTs, 454 men) compared TURP versus electrical vaporisation.[38] It found no significant difference in symptom scores at 12–24 months between TURP and electrical vaporisation, although symptoms were improved more with electrical vaporisation (3 RCTs, figures reported as SMD +0.21, 95% CI –0.03 to +0.44). The fourth systematic review (search date 2002, 16 RCTs) compared TURP versus contact laser vaporisation (7 RCTs, 501 men) or visual laser ablation (8 RCTs, 864 men) or a hybrid laser technique (4 RCTs, 276 men).[39] For men undergoing contact laser vaporisation, the review analysed results separately for comparisons of TURP versus Nd:YAG or versus holmium laser resection. The review found no significant difference in symptom scores at 12 months between transurethral resection and Nd:YAG contact laser (2 RCTs; WMD +2.08 points, 95% CI –0.36 points to +4.51 points) or between TURP and holmium laser resection (5 RCTs; WMD +0.10 points, 95% CI –2.08 points to +1.88 points). It also found no significant difference in peak urinary flow at 12 months between TURP and Nd:YAG contact laser (4 RCTs; WMD 1.9 mL/second, 95% CI –0.21 mL/second to +4.02 mL/second). However, it found that holmium laser resection significantly reduced peak urinary flow rate at 12 months compared with TURP (1 RCT; WMD –4.8 mL/second, 95% CI –8.79 mL/second to –0.81 mL/second). It found similar reductions in symptoms scores at 12 months between TURP and visual laser ablation (mean

decrease 63% with TURP *v* 59% with visual laser). The reported differences in significance between TURP and visual laser ablation varied depending on whether mean changes in symptom scores or mean scores at follow up had been recorded. If mean change in symptom scores was assessed, TURP was significantly less effective than visual laser ablation in reducing symptoms over 7–12 months (3 RCTs; WMD –2.5 points, 95% CI –4.24 points to –0.70 points). However, if mean symptom score at follow up was assessed there was no significant difference between TURP and visual laser ablation at 6 or 12 months (WMD 0.21 points, 95% CI –2.28 points to +2.70 points). The first subsequent RCT (98 men) found that TURP reduced surgical retreatment rates after 5 years compared with laser ablation (18/47 [38%] with visual laser ablation v 8/51 [16%] with TURP; P = 0.006).[40] The other subsequent RCTs compared TURP versus electrical vaporisation; all found similar improvements in symptoms between treatments.[41–43] The second subsequent RCT (100 men) found similar symptom scores at 3 months after treatment between TURP and electrical vaporisation (mean IPSS decreased from 21.6 points to 5.0 points with TURP *v* from 19.4 points to 4.0 points with vaporisation; CI and P value for direct comparison not reported).[41] The third subsequent RCT (185 men) also found similar improvements symptoms at 12 months (mean decrease in IPSS from baseline 12.8 points for TURP *v* 12.5 points for vaporisation; CI and P value not reported).[42] The fourth subsequent RCT (235 men) found no significant difference between TURP and electrical vaporisation after 6 months (mean change in IPSS from baseline: 20.9 to 6.9 with TURP *v* 20.7 to 8.5 with electrical vaporisation; mean increase in flow rate: 10.5 to 22.3 mL/second with TURP *v* 10.1 to 19.6 mL/second with electrical vaporisation; P > 0.12).[43] **Versus transurethral microwave therapy:** See benefits of transurethral microwave thermotherapy, p 1132. **Versus transurethral needle ablation:** See benefits of transurethral needle ablation, p 1133.

Harms: Analysis of administrative data found that mortality in the 30 days after TURP for benign prostatic hyperplasia ranged from 0.4% for men aged 65–69 years to 1.9% for men aged 80–84 years, and has fallen in recent years.[44] In one review of observational studies, TURP for benign prostatic hyperplasia was associated with immediate surgical complications in 12% of men, bleeding requiring intervention in 2%, erectile dysfunction in 14%, retrograde ejaculation in 74%, and incontinence in about 5%.[45–47] Analysis of claims data found a reoperation rate, implying need for retreatment, of about 1% a year.[44] However, in the only comparative trial, men randomised to prostatectomy did not seem to have a greater rate of erectile dysfunction or incontinence than did men assigned to watchful waiting.[33,35] One systematic review found that visual laser ablation was associated with a lower risk of blood transfusion than TURP but with a higher risk of urinary tract infection (blood transfusion: 0/145 [0%] with laser ablation *v* 15/146 [10%] with TURP; RR 0.09, 95% CI 0.02 to 0.47; urinary tract infection: RR 3.85, 95% CI 1.87 to 7.94; absolute figures not reported).[37] The largest RCT found fewer cases of blood transfusion with visual laser ablation compared with TURP (0/76 [0%] with laser ablation *v* 12/75 [16%] with TURP). The third systematic review found that

TURP and electrical vaporisation had similar risks of blood transfusion, irritative symptoms, and urinary tract infections, although confidence intervals were large.[38] However, electrical vaporisation was associated with a significant increase in the risk of urinary retention (17.1% with electrical vaporisation *v* 3.8% with TURP; RR 3.64, 95% CI 1.68 to 7.92; absolute figures not reported) compared with TURP. One RCT (150 men) in the review reported more transient stress urinary incontinence with electrical vaporisation than with TURP (13/70 [19%] with electrical vaporisation *v* 0/80 [0%] with TURP). Most of the RCTs included in the fourth systematic review did not comprehensively report adverse effects.[39] However, the review found that significantly more men undergoing TURP required blood transfusion (RR 25.0, 95% CI 5.9 to 100) and developed urethral strictures (RR 2.3, 95% CI 1.3 to 3.8) than men undergoing any laser procedure. It also found that urinary retention was significantly more common following treatment with any laser technique than treatment with TURP (RR 2.3, 95% CI 1.4 to 3.9), and that visual laser techniques had a higher incidence of dysuria (RR 3.6, 95% CI 1.0 to 13.1) and urinary tract infection (RR 2.2, 95% CI 1.0 to 4.9) than TURP.[39] One subsequent RCT (100 men) found that no-one having either TURP or electrical vaporisation required transfusion.[41] It also found no significant difference in rates of erectile dysfunction between the two groups (22% with TURP *v* 24% with vaporisation; P values and CI not reported). However, another subsequent RCT (185 men) found no significant difference between TURP and electrical vaporisation in rates of postoperative incontinence (6/92 [6.5%] with TURP *v* 5/93 [5.4%] with vaporisation; RR 1.2, 95% CI 0.4 to 3.8).[41] Rates of haemorrhage requiring blood transfusion and of urethral stricture were low in both groups and not significantly different (transfusion: 9/92 [9.8%] with TURP *v* 6/93 [6.5%] with vaporisation; RR 1.5, 95% CI 0.6 to 4.1; urethral stricture: 7/92 [7.6%] with TURP *v* 5/93 [5.4%] with vaporisation; RR 1.4, 95% CI 0.5 to 4.3). A further RCT (340 men) examined sexual function after TURP, laser prostatectomy, and conservative management.[48] It found that TURP reduced the proportions with erectile dysfunction, reduced pain or discomfort on ejaculation, and increased ejaculatory dysfunction compared with conservative management (erectile dysfunction OR 0.37, 95% CI 0.19 to 0.74; pain or discomfort on ejaculation OR 0.06, 95% CI 0.007 to 0.49; ejaculatory dysfunction OR 3.27, 95% CI 1.69 to 6.35).

Comment: Rapid changes in techniques and few controlled trials with adequate follow up make comparisons between TURP and newer surgical techniques difficult. The second review reported that RCTs comparing TURP versus laser ablation were limited generally by small sample size, brief follow up, and lack of blinding.[37] The third review comparing TURP versus electrical vaporisation found that none of the RCTs were blinded or analysed by intention to treat, but four out of five RCTs had less than 10% loss to follow up.[38]

Benign prostatic hyperplasia

OPTION TRANSURETHRAL MICROWAVE THERMOTHERAPY

RCTs found that transurethral microwave thermotherapy reduced symptom scores compared with sham treatment. We found limited evidence that thermotherapy was less effective in relieving short term symptoms than transurethral resection. One RCT found that transurethral microwave thermotherapy improved symptom scores over 18 months compared with α blockers.

Benefits:

Versus sham treatment: We found no systematic review. We found three RCTs comparing transurethral microwave thermotherapy (TUMT) versus sham treatment.[49–51] In the largest RCT (220 men), TUMT improved the International Prostate Symptom Score (IPSS) significantly more than sham treatment (mean 5 points lower; $P < 0.05$).[49] In the second RCT (169 men), TUMT significantly improved IPSS more than sham treatment at 6 months ($P < 0.05$).[50] The third RCT (50 men) compared TUMT versus sham treatment. It found a greater reduction in Madsen symptom score (range 0–27, higher scores indicating worse symptoms) with TUMT compared with sham treatment (reduction in Madsen symptom score reduction 7.3 with TUMT *v* 3.9 with sham treatment; significance was not tested). **Versus transurethral resection of the prostate:** We found one systematic review[38] (search date 1999, 3 RCTs, 200 men) and one additional RCT comparing TUMT versus transurethral resection of the prostate (TURP).[52] In the systematic review, symptom improvement was significantly better with TURP in one RCT ($P < 0.05$) but not significantly different in the other two.[38] The additional RCT (147 men) found better symptomatic outcomes with TURP but the significance was not reported (IPSS improvement from baseline at 1 year: 60% with TUMT *v* 85% with TURP; CI not reported).[52] **Versus α blockers:** We found one RCT (103 men).[53,54] It found that TUMT significantly improved symptom scores at 6 and 18 months compared with terazosin (up to 10 mg/day; difference in IPSS at 18 months 35%; $P < 0.001$).

Harms:

Adverse events associated with TUMT varied among trials, but included the need for catheterisation for more than 1 week (8% with TUMT *v* 2% with sham treatment),[50] persistent irritative symptoms (22% with TUMT *v* 8% with sham treatment),[49] haematuria (14% with TUMT *v* 1% with sham treatment),[49] and sexual dysfunction (mostly haematospermia and other ejaculatory abnormalities; 29% with TUMT *v* 1% with sham treatment).[49] In one RCT retrograde ejaculation was substantially less common after TUMT compared with TURP (27% with TUMT *v* 74% with TURP).[55] The RCT (103 men) comparing TUMT versus α blockers found more adverse events in the α blocker group over the first 6 months (17 events in 52 men with α blockers *v* 7 events in 51 men with TUMT; CI not reported).[53,54] With α blockers, the most common adverse effect was dizziness (7 cases) or asthenia (4 cases); in the TUMT group it was urinary tract infection (3 cases).

Comment: TUMT can be performed in an outpatient setting, and uses heat generated by a microwave antenna in the urethra to coagulate prostate tissue. The long term effects of TUMT have not been adequately evaluated in controlled studies. The systematic review reported that trials were limited by small sample size, short duration of follow up (maximum 30 months), and large loss to follow up.

OPTION TRANSURETHRAL NEEDLE ABLATION

One RCT found that transurethral resection reduced symptom scores compared with transurethral needle ablation after 1 year, although transurethral needle ablation caused fewer adverse effects.

Benefits: We found no systematic review. **Versus transurethral resection:** We found one RCT (121 men) comparing transurethral resection of the prostate (TURP) versus transurethral needle ablation (TUNA).[56] The mean International Prostate Symptom Score was significantly lower with TURP than TUNA at 1 year (11.1 points with TUNA *v* 8.3 points with TURP; P = 0.04).

Harms: Compared with TURP, TUNA was associated with less retrograde ejaculation (38% with TURP *v* 0% with TUNA) and bleeding (100% with TURP *v* 32% with TUNA).[56]

Comment: TUNA can be performed in an outpatient setting, and uses radiofrequency energy through two intraprostatic electrodes to generate heat to coagulate prostate tissue. Anaesthesia requirements vary in reported studies. The long term effects of treatment have not been adequately evaluated.

QUESTION What are the effects of herbal treatments?

OPTION SAW PALMETTO PLANT EXTRACTS

One systematic review has found that saw palmetto plant extracts improve symptom scores compared with placebo. It found no significant difference in symptom scores between saw palmetto plant extracts and the α blocker tamsulosin or the 5α reductase inhibitor finasteride. One RCT found no significant difference in symptom scores between tamsulosin and tamsulosin plus saw palmetto plant extracts.

Benefits: We found one systematic review that included all saw palmetto preparations (search date 1997, 18 RCTs, 2939 men)[57] and two subsequent RCTs.[58,59] **Versus placebo:** The systematic review found that more men reported self rated improvement with saw palmetto compared with placebo (6 relevant RCTs: RR 1.7, 95% CI 1.2 to 2.4).[57] It found a significant reduction in nocturia with saw palmetto compared with placebo (10 RCTs; WMD 0.76 episodes/night, 95% CI 0.32 to 1.21). **Versus α blockers:** We found one RCT (704 men).[58] It found no significant difference between tamsulosin and saw palmetto in International Prostate Symptom Score (IPSS) or peak flow rate at 12 months (increase in peak flow 1.8 mL/second with saw palmetto *v* 1.9 mL/second with tamsulosin).[58] **Versus 5α reductase inhibitors:** The systematic review (2 relevant RCTs, 1440 men) found no significant difference in IPSS

between finasteride and saw palmetto (WMD +0.37 points, 95% CI –0.44 points to +1.19 points).[57] **Plus α blocker:** We found one RCT (352 patients).[59] It found no significant difference in symptom score between tamsulosin and tamsulosin plus saw palmetto (improvement in IPSS: 5.2 with tamsulosin *v* 6.0 with tamsulosin plus saw palmetto).

Harms: **Versus placebo:** The systematic review found significantly higher withdrawal rates with saw palmetto than with placebo (9% with saw palmetto *v* 7% with placebo; P = 0.02).[57] The risk of erectile dysfunction was similar with saw palmetto and placebo (1.1% with saw palmetto *v* 0.7% with placebo; P = 0.58). **Versus α blockers:** In one RCT comparing saw palmetto and tamsulosin, a similar proportion of men withdrew because of adverse events (7.7% with saw palmetto *v* 8.2% with tamsulosin).[58] The risk of ejaculatory disorder was significantly less with saw palmetto than with tamsulosin (2/349 [0.6%] with saw palmetto *v* 15/354 [4.2%] with tamsulosin; P = 0.001).[58] **Versus 5α reductase inhibitors:** The review found no significant difference in withdrawal rates between saw palmetto and finasteride (9% with saw palmetto *v* 11% with finasteride; P = 0.87).[57] Rates of erectile dysfunction were significantly lower with saw palmetto compared with finasteride (1.1% with saw palmetto *v* 4.9% with finasteride; P < 0.001).[57]

Comment: The RCTs included in the systematic reviews were short term and few used a validated symptom score. Different preparations, which may not be equivalent, are available directly to consumers without prescription in many countries.[57] The RCT comparing saw palmetto versus tamsulosin used a standardised preparation of saw palmetto.[58]

OPTION β-SITOSTEROL PLANT EXTRACT

One systematic review has found that β-sitosterol plant extract improves lower urinary tract symptom scores compared with placebo in the short term. We found no RCTs comparing β-sitosterol plant extract versus other treatments.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 4 RCTs, 519 men), which compared β-sitosterol versus placebo.[55] The review found that β-sitosterol significantly reduced the International Prostate Symptom Score (2 RCTs; WMD –4.9 points, 95% CI –6.3 points to –3.5 points) at 4–26 weeks. **Versus other treatments:** We found no RCTs.

Harms: **Versus placebo:** Gastrointestinal adverse effects were more common with β-sitosterol than with placebo (1.6% with β-sitosterol *v* 0% with placebo; CI not reported).[55] Impotence was also more common with β-sitosterol (0.5% β-sitosterol *v* 0% with placebo; CI not reported). Withdrawal rates were similar in both groups (7.8% with β-sitosterol *v* 8.0% with placebo; CI not reported).

Comment: The RCTs were limited by a short follow up period (maximum 26 weeks). Different preparations are available, which may be of variable content, making it difficult to generalise results.

OPTION RYE GRASS POLLEN EXTRACT

One systematic review found limited evidence that rye grass pollen extract increased self rated improvement and reduced nocturia at 12–24 weeks compared with placebo. However, the review identified only two small RCTs, from which we were unable to draw reliable conclusions. We found no RCTs comparing Rye grass pollen extract versus other treatments.

Benefits: **Versus placebo:** We found one systematic review (search date 1997, 2 RCTs, 163 men), which compared rye grass pollen extract versus placebo.[60] It found that pollen extract significantly increased self rated improvement and significantly reduced nocturia compared with placebo (proportion improved: 1 RCT, 60 men; 20/31 [65%] with pollen *v* 7/26 [27%] with placebo; RR 2.40, 95% CI 1.21 to 4.75; NNT 3, 95% CI 2 to 9; proportion with reduced nocturia: 2 RCTs; 50/79 [63%] with pollen *v* 23/74 [31%] with placebo; RR 2.05, 95% CI 1.41 to 3.99). However, the results should be interpreted with caution (see comment below). **Versus other treatments:** We found no RCTs.

Harms: The review found that nausea occurred in one man taking pollen extract (number in placebo group not stated).[60] Withdrawal rates were not significantly different (4.8% with pollen *v* 2.7% with placebo; P = 0.26).

Comment: Both RCTs were limited by small sample sizes and a short follow up period (12 and 24 weeks). Concealment of treatment allocation was unclear. The composition of the preparations was unknown, making it difficult to generalise results.

OPTION PYGEUM AFRICANUM New

One systematic review found limited evidence that *Pygeum africanum* increased peak urinary flow and reduced residual urine volume at 4–16 weeks compared with placebo. We found no RCTs comparing Pygeum africanum versus other treatments.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 11 RCTs, 709 men) comparing *Pygeum africanum* versus placebo.[61] It found that *P africanum* significantly increased peak flow compared with placebo at 4–16 weeks (4 RCTs, 384 men; mean reduction 23% with *P africanum v* with placebo; WMD 2.5 mL/seconds, 95% CI 0.3 mL/seconds to 4.7 mL/seconds) and reduced residual urine volume by 24% (2 RCTs, 284 men; mean reduction 24% with *P africanum v* with placebo; WMD –13ml, 95% CI –23.3 mL to –3.0 mL).[61] These results should be interpreted with caution (see comment below). **Versus other treatments:** We found no RCTs.

Harms: The RCTs identified by the review gave little information on adverse effects.[61] The review found that adverse events in men taking *P africanum* were "generally mild and similar in frequency to placebo"; the most commonly reported adverse events associated with *P africanum* were gastrointestinal and were reported in 7 men in 5 RCTs (no further data reported).

Benign prostatic hyperplasia

Comment: The RCTs were limited by their short follow-up period (maximum 16 weeks). The designs of the RCTs and the composition of the preparations used varied, making it difficult to generalise results.

GLOSSARY

American Urological Association Symptom Index (AUASI) is a patient questionnaire that asks seven questions about the severity of symptoms (range 0–35). Mild symptoms score 0–7 points, moderate symptoms 8–19 points, and severe symptoms 20–35 points.

Boyarsky Symptom Score is a patient questionnaire that asks nine questions about severity of symptoms (range 0–27); no symptoms = 0, maximum severity = 27.

Substantive changes

α Blockers Two RCTs added;[15,21] categorisation unchanged.

5α Reductase inhibitors Two RCTs added;[15,30] categorisation unchanged.

Transurethral resection of the prostate One systematic review[39] and one RCT[43] added; categorisation unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 1146

Key Messages

In men with chronic bacterial prostatitis

- **α Blockers (when added to antimicrobials)** We found no RCTs comparing α blockers versus placebo or no treatment. We found limited evidence from one RCT suggesting that adding α blockers to antimicrobials may improve symptoms and reduce recurrence compared with antimicrobials alone.
- **Local injection of antimicrobials** We found no RCTs comparing local injection of antimicrobials versus placebo or no treatment. One small RCT found that anal submucosal injection of amikacin improved symptom scores and bacterial eradication rates at 3 months compared with intramuscular amikacin.
- **Oral antimicrobial drugs** We found no placebo controlled RCTs. One RCT found no significant difference between lomefloxacin and ciprofloxacin in rates of clinical success or bacteriological cure at 6 months. We found no other RCTs of the effects of oral antimicrobial drugs. Retrospective observational studies reported cure rates of 0–88% depending on the drug used and the duration of treatment.
- **Radical prostatectomy; transurethral resection** We found no RCTs on the effects of these interventions.

In men with chronic abacterial prostatitis

- **α Blockers** One systematic review found limited evidence from two small RCTs that α blockers may improve maximal flow time and pain compared with placebo. However, we were unable to draw reliable conclusions from these small studies.

Chronic prostatitis

- **5α Reductase inhibitors** One systematic review of one small RCT found insufficient evidence about the effects of 5α reductase inhibitors compared with placebo in men with chronic abacterial prostatitis.
- **Allopurinol** We found insufficient evidence from one small RCT about the effects of allopurinol compared with placebo in men with chronic abacterial prostatitis.
- **Anti-inflammatory medications** We found insufficient evidence about the effects of anti-inflammatory medications compared with placebo or no treatment in men with chronic abacterial prostatitis.
- **Transurethral microwave thermotherapy** One systematic review found limited evidence from one small RCT suggesting that transurethral microwave thermotherapy may significantly improve quality of life at 3 months, and symptoms over 21 months, compared with sham treatment. However, we were unable to draw reliable conclusions from this one small study.
- **Biofeedback; prostatic massage; Sitz bath** We found no good evidence on these interventions.

DEFINITION **Chronic bacterial prostatitis** is characterised by a positive culture of expressed prostatic secretions. It can be symptomatic (recurrent urinary tract infection, or suprapubic, lower back, or perineal pain), asymptomatic, or associated with minimal urgency, frequency, and dysuria. **Chronic abacterial prostatitis** is characterised by pelvic or perineal pain, often associated with urinary urgency, nocturia, weak urinary stream, frequency, dysuria, hesitancy, dribbling after micturition, interrupted flow, and inflammation (white cells) in prostatic secretions. Symptoms can also include suprapubic, scrotal, testicular, penile, or lower back pain or discomfort, known as prostodynia, in the absence of bacteria in prostatic secretions.

INCIDENCE/ PREVALENCE One US community based study (58 955 visits by men ≥ 18 years to office based physicians) estimated that 9% of men have a diagnosis of chronic prostatitis at any one time.[1] Another study found that, of men with genitourinary symptoms, 8% presenting to urologists and 1% presenting to primary care physicians are diagnosed with chronic prostatitis.[2] Most cases of chronic prostatitis are abacterial. Acute bacterial prostatitis, although easy to diagnose, is rare.

AETIOLOGY/ RISK FACTORS Organisms commonly implicated in bacterial prostatitis include *Escherichia coli*, other Gram negative Enterobacteriaceae, occasionally *Pseudomonas* species, and rarely Gram positive enterococci. The cause of abacterial prostatitis is unclear, but autoimmunity could be involved.[3]

PROGNOSIS One recent study found that chronic abacterial prostatitis had an impact on quality of life similar to that from angina, Crohn's disease, or a previous myocardial infarction.[4]

AIMS OF INTERVENTION To relieve symptoms and eliminate infection where present, with minimum adverse effects.

OUTCOMES Symptom improvement (symptom scores, bother scores); quality of life; urodynamics; rates of bacteriological cure (clearance of previously documented organisms from prostatic secretions).

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION **What are the effects of treatments for chronic bacterial prostatitis?**

OPTION ORAL ANTIMICROBIAL DRUGS

We found no RCTs comparing oral antimicrobial drugs versus placebo or no treatment. One RCT found no significant difference between lomefloxacin and ciprofloxacin in rates of clinical success or bacteriological cure at 6 months. Retrospective observational studies report cure rates of 0–88% depending on the drug used and the duration of treatment.

Benefits: **Versus placebo or no antmicrobials:** We found no systematic reviews or RCTs. **Oral antimicrobials versus each other:** We found no systematic reviews but we found one RCT (182 men), which compared lomefloxacin (400 mg daily) versus ciprofloxacin (500 mg twice daily) for 4 weeks.[5] It found no significant difference between lomefloxacin and ciprofloxacin in rates of clinical success or bacteriological cure after 6 months (clinical success: 61/93 [81.3%] with lomefloxacin *v* 64/89 [88.9%] with ciprofloxacin; difference –7.6%, 95% CI –23.6% to +6%; biological eradication: 49/93 [62.8%] with lomefloxacin *v* 54/89 [72.0%] with ciprofloxacin; difference –9.2%, 95% CI –26% to +6%). Clinical success was defined as clinical cure (baseline symptoms completely resolved) or improvement (symptoms improved but not completely resolved).

Harms: The RCT (182 men) comparing lomefloxacin with ciprofloxacin found that the most common adverse effects with both treatments were gastrointestinal disorders (5/93 [5%] with lomefloxacin *v* 8/89 [9%] with ciprofloxacin; P value not reported). Adverse effects caused the premature withdrawal of 5/93 [5%] on lomefloxacin compared with 4/89 [4%] on ciprofloxacin.

Comment: We found data from an observational series about the cure rates of different antibiotics. These data do not compare effects of antimicrobials versus placebo, no treatment or other treatment. **Trimethoprim–sulfamethoxazole:** One non-systematic review identified eight retrospective case series in 1140 men with bacteriologically confirmed prostatitis treated with trimethoprim–sulfamethoxazole (sulphamethoxazole) (160 mg/800 mg twice daily for 10–140 days).[6] The studies reported cure rates of 0–71%. Over 30% of men were cured when treated for at least 90 days. The review did not report adverse effects. **Quinolones:** One review summarised three retrospective case series in 106 men treated with norfloxacin (400 mg twice daily for 10, 28, and 174 days).[7] The studies reported cure rates of 64–88%. We also found six retrospective case series in 141 men treated with ciprofloxacin (250–500 mg twice daily for 14–259 days), with cure rates of 60–75%. **Amoxicillin/clavulanic acid and clindamycin:** One case series included 50 men who were resistant to empirical treatment with quinolone. The expressed prostatic secretions from 24 of these men exhibited high colony counts of Gram positive and Gram negative anaerobic bacteria, either alone (18 men) or in combination with aerobic bacteria (6 men). After

treatment with either amoxicillin (amoxycillin)/clavulanic acid or clindamycin for 3–6 weeks, all men had a decrease or total elimination of symptoms and no anaerobic bacteria were detected in prostatic secretions.[8] Higher cure rates with quinolones may be explained by greater penetration into the prostate.[9] We reviewed only studies that used standard methods to localise infection to the prostate.[10]

OPTION LOCAL INJECTION OF ANTIMICROBIALS

We found no RCTs comparing local injection of antimicrobials versus placebo or no treatment. One small RCT found that anal submucosal injection of amikacin improved symptom scores and bacterial eradication rates at 3 months compared with intramuscular amikacin.

Benefits: We found no placebo controlled RCTs. We found one small RCT (50 men with prostatic secretions sensitive to amikacin), which compared anal submucosal injection of amikacin 400 mg versus intramuscular amikacin 400 mg daily for 10 days.[11] It found that anal submucosal injection of amikacin significantly improved NIH–PSI score (see glossary, p 1146) and significantly increased bacteriological cure rates compared with intramuscular amikacin at 3 months (NIH–PSI: 9.0 with submucosal injection *v* 22.5 with intramuscular injection; $P < 0.05$; negative bacterial culture: 28/30 [93%] with submucosal injection *v* 7/20 [35%] with intramuscular; $P < 0.05$).

Harms: The RCT comparing anal submucosal and intramuscular amikacin found no obvious adverse effects other than the passage of slightly blood stained faeces in 3/30 (10%) men after the first anal submucosal injection.[11] Infection is a theoretical risk of this invasive procedure.

Comment: One small cohort study (24 men with refractory chronic bacterial prostatitis) found that eradication of infection was eventually achieved after an unstated period in 15 men with gentamicin (160 mg) plus cefazolin (cephalozin) (3 g) injected directly into the prostate through the perineum.[12]

OPTION α BLOCKERS

We found no RCTs comparing α blockers alone versus placebo or no treatment. We found limited evidence from one RCT suggesting that adding α blockers to antimicrobials may improve symptoms and reduce recurrence compared with antimicrobials alone.

Benefits: We found no systematic review. We found no RCTs comparing α blockers versus placebo. We found one RCT (64 men with bacterial prostatitis; mean age 48 years) of α blockers (either 1–2 mg terazosin daily, 2.5 mg terazosin daily, or 2.5 mg alfuzosin once or twice daily) plus antimicrobials versus antimicrobials alone.[13] It found that α blockers plus antimicrobials significantly increased symptomatic improvement and significantly reduced recurrence rates compared with antimicrobials alone (recurrence rates assessed by culture of expressed prostatic secretion; $P = 0.02$; no RR or CI reported; 5 people withdrew from treatment).

Harms: No adverse effects of α blockers were reported in this study.[13]

Comment: None.

OPTION TRANSURETHRAL RESECTION

We found no RCTs on the effects of transurethral resection.

Benefits: We found no systematic review, RCTs, or prospective cohort studies.

Harms: One RCT in men with benign prostatic hypertrophy found no difference in the incidence of impotence or urinary incontinence with transurethral resection or watchful waiting.[14]

Comment: One retrospective study reported 40–50% cure rates in 50 men with chronic prostatitis treated with transurethral resection. However, proof of bacterial prostatitis was not obtained in many men.[15]

OPTION RADICAL PROSTATECTOMY

We found no RCTs on the effects of radical prostatectomy.

Benefits: We found no systematic review or RCTs.

Harms: Case series found that radical prostatectomy can cause impotence (9–75% depending upon age)[16] and varying degrees of urinary stress incontinence (8%).[17] Other potential harms include those associated with any open surgery.

Comment: We found one report of radical prostatectomy in two young men whose refractory bacterial prostatitis caused relapsing haemolytic crises.[18]

QUESTION What are the effects of treatments for chronic abacterial prostatitis?

OPTION α BLOCKERS

One systematic review found limited evidence from two small RCTs that α blockers may improve maximal flow time and pain compared with placebo. However, we were unable to draw reliable conclusions from these small studies.

Benefits: We found one systematic review (search date 1999, 2 RCTs, 50 men).[19] The first RCT (20 people) identified by the review compared alfuzosin (2.5 mg three times daily) versus placebo. It found a significant improvement in maximal flow time with alfuzosin (with 15.4 mL/second to 20.3 mL/second alfuzosin *v* 13.9 mL/second to 15.6 mL/second with placebo; $P = 0.01$; RR not reported).[20] It found no significant difference in other outcomes (insufficient information was presented to assess comparative effects on symptom scores). The second RCT (30 people) identified by the review found that pain after prostatic massage significantly improved with α blockers (phenoxybenzamine 10 mg twice daily) versus placebo (at 6 weeks; $P < 0.05$).

Chronic prostatitis

Harms: The first RCT reported a transient decrease in systolic blood pressure in four people and a slight decrease in libido in two people all treated with alfuzosin.[19]

Comment: None.

OPTION 5α REDUCTASE INHIBITORS

One systematic review of one small RCT found insufficient evidence on the effects of 5α reductase inhibitors compared with placebo in men with chronic abacterial prostatitis.

Benefits: We found one systematic review (search date 1999, 1 RCT, 41 men), which compared finasteride versus placebo.[19] The RCT found that, although symptom scores decreased significantly with finasteride after 1 year, there was no significant difference in pain between finasteride and placebo.[21] The RCT was small and had low power (31/41 [75%] of men were allocated to finasteride *v* 10/41 [25%] of men to placebo).

Harms: Three people treated with finasteride reported partial impotence compared with none in the placebo group.[21]

Comment: Finasteride is known to decrease prostate volume (as it did in this study; $P < 0.03$), but it is unclear how this relates to symptoms of prostatitis.[21]

OPTION ANTI-INFLAMMATORY MEDICATIONS

We found insufficient evidence about the effects of anti-inflammatory medications compared with placebo or no treatment in men with chronic abacterial prostatitis.

Benefits: We found one systematic review (search date 1999, 1 RCT, 30 men).[19] The included RCT compared pentosan polysulfate sodium (100 mg twice daily) versus placebo. Outcomes included symptom changes by physician rating, symptom score, and uroflowmetry. The RCT found no significant difference in either physician rated improvement (pentosan polysulfate sodium group 7/10 [70%] improved *v* placebo 5/14 [36%] improved; RR 2.0, 95% CI 0.87 to 4.4) or in local symptom scores (pentosan polysulfate sodium 5/10 [50%] improved *v* placebo 6/14 [43%] improved; RR 1.2, 95% CI 0.5 to 2.8).[22] Six people were excluded from the analysis for non-compliance or having bacterial prostatitis (analysis was not intention to treat). The RCT may have been too small to rule out important clinical differences.

Harms: Two people given pentosan polysulfate sodium reported diarrhoea. No people treated with placebo developed gastrointestinal adverse symptoms.

Comment: "Physician rated improvement" is not an objective measurement. There was no significant difference between experimental and control groups with other, more objective and standardised, outcomes.

OPTION TRANSURETHRAL MICROWAVE THERMOTHERAPY

One systematic review found limited evidence from one small RCT suggesting that transurethral microwave thermotherapy may significantly improve quality of life at 3 months and symptoms over 21 months compared with sham treatment. However, we were unable to draw reliable conclusions from this one small study.

Benefits: We found one systematic review (search date 1999,[19] 1 double blind RCT,[23] 20 men). The included RCT compared transurethral microwave thermotherapy versus sham treatment.[23] It found a significant improvement in quality of life at 3 months with thermotherapy compared with sham treatment (scale 0–10; quality of life improved from 4.4 to 3.0 with transurethral microwave thermotherapy *v* unchanged at 5.2 with sham treatment; $P < 0.05$). Significantly more men had improvement of a subjective global assessment by more than 50% over a mean of 21 months with thermotherapy compared with sham treatment (7/10 [70%] *v* 1/10 [10%]; RR 7, 95% CI 1 to 47; NNT 2, 95% CI 2 to 6). The review found no good evidence on the effects of thermotherapy on cure or recurrence rate.

Harms: Four men complained of transient (resolved in 3 weeks) adverse reactions, including haematuria (2 men), urinary tract infection, impotence, urinary retention, urinary incontinence, and premature ejaculation (each occurring in 1 man).[23] However, the RCT did not report if the men with adverse events were treated with active treatment or sham treatment.

Comment: Thermotherapy caused persistent elevation of leucocytes in the prostatic fluid, which could indicate tissue damage.

OPTION ALLOPURINOL

We found insufficient evidence from one small RCT about the effects of allopurinol compared with placebo in men with chronic abacterial prostatitis.

Benefits: We found one systematic review (search date 2000,[24] 1 RCT,[25] 54 men). The RCT compared treatment with allopurinol (600 mg daily), allopurinol (300 mg daily), and placebo. Thirty four men (63%) completed the study, which lasted 240 days. All recorded data were used in the analysis. The RCT found allopurinol significantly reduced the "degree of discomfort" score (pretreatment score = 0; score –1.1 with allopurinol *v* placebo –0.2 with placebo; $P = 0.02$).[25]

Harms: None of the men receiving allopurinol reported any significant adverse events, but the RCT did not explain what constitutes a significant adverse event; 55% of people on placebo and 68% of people on allopurinol completed the trial.[25]

Comment: The symptom score was not validated and the high withdrawal rate makes the results difficult to interpret.[25]

OPTION PROSTATIC MASSAGE

We found no RCTs on the effects of prostatic massage.

Chronic prostatitis

Benefits: We found no systematic review or RCTs.

Harms: We found no good evidence.

Comment: None.

OPTION SITZ BATHS

We found no RCTs on the effects of Sitz baths.

Benefits: We found no systematic review or RCTs.

Harms: We found no good evidence.

Comment: None.

OPTION BIOFEEDBACK

We found no RCTs on the effects of biofeedback.

Benefits: We found no systematic review or RCTs.

Harms: We found no good evidence.

Comment: None.

GLOSSARY

NIH–CPSI (National Institute of Health–Chronic Prostatis Symptom Index). Includes nine items across three domains: pain (4 items; 0–21); urinary symptoms (2 items; 0–10), and quality of life impact (3 items; 0–12). In all domains, higher scores indicate worse outcomes.

QUESTIONS

INTERVENTIONS

See glossary, p 1155

Key Messages

- **Intracavernosal alprostadil** One large RCT found that intracavernosal alprostadil increased the chances of a satisfactory erection compared with placebo. One small RCT found limited evidence that vacuum devices were as effective as intracavernosal alprostadil injection for rigidity but not for orgasm.
- **Intraurethral alprostadil** One large RCT (in men who had previously responded to alprostadil) found limited evidence that intraurethral alprostadil (prostaglandin E1) increased the chances of successful sexual intercourse and at least one orgasm over 3 months compared with placebo. About a third of men suffered penile ache. We found no direct comparisons of intraurethral alprostadil versus either intracavernosal alprostadil or oral drug treatments.
- **Sildenafil** One systematic review and 15 subsequent RCTs have found that sildenafil improves erections and increases rates of successful intercourse compared with placebo. Adverse effects, including headaches, flushing, and dyspepsia, are reported in up to a quarter of men. Deaths have been reported in men on concomitant treatment with oral nitrates.
- **Yohimbine** One systematic review found that yohimbine improves self reported sexual function and penile rigidity at 2–10 weeks compared with placebo. Transient adverse effects are reported in up to a third of men.
- **Topical alprostadil** Two quasi randomised trials found limited evidence that topical alprostadil increased the number of men with erections sufficient for intercourse compared with placebo but was commonly associated with skin irritation.
- **L-arginine** One small RCT found no significant difference in sexual function between L-arginine and placebo, but it may have been too small to exclude a clinically important difference.
- **Penile prostheses** We found no RCTs of penile prostheses in men with erectile dysfunction.

- **Trazodone** One small RCT found no significant difference in erections or libido with trazodone compared with placebo, but it may have been too small to exclude a clinically important difference.
- **Vacuum devices** Vacuum devices have not been adequately assessed in RCTs. One small RCT found limited evidence that they were as effective as intracavernosal alprostadil (prostaglandin E1) injections for rigidity but not for orgasm.

DEFINITION Erectile dysfunction has largely replaced the term "impotence". It is defined as the persistent inability to obtain or maintain sufficient rigidity of the penis to allow satisfactory sexual performance.

INCIDENCE/ PREVALENCE We found little good epidemiological information, but one cross sectional study found that age is the variable most strongly associated with erectile dysfunction and that up to 30 million men in the USA may be affected.[1] Even among men in their 40s, nearly 40% report at least occasional difficulty obtaining or maintaining erection, whereas this approaches 70% in 70 year olds.

AETIOLOGY/ RISK FACTORS About 80% of cases of erectile dysfunction are believed to have an organic cause, the rest being psychogenic in origin. Risk factors include increasing age, smoking, and obesity. Erectile problems fall into three categories: failure to initiate; failure to fill, caused by insufficient arterial inflow into the penis to allow engorgement and tumescence because of vascular insufficiency; and failure to store because of veno-occlusive dysfunction. Erectile dysfunction is a recognised adverse effect of a wide variety of pharmaceutical agents.

PROGNOSIS We found no good evidence on prognosis in untreated organic erectile dysfunction.

AIMS OF INTERVENTION To restore satisfactory erections with minimal adverse effects.

OUTCOMES Patient and partner self reports of satisfaction and sexual function, objective tests of penile rigidity, and adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION What are the effects of treatments?

OPTION YOHIMBINE

One systematic review found that yohimbine improves self reported sexual function and penile rigidity at 2–10 weeks compared with placebo. Transient adverse effects are reported in up to a third of men.

Benefits: **Versus placebo:** We found one systematic review (search date 1997, 7 RCTs, 11–100 men with erectile dysfunction, defined variously as organic, psychogenic, and of unknown cause) that compared yohimbine versus placebo.[2] Duration of treatment ranged from 2–10 weeks, and outcomes varied from self reported change in sexual function to objective tests of penile rigidity. The RCTs found positive responses in significantly more men who took yohimbine than in those who took placebo (34–73% *v* 9–45%;

OR 3.85, 95% CI 2.22 to 6.67; absolute numbers not reported). One subsequent placebo controlled, crossover trial (22 men, randomisation not mentioned) that compared a single daily dose of yohimbine 100 mg for 30 days versus placebo found no significant difference between treatments in erectile function.[3]

Harms: The review found that adverse events were reported in 10–30% of men who received yohimbine compared with 5–16% with placebo (significance not reported) and were generally mild, including agitation, anxiety, headache, mild increase in blood pressure, increased urinary output, and gastrointestinal upset.[2] In the small subsequent trial, no men discontinued treatment.[3]

Comment: The endpoints in some of these trials were subjective and of questionable validity. The subsequent trial did not make clear whether it was randomised.[3]

OPTION SILDENAFIL

One systematic review and 15 subsequent RCTs found that sildenafil improved erections and increased rates of successful intercourse compared with placebo. Adverse effects, including headaches, flushing, and dyspepsia, were reported in up to a quarter of men. Deaths have been reported in men on concomitant treatment with oral nitrates.

Benefits: We found one systematic review (search date 2000, 27 RCTs)[4] and 15 subsequent RCTs.[5–19] **In men with any cause of erectile dysfunction:** The systematic review found that in trials that evaluated flexible "as needed" dosing (14 RCTs, 2283 men with any cause of erectile dysfunction), sildenafil significantly increased the proportion of men who experienced at least one episode of successful intercourse compared with placebo (2283 men: 83% with sildenafil *v* 45% with placebo; RR 1.8, 95% CI 1.7 to 1.9).[4] In trials that evaluated fixed doses of sildenafil (6 RCTs), efficacy was slightly higher on higher doses (> 50 mg) and lower on a low dose (< 25 mg). Eleven subsequent RCTs all found that sildenafil improved sexual function compared with placebo.[5–12,15,17,18] **In men with diabetes:** The systematic review included two RCTs restricted to men with diabetes and 14 trials (551 men with diabetes) that provided subgroup analysis in men with diabetes.[4] Based on subgroup analysis, the review found that sildenafil significantly increased successful erections and successful intercourse compared with placebo (AR for erections 63% with sildenafil *v* 19% with placebo; RR 3, 95% CI 2.5 to 3.7; AR for intercourse 44% with sildenafil *v* 16% with placebo; WMD 26.9, 95% CI 19.9 to 33.9). We found three subsequent RCTs. The first subsequent RCT (219 men) found that sildenafil (25–100 mg) improved participant rated erections and scores on questions 3 and 4 of the International Index of Erectile Dysfunction after 12 weeks (64.6% had improved erections with sildenafil *v* 10.5% with placebo; CI presented graphically; $P < 0.0001$; mean improvement in question 3 score 3.42 with sildenafil *v* 1.86 with placebo; mean improvement in question 4 score 3.35 with sildenafil *v* 1.84 with placebo; $P < 0.0001$ for both comparisons).[19] The second RCT (188 men) also found that sildenafil significantly improved scores on questions 3 and 4 of the

International Index of Erectile Dysfunction compared with placebo after 12 weeks (mean question 3 score 3.61 with sildenafil *v* 2.71 with placebo; P = 0.001; mean question 4 score 3.25 with sildenafil *v* 2.19 with placebo; P = 0.001).[13] Sildenafil also increased the proportion of successful attempts at intercourse compared with placebo, although the result was of borderline significance (P = 0.051); it also increased global efficacy compared with placebo. The third subsequent RCT (112 men) found that sildenafil improved the capacity to obtain and maintain an erection as measured by questions 3 and 4 of the International Index of Erectile Dysfunction (see glossary, p 1155) compared with placebo (obtain erection: P < 0.0001 in favour of sildenafil; maintain an erection: P < 0.0001 in favour of sildenafil).[16] **In men with spinal cord injury:** The systematic review included two RCTs (203 men) restricted to men with spinal cord injury.[4] It found that sildenafil improved erections compared with placebo (AR for improved erections 83% with sildenafil *v* 12% with placebo; RR 7.2, 95% CI 4.7 to 10.9). **In men with prostate cancer:** We found one small RCT (60 men) in men with erectile dysfunction after external beam radiotherapy for prostate cancer.[14] It found that sildenafil significantly improved global efficacy and succesful intercourse compared with placebo after 6 weeks of treatment (AR for global efficacy 45% with sildenafil *v* 8% with placebo; P < 0.001; AR for successful intercourse 55% with sildenafil v 18% with placebo; P < 0.001).[14]

Harms:

The systematic review found that in a subset of 14 flexible dose trials (3780 men), sildenafil significantly increased the risk of at least one adverse effect compared with placebo (AR for at least one adverse effect 48% with sildenafil *v* 36% with placebo; RR 1.4, 95% CI 1.3 to 1.6).[4] Adverse effects included headache (11% with sildenafil *v* 4% with placebo), flushing (12% *v* 2%), dyspepsia (5% *v* 1%), and visual disturbance (3% *v* 0.8%).[4] One RCT (236 men with any cause of erectile dysfunction) found that sildenafil was associated with facial flushing (25.2%), dizziness (6.7%), headache (5.9%), and palpitations (3.4%).[5] A second RCT found that headache, flushing, dyspepsia, and abnormal perception of colour or brightness were more common with sildenafil than placebo (20% *v* 6% for headache, 15% *v* 0% for dyspepsia, 15% *v* 1% for flushing, and 8% *v* 1% for abnormal vision).[6] A third RCT found similar results.[7] Another study reported specifically on adverse effects of sildenafil.[20] It summarised results from a series of RCTs (4274 men aged 19–87 years with erectile dysfunction because of a range of causes for > 6 months and a mean of 5 years). All men were treated for up to 6 months, and 2199 received further open label treatment for up to 1 year. It found more adverse events with sildenafil than with placebo, including headache (16% *v* 4%; significance not reported), flushing (10% *v* 1%; significance not reported), and dyspepsia (7% *v* 2%; significance not reported). Similar proportions in both groups discontinued treatment (about 2.4%).[20] An important contraindication to prescribing sildenafil is concomitant use of oral nitrates. This combination results in precipitous hypotension. One small RCT (105 men) evaluated the cardiovascular effects of sildenafil during exercise in men with coronary heart disease.[21] It found no effect on symptoms, presence, and extent of ischaemia induced by exercise. By 1999, about

Erectile dysfunction

60 deaths had been reported to the US Food and Drug Administration in men who had been prescribed sildenafil, but it is not known whether any of the deaths were directly attributable to the drug. Long term (> 1 year) safety of sildenafil is unknown. One of the RCTs in men with psychogenic or mixed aetiology erectile dysfunction found that adverse effects were mild and transient.[22] One small RCT (133 men) found sildenafil increased treatment related adverse events compared with placebo after 8 weeks (56.1% with sildenafil *v* 20.9% with placebo; P value not reported). The most common adverse events were flushing (21/66 [31.8%] with sildenafil *v* 3/67 [4.5%] with placebo; P value not reported), headache (15/66 [22.7%] with sildenafil *v* 6/67 [9.0%] with placebo; P value not reported), and abnormalities in colour vision (4/66 [6.1%] with sildenafil *v* 0/67 [0%] with placebo; P value not reported).[15] One RCT in men with diabetes (188 men) found that sildenafil increased adverse events compared with placebo (headache: 20% *v* 8%, flushing: 18% *v* 3%, and dyspepsia: 32% *v* 8%; significance not reported).[13] Another small RCT (60 men) reported similar results (headache 42% with sildenafil *v* 15% with placebo, P < 0.001; and dyspepsia: 32% *v* 8%, P < 0.001). It found no significant difference between sildenafil and placebo for other adverse effects, including myalgia, nasal congestion, visual disturbance, and dizziness.[14]

Comment: None.

OPTION L-ARGININE

One small RCT found no significant difference in sexual function between L-arginine and placebo, but it may have been too small to exclude a clinically important difference.

Benefits: We found no systematic review. We found one small RCT (50 men with erectile dysfunction) that compared high dose L-arginine (5 g/day given orally) versus placebo.[23] It found no significant difference in sexual function between L-arginine and placebo, although the power of the study was not adequate to rule out a clinically important difference (sexual function improved in 9/29 [31%] men with L-arginine *v* 2/17 [12%] with placebo; RR 2.6, 95% CI 0.6 to 10.8).

Harms: The trial reported decreases in systolic or diastolic blood pressure, or both, although this caused no systemic effects and required no drug interruptions. The trial found some "fluctuation in heart rate", which was described as clinically insignificant.[23]

Comment: Nausea, vomiting, diarrhoea, headache, flushing, and numbness have been reported after the administration of L-arginine, although none of the men in this study reported any such complaints.

OPTION TRAZODONE

One small RCT found no significant difference in erections or libido with trazodone compared with placebo, but it may have been too small to exclude a clinically important difference.

Benefits: We found no systematic review. One small crossover RCT (48 men with erectile dysfunction, washout period 3 weeks) compared trazodone versus placebo.[24] Men were treated with either trazodone (50 mg) or placebo at bedtime for 3 months. It found no evidence that trazodone improved erections or libido (improved erections reported by 19% with trazodone *v* 24% with placebo; CI and P value not reported, described as NS; improved libido reported by 35% with trazodone *v* 20% with placebo; CI and P value not reported, described as NS).

Harms: The trial reported drowsiness (31%), dry mouth (1%), and fatigue (19%) with trazodone. It did not report comparative rates of adverse effects for trazadone compared with placebo.[24]

Comment: None.

OPTION INTRAURETHRAL ALPROSTADIL

One large RCT (in men who had previously responded to alprostadil) found limited evidence that intraurethral alprostadil (prostaglandin E1) increased the chances of successful sexual intercourse and at least one orgasm over 3 months compared with placebo. About a third of men suffered penile ache. We found no direct comparisons of intraurethral alprostadil versus either intracavernosal alprostadil or oral drug treatments.

Benefits: We found no systematic review. We found one RCT (996 men aged 27–88 years who had previously responded to intraurethral alprostadil) that compared alprostadil versus placebo.[25] It found that those given alprostadil were more likely to report having successful sexual intercourse over 3 months (65% with alprostadil *v* 19% with placebo; $P < 0.001$) and at least one orgasm (64% with alprostadil *v* 24% with placebo; $P < 0.001$).

Harms: The most common adverse effect was mild to moderate penile ache, which occurred in about a third of men during clinic testing (36%). In total 36/1511 (2.4%) men withdrew from the trial because of this adverse effect.[25] We found no reports of priapism, penile fibrosis, or other serious adverse events.

Comment: The RCT preselected men who had a good response to alprostadil before randomisation. This would tend to increase the size of the effect compared with placebo.

OPTION INTRACAVERNOSAL ALPROSTADIL

One large RCT found that intracavernosal injection of alprostadil (prostaglandin E1) increased the chances of a satisfactory erection compared with placebo. We found no direct comparisons of intracavernosal alprostadil versus either intraurethral or oral drug treatments. One small RCT found limited evidence that vacuum devices were as effective as intracavernosal alprostadil injections for rigidity but not for orgasm.

Benefits: We found no systematic review. **Versus placebo:** We found one large multicentre trial (1128 men, of whom 300 were assigned randomly with all causes of erectile dysfunction; heavy smokers and

men with uncontrolled hypertension or diabetes were excluded) that compared 2.5, 5, 10, or 20 μg alprostadil versus placebo.[26] Injections were given and outcome was assessed by an investigator or research nurse. None of the 59 men who received placebo had a response. Significant differences were seen in clinical evaluation with all the doses of alprostadil compared with placebo and a significant dose–response relation. **Versus vacuum devices:** One crossover RCT (50 men with erectile dysfunction, 44 of whom completed the study) compared intracavernosal self injections of alprostadil versus vacuum devices.[27] Outcome was assessed by a questionnaire given to men and their partners after 15 uses for each device, and couples were assessed for 18–24 months. No significant difference was noted in the ability to achieve an erection suitable for intercourse; however, the ability to attain orgasm was significantly better with alprostadil ($P < 0.05$). On a scale of 1 to 10, overall satisfaction was significantly better when using alprostadil both for men (6.5 with alprostadil *v* 5.4 with vacuum device; $P < 0.05$) and their partners (6.5 with alprostadil *v* 5.1 with vacuum device; $P < 0.05$). Younger men (< 60 years) and those with shorter duration of erectile dysfunction (< 12 months) favoured alprostadil ($P < 0.05$).

Harms: Penile pain was reported by a half of the men in the multicentre trial and priapism (prolonged erection for > 4 hours) by 1%.[26] No significant difference was noted in the frequency of adverse events between vacuum devices and alprostadil.[27]

Comment: Most men can be taught to inject themselves using small gauge needles. In the RCT that compared injections and vacuum devices, 80% of the 44 couples who completed the study were still using one or other treatment after 18–24 months.[27]

OPTION TOPICAL ALPROSTADIL

Two quasi randomised trials found limited evidence that topical alprostadil increased the number of men with erections sufficient for intercourse compared with placebo, but that it was associated commonly with skin irritation.

Benefits: We found no systematic review. We found two quasi randomised trials (see comment below).[28,29] The first, a single blind trial (48 men with erectile dysfunction because of organic, psychogenic, or mixed causes), compared topical alprostadil versus placebo.[28] Men were assigned in sequential order to either 0.5, 1, or 2.5 mg alprostadil gel (36 men) or placebo (12 men). One dose of alprostadil or placebo gel was applied to the glans and shaft of the penis and washed off after 3 hours. Alprostadil significantly increased the proportion of men who achieved an erection sufficient for intercourse compared with placebo (25/36 [69%] with alprostadil *v* 2/12 [17%] with placebo; RR 4.2, 95% CI 1.8 to 5.5; NNT 2, 95% CI 1 to 8). The second RCT (62 men) compared alprostadil topically applied only to the glans of the penis in a clinic setting versus placebo. Significantly more men reported an erection deemed sufficient for penetration with alprostadil compared with placebo (12/31 [39%] versus 2/29 [7%]; RR 5.6, 95% CI 1.4 to 23.0; NNT 3, 95% CI 2 to 9).[29]

Harms: Men who received alprostadil to the glans and shaft of the penis were more likely to have skin irritation than those who received placebo (100% on 0.5 mg dose *v* 67% on placebo; no P value reported). Irritation measured by mean irritation score (range 0–2) was more severe with alprostadil than with placebo (1.75 with 0.5 mg dose *v* 0.67 with placebo; $P < 0.0013$).[28] In the trial in which alprostadil was applied to the glans only, significantly greater erythema was reported with alprostadil than with placebo ($P < 0.001$; absolute figures not reported).[29] Severe erythema was reported by 3% of men.

Comment: Allocation of men in both trials was sequential and may mean that the groups were systematically different; the characteristics of each group were not reported.[28,29]

OPTION VACUUM DEVICES

Vacuum devices have not been adequately assessed in RCTs. One small RCT found limited evidence that they were as effective as intracavernosal alprostadil (prostaglandin E1) injections for rigidity but not for orgasm.

Benefits: **Versus placebo:** We found no systematic review and no RCTs. **Versus intracavernosal injections:** See benefits of intracavernosal alprostadil, p 1153.

Harms: We found insufficient evidence.

Comment: Vacuum devices may be less popular than injections because only the distal portion of the penis becomes firm, but they are presumed to be safe.[27]

OPTION PENILE PROSTHESES

We found no systematic reviews or RCTs of penile prostheses in men with erectile dysfunction. Use of penile prostheses is usually considered only after less invasive treatments have failed.

Benefits: We found no RCTs. Anecdotal evidence suggests that patient satisfaction may be high, but we found no good studies.

Harms: One recent study found the morbidity of penile prostheses to be 9% (surgical revision 7%, mechanical failure 2.5%). Infection rates were between 2% and 7%.[30]

Comment: Use of penile prostheses is usually considered only after less invasive treatments have failed.

GLOSSARY

International Index of Erectile Function: questions 3 and 4 The questions have been validated for assessing the effects of sildenafil on sexual function. The questions ask "over the past 4 weeks, when you have attempted sexual intercourse, how often were you able to penetrate (enter) your partner?", and "over the past 4 weeks, during sexual intercourse, how often were you able to maintain your erection after you have penetrated (entered) your partner?" Questions are answered on a six point scale.

Erectile dysfunction

Substantive changes

Sildenafil Eight RCTs added;[11–18] categorisation unchanged.

QUESTIONS

INTERVENTIONS

*Categorisation based on observational evidence; RCTs unlikely to be conducted.

See glossary, p 1166

Key Messages

In men with metastatic prostate cancer

- **Androgen deprivation** We found limited evidence from RCTs suggesting that androgen deprivation reduced mortality compared with no initial treatment. One non-systematic review of RCTs found that orchidectomy, diethylstilbestrol, and gonadorelin analogues initially improved symptoms and objective signs of disease in most men, but found no evidence of a difference between different types of androgen deprivation.
- **Combined androgen blockade (androgen deprivation and antiandrogen) versus androgen deprivation alone** Systematic reviews found limited evidence of a 2–5% improvement in 5 year survival associated with combined androgen blockade (androgen deprivation plus a non-steroidal antiandrogen) compared with androgen deprivation alone.
- **Intermittent androgen deprivation** We found no RCTs comparing long term effects of intermittent androgen deprivation versus those of continuous androgen deprivation on mortality, morbidity, or quality of life.

- **Deferred androgen deprivation without surveillance** One systematic review found limited evidence of a small survival advantage at 10 years for immediate androgen deprivation therapy with gonadorelin analogues or orchidectomy in men with advanced, asymptomatic prostate cancer. There was no significant change in overall survival at 1, 2, or 5 years. The risk of major complications is increased in men whose treatment is deferred until disease progression.

In men with symptomatic androgen independent metastatic prostate cancer

- **Chemotherapy (palliation but no evidence of an effect on survival)** RCTs found limited evidence that chemotherapy with some new agents plus corticosteroids reduced pain, lengthened palliation, and improved quality of life, but found no improvement in overall survival compared with corticosteroids alone. Earlier RCTs failed to demonstrate any benefit of chemotherapy in men with metastatic prostate cancer.
- **External beam radiation (palliation but no evidence of an effect on survival)** We found no RCTs comparing external beam radiation with palliative treatments other than radionuclides. Observational evidence suggests that complete pain relief is avoided in about a quarter of people, and placebo controlled RCTs would probably be considered unethical.
- **Radionuclides (palliation but no clear evidence of an effect on survival)** One systematic review found one small RCT in men with symptomatic bone metastases, which found no significant difference in survival between external beam radiation plus placebo and external beam radiation plus strontium-89. However, strontium-89 significantly reduced the number of new sites of pain. One small subsequent RCT in men with painful bone metastases found that samarium-153 significantly reduced pain scores compared with placebo. A second small subsequent RCT, in a selected population, found an improvement in survival with strontium-89 compared with placebo, but the results are difficult to generalise.
- **Bisphosphonates** One systematic review of two RCTs found insufficient evidence about the effects of bisphosphonates.

DEFINITION See prostate cancer (non-metastatic), p 1169. Androgen independent metastatic disease is defined as disease that progresses despite androgen deprivation.

INCIDENCE/ PREVALENCE See prostate cancer (non-metastatic), p 1169.

AETIOLOGY/ RISK FACTORS See prostate cancer (non-metastatic), p 1169.

PROGNOSIS Prostate cancer metastasises predominantly to bone. Metastatic prostate cancer can result in pain, weakness, paralysis, and death.

AIMS OF INTERVENTION To reduce mortality and disability; to control symptoms and maximise quality of life; and to minimise adverse effects of treatment.

OUTCOMES Survival; response in terms of symptoms and signs; quality of life; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal September 2002.

Prostate cancer (metastatic)

QUESTION **What are the effects of treatment for men with metastatic prostate cancer?**

OPTION ANDROGEN DEPRIVATION

We found limited evidence from RCTs suggesting that androgen deprivation reduced mortality compared with no initial treatment. One systematic review and one subsequent RCT found no evidence of a difference in effectiveness between different methods of androgen deprivation (orchidectomy, diethylstilbestrol, and gonadorelin analogues).

Benefits:

Versus no initial treatment: We found no systematic review or recent RCTs comparing androgen deprivation (see glossary, p 1166) versus no initial treatment. Three RCTs (about 4000 men with all stages of prostate cancer) performed between 1959 and 1975 compared androgen deprivation (diethylstilbestrol [stilboestrol], orchidectomy [see glossary, p 1166], or oestrogens) versus no initial treatment. They found no difference in overall survival. Reanalysis of updated data from these RCTs found a modest survival advantage with androgen deprivation.[1] The report did not provide statistical details. **Different types of androgen deprivation:** We found one systematic review[2] and one subsequent RCT.[3] The systematic review (search date 1998, 24 RCTs, > 6600 men with metastatic prostate cancer) found no significant differences between treatment groups in overall progression free survival, time to progression, or overall survival in the most of the trials.[2] It found no significant differences in 2 year survival between orchidectomy and the gonadorelin analogues leuprolide or goserelin acetate (HR 1.26, 95% CI 0.91 to 1.39), diethylstilbestrol (HR 0.98, 95% CI 0.76 to 1.27), or non-steroidal antiandrogen (see glossary, p 1166) monotherapy (HR 1.22, 95% CI 0.99 to 1.50). One large subsequent RCT (915 men with advanced prostate cancer stage T0–4, M1; see table 1 in prostate cancer non-metastatic, p 1169) compared parenteral oestrogen versus total androgen ablation (orchidectomy or triptorelin).[3] It found no significant difference in mortality at follow up (mortality at 18 months' median follow up 266/458 [58%] with oestrogen *v* 269/457 [59%] with total androgen ablation; RR 0.99, 95% 0.89 to 1.10).

Harms:

All forms of androgen deprivation are known to be associated with vasomotor flushing, loss of libido, gynaecomastia, weight gain, osteoporosis, and loss of muscle mass; we found insufficient prospective frequency data for these adverse effects. One RCT (915 men with metastatic prostate cancer) found that androgen deprivation by orchidectomy, or by combination of gonadotrophin releasing hormone analogue with an antiandrogen, induces significantly more hot flushes than polyestradiol phosphate (1 or more flushes, 336/452 [74.3%] *v* 135/449 [30.1%]; RR 2.5, 95% CI 2.1 to 2.9; NNH 3, 95% CI 2 to 3).[4] Diethylstilbestrol is associated with an increased risk of cardiovascular events, gastric irritation, and allergic reactions, and for these reasons is not used routinely.[1] Orchidectomy has cosmetic and potential psychological consequences. Gonadorelin analogues may cause an initial clinical flare owing to transient increases in androgen levels.

Comment: Androgen deprivation therapy has been used as the standard of care for men with metastatic disease because of the frequency and duration of effect; therefore, there are no contemporary randomised trials with a no treatment arm. The lack of apparent benefit in earlier trials[1] was probably because of the high cardiovascular event rate associated with high dose diethylstilbestrol.

OPTION IMMEDIATE VERSUS DEFERRED ANDROGEN DEPRIVATION

One systematic review found limited evidence of a small survival advantage at 10 years for immediate androgen deprivation therapy in men with advanced, asymptomatic prostate cancer. There was no significant change in overall survival at 1, 2, or 5 years. The risk of major complications is increased in men whose treatment is deferred until disease progression.

Benefits: We found one systematic review (search date 2001, 4 RCTs, 2167 men with locally advanced prostate cancer or asymptomatic metastases), which compared immediate versus deferred androgen deprivation (see glossary, p 1166) therapy.[5] Outcome measures were overall survival, progression free survival, and complications due to prostate cancer at 1, 2, 5, and 10 years. The review found a significant improvement in overall survival only at 10 years, favouring the immediate therapy group (at 1 year: OR 1.16, 95% CI 0.90 to 1.49; at 2 years: OR 1.08, 95% CI 0.89 to 1.33; at 5 years: 1.19, 95% CI 0.95 to 1.50; and at 10 years: 1.50, 95% CI 1.04 to 2.16). Progression free survival was consistently better in all studies in the immediate therapy group, but disease specific survival was not significantly different at any point. One large RCT included in the review reported complications due to disease progression. It found an approximate halving of the risk of major complications, including spinal cord compression (9/469 [1.9%] with immediate treatment *v* 23/465 [4.9%] with deferred treatment; $P < 0.025$), ureteric obstruction (33/469 [7%] with immediate treatment *v* 55/465 [12%] with deferred treatment: $P < 0.025$), extraskeletal metastases (37/469 [7.9%] with immediate treatment *v* 55/465 [12%] with deferred treatment; $P < 0.05$), and a non-significant reduction in pathological fractures (11/469 [2.3%] with immediate treatment *v* 21/465 [4.5%] with deferred treatment; $P > 0.05$).[6] The trial did not make clear the time interval over which outcomes were recorded, although this seemed to be at least 10 years.

Harms: We found no systematic review or RCTs with prospective data on adverse effects of immediate compared with deferred androgen deprivation in men with metastatic prostate cancer. Adverse effects of immediate therapy were not analysed in the systematic review. However, adverse events reported in one trial were much more common in the immediate treatment arm (OR 5.66, 95% CI 2.76 to 11.62).[5]

Comment: The systematic review included two RCTs published in the 1970s, and the remaining two in 1997 and 1999. Treatments received and indications varied between RCTs.[5] Androgen deprivation therapy may be offered at an earlier stage of disease than that considered for participants in the systematic review.

Prostate cancer (metastatic)

OPTION COMBINED ANDROGEN BLOCKADE (ANDROGEN DEPRIVATION AND ANTIANDROGEN)

Systematic reviews found limited evidence of a 2–5% improvement in 5 year survival associated with combined androgen blockade (androgen deprivation plus a non-steroidal antiandrogen) compared with androgen deprivation alone.

Benefits: We found two systematic reviews.[7,8] The first and largest systematic review (search date not stated, 27 RCTs, 8275 men, most of whom had stage D2 disease [see table 1 in non-metastatic prostate cancer, p 1169]) compared different methods of androgen deprivation (orchidectomy, flutamide, gonadorelin analogue, or a combination of these [see glossary] versus androgen deprivation alone. 1166) It found no clearly significant difference in mortality (72.4% with androgen deprivation alone *v* 70.4% with combined blockage; RR 0.96, 95% CI 0.94 to 1.00). Exclusion of seven trials (1784 men) of cyproterone acetate found a small reduction in mortality from combined androgen blockade (see glossary, p 9) (20 RCTs, 6491 men: 75.3% with androgen deprivation alone *v* 72.4% combined with non-steroidal antiandrogens [see glossary, p 1166]; ARR 2.9%; P = 0.005). The second systematic review (search date 1998, 21 RCTs, 6871 men) compared androgen deprivation alone (orchidectomy or gonadorelin analogues) versus androgen deprivation combined with steroidal or non-steroidal antiandrogens (cyproterone, nilutamide, and flutamide).[8] Overall, the review found a significant improvement in 5 year survival in men receiving combined androgen blockade (HR 0.871, 95% CI 0.805 to 0.942). No significant differences were seen at 1 or 2 years' follow up. Five years' follow up was only provided in 10 of the 21 RCTs.

Harms: The most recent review did not report on adverse events.[8] An overlapping, earlier systematic review of 6320 men in 20 RCTs found that, compared with monotherapy (androgen deprivation alone), combined androgen blockade using non-steroidal antiandrogens increased the risk of diarrhoea (10% with combined antiandrogen blockade *v* 2% with monotherapy), gastrointestinal pain (7% with combined antiandrogen blockade *v* 2% with monotherapy), and non-specific ophthalmologic events (29% with combined antiandrogen blockade *v* 5% with monotherapy).[9] Flutamide is also associated with a higher rate of anaemia (8% *v* 5%).[4]

Comment: The authors of the most recent overview note the need for quality of life data, given the modest survival benefit and the potential for toxicity.[8]

OPTION INTERMITTENT VERSUS CONTINUOUS ANDROGEN DEPRIVATION

We found insufficient evidence on the effects of intermittent androgen deprivation in men with metastatic prostate cancer.

Benefits: We found no systematic review and no RCTs assessing the long term effects of intermittent androgen deprivation on mortality, morbidity, or quality of life.

Harms: We found insufficient evidence to assess harms.

Comment: None.

QUESTION **What are the effects of treatments for men with symptomatic androgen independent metastatic disease?**

OPTION **CHEMOTHERAPY**

RCTs found limited evidence that chemotherapy with some new agents (mitoxantrone or suramin) plus corticosteroids reduced pain, lengthened palliation, and improved quality of life, but found no improvement in overall survival compared with corticosteroids alone. Earlier RCTs failed to demonstrate any benefit of chemotherapy in men with metastatic prostate cancer.

Benefits: We found no systematic review. Multiple earlier RCTs found no benefit in men with metastatic prostate cancer of various chemotherapy drugs, including mitomycin C, cyclophosphamide, doxorubicin, methotrexate, 5-fluorouracil, or estramustine phosphate (EMP).[10–14] In the largest of these studies, 419 men with untreated metastatic or locally advanced prostate cancer were randomised to orchiectomy (see glossary, p 1166) alone versus orchiectomy plus EMP.[12] There was no difference between groups in overall survival or time to progression. Subgroup analyses demonstrated no benefit in the group of men with metastatic disease, but did demonstrate significant delay in time to progression in younger patients (aged < 73 years). An earlier study randomised 319 men to androgen deprivation therapy, combination of androgen deprivation therapy and chemotherapy (cyclophosphamide plus 5-fluorouracil), or EMP alone.[10] It found no significant differences between the groups in progression free or overall survival. However, we found three more recent RCTs demonstrating benefit of newer chemotherapy agents in men with advanced prostate cancer.[15–17] The first of these (161 men with symptomatic androgen independent metastatic prostate cancer) compared mitoxantrone plus prednisone versus prednisone alone.[15] Men taking placebo were crossed over to mitoxantrone at disease progression or if not responding at 6 weeks. It found that men receiving chemotherapy were significantly more likely to experience pain reduction (29% with chemotherapy plus prednisone *v* 12% with prednisone alone; P = 0.01), enjoy longer pain relief (43 *v* 18 weeks; P < 0.0001), and show improvements in quality of life. It found no significant difference in overall survival. The comparison was done before crossover. The second unblinded RCT (242 men) compared mitoxantrone plus hydrocortisone versus hydrocortisone alone.[16] Men were allowed alternative chemotherapy after disease progression. It found no significant difference in survival (median duration 12.3 months with mitoxantrone plus hydrocortisone *v* 12.6 months with hydrocortisone; P = 0.77). However, pain and analgesic use were significantly reduced after chemotherapy. The third RCT (458 men with prostate cancer and painful bone metastases) compared suramin plus hydrocortisone versus placebo plus hydrocortisone.[17] Men on placebo were allowed to cross over to suramin

at disease progression. It found that chemotherapy reduced pain (pain response 43% *v* 28%; P = 0.01). It found no significant effect on survival (median survival 286 days with suramin *v* 279 days with placebo; reported as non-significant, statistics not reported).

Harms: The RCTs reported no treatment related deaths. There were nine episodes of febrile neutropenia (World Health Organization grade 3 or 4) among 130 men treated with 796 courses of mitoxantrone.[17] Five men experienced cardiac arrhythmias or decreased left ventricular ejection fraction, including two who developed congestive heart failure. A higher incidence of nausea and cardiovascular events was observed in men receiving EMP plus orchiectomy compared with orchiectomy alone.[12]

Comment: The crossover design in the recent chemotherapy trials reduced the contrast between treatment arms and increased the study size in order to find small survival benefits, as most people allocated to placebo eventually received chemotherapy. Early, unpublished clinical trials have suggested high response rates for taxane based chemotherapy, and an intergroup RCT comparing it with established regimens is ongoing.

OPTION EXTERNAL BEAM RADIATION THERAPY

We found no RCTs comparing external beam radiation versus palliative treatments other than radionuclides. Observational evidence suggests complete pain relief in about a quarter of people, and placebo controlled RCTs would probably be considered unethical. A systematic review of one RCT in men with symptomatic bone metastases found no difference in survival between external beam radiation and strontium-89; however, strontium-89 was associated with significantly fewer new sites of pain and reduced need for additional radiotherapy. One systematic review found no significant differences in pain relief between different radiation treatment fraction schedules and doses.

Benefits: **Versus no treatment or placebo:** We found one systematic review (search date 1996, no RCTs), which found no RCTs comparing external beam radiation versus no treatment or placebo.[18] We found no additional RCTs (see comment below). Eleven observational studies of 1486 people found complete pain relief in 368/1373 (27%) of people and at least 50% pain relief in 628/1486 (42%) of people treated with external beam radiotherapy (see comment below). **External beam versus radionuclides:** We found one systematic review (search date 1996, 1 RCT, 284 men).[18] The RCT (305 men) compared external beam radiation versus strontium-89.[19] It found that strontium-89 was associated with significantly fewer new sites of pain (P < 0.05), and significantly reduced the need for additional radiotherapy (P < 0.04). However, it found no significant difference in survival (median survival 33 weeks with strontium-89 *v* 28 weeks with radiotherapy; P = 0.10).[19] **Different schedules and doses:** We found one systematic review (search date 1996, 9 RCTs, 1486 men with

symptomatic bone metastases from a variety of malignancies).[18] The RCTs compared different radiation treatment fractionation schedules and doses of external beam radiation. It found minimal differences in pain relief between different fractionation schedules and doses.

Harms: The systematic review reported that adverse event reporting was poor.[18]

Comment: In men with painful bone metastases, it would be considered unethical to compare external beam radiation versus placebo or no treatment. It is reasonable to consider the effectiveness of no treatment to be zero, as spontaneous remission has not been described in bone metastases from prostate cancer.

OPTION RADIONUCLIDE THERAPY

One systematic review found one small RCT in men with symptomatic bone metastases, which found no difference in survival between external beam radiation plus placebo and external beam radiation plus strontium-89. However, strontium-89 significantly reduced the number of new sites of pain. One small subsequent RCT in men with painful bone metastases found that samarium-153 significantly reduced pain scores compared with placebo. A second small subsequent RCT in a selected population found an improvement in survival with strontium-89 compared with placebo, but the results are difficult to generalise.

Benefits: **Versus other palliative treatments:** We found one systematic review (search date 1996, 1 RCT, 126 men)[18] and two subsequent RCTs.[20,21] The RCT in the systematic review (126 men) compared external beam radiation plus strontium-89 versus external beam radiation plus placebo.[22] Although the RCT found no significant difference in overall survival or symptom relief, strontium-89 significantly reduced the number of new sites of pain ($P < 0.02$) and significantly reduced analgesic requirement (17% stopped taking analgesics with radionuclide *v* 2% on placebo; $P < 0.05$). The first subsequent RCT (118 people with painful bone metastases from multiple primaries) compared samarium-153 lexidronam 0.5 mCi/kg versus samarium-153 lexidronam 1 mCi/kg versus placebo over 4 weeks.[21] It found that samarium-153 1 mCi/kg significantly reduced pain scores compared with placebo at weeks 1–4 ($P < 0.034$). Samarium-153 0.5 mCi/kg reduced pain scores significantly more than placebo at week 1 ($P = 0.044$) but not at other weeks ($P > 0.078$). The second subsequent RCT (72 men with androgen independent, metastatic prostate cancer who had initially responded to "induction" chemotherapy with ketoconazole and doxorubicin alternating with estramustine and vinblastine) compared maintenance chemotherapy (doxorubicin) with and without strontium-89.[20] From follow up of 67 people to death, it was estimated that strontium-89 significantly increased median overall survival (27.7 months with chemotherapy plus strontium-89 *v* 16.8 months with chemotherapy alone; $P < 0.002$) and significantly

increased time to progression (13.9 months with chemotherapy plus strontium-89 *v* 7.0 months with chemotherapy alone; $P < 0.0001$) (see comment below). **Versus external beam radiation:** See external beam versus radionuclides under benefits of external beam radiation therapy, p 1164.

Harms: Strontium-89 was associated with thrombocytopenia (World Health Organization grade 3 or 4) in 7–33% of men and leukopenia (World Health Organization grade 3 or 4) in 3–12% of men.[18,23] Other radionuclides with selective bone localisation have similar rates of haematological toxicity. There was no significant difference between treatment schedules and doses of external beam radiation in rates of nausea, vomiting, or diarrhoea.[24]

Comment: One RCT[23] included in previous versions of *Clinical Evidence* was removed because of its small size and weak methods. The results of the second subsequent RCT are difficult to generalise because a selected population was used, and participants reacted favourably to a particular chemotherapy regimen.[20]

OPTION BISPHOSPHONATES

One systematic review of two RCTs found insufficient evidence about the effects of bisphosphonates compared with no treatment.

Benefits: One systematic review (search date not stated, 2 RCTs, 156 men with prostate cancer and symptomatic bone metastases) found no reduction in bone pain with bisphosphonates compared with no bisphosphonates.[25]

Harms: The systematic review identified 18 RCTs of bisphosphonates in men with bone metastases from a variety of cancers.[25] No RCT reported major toxicity. Treatment with pamidronate was associated with increased frequency of anterior uveitis and episcleritis.[25]

Comment: Both RCTs in the systematic review[25] had weak methods; one did not use a pain scale, whereas the other assessed etidronate, a bisphosphonate that is pharmacologically unsuitable for treating bone metastases. One RCT found potential benefit of pamidronate in preventing bone loss in men receiving androgen deprivation therapy, but it was not designed to assess effect on disease progression.

GLOSSARY

Androgen deprivation Orchiectomy, gonadorelin analogue (leuprolide or goserelin), or estrogenic treatment.

Antiandrogen Androgen receptor blockers such as flutamide, nilutamide or bicalutamide.

Combined androgen blockade A combination of gonadorelin analogues or orchiectomy (androgen deprivation therapy) plus an androgen receptor blocker (antiandrogen).

Orchidectomy Also known as orchiectomy, meaning surgical removal of the testicles.

QUESTIONS

INTERVENTIONS

See glossary, p 1182

Key Messages

Clinically localised prostate cancer

- **Radical prostatectomy** Two RCTs found no significant difference in death from any cause between radical prostatectomy and watchful waiting in men with clinically detected disease after median follow up of 6.2 and 23 years. The larger of the RCTs found that radical prostatectomy reduced death due to prostate cancer and metastases at 6 years compared with watchful waiting. Two small RCTs found that radical prostatectomy reduced the risk of treatment failure compared with external beam radiation. Radical prostatectomy carries the risks of major surgery and of sexual and urinary dysfunction.
- **Watchful waiting** Two RCTs found no significant difference in overall survival between watchful waiting and radical prostatectomy in men with clinically detected disease after median follow up of 6 and 23 years. The larger RCT found that radical prostatectomy reduced death rates due to prostate cancer

and metastases at 6 years compared with watchful waiting. One RCT found that radical prostatectomy increased erectile dysfunction compared with watchful waiting but found no significant difference in quality of life after 12 months.

- **Androgen suppression** We found no RCTs of early androgen suppression on length or quality of life in men with asymptomatic, clinically localised prostate cancer. One RCT identified by a systematic review found limited evidence that oestrogen decreased prostate cancer related deaths compared with watchful waiting. It found no significant difference in overall survival. One preliminary report of three large ongoing RCTs in men with localised or locally advanced prostate cancer found that bicalutamide plus standard care reduced rates of radiological progression and bone metastases at 2–3 years compared with standard care alone. There was no significant difference between treatments in overall survival.
- **External beam radiation** We found no RCTs comparing external beam radiation versus watchful waiting. Two RCTs found that external beam radiation increased the risk of treatment failure compared with radical prostatectomy. Two small RCTs found no significant difference between conformal radiotherapy and conventional radiotherapy in overall survival or tumour control at 3–5 years. One systematic review found limited evidence that conformal radiotherapy with dose escalation reduced acute and late treatment related morbidity compared with conventional radiotherapy for men with T1 or T2 low or intermediate risk prostate cancer.
- **Androgen suppression in asymptomatic men with raised prostate specific antigen concentrations after early treatment; brachytherapy; cryosurgery** We found no RCTs on the effects of these interventions.

Locally advanced prostate cancer

- **Immediate androgen suppression after radical prostatectomy and pelvic lymphadenectomy in men with node positive prostate cancer (compared with radical prostatectomy and deferred androgen suppression)** One small RCT in men with node positive prostate cancer found that immediate androgen suppression compared with deferred androgen suppression after radical prostatectomy and pelvic lymphadenectomy reduced mortality over a median of 7 years' follow up.
- **Androgen suppression initiated at diagnosis** RCTs found no significant difference in overall survival between androgen suppression with bicalutamide and no androgen suppression in men with localised or locally advanced prostate cancer at 2–10 years. The RCTs found that bicalutamide reduced objective progression compared with no bicalutamide. One systematic review found that early androgen suppression increased survival at 10 years compared with deferred treatment in men with locally advanced prostate cancer but found no significant difference in survival at 5 years. One RCT found limited evidence that immediate androgen suppression reduced complications compared with deferred androgen suppression.
- **Early androgen suppression plus external beam radiation (compared with radiation and deferred androgen suppression)** RCTs found limited evidence that androgen suppression initiated at diagnosis plus external beam radiation improved long term survival compared with radiation alone or radiation plus deferred androgen suppression. One RCT found limited evidence that immediate androgen suppression reduced complications compared with deferred androgen suppression.

DEFINITION

Prostatic cancer is staged according to two systems: the tumour, node, metastasis (TNM) classification system and the American urologic staging system (see table 1, p 1185). Non-metastatic prostate cancer can be divided into clinically localised disease and locally advanced disease. Clinically localised disease is prostate cancer thought, after clinical examination, to be confined to the prostate gland. Locally advanced disease is prostate cancer that has spread outside the capsule of the prostate gland but has not yet spread to other organs. Metastatic disease is prostate cancer that has spread outside the prostate gland to either local, regional, or systemic lymph nodes, seminal vesicles, or to other body organs (e.g. bone, liver, brain) and is not connected to the prostate gland. We consider clinically localised and locally advanced disease here. Metastatic disease is covered in a separate chapter (see prostate cancer [metastatic], p 1158).

INCIDENCE/ PREVALENCE

Prostate cancer is the sixth most common cancer in the world and the third most common cancer in men. In 2000, an estimated 513 000 new cases of prostate cancer were diagnosed and about 250 000 deaths were attributed to prostate cancers worldwide. Prostate cancer is uncommon under the age of 50 years. About 85% of men with prostate cancer are diagnosed after the age of 65 years. Autopsy studies suggest that the prevalence of subclinical prostate cancer is high at all ages: 30% for men aged 30–39 years, 50% for men aged 50–59 years, and more than 75% for men older than 85 years. Incidence varies widely by ethnic group and around the world. The highest rates occur in men of black ethnic group living in the USA and the lowest among men living in China.[1]

AETIOLOGY/ RISK FACTORS

Risk factors for prostate cancer include increasing age, family history of prostate cancer, black ethnic group, and possibly higher dietary consumption of fat and meat, low intake of lycopene (from tomato products), low intake of fruit, and high dietary calcium. In the USA, black men have about a 60% higher incidence than white men.[2] The prostate cancer incidence for black men living in the USA is about 90/100 000 in men aged less than 65 years and about 1300/100 000 in men aged 65–74 years. For white men, incidence is about 44/100 000 in men aged less than 65 years and 900/100 000 in men aged 65–74 years.[2]

PROGNOSIS

The chance that men with well to moderately differentiated, palpable, clinically localised prostate cancer will remain free of symptomatic progression is 70% at 5 years and 40% at 10 years.[3] The risk of symptomatic disease progression is higher in men with poorly differentiated prostate cancer.[4] One retrospective analysis of a large surgical series in men with clinically localised prostate cancer found that the median time from the increase in prostate specific antigen (PSA) concentration to the development of metastatic disease was 8 years.[5] Time to PSA progression, PSA doubling time, and Gleason score (see glossary, p 1183) were predictive of the probability and time to development of metastatic disease. Once men developed metastatic disease, the median actuarial time to death was less than 5 years.[5] Morbidity from local or regional disease progression includes haematuria, bladder obstruction, and lower extremity oedema. The age adjusted prostate cancer specific mortality in the

Prostate cancer (non-metastatic)

USA for all men aged 65 years and older has decreased by about 15% (244 deaths/100 000 to 207 deaths/100 000) from 1991–1997. The reasons for this are unclear, although inaccurate death certification, PSA screening, and earlier, more intensive treatment, including radical prostatectomy (see glossary, p 1183), radiotherapy, and androgen suppression (see glossary, p 1182), have been suggested. However, regions of the USA and Canada where PSA testing and early treatment are more common have similar prostate cancer mortality to regions with lower testing and early treatment rates.[6] Similarly, countries with low rates of PSA testing and treatment, such as the UK, have similar age adjusted prostate cancer mortality to countries with high rates of testing and treatment, such as the USA.[7]

AIMS OF INTERVENTION To prevent premature death and disability, and to minimise adverse effects of treatment.

OUTCOMES Survival; development of metastatic disease; development of symptomatic local or regional disease progression; time to progression; response in terms of symptoms and signs; quality of life; adverse effects of treatment. Where clinical outcomes are not available, surrogate outcomes have been used (PSA concentration; Gleason score for histological grade).

METHODS *Clinical Evidence* search and appraisal February 2003. Additional author search: Cochrane Library and Medline to 2001 for systematic reviews and RCTs, and using the search strategy of the Department of Veterans' Affairs Coordinating Center for the Cochrane Review Group on Prostatic Diseases.

QUESTION What are the effects of treatments for clinically localised prostate cancer?

OPTION WATCHFUL WAITING

Two RCTs found no significant difference in overall survival between watchful waiting and radical prostatectomy in men with clinically detected disease after median follow up of 6 and 23 years. One RCT found that radical prostatectomy reduced death due to prostate cancer and reduced metastases at 6 years compared with watchful waiting. One RCT found that radical prostatectomy increased erectile dysfunction compared with watchful waiting but found no significant difference in quality of life after 4 years.

Benefits: **Versus radical prostatectomy:** See benefits of radical prostatectomy, p 1173. **Versus early androgen suppression:** See glossary, p 1182. See benefits of androgen suppression, p 1177.

Harms: **Versus radical prostatectomy:** See harms of radical prostatectomy, p 1174. **Versus early androgen suppression:** See harms of androgen suppression, p 1178.

Comment: We found two large cohort studies, which found that, in men with clinically detected localised prostate cancer managed with watchful waiting, 15 year disease specific survival was 80% — ranging from

95% for well differentiated to 30% for poorly differentiated cancers.[10,11] However, most men with newly diagnosed prostate cancer are now detected by prostate specific antigen (PSA) testing. There is about a 10–15 year lead time between the detection of cancers by raised PSA concentrations and clinical detection by digital rectal examination or the development of symptoms.[12] This means that outcomes are likely to be similar in men with palpable tumours who are followed for 15 years and men whose tumours are detected because of raised PSA concentrations who are followed for 25–30 years (lead time bias). Therefore, compared with men with clinically detected prostate cancer, any benefit in men with PSA detected tumours (if it exists) is likely to be of smaller magnitude and require a longer period of time to occur. Until better information is available to guide treatment selection men have to weigh the potential but unproved risks and benefits of various treatment options. For example, men treated with watchful waiting may avoid the risks of surgery and may have similar overall survival and quality of life compared with men treated with other interventions. However, they do not have the opportunity to have their cancer removed or "definitively" treated with radiotherapy. This could potentially result in disease progression, disability, and premature death. Preliminary results from one RCT indicate that, on average, 25 men with clinically detected prostate cancer would need to be treated with surgery to prevent one death attributed to prostate cancer over a 6 year time period, without evidence that this would improve length or quality of life.[9] People should balance the potential risks and benefits of various treatment options.

OPTION RADICAL PROSTATECTOMY

Two RCTs found no significant difference in death from any cause between radical prostatectomy and watchful waiting in men with clinically detected disease after median follow up of 6.2 and 23 years. The larger of the RCTs found that radical prostatectomy reduced death due to prostate cancer and metastases at 6 years compared with watchful waiting. Two small RCTs found that that radical prostatectomy reduced the risk of treatment failure compared with external beam radiation. Radical prostatectomy carries the risks of major surgery and of sexual and urinary dysfunction.

Benefits:

Versus watchful waiting: We found one systematic review (search date 2002, 2 RCTs) that compared radical prostatectomy (see glossary, p 1183) versus watchful waiting in men with clinically localised prostate cancer.[8] The first RCT in the review (142 men) found no significant difference in survival after median follow up of 23 years (range 19–27 years) between radical prostatectomy and watchful waiting (median survival 10.6 years with prostatectomy *v* 8 years with watchful waiting; CI not reported).[13] Analysis was not by intention to treat, treatment groups were not comparable at baseline for important prognostic factors, and the RCT is likely to have been too small to exclude a clinically important difference between groups. The second RCT in the review (695 men with newly diagnosed prostate cancer, clinical stage T1b, T1c, or T2) found that radical prostatectomy significantly reduced death due to prostate cancer after a median of 6.2 years follow up compared with

watchful waiting.[9] There was no significant difference in overall death rates (death due to prostate cancer: 16/374 [4.6%] with surgery *v* 31/348 [8.9%] with watchful waiting; HR 0.50, 95% CI 0.27 to 0.91; distant metastases: HR 0.63, 95% CI 0.41 to 0.96; death from any cause: 53/347 [15.3%] with surgery *v* 62/348 [17.8%] with watchful waiting; HR 0.83, 95% CI 0.57 to 1.20). **Versus external beam radiation:** We found one systematic review (search date 2002, 1 RCT)[8] and one additional RCT.[14] The RCT in the review (95 men with either localised or locally advanced cancer) found that radical prostatectomy significantly increased prostate cancer specific survival after 5 years compared with external beam radiation (96.6% with prostatectomy *v* 84.6% with radiation, P = 0.02).[8] The additional RCT (106 men with clinically localised prostate cancer) found that radical prostatectomy significantly reduced treatment failure, primarily defined as a positive bone scan, compared with external beam radiation (4/41 [9.8%] treatment failures with prostatectomy *v* 17/56 [30.4%] with radiation; RR 0.32, 95% CI 0.12 to 0.88; NNT 5, 95% CI 3 to 25).[14]

Harms: One RCT (376 men with localised prostate cancer, 326 men followed up) compared self reported adverse effects and quality of life in men treated with radical prostatectomy and watchful waiting.[15] It found that radical prostatectomy increased erectile dysfunction and urinary leakage at 12 months or more after surgery compared with watchful waiting but reduced symptoms of urinary obstruction (erectile dysfunction: 80% with radical prostatectomy *v* 45% with watchful waiting; urinary leakage: 49% with surgery *v* 21% with watchful waiting; weak urinary stream: 28% with surgery *v* 44% with watchful waiting). The RCT found no significant difference between radical prostatectomy and watchful waiting in bowel function, anxiety, depression, wellbeing, or subjective quality of life (distress from bowel symptoms: 5/159 [3%] with surgery *v* 10/156 [6%] with watchful waiting; low or moderate psychological wellbeing: 35% with surgery *v* 36% with watchful waiting; low or moderate quality of life: 40% with surgery *v* 45% with watchful waiting). One systematic review found that 12 months after radical prostatectomy 20–70% of men reported reduced sexual function and 15–50% reported urinary problems.[8] Fatal complications have been reported in 0.5–1.0% of men treated with radical prostatectomy and may exceed 2% in men aged 75 years and older.[16] Nearly 8% of men older than 65 years suffered major cardiopulmonary complications within 30 days of operation. The incidence of other adverse effects of surgery was over 80% for sexual dysfunction, 30% for urinary incontinence requiring pads or clamps to control wetness, 18% for urethral stricture, 3% for total urinary incontinence, 5% for faecal incontinence, and 1% for bowel injury requiring surgical repair.[17–20]

Comment: Both RCTs of radical prostatectomy took place before the advent of tests for prostate specific antigen.[13,14] Radical prostatectomy may benefit selected groups of men with localised prostate cancer, particularly younger men with higher grade tumours, but the RCTs did not look for this effect. The available evidence suggests that in most men the benefits of radical prostatectomy in quality adjusted life expectancy are at best small and sensitive to

individual preferences.[21] A non-randomised study examining a population based, self administered survey of men aged over 65 years in the USA found no differences in general health related quality of life between radical prostatectomy, radiation, or watchful waiting.[22] We are aware of two further ongoing trials comparing radical prostatectomy versus watchful waiting.[23,24] Any benefit of radical prostatectomy in men with prostate specific antigen detected tumours is likely to be of smaller magnitude and require a longer period of time to occur than clinically detected tumours. People should balance the potential risks and benefits of various treatment options.

OPTION EXTERNAL BEAM RADIATION

We found no RCTs comparing external beam radiation versus watchful waiting. Two RCTs found that external beam radiation increased the risk of treatment failure compared with radical prostatectomy. Two small RCTs found no significant difference between conformal radiotherapy and conventional radiotherapy in overall survival or tumour control at 3–5 years. One systematic review found limited evidence that conformal radiotherapy with dose escalation reduced acute and late treatment related morbidity compared with conventional radiotherapy for men with T1 or T2 low or intermediate risk prostate cancer.

Benefits: **Versus watchful waiting:** We found no RCTs. **Versus radical prostatectomy:** See glossary, p 1183. See benefits of radical prostatectomy, p 1173.[14] **Conformal versus conventional radiotherapy:** We found one systematic review (search date 2001, 1 RCT)[25] and one additional RCT that compared conformal radiotherapy (see glossary, p 1183) versus conventional radiotherapy.[26] The RCT identified by the review (301 men with T1 or T2, low or intermediate risk prostate cancer) found no significant difference in overall survival at 5 years between conformal radiotherapy and conventional radiotherapy when used as sole treatment, but survival was greater with conformal treatment (69% with conventional *v* 79% with conformal, P = 0.06).[25] The additional RCT (225 men with non-metastatic prostate cancer T1–T4, N0, or M0) did not report on survival, but found no significant difference in tumour control (measured by prostate specific antigen [PSA] level) between treatments after a median follow up of 3.6 years.[26]

Harms: One systematic review (search date 2002) found that 20–40% of men with no prior erectile dysfunction who received external beam radiation developed dysfunction after 12–24 months.[8] One survey of men treated with external beam radiation found that 7% wore pads to control wetness, 23–32% were impotent, and 10% reported problems with bowel dysfunction.[27] Treatment related mortality was less than 0.5%.[17] External beam radiation requires that men return for daily outpatient treatment for up to 6 weeks. **Versus radical prostatectomy:** One systematic review (search date 2002, 1 meta-analysis of 40 non-randomised studies published before 1995) found that radiation increased the probability of retaining sexual function compared with radical prostatectomy (69% with radiotherapy *v* 42% with prostatectomy).[8] **Conventional versus conformal radiotherapy:** We found one systematic review

(search date 2001, 3 RCTs reporting on toxicity).[25] Two of the three RCTs found that conformal radiotherapy (without an increase in dose) reduced acute toxicity compared with conventional radiotherapy. The third RCT found no significant difference in acute toxicity between conformal radiotherapy (with dose escalation) and conventional radiotherapy. Two of the three RCTs in the review reporting on chronic adverse effects (> 1 year after treatment) found no significant difference between an increased dose of conformal radiotherapy and conventional radiotherapy but the third RCT reporting on chronic adverse effects found that conventional radiotherapy significantly increased radiation induced proctitis and rectal bleeding compared with the same dose of conformal radiotherapy (proctitis ≥ grade 1 radiation and oncology grade 56% with conventional *v* 36% with conformal, P = 0.004; rectal bleeding ≥ grade 2 radiation and oncology grade 3% with conventional *v* 12% with conformal, P = 0.01).

Comment: Up to 30% of men with clinically localised prostate cancer treated with radiotherapy still have positive biopsies 2–3 years after treatment.[28] One retrospective, non-randomised, multicentre pooled analysis estimated overall survival at 5 years at 85%, disease specific survival at 95%, and freedom from biochemical failure (as defined by raised PSA) at 66%.[29] Estimated 5 year rates of no biochemical recurrence according to PSA concentrations before treatment and Gleason scores (see glossary, p 1183) ranged from 81% for pretreatment PSA less than 10 ng/mL to 29% for PSA of 20 ng/mL or more, and a Gleason score from 7–10.

OPTION BRACHYTHERAPY

A systematic review found no RCTs of brachytherapy in men with clinically localised prostate cancer.

Benefits: We found one systematic review (search date 2002), which identified no RCTs comparing brachytherapy (see glossary, p 1183) alone or in combination with other treatments (androgen suppression [see glossary, p 1182] or radiation).[8]

Harms: The systematic review reported that 36% of men had some erectile dysfunction, 2–12% had some urinary symptoms (including urinary incontinence in 7%), and 18% had some bowel dysfunction 1 year after treatment.[8] However the review stated that these figures came from poor quality studies and should be interpreted with caution.

Comment: We found two older systematic reviews that have not been presented in the benefits section (search date 1999).[30,31] One systematic review[30] identified 13 case series and three cohort studies (2 retrospective, 1 prospective) and we found one additional retrospective cohort study.[32] The studies used proxy outcomes (evidence of disease measured by prostate specific antigen [PSA] testing).[30,32] Results varied considerably from one series to another and were highly dependent on tumour stage, grade, and pretreatment serum PSA levels. Results in men with T1 or T2 tumours, Gleason score (see glossary, p 1183) of 6 or lower, and

serum PSA level of 10 ng/mL or less were similar to those from case series of people having a radical prostatectomy (see glossary, p 1183). The additional cohort study (1872 men) found that in low risk men (stage T1c, stage T2, PSA concentration ≤ 10 ng/mL, and Gleason score ≤ 6) the chance of a high PSA concentration at 5 years was similar whether they were treated with radiation or brachytherapy implant (with or without preceding androgen suppression) or with radical prostatectomy.[32] Men at intermediate or high risk (Gleason score > 6 or PSA > 10 ng/mL) were more likely to have high PSA concentration at 5 years with brachytherapy than with radical prostatectomy (RR of high PSA in men at intermediate risk 3.1, 95% CI 1.5 to 6.1; RR in men at high risk 3.0, 95% CI 1.8 to 5.0).[32] RCTs comparing brachytherapy versus radical prostatectomy are ongoing (Wilt T, personal communication, 2000).

OPTION CRYOSURGERY

We found no RCTs of cryotherapy in men with clinically localised prostate cancer.

Benefits: We found no systematic review or RCTs.

Harms: Complications reported in case series include impotence (65%), transient scrotal oedema (10%), sloughed urethral tissue (3%), urethral stricture (1%), incontinence, urethrorectal fistula, and prostatic abscess (1%).[33]

Comment: One ongoing trial is comparing cryosurgery versus radiation (Wilt T, personal communication, 2000).

OPTION ANDROGEN SUPPRESSION

We found no RCTs of early androgen suppression on length or quality of life in men with asymptomatic, clinically localised prostate cancer. One RCT identified by a systematic review found limited evidence that oestrogen decreased prostate cancer related deaths compared with watchful waiting but it found no significant difference in overall survival. One preliminary report of three large ongoing RCTs in men with localised or locally advanced prostate cancer found that bicalutamide plus standard care reduced rates of radiological progression and bone metastases at 2–3 years compared with standard care alone but there was no significant difference between treatments in overall survival.

Benefits: We found no RCTs of primary treatment with early androgen suppression (see glossary, p 1182) in the absence of symptoms on length or quality of life in men with clinically localised prostate

cancer. **Versus watchful waiting:** We found one systematic review (search date 2002, 1 RCT) in men with clinically localised prostate cancer.[8] The RCT identified by the review (285 men) compared three treatments: oestrogen, estramustine, and watchful waiting.[8] It found that oestrogen significantly reduced prostate cancer specific deaths compared with watchful waiting (prostate cancer related deaths: 12% with oestrogen *v* 28% with watchful waiting; P = 0.03). It found no significant difference between treatments in overall survival (overall survival: 47% with oestrogen *v* 40% with deferred treatment; P = 0.48). The RCT was methodologically flawed (see comment below). **Plus standard care versus standard care alone:** We found one preliminary report of three ongoing RCTs (8113 men with localised or locally advanced prostate cancer T1–T4, Nx/N, M0) comparing bicalutamide 150 mg daily plus standard care versus standard care alone.[1] Standard care included radical prostatectomy (see glossary, p 1183), radiotherapy, and watchful waiting. The meta-analysis in the report found that bicalutamide plus standard care significantly reduced rates of radiological progression and bone metastases at 2–3 years compared with standard care alone (progression: 363/4052 [9.0%] with bicalutamide plus standard care *v* 595/4061 [14.7%] with standard care alone; HR 0.58, 95% CI 0.51 to 0.66; P < 0.0001; bone metastases: 214 events with bicalutamide plus standard care *v* 321 events with standard care alone; RR 0.67, 95% CI 0.56 to 0.79). There was no significant difference between treatments in overall survival (overall survival: HR 0.93, 95% CI 0.79 to 1.11).[1]

Harms: See harms of androgen suppression in men with locally advanced prostate cancer, p 1181. One preliminary report of three ongoing RCTs (8113 men with localised or locally advanced prostate cancer) found that bicalutamide plus standard care increased gynaecomastia, breast pain, asthenia, impotence, and hot flushes compared with standard care alone but the statistical significance of differences was not reported (gynaecomastia 66% with bicalutamide plus standard care *v* 8% with standard care alone; breast pain 73% with bicalutamide plus standard care *v* 7% with standard care alone; asthenia 10% with bicalutamide plus standard care *v* 7% with standard care alone; impotence 9% with bicalutamide plus standard care *v* 6% with standard care alone; hot flushes 9% with bicalutamide plus standard care *v* 5% with standard care alone).[1] The systematic review found that androgen deprivation treatment with luteinising hormone releasing hormone agonist reduced sexual function in 40–70% and led to breast swelling in 5–25%, and hot flushes in 50–60%.[8]

Comment: One RCT identified by the systematic review compared oestrogen with deferred treatment. It was not analysed on an intention to treat basis, 24% were excluded or withdrew, treatment groups were not comparable at baseline, and there was a high cardiovascular mortality in the oestrogen group.[8] We found one additional RCT, which is awaiting translation.[34]

QUESTION **In men who have received primary treatment and remain asymptomatic, should androgen suppression be offered when raised concentrations of prostate specific antigens are detected?**

OPTION **ANDROGEN SUPPRESSION IN ASYMPTOMATIC MEN WITH RAISED PROSTATE SPECIFIC ANTIGEN CONCENTRATIONS AFTER EARLY TREATMENT**

We found no RCTs of initiating androgen suppression when prostate specific antigen rises or persists after primary treatment.

Benefits: We found one systematic review (search date 1998), which identified no RCTs.[35]

Harms: See harms of androgen suppression in men with locally advanced prostate cancer, p 1181.

Comment: In the USA, clinicians often monitor blood concentrations of prostate specific antigen and offer androgen suppression (see glossary, p 1182) when these rise.[35] Consequently, more men with persistent disease are considered for androgen suppression and treatment is initiated earlier in the natural course of the disease. RCTs are needed to evaluate the effectiveness of this approach and of intermittent treatment, in which androgen suppression is initiated when prostate specific antigen rises after primary treatment and discontinued when the antigen concentrations return to the lowest level.[35]

QUESTION **What are the effects of treatments for locally advanced prostate cancer?**

OPTION **ANDROGEN SUPPRESSION**

RCTs found no significant difference in overall survival between androgen suppression with bicalutamide and no androgen suppression in men with localised or locally advanced prostate cancer after 2–10 years. The RCTs found that bicalutamide reduced radiological progression compared with no bicalutamide. One systematic review found that early androgen treatment increased survival at 10 years compared with deferred treatment in men with locally advanced prostate cancer. It found no significant difference in survival at 5 years. One RCT found limited evidence that immediate androgen suppression reduced complications compared with deferred androgen suppression.

Benefits: **Versus no androgen suppression:** We found one preliminary report of three ongoing RCTs[1] and one reanalysis of three RCTs performed between 1960 and 1975.[36] The three ongoing RCTs (8113 men with localised or locally advanced prostate cancer T1–T4, Nx/N, M0) compared bicalutamide 150 mg once daily plus standard care with standard care alone.[1] Standard care included radical prostatectomy (see glossary, p 1183), radiotherapy, and watchful waiting. Meta-analysis found that bicalutamide plus standard care significantly reduced radiological progression and bone metastases after 2–3 years compared with standard care alone

(progression: 363/4052 [9.0%] with bicalutamide plus standard care *v* 595/4061 [14.7%] with standard care alone; HR 0.58, 95% CI 0.51 to 0.66; P < 0.0001; bone metastases: 214 events with bicalutamide plus standard care *v* 321 events with standard care alone; RR 0.67, 95% CI 0.56 to 0.79). There was no significant difference between treatments in overall survival (overall survival: HR 0.93, 95% CI 0.79 to 1.11).[1] The three earlier RCTs (about 4000 men with all stages of newly diagnosed prostate cancer) compared androgen suppression (see glossary, p 1182) (diethylstilbestrol [stilboestrol], orchidectomy, or oestrogens) versus no initial treatment.[36] They found no significant difference in overall survival. Reanalysis of updated data (published 1988) from these RCTs provided limited evidence of a modest survival advantage with androgen suppression, particularly in younger people with more advanced disease.[36] **Immediate (initiated at diagnosis) versus deferred androgen suppression:** We found one systematic review (search date 2001, 4 RCTs, 2167 men with locally advanced prostate cancer).[37] All RCTs included in the review were conducted before prostate specific antigen testing was introduced. Each RCT used different methods of androgen suppression and had different requirements for initiation of treatment. It found no significant difference in overall survival at 1, 2, or 5 years with early compared with deferred androgen suppression (3 RCTs, 1307 men, at 1 year 88% with early *v* 86% with deferred; RR 1.04, 95% CI 0.99 to 1.09; at 2 years 73% with early *v* 71% with deferred; RR 1.05, 95% CI 0.97 to 1.12; at 5 years 44% with early *v* 37% with deferred; RR 1.08, 95% CI 0.96 to 1.22). However, it found that early treatment significantly increased survival at 10 years compared with deferred treatment (18% with early *v* 12% with deferred; OR 1.50, 95% CI 1.04 to 2.16). The most recent of the RCTs[38] identified by the review (938 men with stage C [locally advanced] or stage D [asymptomatic metastatic] disease) was not included in the meta-analysis (see comment below). It found that in men with stage C disease, immediate androgen suppression significantly improved survival compared with deferred treatment (survival benefit measured by survival curve; P = 0.02; CI not reported). The RCT found that in people with stage C disease, immediate androgen suppression was associated with a non-significant lower risk of major complications, such as pathological fractures compared with deferred treatment (3/256 [1.2%] with immediate *v* 6/244 [2.5%] with deferred; RR 0.48, 95% CI 0.12 to 1.90), ureteric obstruction (22/256 [8.6%] with immediate *v* 28/244 [11.5%] with deferred; RR 0.75, 95% CI 0.44 to 1.30), and extraskeletal metastases (17/256 [6.6%] with immediate *v* 26/244 [10.7%] with deferred; RR 0.62, 95% CI 0.35 to 1.10). Analysis including all participants found a significant reduction for combined results of pathological fracture and cord compression (RR 0.48, 95% CI 0.28 to 0.79). The RCT did not make clear the time interval over which outcomes were recorded, although this seemed to be at least 10 years.[38] One additional RCT in men with cancers of different stages found that bicalutamide significantly improved disease free progression at 2.6 years compared with placebo.[39] See benefits of androgen suppression under effects of treating clinically localised prostate cancer, p 1177.

Harms: Adverse events were not well reported in the review.[37] Earlier initiation of androgen suppression means longer exposure to adverse effects, which include osteoporosis, weight gain, hot flushes (10–60%), loss of muscle mass, gynaecomastia (5–10%), impotence (10–30%), and loss of libido (5–30%).[35] These adverse effects are particularly important in the treatment of men with long life expectancy or younger men with lower grade cancers. The review did not report on quality of life. See harms of androgen suppression under effects of treating clinically localised prostate cancer, p 1178.

Comment: The RCTs conducted in the 1960s and 1970s[35] included men who were older and had more advanced cancers than those in the more recent RCT.[38] The most recent RCT[38] will be included in the meta-analysis of the systematic review[37] in future updates of the Cochrane Library. RCTs are needed to evaluate the effectiveness of androgen suppression before surgery when disease extends beyond the capsule.

OPTION ANDROGEN SUPPRESSION PLUS EXTERNAL BEAM RADIATION VERSUS EXTERNAL BEAM RADIATION ALONE

RCTs found limited evidence that androgen suppression initiated at diagnosis plus external beam radiation improved long term survival compared with radiation alone or radiation plus deferred androgen suppression. One RCT found limited evidence that immediate androgen suppression reduced complications compared with deferred androgen suppression.

Benefits: We found one systematic review (search date 1998, 4 RCTs, 1565 men)[35] and one additional RCT.[40] The review compared early versus deferred androgen suppression (see glossary, p 1182) in men receiving external beam radiation.[35] Early androgen suppression was initiated at the same time as radiation treatment for locally advanced, or asymptomatic but clinically evident, metastatic prostate cancer, and was continued until the development of hormone refractory disease. The deferred group received radiation treatment alone, with androgen suppression initiated only in those in whom the disease progressed. The systematic review found that early androgen suppression significantly improved overall 5 year survival compared with deferred treatment (percentage surviving at 5 years 76.5% with early *v* 68.2% with deferred; ARR 8.3%; HR 0.63, 95% CI 0.48 to 0.83; NNT at 5 years 12).[35] Long term follow up of one of the RCTs included in the review (476 men, stages T2–T4, with or without pelvic lymph node involvement) found that more people survived with early androgen suppression at 8 years compared with deferred treatment, but the difference was not significant (53% with early *v* 44% with deferred; $P = 0.1$). There was a significant improvement in disease free survival (33% with early *v* 21% with deferred; $P = 0.004$) and in the incidence of distant metastases (34% with early *v* 45% with deferred; $P = 0.04$).[41] The additional RCT (277 men with advanced localised prostate cancer; T2–T4, M0, with and without nodal disease) compared three treatments: orchidectomy alone, radiotherapy alone, or radiotherapy in addition

to orchidectomy.[40] It found no significant difference in overall survival or need for further treatment for local disease progression between the three treatment groups (data presented graphically; P value not reported), but it is likely to have been underpowered to detect a clinically important difference.

Harms: The review reported adverse effects of androgen suppression (see harms of androgen suppression for the treatment of men with locally advanced prostate cancer, p 1181).[35] In the additional RCT, adverse effects associated with radiotherapy included bowel symptoms (19%), urinary symptoms including transient frequency (8%), bowel and urinary complications (1%), rectal bleeding necessitating blood transfusion (2%), and radiation proctitis (1%), which was a contributory factor in two deaths. It found that the predominant adverse effect after orchidectomy was hot flushes (15%).[40]

Comment: We found no evidence from RCTs of external beam radiation alone in men with locally advanced prostate cancer.

OPTION ANDROGEN SUPPRESSION AFTER RADICAL PROSTATECTOMY AND PELVIC LYMPHADENECTOMY

One small RCT in men with node positive prostate cancer found that immediate androgen suppression compared with deferred androgen suppression after radical prostatectomy and pelvic lymphadenectomy reduced mortality over a median of 7 years' follow up.

Benefits: We found one RCT (98 men who had had a radical prostatectomy [see glossary, p 1183] and pelvic lymphadenectomy for nodal metastases) comparing immediate androgen suppression (see glossary, p 1182) (with either goserelin or bilateral orchidectomy) versus androgen suppression deferred until disease progression.[42] It found that androgen suppression significantly reduced mortality in the long term compared with watchful waiting (median follow up 7.1 years; mortality 7/47 [14.9%] with androgen suppression *v* 18/51 [35.3%] with watchful waiting; ARR 20.4%; RR 0.42, 95% CI 0.19 to 0.92; NNT 4, 95% CI 3 to 33), and resulted in a higher proportion of men with undetectable prostate specific antigen ($P < 0.001$).

Harms: The RCT found that, compared with deferred androgen suppression, immediate androgen suppression caused more haematological effects (15% with immediate *v* 4% with deferred), gastrointestinal effects (25% with immediate *v* 6% with deferred), non-specific genitourinary effects (48% with immediate *v* 12% with deferred), hot flushes (56% with immediate *v* 0% with deferred), and weight gain (18% with immediate *v* 2% with deferred).[42]

Comment: None.

GLOSSARY

Androgen suppression Monotherapy uses a single drug or surgical procedure for androgen suppression. Methods include orchidectomy (removal of both testes), diethylstilbestrol, luteinising hormone releasing hormone agonist injections, or non-steroidal antiandrogens. Combined androgen blockade uses the addition of a non-steroidal antiandrogen to standard androgen suppression monotherapy with orchidectomy, diethylstilbestrol, or luteinising hormone releasing hormone agonist injection.

Brachytherapy Radiotherapy where the sources of ionising radiation are radioactive implants, many of which are permanently inserted directly into the prostate gland.
Conformal radiotherapy Three dimensional radiotherapy planning systems and methods to match the radiation treatment to irregular tumour volumes.
Gleason score A number from 1–10 with 1 being the most well differentiated and 10 being the most poorly differentiated tumour or a histological examination.
Radical prostatectomy Surgical removal of the prostate with its capsule, seminal vesicles, ductus deferens, some pelvic fasciae, and sometimes pelvic lymph nodes; performed through either the retropubic or the perineal route.

TABLE 1 **Prostatic cancer staging systems (see text, p 1171).**

Tumour, node, metastasis (TNM) classification system	
Tumour	
T0	Clinically unsuspected
T1	Clinically inapparent (not palpable or visible by imaging)
T2	Tumour confined within prostate
T3	Tumour outside capsule or extension into vesicle
T4	Tumour fixed to other tissue
Nodes	
N0	No evidence of involvement of regional nodes
N1	Involvement of regional nodes
Metastases	
M0	No evidence of distant metastases
M1	Evidence of distant metastases
American urologic staging system	
Stage A	No palpable tumour
Stage B	Tumour confined to the prostate gland
Stage C	Extracapsular extension
Stage D	Metastatic prostate cancer
Stage D1	Pelvic lymph node metastases
Stage D2	Distant metastases

Key Messages

- **Effects of treatments on pain or discomfort due to varicocele** We found no evidence examining the effects of expectant management, surgical ligation, sclerotherapy, or transcatheter embolisation on pain or discomfort due to varicocele.
- **Expectant management** One systematic review and subsequent RCTs in couples with male factor subfertility found no significant difference in pregnancy rate between expectant management and occlusive treatments (surgery or sclerotherapy). However, the studies were heterogeneous and of poor methodological quality.
- **Sclerotherapy** One RCT found no significant difference in pregnancy rate between sclerotherapy and no treatment.
- **Surgical ligation** We found insufficient evidence on the effects of surgical ligation in improving pregnancy rate compared with no treatment, sclerotherapy, or embolisation in men with varicocele. We also found insufficient evidence comparing the effects of different ligation techniques.
- **Embolisation** We found no RCTs comparing embolisation versus no treatment. We found insufficient evidence on the effects of embolisation for improving fertility in men with varicocele compared with ligation techniques.

DEFINITION Varicocele is a dilation of the pampiniform plexus of the spermatic cord. Severity is commonly graded as follows: grade 0, only demonstrable by technical investigation; grade 1, palpable or visible only on Valsalva manoeuvre (straining); grade 2, palpable but not visible when standing upright at room temperature; and grade 3, visible when standing upright at room temperature. Varicocele is unilateral and left sided in at least 85% of cases. In most of the remaining cases, the condition is bilateral. Unilateral right sided varicocele is rare. Many men who have a varicocele have no symptoms. Symptoms may include testicular ache or discomfort and distress about cosmetic appearance. The condition is widely believed to be associated with male factor infertility, which is the commonest reason for referral for treatment. However, evidence for a causal relationship is sparse (see incidence/prevalence, below).[1]

INCIDENCE/ PREVALENCE We found few data on the prevalence of varicocele. Anecdotally, it has been estimated that about 10–15% of men and adolescent boys in the general population have varicocele.[1] One multicentre study found that, in couples with subfertility, the prevalence of varicocele in male partners was about 12%.[2] In men with abnormal semen analysis, the prevalence of varicocele was about 25%.

AETIOLOGY/ RISK FACTORS We found no reliable data on epidemiological risk factors for varicocele, such as a family history or environmental exposures. Anatomically, varicoceles are caused by dysfunction of the valves in the spermatic vein, which allows pooling of blood in the pampiniform plexus. This is more likely to occur in the left spermatic vein than in the right because of normal anatomical asymmetry.

PROGNOSIS Varicocele is believed to be associated with subfertility, although reliable evidence is sparse (see incidence/prevalence, above). The natural history of varicocele is unclear.

AIMS OF INTERVENTION To improve the rate of pregnancy in couples in which the male partner has varicocele and the woman has no identified fertility problems; to reduce pain and discomfort associated with varicocele.

OUTCOMES Where available, we have reported on spontaneous live birth rate (i.e. without assisted reproductive techniques such as in vitro fertilisation), spontaneous pregnancy rate, pain or discomfort (we found no scales that have been specifically validated for this condition), quality of life, and adverse effects of treatments. Non-clinical outcomes such as testicular temperature, blood flow, or sperm count were excluded.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments in men with varicocele? New

OPTION EXPECTANT MANAGEMENT (NO TREATMENT)

One systematic review and subsequent RCTs in couples with male factor subfertility found no significant difference in pregnancy rate between expectant management and occlusive treatments (surgery or

sclerotherapy). However, the studies were heterogeneous and of poor methodological quality. We found no evidence examining the effects of expectant management on pain or discomfort due to varicocele.

Benefits: We found no RCTs examining the effects of expectant management on pain or discomfort due to varicocele. **Versus surgical ligation:** We found one systematic review (search date 2000; 3 RCTs; 430 subfertile men with varicocele),[1] and one subsequent RCT[3] that evaluated effects on fertility see comment). All but one of these RCTs found no significant difference between expectant management and surgical ligation.The first RCT included in the review (45 subfertile men with varicocele grade 1–3) found that surgical ligation of the spermatic vein (Palomo technique [see glossary, p 1191]) significantly improved pregnancy rate compared with no treatment after 12 months (15/25 with ligation *v* 2/20 with no treatment; OR 8.0, 95% CI 2.41 to 26.55).[4] The second RCT included in the review (96 subfertile men with varicocele) found no significant difference in pregnancy rate between surgical ligation (Palomo technique) of one or both internal spermatic veins and no treatment after a mean of 53 months of follow up (4/51 with ligation *v* 8/45 with no treatment; OR 0.41, 95% CI 0.12 to 1.36).[5] The third RCT included in the review (85 subfertile men with varicocele) found no significant difference in pregnancy rate between high ligation of the internal spermatic vein(s) and no treatment (3/45 with ligation *v* 4/40 with no treatment; OR 0.65, 95% CI 0.14 to 3.02).[6] The subsequent RCT (68 men with low grade varicocele) reported no significant difference in rate of pregnancy between spermatic vein ligation (Palomo technique) and no treatment at 12 months (1/34 with vein ligation *v* 2/34 with no treatment; P value not reported).[3] **Versus sclerotherapy:** We found no systematic review. We found one RCT (67 men with varicocele who were childless for at least 12 months), which found no significant difference in pregnancy rate between sclerotherapy and no treatment after 12 months (15.6% with sclerotherapy *v* 18.2% with no treatment; OR 0.875, 95% CI +0.181 to −4.06).[7] However, the study had important methodological weaknesses (see comment, below). **Versus embolisation:** We found one systematic review,[1] which found no RCTs. We found no RCTs.

Harms: **Versus surgical ligation:** The systematic review did not report on harms.[1] The subsequent RCT reported no complications after surgery.[3] **Versus sclerotherapy:** The RCT did not report on harms.[7] **Versus embolisation:** See harms of embolisation, p 1190.

Comment: **Versus surgical ligation:** The systematic review found that the studies included were heterogeneous and of poor methodological quality.[1] The third RCT in the review described a high ligation technique; it is not explicit that this was the Ivanissevich technique (see glossary, p 1191).[6] Furthermore, seven men did not return for follow up, but the authors state that an intention to treat analysis was not possible. The systematic review found two RCTs that had more than two treatment arms. One compared ligation (Palomo technique), sclerotherapy, embolisation, and no treatment. The other compared ligation (Bernardi technique [see glossary, p 1191]), embolisation, and no treatment. We excluded these two

studies because men were randomised in the treatment group regardless of treatment technique, and therefore the effects of ligation or embolisation alone could not be reliably assessed.[1] **Versus sclerotherapy:** The sclerotherapy RCT did not achieve the estimated sample size (460 men) needed for adequate power, recruiting only 67 men.[7] Out of these, 34 (51%) men did not return for follow up and it was assumed that their partners did not become pregnant in the intention to treat analysis.

OPTION SURGICAL LIGATION

We found insufficient evidence on the effects of surgical ligation in improving pregnancy rates compared with no treatment, sclerotherapy, or embolisation in men with varicocele. We also found insufficient evidence comparing the effects of different ligation techniques. We found no evidence examining the effects of ligation on pain or discomfort due to varicocele.

Benefits: We found no evidence examining the effects of surgical ligation on pain or discomfort due to varicocele. **Versus no treatment:** See benefits of expectant management, p 1188. **Versus embolisation:** See benefits of embolisation, p 1190. **Versus sclerotherapy:** See benefits of sclerotherapy, p 1190. **Ligation techniques versus each other:** We found no systematic review. We found two RCTs.[8,9] The first RCT (137 infertile men with varicocele) compared the Ivanessivich technique of ligation (see glossary, p 1191), the Bernardi technique of ligation (see glossary, p 1191), and embolisation of the internal spermatic vein.[8] It found no significant difference in pregnancy rate between the Ivanissevich technique and the Bernardi technique (13/34 with the Ivanissevich technique *v* 9/35 with the Bernardi technique; P value not reported). The second RCT (119 infertile men with varicocele) compared the Palomo technique of ligation (see glossary, p 1191), the Bernardi technique of ligation, and transcatheter embolisation.[9] It found no significant difference in pregnancy rate between the ligation techniques after 2 years (29% with Palomo ligation *v* 25% with Bernardi ligation; P value not reported).

Harms: **Versus no treatment:** See harms of expectant management, p 1188. **Versus embolisation:** See harms of embolisation, p 1190. **Versus sclerotherapy:** We found insufficent evidence on harms. **Ligation techniques versus each other:** The RCT that compared high ligation, transinguinal ligation, and percutaneous embolisation reported two cases of pyrexia and flank tenderness in the embolisation group, and one case of wound infection in the ligation group.[9]

Comment: **Versus no treatment:** See comment under expectant management, p 1188.

OPTION EMBOLISATION

We found no RCTs comparing embolisation versus no treatment. We found insufficient evidence on the effects of embolisation for improving fertility in men with varicocele compared with ligation techniques. We found no evidence examining the effects of transcatheter embolisation on pain or discomfort due to varicocele.

Varicocele

Benefits: We found no evidence examining the effects of embolisation on pain or discomfort due to varicocele. **Versus no treatment:** We found one systematic review,[1] which found no RCTs. We found no RCTs. **Versus surgical ligation:** We found no systematic review. We found three RCTs.[8–10] One of the RCTs (119 men with primary and secondary infertility) compared Palomo technique of ligation (see glossary, p 1191), Bernardi technique of ligation (see glossary, p 1191), and transcatheter embolisation.[9] It found no significant difference in pregnancy rate between the three treatment options after 2 years (29% with Palomo technique *v* 25% with Bernardi technique *v* 28% with embolisation; P values not reported). The second RCT (107 men with primary infertility and 30 men with secondary infertility) compared Ivanissevich technique of ligation (see glossary, p 1191), Bernardi technique of ligation, and embolisation.[8] It found that the Ivanissevich technique significantly increased the rate of pregnancy compared with embolisation (13/34 with Ivanissevich technique *v* 9/35 with Bernardi technique *v* 7/34 with embolisation; $P < 0.05$ between Ivanissevich technique and embolisation; other P values not reported). The third RCT (71 infertile men) found no significant difference in pregnancy rate between surgical ligation and embolisation at 12 months (11/38 with ligation *v* 11/33 with embolisation; $P > 0.05$) [10]

Harms: The RCT that compared embolisation versus left internal sperm ligation reported some complications (3/51 with embolisation *v* 2/43 with Palomo technique *v* 2/43 with Bernardi technique; P value not reported).[8] Left lower abdominal pain was the most common complaint in the embolisation group, and wound infection was the most common complaint in the ligation groups.

Comment: One systematic review described two RCTs that had more than two treatment arms.[1] One compared ligation (Palomo technique), sclerotherapy, embolisation, and no treatment. The other compared ligation (Bernardi technique), embolisation, and no treatment. We excluded these two studies because people were randomised in the treatment group regardless of treatment technique, and therefore the effects of ligation or embolisation alone could not be reliably assessed.[1]

OPTION SCLEROTHERAPY

One RCT found no significant difference in pregnancy rate between sclerotherapy and no treatment. We found no evidence examining the effects of sclerotherapy on pain or discomfort due to varicocele.

Benefits: We found no RCTs examining the effects of sclerotherapy on pain or discomfort due to varicocele. **Versus no treatment:** See benefits of expectant management, p 1188. **Versus surgical ligation:** We found one RCT (120 infertile men with varicocele), which compared Ivanessevich technique of ligation (see glossary, p 1191) and sclerotherapy.[11] The report was published in Italian and is being translated. **Versus embolisation:** We found no RCTs.

Harms: **Versus no treatment:** The RCT comparing sclerotherapy versus no treatment did not report on harms.[7] **Versus surgical ligation:** We found insufficient evidence. **Versus embolisation:** We found insufficient evidence.

Comment: We found one systematic review,[1] which describes one RCT comparing ligation (Palomo technique [see glossary, p 1191]), sclerotherapy, embolisation, and no treatment.[12] We have excluded this study from this option because men were randomised in the treatment group regardless of treatment technique, and therefore the effects of ligation or embolisation alone could not be reliably assessed.[1]

GLOSSARY

Ivanissevich technique of ligation The spermatic vein(s) are ligated high, close to the iliac crest.

Bernardi technique of ligation The spermatic vein(s) are ligated close to the inguinal ring.

Palomo technique of ligation The retroperitoneal internal spermatic vein(s) are ligated at the level of the anterior superior iliac spine.

QUESTIONS

INTERVENTIONS

Unknown effectiveness

Likely to be ineffective or harmful

See glossary, p 1201

Key Messages

- **Inpatient versus outpatient treatment setting (in people not requiring emergency intervention)** One small RCT found no significant difference between outpatient treatment and inpatient treatment for increasing weight and improving Morgan Russell scale global scores at 1, 2, and 5 years in people who did not need emergency intervention.
- **Oestrogen treatment (for prevention of fractures)** We found no good evidence about the effects of oestrogen treatment on fracture rates in people with anorexia. Two small RCTs found no significant difference between oestrogen and placebo or no treatment in bone mineral density in people with anorexia.
- **Psychotherapies** We found insufficient evidence from small RCTs to compare psychotherapies versus dietary counselling or versus each other.
- **Selective serotonin reuptake inhibitors** We found insufficient evidence from three small RCTs about effects of selective serotonin reuptake inhibitors compared with placebo or no treatment in people with anorexia.
- **Zinc** One small RCT found limited evidence that zinc may improve daily body mass index gain compared with placebo in people managed in an inpatient setting. However, we were unable to draw reliable conclusions from this small study.
- **Cisapride** One small RCT found no significant difference between cisapride and placebo in weight gain at 8 weeks. Use of cisapride has been restricted in many countries because of concern about cardiac irregularities, including ventricular tachycardia, torsades de pointes, and sudden death.
- **Cyproheptadine** One small RCT in an outpatient setting and two RCTs in inpatient settings found no significant difference between cyproheptadine and placebo for weight gain.

- **Neuroleptic drugs** We found no RCTs. The QT interval may be prolonged in people with anorexia nervosa, and many neuroleptic drugs (haloperidol, pimozide, sertindole, thioridazine, chlorpromazine, and others) also increase the QT interval. Prolongation of the QT interval may be associated with increased risk of ventricular tachycardia, torsades de pointes, and sudden death.
- **Tricyclic antidepressants** Two small RCTs found no evidence of benefit with amitriptyline compared with placebo. They found that amitriptyline was associated with more adverse effects, such as palpitations, dry mouth, and blurred vision.

DEFINITION Anorexia nervosa is characterised by a refusal to maintain weight at or above a minimally normal weight (< 85% of expected weight for age and height, or body mass index [see glossary, p 1201] < 17.5 kg/m^2), or a failure to show the expected weight gain during growth. In association with this, there is often an intense fear of gaining weight, preoccupation with weight, denial of the current low weight and its adverse impact on health, and amenorrhoea. Two subtypes of anorexia nervosa, binge–purge and restricting, have been defined.[1]

INCIDENCE/ PREVALENCE A mean incidence in the general population of 19/100 000 a year in females and 2/100 000 a year in males has been estimated from 12 cumulative studies.[2] The highest rate was in female teenagers (age 13–19 years), where there were 50.8 cases/100 000 a year. A large cohort study screened 4291 Swedish school children, aged 16 years, by weighing and subsequent interview, and found the prevalence of anorexia nervosa (defined using DSM-III and DSM-III-R criteria) to be 7/1000 for girls and 1/1000 for boys.[3] Little is known of the incidence or prevalence in Asia, South America, or Africa.

AETIOLOGY/ RISK FACTORS Anorexia nervosa has been related to family, biological, social, and cultural factors. Studies have found that anorexia nervosa is associated with a family history of anorexia nervosa (adjusted HR 11.4, 95% CI 1.1 to 89.0), of bulimia nervosa (adjusted HR 3.5, 95% CI 1.1 to 14.0),[4] depression, generalised anxiety disorder, obsessive compulsive disorder, or obsessive compulsive personality disorder (adjusted RR 3.6, 95% CI 1.6 to 8.0).[5] A twin study suggested that anorexia nervosa may be related to genetic factors but it was unable to estimate reliably the contribution of non-shared environmental factors.[6] Specific aspects of childhood temperament thought to be related include perfectionism, negative self evaluation, and extreme compliance.[7] Perinatal factors include prematurity, particularly if the baby was small for gestational age (prematurity: OR 3.2, 95% CI 1.6 to 6.2; small for gestational age: OR 5.7, 95% CI 1.1 to 28.7).[8]

PROGNOSIS One prospective study followed up 51 people with teenage-onset anorexia nervosa, about half of whom received no or minimal treatment (< 8 sessions). After 10 years, 14/51 people (27%) had a persistent eating disorder, three (6%) had ongoing anorexia nervosa, and six (12%) had experienced a period of bulimia nervosa. People with anorexia nervosa were significantly more likely to have an affective disorder than controls matched for sex, age, and school (lifetime risk of affective disorder 96% in people with anorexia *v* 23% in controls; ARI 73%, 95% CI 60% to 85%).

Anorexia nervosa

Obsessive compulsive disorder was, similarly, significantly more likely in people with anorexia nervosa compared with controls (30% *v* 10%; ARI 20%, 95% CI 10% to 41%). However, in 35% of people with obsessive compulsive disorder and anorexia nervosa, obsessive compulsive disorder preceded the anorexia. About half of all participants continued to have poor psychosocial functioning at 10 years (assessed using the Morgan Russell scale (see glossary, p 1201) and Global Assessment of Functioning Scale).[9] A summary of treatment studies (68 studies published between 1953 and 1989, 3104 people, length of follow up 1–33 years) found that 43% of people recover completely (range 7–86%), 36% improve (range 1–69%), 20% develop a chronic eating disorder (range 0–43%), and 5% die from anorexia nervosa (range 0–21%).[10] Favourable prognostic factors include an early age at onset and a short interval between onset of symptoms and the beginning of treatment. Unfavourable prognostic factors include vomiting, bulimia, profound weight loss, chronicity, and a history of premorbid developmental or clinical abnormalities. The all cause standardised mortality ratio of eating disorders (anorexia nervosa and bulimia nervosa) has been estimated at 538, about three times higher than other psychiatric illnesses.[11] The average annual mortality was 0.59% a year in females in 10 eating disorder populations (1322 people) with a minimum follow up of 6 years.[12] The mortality was higher for people with lower weight and with older age at presentation. Young women with anorexia nervosa are at an increased risk of fractures later in life.[13]

AIMS OF INTERVENTION To restore physical health (weight within the normal range and no sequelae of starvation, e.g. regular menstruation, normal bone mass), normal patterns of eating and attitudes towards weight and shape, and no additional psychiatric comorbidity (e.g. depression, anxiety, obsessive compulsive disorder); to reduce the impact of the illness on social functioning and quality of life.

OUTCOMES The most widely used measure of outcome is the Morgan Russell scale,[14] which includes nutritional status, menstrual function, mental state, and sexual and social adjustment. Biological outcome criteria alone such as weight (body mass index or in relation to matched population weight) and menstrual function are used infrequently as outcome measures. RCTs do not usually have sufficient power or long enough follow up periods to examine mortality. Other validated outcome measures include eating symptom measures.[15–18] Bone mineral density is included as a proxy outcome for fracture risk.

METHODS *Clinical Evidence* search and appraisal April 2003 and hand searches of reference lists of identified reviews. To be included, an RCT had to have at least 30 people and follow up greater than 75%. Results from each of the identified trials were extracted independently by the two reviewers. Any disagreements were discussed until a consensus was reached.

QUESTION What are the effects of treatments in anorexia nervosa?

OPTION PSYCHOTHERAPY

We found insufficient evidence from small RCTs to compare psychotherapies versus dietary counselling or versus each other.

Benefits: **Versus treatment as usual or dietary counselling:** We found no systematic review. We found three small RCTs of limited quality that compared different psychotherapies versus dietary counselling (see glossary, p 1201) or treatment as usual (see table A on web extra). All three RCTs were carried out in an outpatient setting in people with a late age of onset and long duration of illness.[19–21] The largest RCT found significant improvements in weight gain for some psychotherapies compared with treatment as usual and for the proportion of people classified as recovered.[19] The second RCT found a significant improvement from baseline for cognitive therapy.[21] All people treated with dietary counselling either did not take up or withdrew from treatment and refused release of their results, making it impossible to compare the two groups. The third RCT found no difference in outcomes between the groups.[20] **Versus each other:** We found six small RCTs of limited quality that compared different psychotherapies (see glossary, p 1201).Three of these were undertaken in an outpatient setting in people with an early age of onset and short illness duration.[22–24] Two of the RCTs were carried out in an outpatient setting in people with a later age of onset and longer duration of illness.[19,25] One RCT included people with early and late onset anorexia nervosa and with long and short duration of illness (see table A on web extra).[26,27] None of the RCTs found an overall significant difference between different psychotherapies.

Harms: The acceptability of the treatment varied among RCTs. Failure to take up treatment ranged from 0–30% and withdrawal from treatment ranged from 0–70% among RCTs but this may have been caused by different methods of case ascertainment (see table A on web extra). The proportion of people admitted for inpatient treatment (see glossary, p 1201) also varied among RCTs, ranging from 0–36%. One death was attributed to anorexia nervosa in the control group in one outpatient RCT with a 1 year follow up.[19] Three deaths attributed to anorexia nervosa occurred in the 5 year follow up period of one inpatient based RCT.[27]

Comment: All the RCTs were small and had limited power to detect clinically important differences. The amount of therapeutic input varied considerably among and within the RCTs. There was variation in methods of recruitment, reporting of key results (e.g. withdrawal rates), and the description of participants' characteristics and selection. The people in the inpatient RCT covered a broad range of severity.[26]

OPTION TRICYCLIC ANTIDEPRESSANTS

Two small RCTs found no evidence of benefit with amitriptyline compared with placebo. They found that amitriptyline was associated with more adverse events, such as palpitations, dry mouth, and blurred vision.

Anorexia nervosa

Benefits: We found no systematic review. We found two small RCTs.[28,29] The first RCT (43 people, 5 of them outpatients, with early onset and short duration anorexia nervosa, mean age 16.6 years, mean 27% below average weight, mean duration of anorexia nervosa 1.5 years) compared amitriptyline versus placebo.[29] Participants could also receive various kinds of psychotherapy (see glossary, p 1201). Eighteen people refused to participate and were used as a third comparison group. The RCT found no significant difference between the groups on any of the outcome scales measured at 5 weeks (> 50% improvement in global response 1/11 [9%] with amitriptyline *v* 1/14 [7%] with placebo; RR 1.2, 95% CI 0.1 to 16.7). The second RCT (72 women, mean age 20.6 years, mean 2.9 years' duration) compared amitriptyline (up to a maximum of 160 mg), cyproheptadine, and placebo.[29] It found no significant difference between amitriptyline and placebo for rate of weight gain.[29]

Harms: Adverse events more common with amitriptyline included increased perspiration (2/11 [18%] with amitriptyline *v* 0/14 [0%] with placebo), drowsiness (6/11 [55%] line *v* 0/14 [0%]), dry mouth (4/11 [36%] *v* 2/14 [14%]), blurred vision (1/11 [9%] *v* 0/14 [0%]), urinary retention (1/11 [9%] *v* 0/14 [0%]), hypotension (2/11 [18%] *v* 0/14 [0%]), and leukopenia (1/11 [9%] *v* 0/14 [0%]). Adverse events more common with placebo included palpitations (0/11 [0%] with amitriptyline *v* 1/14 [7%] with placebo) and dizziness (0/11 [0%] *v* 2/14 [14%]). The QT interval may be prolonged in people with anorexia nervosa[30] and tricyclic antidepressants (amitriptyline, protriptyline, nortriptyline, doxepin, and maprotiline) also increase the QT interval.[31–33] In an observational study (495 people with mental illness and 101 healthy controls) an increased risk of prolonged QT interval was seen with tricyclic antidepressant use, adjusting for age and other drug use (adjusted OR 2.6, 95% CI 1.2 to 5.6).[34] The RCT comparing amitriptyline with placebo found more adverse effects with amitriptyline than placebo. General harms of tricyclic antidepressants are described in the section on depression (see depressive disorders, p 1278).

Comment: The RCTs were both of short duration. Prolongation of the QT interval may be associated with increased risk of ventricular tachycardia, torsades de pointes, and sudden death.[32,33] It is not clear if people in the second amitriptyline RCT also received psychotherapy.[29]

OPTION SELECTIVE SEROTONIN REUPTAKE INHIBITORS

We found insufficient evidence from three small RCTs about effects of selective serotonin reuptake inhibitors compared with placebo or no treatment in people with anorexia.

Benefits: We found no systematic review. We found three small RCTs.[35–37] The first RCT (33 women; mean age 26.2 years; mean body mass index (see glossary, p 1201) 15.0 kg/m^2; mean duration of anorexia nervosa 8.0 years) compared fluoxetine 60 mg versus placebo for the duration (mean 36 days) of inpatient treatment, which included individual and group psychotherapy (see glossary, p 1201).[35] There were two early withdrawals from the fluoxetine group. The RCT found no significant differences in weight gain, eating symptoms, or

depressive symptoms between the groups. The second RCT (39 women, binge–purge type anorexia excluded, mean age about 22 years, mean duration of anorexia nervosa 4–7 years) compared fluoxetine (starting dosage 20 mg/day) with placebo for 1 year. All women had been discharged from hospital after weight gain (minimum weight restoration was 75% of average body weight). Women were allowed additional psychotherapy. Women who had substantial and incapacitating symptoms were encouraged to withdraw from the study. Withdrawal rates were too high to draw reliable conclusions about effects, although withdrawal rate was significantly lower with fluoxetine compared with placebo (6/16 [37%] with fluoxetine *v* 16/19 [84%] with placebo; RR 0.45, 95% CI 0.23 to 0.86).[36] The third RCT (52 adults with moderately severe restricting anorexia nervosa [body mass index 15.8 kg/m^2]) compared citalopram (10 mg/day increasing to 20 mg/day) versus waiting list control for 12 weeks before the start of standard integrated dietary and psychiatric treatment.[37] Reliability was limited because withdrawal rates were high (7/26 [29.5%] with citalopram *v* 6/26 [23.1%] with control). The RCT found no significant difference in weight gain between citalopram and control. It found that self reported depressive symptoms (and some additional measures of comorbidity) improved in the citalopram group only (change in weight from baseline to 12 weeks: from 43.5 kg to 46.5 kg with citalopram *v* from 42.5 kg to 43.9 kg with control; P value not reported; Beck Depression Inventory: 14.5 to 7.3 with citalopram *v* 12.7 to 12.3 with control; P value not reported).

Harms: General harms of selective serotonin reuptake inhibitors are described in the section on depression (see depressive disorders, p 1278). The RCT comparing citalopram with control did not report adverse effects or reasons for withdrawal.[37]

Comment: In the second RCT, four further women were excluded from the analysis. Three became aware of the treatment and one stopped taking medication before the end of 30 days.[36]

OPTION NEUROLEPTIC DRUGS

We found no good evidence of benefit. Some neuroleptic drugs may prolong the QT interval.

Benefits: We found no systematic review and no RCTs.

Harms: General harms of neuroleptic drugs are described in the section on schizophrenia (see schizophrenia, p 1362). The QT interval may be prolonged in people with anorexia nervosa[30,31] and many neuroleptic drugs (haloperidol, pimozide, sertindole, thioridazine, chlorpromazine, and others) may also increase the QT interval.[32,33] An observational study (495 people with mental illness and 101 healthy controls) found an increased risk of prolonged QT interval with high and very high dose neuroleptic use after adjusting for age and other drug use (high dose: adjusted OR 3.4, 95% CI 1.2 to 10.1; very high dose: adjusted OR 5.6, 95% CI 1.6 to 19.3).[34]

Comment: Prolongation of the QT interval may be associated with increased risk of ventricular tachycardia, torsades de pointes, and sudden death.[32,33]

OPTION ZINC

One small RCT found limited evidence that zinc may improve daily body mass index gain compared with placebo in people managed in an inpatient setting. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found no systematic review. We found one RCT (54 people aged > 15 years, mean body mass index (see glossary, p 1201) 15.8 kg/m^2, mean duration of anorexia nervosa 3.7 years, admitted to 2 eating disorder units), which compared 100 mg zinc gluconate versus placebo.[38] All but three of the people had normal zinc levels before treatment. Treatment was continued until the individual had gained 10% of weight over the admission weight on two consecutive weeks. Ten people in the zinc group and nine in the placebo group did not complete the study. The RCT found that zinc significantly increased the daily rate of gain in body mass index compared with placebo (0.079 with zinc *v* 0.039 with placebo; P = 0.03).[38]

Harms: None reported.

Comment: The rationale for zinc supplements in people with normal zinc levels is unclear.

OPTION CYPROHEPTADINE

One small RCT in an outpatient setting and two RCTs in inpatient settings found no significant difference between cyproheptadine and placebo for weight gain.

Benefits: We found no systematic review. We found three small RCTs. The first RCT (24 women in an outpatient setting) compared cyproheptadine with placebo.[39] It found no significant difference in response to treatment after 2 months. The second RCT (81 women in 3 specialised inpatient units) compared cyproheptadine versus placebo, and behaviour therapy versus no behaviour therapy.[40] The effect of behaviour therapy was not reported. There were no significant differences in weight gain between the cyproheptadine and placebo groups. The third RCT (72 women, mean age 20.6 years, mean 77% of target weight, mean duration of anorexia 2.9 years, at 2 specialised inpatient units) compared amitriptyline versus cyproheptadine (up to a maximum of 32 mg) and versus placebo.[29] It found no significant difference between cyproheptadine and placebo for rate of weight gain.

Harms: No harms were reported in the first two RCTs.[39,40] In the third RCT, on both day 7 and day 21, placebo exceeded the amitriptyline group in number of physical adverse events rated moderate or severe. Adverse effects were less frequent with cyproheptadine. No one had to be withdrawn from the protocol because of adverse effects.[29]

Comment: All three RCTs were of short duration.

OPTION INPATIENT VERSUS OUTPATIENT TREATMENT SETTING IN ANOREXIA NERVOSA

One small RCT found no significant difference between outpatient treatment and inpatient treatment for increasing weight and improving Morgan Russell scale global scores at 1, 2, and 5 years in people who did not need emergency intervention.

Benefits: We found one systematic review (search date 1999) comparing inpatient treatment (see glossary, p 1201) versus outpatient care.[41] The review identified one RCT, which had a 5 year follow up.[42,43] Ninety people referred with anorexia nervosa (mean age 22 years, weight loss 26% of matched population mean weight, mean duration 3.2 years) were randomised to four treatment groups: inpatient treatment, outpatient treatment (individual and family therapy [see glossary, p 1201]), outpatient group therapy, and assessment interview only. Assessors were not blind to treatment allocation. Adherence to allocated treatment (defined as accepting allocation and at least 1 attendance at a treatment group or individual treatment session) differed significantly among groups (adherence rates: inpatient treatment 18/30 [60%], outpatient treatment [individual and family therapy] 18/20 [90%], outpatient group psychotherapy 17/20 [85%], and assessment interview only 20/20 [100%]). Treatment adherence differed significantly between outpatient and inpatient treatment (RR 1.5, 95% CI 1.1 to 2.0). Average acceptance of treatment also varied among groups (20 weeks' inpatient treatment, 9 outpatient sessions, and 5 group sessions). In the assessment interview only group, six people had no treatment of any kind in the first year and the others had treatment elsewhere (6 had inpatient treatment, 5 had outpatient hospital treatment, and 3 had at least weekly contact with their general practitioners). Six people in this group spent almost the entire year in treatment. There were no significant differences in mean weight or in the Morgan Russell scale (see glossary, p 1201) global scores among any of the four groups at 1, 2, and 5 years. The proportion of people with a good outcome with inpatient treatment was 5/29 (17%) at 2 years and 9/27 (33%) at 5 years; with outpatient treatment (individual and family therapy) 4/20 (20%) at 2 years and 8/17 (47%) at 5 years; with outpatient group psychotherapy 5/19 (26%) at 2 years and 10/19 (53%) at 5 years; and with assessment interview only 2/20 (10%) at 2 years and 6/19 (32%) at 5 years.

Harms: One person died from anorexia nervosa between the assessment and the start of outpatient group treatment, and one of the people allocated to inpatient treatment died from anorexia nervosa within 5 years.[42,43]

Comment: The systematic review[41] was unable to draw meaningful conclusions from numerous case series because participant characteristics, treatments, mortality, and outcomes varied widely. People admitted for inpatient treatment had a lower mean weight than those treated as outpatients. One subsequent observational study (355 people with anorexia nervosa; 169 of whom had bulimic type anorexia nervosa; mean age 25 years; mean duration of illness 5.7

years; 75% available for 2.5 years' follow up) found that people with longer duration of illness had a higher likelihood of good outcome with longer than with briefer duration of inpatient treatment.[44] People with a shorter duration of illness had a higher likelihood of good outcome with briefer inpatient treatment. Median duration of inpatient treatment was 11.6 weeks for anorexia nervosa and 10.6 weeks for bulimic type anorexia nervosa.

OPTION CISAPRIDE

One small RCT found no significant difference between cisapride and placebo in weight gain at 8 weeks. Use of cisapride has been restricted in many countries because of concern about cardiac irregularities, including ventricular tachycardia, torsades de pointes, and sudden death.

Benefits: We found no systematic review. We found one small RCT (34 inpatients aged 18–40 years at 2 hospitals; mean duration 2.7 years; body mass index (see glossary, p 1201) 15.1 kg/m^2) comparing cisapride 30 mg with placebo for 8 weeks.[45] The trial found no difference in weight gain (5.1 kg with cisapride *v* 5.7 kg with placebo; $P > 0.05$).

Harms: No adverse events were noted in this RCT. The QT interval in anorexia nervosa is prolonged even in the absence of medication. Therefore, cisapride, which may prolong the QT interval, is not recommended in anorexia nervosa. Use of cisapride has been restricted in many countries because of concern about cardiac irregularities, including ventricular tachycardia, torsades de pointes, and sudden death.[32,33]

Comment: Five people withdrew from the RCT and were not included in the analysis.

QUESTION What are the effects of interventions to prevent or treat complications of anorexia nervosa?

OPTION OESTROGEN TREATMENT

We found no good evidence about the effects of oestrogen treatment on fracture rates in people with anorexia. Two small RCTs found no significant difference between oestrogen and placebo or no treatment in bone mineral density.

Benefits: We found no systematic review. We found two RCTs.[46,47] The first RCT (48 women, mean age 23.7 years, mean duration of anorexia nervosa 4.0 years) compared hormone replacement therapy (conjugated oestrogens 0.625 mg on days 1–25 of each month plus medroxyprogesterone 5 mg on days 16–25) versus an oral contraceptive containing 35 μg ethinyl oestradiol versus no medication over 6 months.[46] All women maintained a calcium intake of 1500 mg using oral calcium carbonate. Spinal bone mineral density was measured at 6 monthly intervals. There was no significant difference in the final bone density at follow up of 0.5–3.0 years. The second RCT (60 women aged 18–38 years, mean weight 44.7 kg; body mass index (see glossary, p 1201) 16.6 kg/m^2, duration of anorexia nervosa 2.3 years and with osteopenia at

entry) compared four treatments: oral contraceptive alone (35 μg ethinyl oestradiol plus 0.4 mg norethindrone); placebo; recombinant human insulin-like growth factor-1 alone; and oral contraceptive plus recombinant human insulin-like growth factor-1.[47] In addition, all women received calcium 1500 mg/day and vitamin D 400 IU/day. The RCT found no significant difference between oral contraceptives and placebo in bone density at 9 months (hip density: $P = 0.071$; spine density: $P = 0.21$).

Harms: In the first RCT comparing hormone replacement therapy with the oral contraceptive pill and placebo, three women withdrew from the oestrogen treatment; two because of adverse effects, and one because she had left the country.[46] One woman who was in the control group was unwilling to return for further testing.

Comment: Improvements in bone mineral density may not reduce fracture risk.

GLOSSARY

Body mass index Weight (kg) divided by height (m) squared.
Dietary counselling Dieticians with experience of eating disorders discuss diet, mood, and daily behaviours.
Family therapy Treatment that includes members of the family of origin or the constituted family, and that addresses the eating disorder as a problem of family life.
Inpatient treatment This has been regarded as the standard approach to the management of anorexia nervosa.[48] One of the key components of inpatient treatment is refeeding, which is achieved through structured, supervised meals. Psychotherapy (of a variety of different types) and pharmacotherapy are included in many programmes.
Morgan Russell scale A widely used measure of outcome for anorexia nervosa that consists of two scores: an average outcome score and a general outcome score. The average outcome score is based on the outcome in five areas: nutritional status, menstrual function, mental state, sexual adjustment, and socioeconomic status.
Psychotherapy Different types of psychological treatments given individually or in groups are included here. These use psychodynamic, cognitive behavioural, or supportive techniques, or combinations of these.

Substantive changes

Selective serotonin reuptake inhibitors One RCT added;[37] conclusions unchanged.
Hormonal treatment One RCT added;[47] conclusions unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 1221

Key Messages

Mania

- **Lithium** One RCT in people with bipolar type I disorder experiencing a manic episode found that lithium increased the proportion of people who responded after 3–4 weeks compared with placebo. One systematic review found that lithium increased the proportion of people who had remission of manic symptoms at 3 weeks compared with chlorpromazine, and found no significant

difference in symptoms at 3–6 weeks between lithium and haloperidol, olanzapine, valproate, lamotrigine, or clonazepam. One RCT found that lithium was less effective than risperidone in reducing manic symptoms at 4 weeks. Lithium can cause a range of adverse effects. The RCTs provided insufficient evidence about how the adverse effects of lithium compared with those of other antipsychotic drugs.

- **Olanzapine** One systematic review in people with bipolar type I disorder found that olanzapine increased the proportion of people who responded at 3–6 weeks compared with placebo, both as monotherapy and as add on therapy to lithium or valproate, and found no significant difference in symptoms at 28 days between olanzapine and lithium. RCTs found that olanzapine was more effective in reducing symptoms than valproate, but was also more likely to cause adverse effects such as sedation and weight gain. The acceptability of olanzapine may be limited by weight gain.
- **Valproate** One systematic review in people with bipolar type I disorder experiencing a manic episode found that valproate increased the proportion of people who responded over 3 weeks compared with placebo. It found no significant difference in response at 1–6 weeks between valproate and lithium, haloperidol, or carbamazepine. It found that valproate was less effective in reducing manic symptoms than olanzapine, but was also less likely to cause adverse effects such as sedation and weight gain.
- **Carbamazepine** RCTs in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 4–6 weeks between carbamazepine and lithium or valproate.
- **Clonazepam** We found no RCTs comparing clonazepam versus placebo in people with bipolar mania. RCTs in people with bipolar type I disorder experiencing a manic episode suggest that clonazepam may be as effective as lithium in improving manic symptoms at 1–4 weeks.
- **Haloperidol** We found no RCTs comparing haloperidol versus placebo in people with bipolar mania. RCTs in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 1–3 weeks between haloperidol and lithium or valproate, although haloperidol was associated with more extrapyramidal adverse effects and sedation than valproate.
- **Risperidone** We found no RCTs comparing risperidone versus placebo in people with bipolar mania. One RCT in people with bipolar type I disorder experiencing a manic episode found that risperidone reduced manic symptoms at 4 weeks compared with lithium. It gave no information on adverse effects.
- **Chlorpromazine** One very small RCT in people with mania found limited evidence that chlorpromazine may improve manic symptoms over 7 weeks more than placebo or imipramine. One systematic review found that fewer people had remission of symptoms at 3 weeks with chlorpromazine than with lithium.
- **Lamotrigine** We found no RCTs comparing lamotrigine versus placebo in people with bipolar mania. One RCT in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 4 weeks between lamotrigine and lithium.

Bipolar depression

- **Lamotrigine** One RCT in people with bipolar type I disorder experiencing a major depressive episode found that lamotrigine increased the proportion of people who responded over 7 weeks compared with placebo.

Bipolar disorder

- **Antidepressants** Systematic reviews found that antidepressants improved depressive symptoms at the end of the trial (unspecified) compared with placebo. They found limited evidence that selective serotonin reuptake inhibitors were more effective than tricyclic antidepressants, and found no significant difference in symptoms between monoamine oxidase inhibitors and tricyclic antidepressants or between selective serotonin reuptake inhibitors and serotonin noradrenaline reuptake inhibitors. The reviews provided insufficient evidence to assess whether antidepressants induce bipolar mania.
- **Carbamazepine; lithium** One systematic review identified no RCTs of sufficient quality to assess these treatments in people with bipolar depression.
- **Psychological treatments; valproate** We found no RCTs of these treatments in people with bipolar depression.

Preventing relapse of mania or bipolar depression

- **Lithium** RCTs have found that lithium reduces relapse over 2 years compared versus placebo, and have found no significant difference in relapse between lithium and valproate, carbamazepine, or lamotrigine.
- **Carbamazepine** We found no RCTs comparing carbamazepine versus placebo in preventing relapse. One systematic review found no significant difference between carbamazepine and lithium in the proportion of people who relapsed over 1–3 years.
- **Education to recognise symptoms of relapse** One RCT found limited evidence that an educational programme to recognise symptoms of relapse reduced manic relapse over 18 months, but that it may increase depressive episodes.
- **Lamotrigine (bipolar depressive episodes)** Three RCTs have found that lamotrigine reduces relapse compared with placebo. However, secondary analyses in two of the RCTs suggested that lamotrigine protected against depressive relapse, but not manic relapse. RCTs have found no significant difference between lamotrigine and lithium in the proportion of people who relapse.
- **Valproate** One RCT found that valproate reduced relapse over 12 months compared with placebo. One systematic review found no significant difference between lithium and valproate in relapse over 12 months.
- **Antidepressant drugs** One systematic review provided insufficient evidence to assess antidepressants in preventing relapse of bipolar disorder.
- **Family focused psychoeducation** One RCT found that 21 sessions of family focused psychoeducation reduced relapse over 12 months compared with two family sessions plus crisis management.

DEFINITION Bipolar disorder (bipolar affective disorder, manic depressive disorder) is characterised by marked mood swings between mania (mood elevation) and bipolar depression that cause significant personal distress or social dysfunction, and are not caused by drugs or known physical disorder. **Bipolar type I disorder** is diagnosed when episodes of depression are interspersed with mania or mixed episodes. **Bipolar type II disorder** is diagnosed when depression is interspersed with less severe episodes of elevated mood that do not lead to dysfunction or disability (hypomania). Bipolar disorder has been subdivided in several further ways (see table 1, p 1223).[1]

INCIDENCE/ PREVALENCE One 1996 cross-national community based study (38 000 people) found lifetime prevalence rates of bipolar disorder ranging from 0.3% in Taiwan to 1.5% in New Zealand.[2] It found that men and

women were at similar risk, and that the age at first onset ranged from 19–29 years (average of 6 years earlier than first onset of major depression).

AETIOLOGY/ RISK FACTORS The cause of bipolar disorder is uncertain, although family and twin studies suggest a genetic basis.[3] The lifetime risk of bipolar disorder is increased in first degree relatives of a person with bipolar disorder (40–70% for a monozygotic twin; 5–10% for other first degree relatives). If the first episode of mania occurs in an older adult, it may be secondary mania due to underlying medical or substance induced factors.[4]

PROGNOSIS Bipolar disorder is a recurring illness and one of the leading causes of worldwide disability, especially in the 15–44 year age group.[5] One 4 year inception cohort study (173 people treated for a first episode of mania or mixed affective disorder) found that 93% of people no longer met criteria for mania at 2 years (median time to recover from a syndrome 4.6 weeks), but that only 36% had recovered to premorbid function.[6] It found that 40% of people had a recurrent manic (20%) or depressive (20%) episode within 2 years of recovering from the first episode. A meta-analysis, comparing observed suicide expected rates of suicide in an age and sex matched sample of the general population, found that the lifetime prevalence of suicide was about 2%, or 15 times greater than expected, in people with bipolar disorder.[7]

AIMS OF INTERVENTION To alleviate mania and bipolar depressive symptoms; to prevent relapse (see glossary, p 1221) and suicide; to optimise social and occupational functioning; and to improve quality of life, with minimal adverse effects of treatment.

OUTCOMES Level of symptoms on rating scales (completed by clinician, patient, or both); proportion of people with clinically important response to treatment; time to remission; quality of life scores; social and occupational functioning scores; relapse; hospital admission; rates of suicide; frequency of adverse events; and clinical trial withdrawal rates. Commonly used instruments for assessing symptoms include the Young Mania Rating Scale, which rates 11 manic symptoms with a total score of 0–60; the Schedule for Affective Disorders Change Mania Sub Scale, which rates 18 manic items with a total score of 10–65; and the Hamilton Depression Rating Scale, which has both a 17 and a 21 item version. On these scales, a clinically important response to treatment is usually defined as a $>50\%$ reduction in score from baseline.[8] A person is usually considered to be in remission if, at the end of trial, they score ≤ 12 on the Young Mania Rating Scale and ≤ 8 on the Hamilton Depression Rating Scale.[8] Quality of life is assessed by scales such as the SF-36, and social and occupational functioning on scales such as the Clinical Global Impression Scale.

METHODS *Clinical Evidence* search and appraisal April 2002, including a search for observational studies on adverse effects of treatments. The author also performed a search for systematic reviews in the Cochrane Library, Issue 3, 2003.

QUESTION What are the effects of treatments in mania?

OPTION LITHIUM

One RCT in people with bipolar type I disorder experiencing a manic episode found that lithium increased the proportion of people who responded after 3–4 weeks compared with placebo. One systematic review found that lithium increased the proportion of people who had remission of manic symptoms at 3 weeks compared with chlorpromazine, and found no significant difference in symptoms at 3–6 weeks between lithium and haloperidol, olanzapine, valproate, lamotrigine, or clonazepam. One RCT found that lithium was less effective than risperidone in reducing manic symptoms at 4 weeks. Lithium can cause a range of adverse effects. The RCTs provided insufficient evidence about how the adverse effects of lithium compared with those of other antipsychotic drugs.

Benefits:

Versus placebo: We found one systematic review (search date 1999, 1 RCT, 179 people with bipolar type I disorder).[9] The RCT compared three treatments: lithium (36 people); valproate (69 people); and placebo (74 people). It found that lithium significantly increased the proportion of people who responded after 3–4 weeks compared with placebo (response defined as ≥ 50% improvement in mania score on the Schedule for Affective Disorders and Schizophrenia-Change [SADS-C]; 18/36 [50%] with lithium *v* 19/74 [27%] with placebo; RR 1.95, 95% CI 1.17 to 3.23; NNT 5, 95% CI 3 to 20). **Versus chlorpromazine:** We found one systematic review (search date 1999, 4 RCTs, 114 people with bipolar type 1 disorder).[9] It found that lithium significantly increased the proportion of people who had remission of symptoms at 3 weeks compared with chlorpromazine (remission not defined, 3 RCTs that assessed outcomes at 3 weeks: 23/57 [40%] with lithium *v* 7/57 [12%] with chlorpromazine; RR 1.96, 95% CI 1.02 to 3.77; NNT 4, 95% CI 3 to 9). **Versus haloperidol:** We found one systematic review (search date 1999, 2 RCTs, 50 people with bipolar type I disorder).[9] It found no significant difference between haloperidol and lithium in symptom scores at 3 weeks (assessed by the Brief Psychiatric Rating Scale [BPRS]: effect size –2.14, 95% CI –6.57 to +2.30). **Versus risperidone:** We found one systematic review (search date 1999, 1 RCT, 54 people with bipolar type I disorder).[9] It found that risperidone was significantly more effective than lithium in improving symptom severity score at 4 weeks (assessed by BPRS: effect size –2.79, 95% CI –4.22 to –1.36). **Versus olanzapine:** We found no systematic review but found one RCT (30 people with bipolar type I disorder).[10] It found no significant difference between lithium and olanzapine in Young Mania Rating Scale [YMRS] score at 28 days (13.2 with lithium *v* 10.2 with olanzapine; P = 0.315). **Versus valproate:** We found one systematic review (search date 2002, 3 RCTs, 158 people with bipolar type 1 disorder).[8] It found no significant difference between valproate and lithium in the proportion of people who failed to respond over 3–6 weeks (response defined as 50% reduction in mania score on the YMRS or the SADS-C; 45/97 [46%] with valproate *v* 26/61 [43%] with lithium; RR 1.05, 95% CI 0.74 to 1.50). **Versus**

carbamazepine: We found one systematic review (search date 1999, 3 RCTs, 176 people with bipolar type I disorder).[9] The review could not perform a meta-analysis of all three RCTs because of differences in outcomes assessed. The first RCT (105 people) found no significant difference in the proportion of people who responded over 4 weeks between lithium and carbamazepine (15/54 [28%] with lithium *v* 14/51 [27%] with carbamazepine; RR 1.01, 95% CI 0.54 to 1.88). The other two RCTs (71 people) found no significant difference in global severity of symptoms over 4 weeks between lithium and carbamazepine (assessed by Clinical Global Impression [CGI] scores: effect size +0.44, 95% CI −0.78 to +1.67).[9] **Versus lamotrigine:** We found no systematic review but found one RCT (30 people with bipolar type I disorder).[11] It found no significant difference between lithium and lamotrigine in YMRS scores at 4 weeks (mean 13.2 with lithium *v* 14.3 with lamotrigine; reported as non-significant; no further data reported). **Versus clonazepam:** We found one systematic review (search date 1999, 2 RCTs, 52 people with bipolar type I disorder).[9] The review could not perform a meta-analysis because the RCTs assessed different outcomes. The first RCT (12 people) found limited evidence that clonezepam improved some measures of mania more than lithium after 10 days treatment (mean motor activity score 1.8 with clonazepam *v* 2.8 with lithium; mean logorrhoea score 2.2 with clonazepam *v* 2.9 with lithium; CI not reported). The second RCT (40 people, unblinded) found no significant difference between lithium and clonezepam in symptom severity at 4 weeks assessed by BPRS (mean score 6.27 with lithium *v* 7.79 with clonazepam) or global severity of symptoms assessed by CGI Scale (mean score 2.07 with lithium *v* 1.68 with clonazepam; reported as non-significant, CI not reported) after 4 weeks.

Harms:

Versus placebo: The RCT identified by the review found that lithium significantly increased the proportion of people who had adverse effects compared with placebo (33/36 [92%] with lithium *v* 58/74 [78%] with placebo; RR 1.17, 95% CI 1.00 to 1.37; NNH 8, 95% CI 4 to 334).[9] Adverse effects were not specified. **Versus chlorpromazine:** The review gave no information on adverse effects.[9] **Versus haloperidol:** The review gave no information on adverse effects.[9] **Versus risperidone:** The review gave no information on adverse effects.[9] **Versus olanzapine:** The RCT found no extrapyramidal adverse effects associated with lithium or olanzapine.[10] **Versus valproate:** The review found that valproate significantly reduced the proportion of people who had fever compared with lithium (1 RCT 1/69 [1%] with valproate *v* 5/36 [14%] with lithium; RR 0.10, 95% CI 0.01 to 0.86), but found no significant difference in the rates of other adverse events.[8] **Versus carbamazepine:** The review found no significant difference in adverse effects between lithium and carbamazepine (2 RCTs: 27/73 [37%] with lithium *v* 35/66 [53%] with carbamazepine; RR 0.71, 95% CI 0.49 to 1.02).[9] **Versus lamotrigine:** The RCT found no significant difference in adverse effects between lithium

and lamotrigine, but it is likely to have been too small to detect a clinically important difference.[11] One person taking lithium withdrew because of a seizure and one person taking lamotrigine withdrew because of aggravation of diabetes. **Versus clonazepam:** The review gave no information on adverse effects.[9]

Comment: None.

OPTION VALPROATE

One systematic review in people with bipolar type I disorder experiencing a manic episode found that valproate increased the proportion of people who responded over 3 weeks compared with placebo. It found no significant difference in response at 1–6 weeks between valproate and lithium, haloperidol, or carbamazepine. It found that valproate was less effective in reducing manic symptoms than olanzapine, but was also less likely to cause adverse effects such as sedation and weight gain.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 3 RCTs, 316 people with bipolar type I disorder).[8] It found that valproate significantly increased the proportion of people who responded over 3 weeks compared with placebo (response defined as 50% reduction in mania score on the Young Mania Rating Scale [YMRS] or the Schedule for Affective Disorders and Schizophrenia-Change [SADS-C]; proportion of people who failed to respond: 66/155 [42%] with valproate *v* 111/161 [69%] with placebo; RR of failing to respond 0.62, 95% CI 0.51 to 0.77).[8] **Versus lithium:** See benefits of lithium, p 1208. **Versus haloperidol:** We found one systematic review (search date 2002, 1 RCT, 36 people with bipolar type I disorder).[8] The RCT found no significant difference in the proportion of patients who failed to respond over 6 days between valproate and haloperidol (11/21 [52%] with valproate *v* 10/15 [67%] with lithium; RR 0.79, 95% CI 0.46 to 1.35). **Versus olanzapine:** We found one systematic review (search date 2002, 2 RCTs, 363 people with bipolar type I disorder).[8] It found that people taking olanzapine had greater symptom reductions at the end of the trial (unspecified) than those taking valproate (symptoms assessed by the YMRS: WMD 2.81, 95% CI 0.83 to 4.79). One of the RCTs (251 people) found that olanzapine significantly increased the proportion of people who responded at the end of the trial (unspecified) compared with valproate (response defined as 50% reduction in YMRS; proportion of people who failed to respond: 77/123 [63%] with valproate *v* 57/125 [46%] with olanzapine; RR of failing to respond 1.27, 95% CI 0.99 to 1.62). **Versus carbamazepine:** We found one systematic review (2 RCTs, 59 people with bipolar type I disorder), which found no significant difference between valproate and carbamazepine in the proportion of people who failed to respond at 4–6 weeks (response defined with 50% reduction in mania score on the YMRS or the SADS-C; 11/30 [37%] with valproate *v* 16/29 [55%] carbamazepine; RR 0.66, 95% CI 0.38 to 1.16).[8]

Harms: **Versus placebo:** The review found no significant difference between valproate and placebo in the proportion of people who withdrew from the trial because of adverse effects (9/158 [6%] with

valproate *v* 5/163 [3%] with placebo; RR 1.95, 95% CI 0.66 to 5.71), but found that people taking valproate were significantly more likely to suffer from dizziness (13/138 [9%] with valproate *v* 4/141 [3%] with placebo; RR 3.17, 95% CI 1.13 to 8.88).[8] No other adverse effects were more commonly reported with valproate than with placebo. **Versus lithium:** See harms of lithium, p 1209. **Versus haloperidol:** The RCT found that valproate caused significantly fewer extrapyramidal adverse effects compared with haloperidol (0/21 [0%] with valproate *v* 8/15 [53%] with haloperidol; RR 0.04, 95% CI 0.00 to 0.69), dry mouth (1/21 [5%] with valproate *v* 3/15 [20%] with haloperidol; RR 0.24, 95% CI 0.03 to 2.07), and was less likely to cause sedation than haloperidol (1/21 [5%] with valproate *v* 4/15 [27%] with haloperidol; RR 0.18, 95% CI 0.02 to 1.44).[8] **Versus olanzapine:** The review found no significant difference between valproate and olanzapine in the proportion of patients who withdrew because of adverse events (1 RCT: 9/126 [7%] with valproate *v* 12/125 [10%] with olanzapine; RR 0.74, 95% CI 0.33 to 1.70) or had movement disorders (akathisia: WMD –0.02, 95% CI –0.27 to +0.23; abnormal involuntary movement: WMD –0.17, 95% CI –0.62 to +0.28).[8] It found that valproate caused significantly more nausea than olanzapine (1 RCT: 36/126 [28%] with valproate *v* 13/125 [10%] with olanzapine; RR 2.75, 95% CI 1.53 to 4.93), but caused less increased appetite (1 RCT: 3/126 [2%] with valproate *v* 15/125 [12%] with olanzapine; RR 0.20, 95% CI 0.06 to 0.67), weight gain (WMD –2.14 kg, 95% CI –2.65 kg to –1.62 kg), dry mouth (8/126 [6%] with valproate *v* 42/125 [34%] with olanzapine; RR 0.19, 95% CI 0.09 to 0.39), and sedation (2 RCTs: 44/189 [23%] with valproate *v* 76/182 [42%] with olanzapine; RR 0.55, 95% CI 0.41 to 0.76). **Versus carbamazepine:** One RCT (28 people) assessed adverse effects.[8] It found no significant difference in adverse effects between valproate and carbamazepine, but it is likely to have been underpowered to detect a clinically important difference.

Comment: None.

OPTION CHLORPROMAZINE

One very small RCT in people with mania found limited evidence that chlorpromazine may improve manic symptoms over 7 weeks compared with placebo or imipramine. One systematic review found that fewer people had remission of symptoms at 3 weeks with chlorpromazine than with lithium.

Benefits: **Versus placebo:** We found one non-systematic review, which identified one very small RCT (13 people with mania) comparing three treatments: chlorpromazine, imipramine, and placebo.[12] It found that chlorpromazine significantly improved global outcome at 7 weeks compared with imipramine or placebo (assessed on a scale from –9 to +9 where +9 = improvement: +6.1 with chlorpromazine *v* +2.0 with imipramine *v* –2.8 with placebo; reported as significant; no further data reported). **Versus lithium:** See benefits of lithium, p 1208.

Harms: **Versus placebo:** The non-systematic review gave no information on adverse effects.[12] **Versus lithium:** See harms of lithium, p 1209.

Comment: The evidence for older antipsychotic drugs is sparse and there are currently no systematic reviews available. The drugs are, however, widely used in mania.

OPTION HALOPERIDOL

We found no RCTs comparing haloperidol versus placebo in people with bipolar mania. RCTs in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 1–3 weeks between haloperidol and lithium or valproate, although haloperidol was associated with more extrapyramidal adverse effects and sedation than valproate.

Benefits: **Versus placebo:** We found no systematic review and no RCTs comparing haloperidol versus placebo. **Versus lithium:** See benefits of lithium, p 1208. **Versus valproate:** See benefits of valproate, p 1210.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See harms of lithium, p 1209. **Versus valproate:** See harms of valproate, p 1210.

Comment: The evidence for older antipsychotics is sparse and there are currently no systematic reviews available. The drugs are, however, widely used in bipolar mania.

OPTION RISPERIDONE

We found no RCTs comparing risperidone versus placebo in people with bipolar mania. One RCT in people with bipolar type I disorder experiencing a manic episode found that risperidone reduced manic symptoms at 4 weeks compared with lithium. It gave no information on adverse effects.

Benefits: **Versus placebo:** We found no systematic review and no RCTs. **Versus lithium:** See benefits of lithium, p 1208.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See harms of lithium, p 1209.

Comment: None.

OPTION OLANZAPINE

One systematic review in people with bipolar type I disorder found that olanzapine increased the proportion of people who responded at 3–6 weeks compared with placebo, both as monotherapy and as add on therapy to lithium or valproate, and found no significant difference in symptoms at 28 days between olanzapine and lithium. RCTs found that olanzapine was more effective in reducing symptoms than valproate, but was also more likely to cause adverse effects such as sedation and weight gain. The acceptability of olanzapine may be limited by weight gain.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 6 RCTs, 1422 people with bipolar type I disorder).[13] It found that olanzapine significantly increased the proportion of people who responded over 3–4 weeks compared with placebo (response defined as 50% reduction in mania score on the Young Mania Rating Scale; 2 RCTs: proportion who failed to respond 56/125 [45%] with olanzapine *v* 89/129 [69%] with placebo; RR of failing to respond 0.64, 95% CI 0.52 to 0.81). It also found that adding olanzapine to lithium or valproate significantly increased the proportion of people who responded at 6 weeks compared with placebo (1 RCT; proportion who failed to respond: 80/229 [35%] with olanzapine *v* 64/115 [56%] with placebo; RR of failing to respond 0.63, 95% CI 0.49 to 0.80). **Versus lithium:** See benefits of lithium, p 1208. **Versus valproate:** See benefits of valproate, p 1210.

Harms: The review found that olanzapine, both as monotherapy and as add-on therapy to lithium or valproate, caused significantly more weight gain than placebo (3 RCTs, 581 people: WMD 2.27 kg, 95% CI 1.56 kg to 2.99 kg).[13] It found no significant difference in movement disorders between olanzapine and placebo (measured on the Barnes Akathisia Scale; 2 RCTs, 246 people: WMD –0.13, 95% CI –0.32 to +0.06), but found that olanzapine significantly increased somnolence (162/354 [46%] with olanzapine *v* 48/244 [20%] with placebo; RR 2.13, 95% CI 1.62 to 2.79), dry mouth (100/354 [28%] *v* 18/244 [7%]; RR 3.64, 95% CI 2.24 to 5.91), dizziness (54/354 [15%] *v* 16/244 [6%]; RR 2.37, 95% CI 1.39 to 4.04), muscle weakness (61/354 [17%] *v* 23/244 [9%]; RR 1.69, 95% CI 1.09 to 2.64), increased appetite (54/229 [23%] *v* 9/115 [8%]; RR 3.01, 95% CI 1.54 to 5.88), and speech disorder (15/229 [6%] with olanzapine *v* 1/115 [0.9%] with placebo; RR 7.53, 95% CI 1.01 to 56.32).**Versus lithium:** See harms of lithium, p 1209. **Versus valproate:** See harms of valproate, p 1210.

Comment: None.

OPTION CARBAMAZEPINE

RCTs in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 4–6 weeks between carbamazepine and lithium or valproate.

Benefits: **Versus placebo:** We found no RCTs. **Versus lithium:** See benefits of lithium, p 1208. **Versus valproate:** See benefits of valproate, p 1210.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See harms of lithium, p 1209. **Versus valproate:** See harms of valproate, p 1210.

Comment: None.

OPTION LAMOTRIGINE

We found no RCTs comparing lamotrigine versus placebo in people with bipolar mania. One RCT in people with bipolar type I disorder experiencing a manic episode found no significant difference in manic symptoms at 4 weeks between lamotrigine and lithium.

Bipolar disorder

Benefits: **Versus placebo:** We found no systematic review or RCTs comparing lamotrigine versus placebo in people with bipolar mania. **Versus lithium:** See benefits of lithium, p 1208.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See harms of lithium, p 1209.

Comment: None.

OPTION CLONAZEPAM

We found no RCTs comparing clonazepam versus placebo in people with bipolar mania. RCTs in people with bipolar type I disorder experiencing a manic episode suggest that clonazepam may be as effective as lithium in improving manic symptoms at 1–4 weeks.

Benefits: **Versus placebo:** We found no systematic review or RCTs comparing clonazepam versus placebo in people with bipolar mania. **Versus lithium:** See harms of lithium, p 1209.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See harms of lithium, p 1209.

Comment: None.

QUESTION What are the effects of treatments in bipolar depression?

OPTION PSYCHOLOGICAL TREATMENTS

We found no RCTs of psychological treatments in people with bipolar depression.

Benefits: We found no systematic review or RCTs in people with bipolar depression (see comment below).

Harms: We found no RCTs.

Comment: We found no RCTs of psychological interventions in bipolar depression. It is unclear if it is reasonable to extrapolate from the evidence for treatments for unipolar depression. It is likely that specific interventions will have some effect, but RCTs are needed to estimate the size of any benefits and harms of these treatments. See depressive disorders in adults, p 1278.

OPTION ANTIDEPRESSANTS

Systematic reviews found that antidepressants improved depressive symptoms at the end of the trial (unspecified) compared with placebo. They found limited evidence that selective serotonin reupdate inhibitors were more effective that tricyclic antidepressants, and found no significant difference in symptoms between monoamine oxidase inhibitors and tricyclic antidepressants or between selective serotonin reuptake inhibitors and serotonin noradrenaline reuptake inhibitors. The reviews provided insufficient evidence to assess whether antidepressants induce bipolar mania.

Benefits: We found two systematic reviews of antipressents in people with bipolar depression or mixed unipolar/bipolar depression.[14,15] **Versus placebo:** The first review (search date not reported, 12 RCTs; 732 people with depressive disorder or mixed episode disorder with at least one previous episode of mania), published only as an abstract, found that people taking antidepressants (tricyclic antidepressants [TCAs], selective serotonin reuptake inhibitors [SSRIs], selective noradrenaline reuptake inhibitors [SNRIs], or monoamine oxidase inhibitors [MAOIs]) were significantly less likely to fail to respond to treatment at the end of the trial (unspecified) than people taking placebo (302 people: 87/180 [48%] *v* 92/122 [75%]; OR 0.30, 95% CI 0.18 to 0.48; NNT 4, 95% CI 3 to 7).[14] **Versus each other:** The first review found no significant difference between SSRIs and TCAs in the proportion of people who responded to treatment at the end of the trial (unspecified), although people taking SSRIs were less likely to fail to respond (31/65 [48%] *v* 44/69 [64%]; OR 0.53, 95% CI 0.27 to 1.04).[14] It also found no significant difference in the proportion of people who responded at the end of the trial (unspecified) between MAOIs and TCAs (54/109 [49%] *v* 54/103 [52%]; OR 0.89, 95% CI 0.52 to 1.52) or between SSRIs and SNRIs (19/34 [56%] *v* 21/35 [60%]; OR 0.85, 95% CI 0.33 to 2.17). The second review (search date 2000; 6 RCTs; 422 people with bipolar depression, 190 people with unipolar depression, about 25% taking lithium, carbamazepine, or valproate) also found similar responses to treatment among antidepressants, but did not quantify its conclusions.[15] **Versus adding lithium or valproate:** We found one small RCT (27 people with mania or bipolar depression receiving lithium or valproate), which compared the addition of paroxetine versus the addition of a second dose of lithium or valproate. It found no significant difference between groups in depressive or manic symptoms over 6 weeks (results presented graphically).[16]

Harms: **Versus each other:** The first review found that SSRIs were significantly less likely to induce mania than TCAs (OR 0.14, 95% CI 0.02 to 0.81).[14] The second review also concluded that tricyclic drugs were more likely to induce mania than other antidepressants, but did not quantify its conclusions.[15]

Comment: A systematic review of antidepressants in bipolar depression is in progress.[17] The evidence for treatment of unipolar depression (see depressive disorders in adults, p 1278) is believed to be applicable, although the efficacy of the treatments may be different, and specific adverse effects such as antidepressant induced mania should be considered.

OPTION LITHIUM

One systematic review identified no RCTs of sufficient quality to assess lithium in people with bipolar depression.

Benefits: We found one systematic review (search date 2000), which identified no RCTs of sufficient quality in people with bipolar depression (see comment below).[15]

Harms: We found no good RCTs.

Comment: The review identified one crossover trial in people with depression (52 people, 40 with bipolar depression).[15] Participants were randomised to 2 weeks of lithium and then crossed over to 6 days of placebo. The trial found that lithium improved symptoms in 32/40 (80%) people over 2 weeks, and that 12/32 (38%) of these relapsed when taking placebo. It found limited evidence that lithium did not induce more manic switching (see glossary, p 1221) than placebo in bipolar depression.[15]

OPTION CARBAMAZEPINE

One systematic review identified no RCTs of sufficient quality to assess carbamazepine in people with bipolar depression.

Benefits: We found one systematic review (search date 2000), which identified no RCTs of sufficient quality in people with bipolar depression (see comment below).[15]

Harms: We found no good RCTs.

Comment: The review identified one crossover trial in people with depression (35 people, 24 with bipolar depression).[15] Participants were randomised to placebo before and after being crossed over to carbamazepine over 45 days. The trial found that carbamazepine improved symptoms in 62% of people over a mean 45 days. It found limited evidence that lithium did not induce more manic switching (see glossary, p 1221) than placebo in bipolar depression.

OPTION VALPROATE

We found no RCTs of valproate in people with bipolar depression.

Benefits: We found no systematic review or RCTs of valproate in people with bipolar depression.

Harms: We found no RCTs.

Comment: None.

OPTION LAMOTRIGINE

One RCT in people with bipolar type I disorder experiencing a depressive episode found that lamotrigine increased the proportion of people who responded over 7 weeks compared with placebo.

Benefits: We found one systematic review (search date 2000),[15] which identified one RCT (195 people aged 19–75 years with bipolar type 1 disorder experiencing a major depressive episode).[18] The RCT compared three treatments: lamotrigine 200 mg daily, lamotrigine 50 mg daily, and placebo.[18] It found no significant difference between lamotrigine and placebo in Hamilton Depression Rating Scale score over 7 weeks, but found that lamotrigine 200 mg daily significantly improved Mongometry–Asberg Depression Rating Scale score (mean reduction –13.3 with lamotrigine *v* –7.8 with placebo; $P < 0.05$) and increased the proportion of people who responded to treatment (measured by Clinical Global Impression Scale scores: mean change 2.6 with lamotrigine *v* 3.3 with placebo; $P < 0.05$).

Harms: The RCT found that significantly more people had headache with lamotrigine compared with placebo (20/63 [32%] with lamotrigine 200 mg *v* 11/65 [17%]; $P < 0.05$).[18]

Comment: None.

QUESTION **What are the effects of interventions to prevent relapse of mania or bipolar depression?**

OPTION **PSYCHOLOGICAL TREATMENTS**

One RCT found limited evidence that an educational programme to recognise symptoms of relapse reduced manic relapse over 18 months, but that it may increase depressive episodes. Another RCT found that 21 sessions of family focused psychoeducation reduced relapse over 12 months compared with two family sessions plus crisis management.

Benefits: **Education to recognise symptoms of relapse:** We found one RCT (69 outpatients with bipolar disorder who had relapsed in the previous year) comparing an educational programme to recognise symptoms of relapse (see glossary, p 1221) versus treatment as usual over 18 months.[19] It found that people in the educational programme were significantly less likely to suffer a manic relapse over 18 months compared with people receiving usual care (9/33 [27%] with educational programme v 20/35 [57%] with usual care; RR 0.48, 95% CI 0.25 to 0.86; NNT 4; 95% CI 2 to 16), but may have been more likely to suffer from a depressive episode (18/33 [55%] with educational programme v 13/35 [37%] with usual care; RR 1.47, 95% CI 0.87 to 2.54), although the difference was not significant. It found that, compared with usual care, the educational programme significantly improved social function from baseline at 18 months (measured on a 4 point scale assessing 8 areas of social activity where 0 is fair/good performance and 4 inability to carry out function; mean difference in score 1.97, 95% CI 0.71 to 3.23).[19] **Family focused psychoeducation:** We found one RCT (101 people with bipolar disorder who had recently recovered from an acute episode recruited from inpatient and outpatient facilities, all taking antipsychotic drugs) comparing 21 sessions of family focused pyschoeducation versus two family sessions plus crisis management over 12 months.[20] Family focused psychoeducation involved education about the symptoms, causes and treatment of bipolar disorder, education to recognise symptoms of relapse, preparation of a relapse prevention plan, and training in problem solving and communication skills. Crisis management involved emergency counselling sessions as needed, with a minimum of a monthly telephone call. The RCT found that family focused psychoeducation significantly reduced the proportion of people who relapsed over 12 months compared with family session plus crisis management (HR 1.47, CI not reported; $P = 0.42$).

Harms: **Education to recognise symptoms of relapse:** The RCT found that, compared with usual care, education may increase depressive relapse; (see benefits above). **Family focused psychoeducation:** The RCT gave no information on harms.[20]

Comment: None.

OPTION LITHIUM

RCTs have found that lithium reduces relapse over 2 years compared with placebo, and have found no significant difference in relapse between lithium and valproate, carbamazepine, or lamotrigine.

Benefits:

Versus placebo: We found three systematic reviews in people with bipolar disorder, unipolar disorder, or mixed unipolar/bipolar disorder,[21–23] and two subsequent RCTs.[24,25] The first review (search date not reported, 9 RCTs, 825 people with bipolar or unipolar disorder) found that lithium reduced the risk of relapse (see glossary, p 1221) by 41% at up to 2 years compared with placebo (3 RCTs, 412 people with bipolar disorder: relapse as defined in the trial [including hospital admission or requiring additional medication]; 73/202 [36%] with lithium *v* 128/210 [61%] with placebo; RR 0.59, 95% CI 0.48 to 0.73).[21] The review found no significant difference between lithium and placebo in the proportion of people with bipolar or unipolar disorder who committed suicide, but it is likely to have been underpowered to detect a clinically important difference (4 RCTs, 0/186 [0%] *v* 2/189 [1%]; RR 0.32, 95% CI 0.03 to 2.98). The second review (search date not reported, 15 RCTs, including 8 identified by the first review, 558 people with bipolar disorder) found that, in people with bipolar disorder, there was an average 48% decrease in the absolute risk of relapse by the end of the trial (unspecified) with lithium compared with placebo.[22] The third review (search date 2000, 3 RCTs identified by the first review, 19 observational studies) assessed the effect of long term lithium treatment on suicide rates.[23] It found that people with bipolar or unipolar disorder treated with lithium had lower suicide rates compared with untreated people (159 *v* 876 deaths per 100 000 patient years of treatment; RR 8.85, 95% CI 4.12 to 19.1). Two subsequent RCTs (647 people aged 18 years or over with bipolar type I or type II disorder who had recently recovered from a manic or depressive/hypomanic episode and remained stable after an 8–16 week run in, during which they began taking lamotrigine and withdrew other psychotropic drugs), compared three treatments: lithium, lamotrigine, and placebo over 76 weeks.[24,25] Both RCTs found that, compared with placebo, lithium significantly increased the time to requirement of additional intervention for a manic or a depressive episode (median time to additional medication 24–42 weeks with lithium *v* 12–13 weeks with placebo: P = 0.05 in both RCTs). Secondary analyses in the RCTs suggested that lithium protected against manic but not depressive relapse.
Versus valproate: We found one systematic review (search date not reported), which identified one RCT (372 people) comparing three treatments: lithium, valproate, and placebo.[26] It found no significant difference between lithium and valproate in relapse at 12 months (relapse defined as withdrawal due to episode of bipolar disorder; 12/187 [6%] *v* 9/91 [10%]; RR 0.8, 95% CI 0.5 to 1.2), but it is likely to have been too small to detect a clinically important difference.
Versus carbamazepine: We found one systematic review (search date not reported, 10 RCTs, 572 people with unipolar or bipolar disorder) comparing lithium versus carbamazepine.[22] It found no significant difference between lithium and carbamazepine in the proportion of people who relapsed over 1–3 years (60% with lithium *v* 55% with carbamazepine; reported as non-significant; no further data reported; see comment below). **Versus lamotrigine:** We found no

systematic review but found two RCTs comparing three treatments: lithium, lamotrigine, and placebo.[24,25] Both RCTs (647 people with bipolar type I or type II disorder who had recently recovered from a manic or depressive/hypomanic episode and remained stable after an 8–16 week run in, during which they began taking lamotrigine and withdrew other psychotropic drugs) found no significant difference between lithium and lamotrigine in the time to requirement of additional intervention for a mood episode (median time to additional medication 24–42 weeks with lithium *v* 20–29 weeks with lamotrigine: $P > 0.05$ in both RCTs). Secondary analysis in one of the RCTs suggested that lithium may significantly reduce manic relapse compared with lamotrigine ($P = 0.092$).[25]

Harms:

Versus placebo: The first review found that significantly more people had overall adverse effects (not specified) with lithium than with placebo (160/233 [69%] with lithium *v* 112/225 [50%] with placebo; RR 1.4, 95% CI 1.2 to 1.6), and that lithium may increase hypothyroidism (7/158 [4%] with lithium *v* 0/152 [0%] with lithium; RR 5.1, 95% CI 0.9 to 27.7).[21] **Versus valproate:** The review found that valproate was significantly more likely than lithium to cause sedation (1 RCT: 78/187 [42%] with valproate *v* 24/91 [26%] with lithium; RR 1.6, 95% CI 1.1 to 2.3) and infection (1 RCT: 51/187 [27%] with valproate *v* 12/91 [13%] with lithium; RR 2.1, 95% CI 1.2 to 3.7), but significantly less likely to cause polyuria (15/187 [8%] with valproate *v* 17/91 [19%] with lithium; RR 0.4, 95% CI 0.2 to 0.8), thirst (11/187 [6%] with valproate *v* 14/91 [15%]; RR 0.4, 95% CI 0.2 to 0.8), and possibly diarrhoea (65/187 [35%] with valproate *v* 42/91 [46%] with lithium; RR 0.75, 95% 0.6 to 1.0).[26] **Versus carbamazepine:** The review gave no information on adverse effects.[22] One RCT (144 people with bipolar disorder) identified by the review found that, although more people taking carbamazepine than taking lithium withdrew from the trials (9/70 [13%] with carbamazepine *v* 4/74 [5%] with lithium; reported as non-significant; no further data reported), a significantly higher proportion of people taking lithium compared with carbamazepine had "slight or moderate" adverse effects over 2.5 years (61% *v* 21%; $P < 0.001$).[27] **Versus lamotrigine:** The first RCT found that lithium caused significantly fewer headaches than lamotrigine (4% *v* 20%; $P = 0.02$) but more diarrhoea (28% *v* 5%, $P = 0.002$).[24] The second RCT gave no information on adverse effects.[25]

Comment:

Versus carbamazepine: The results of the review should be interpreted with caution as it combined trials of unipolar and bipolar disorder.[22]

OPTION VALPROATE

One RCT found that valproate reduced relapse over 12 months compared with placebo. One systematic review found no significant difference between lithium and valproate in relapse over 12 months.

Benefits:

Versus placebo: We found one systematic review (search date not reported, 1 RCT, 372 people with bipolar disorder) comparing three treatments: valproate, lithium, and placebo.[26] It found that lithium significantly reduced relapse (see glossary, p 1221) over 12 months

compared with placebo (relapse defined as withdrawal because of an episode of bipolar disorder; 45/187 [24%] with valproate *v* 36/94 [38%] with placebo; RR 0.6, 95% CI 0.4 to 0.9), but found no significant difference in time to relapse (P = 0.33; no further data reported). **Versus lithium:** See benefits of lithium, p 1218.

Harms: **Versus placebo:** The review found that valproate was significantly more likely than placebo to cause tremor (RR 3.2, 95% CI 1.9 to 5.6); weight gain (RR 2.9, 95% 1.3 to 6.2); alopecia (RR 2.4, 95% CI 1.1 to 5.7), and nausea (RR 1.37, 95% CI 1.0 to 1.9).[26] **Versus lithium:** See harms of lithium, p 1219.

Comment: None.

OPTION CARBAMAZEPINE

We found no RCTs comparing carbamazepine versus placebo in preventing relapse, but one systematic review found no significant difference between carbamazepine and lithium in the proportion of people who relapsed over 1–3 years.

Benefits: **Versus placebo:** We found no systematic review or RCTs comparing carbamazepine versus placebo in preventing relapse (see glossary, p 1221). **Versus lithium:** See benefits of lithium, p 1218.

Harms: **Versus placebo:** We found no RCTs. **Versus lithium:** See benefits of lithium, p 1218.

Comment: A systematic review of the effects of carbamazepine in preventing relapse is in progress.[28]

OPTION LAMOTRIGINE

Three RCTs have found that lamotrigine reduces relapse compared with placebo. However, secondary analyses in two of the RCTs suggested that lamotrigine protected against depressive relapse, but not manic relapse. RCTs have found no significant difference between lamotrigine and lithium in the proportion of people who relapse.

Benefits: **Versus placebo:** We found no systematic review but found three RCTs.[24,25,29] Two RCTs (647 people aged 18 years or over with bipolar type I or type II disorder who had recently recovered from a manic episode or depressive/hypomanic episode and remained stable after 8–16 weeks during which they began taking lamotrigine and withdrew other psychotropic drugs) compared three treatments over 76 weeks: lamotrigine, lithium, and placebo (see comment below).[24,25] Both RCTs found that, compared with placebo, lamotrigine significantly increased the time to requiring additional medication for a manic or bipolar depressive episode (median time to additional medication 20–29 weeks with lamotrigine *v* 12–13 weeks with placebo; P = 0.05 in both RCTs). Secondary analyses suggested that lamotrigine reduced depressive but not manic relapse (see glossary, p 1221).[24,25] The third RCT (182 people with rapid cycling bipolar disorder (see table 1, p 1223) found no significant difference between lamotrigine and placebo in the time to requiring additional medication (P = 0.177, results presented graphically).[29] **Versus lithium** See benefits of lithium, p 1218.

Harms: **Versus placebo:** The RCTs gave no information on adverse effects.[24,25] The third RCT found no significant difference between lamotrigine and placebo in the proportion of people who had adverse effects, including nausea and headache (67% with lamotrigine *v* 68% with placebo, reported as non-significant, CI not reported).[29] **Versus lithium** See benefits of lithium, p 1218.

Comment: The first RCT is published only as an abstract.[24]

OPTION ANTIDEPRESSANTS

One systematic review provided insufficient evidence to assess antidepressants in preventing relapse of bipolar disorder.

Benefits: We found one systematic review (search date 2000; 4 RCTs, 258 people with bipolar type I or type II disorder) comparing tricyclic antidepressants with placebo or lithium.[30] The review did not perform a meta-analysis. It provided a narrative overview of the studies and found no clear evidence that tricyclic antidepressants reduce relapse (see glossary, p 1221) over 1–2 years compared with placebo. It suggested that tricyclic antidepressants may be less effective in preventing relapse over 1–2 years than lithium.

Harms: The review suggested that antidepressants may induce mood instability or manic episodes.[30]

Comment: None.

GLOSSARY

Manic switching involves onset of a manic episode shortly after treatment for a depressive episode. It may be more likely after treatment with antidepressants.
Relapse A return of symptoms to the extent that the disorder again meets criteria for the full syndromes. In practice, patients with bipolar disorder learn to recognise early warning signs and begin treatment before criteria are met. For this reason, relapse is often pragmatically defined as the need for drug treatment due to re-emergence of depressive or manic symptoms.

TABLE 1 **DSM-IV classification of bipolar disorders (see text, p 1206). Reprinted with permission from Elsevier (Müller-Oerlinghausen B, Berghöfer A, Bauer M Bipolar Disorder Lancet 2002; 359: 241–47).[1]**

DSM IV Category	Criteria	Course specifiers and examples
Bipolar I disorder	One or more manic or mixed episodes, usually accompanied by one or more major depressive episodes	To describe current (or most recent episode): mild, moderate, severe without psychotic features; severe with psychotic features; in partial or full remission; with catatonic features; with postpartum onset To describe current (or most recent) major depressive episode: chronic; with melancholic features; with atypical features To describe pattern of episodes: with or without full interepisode recovery; with seasonal pattern; with rapid cycling (> 4 episodes in previous 12 months)
Bipolar II disorder	Recurrent major depressive episodes with one or more hypomanic (milder than manic) episodes	To describe current (or most recent episode): hypomanic; depressed To describe current (or most recent) major depressive episode and pattern of episodes: see bipolar I disorder
Cyclothymic disorder	Chronic (> 2 years), fluctuating mood disturbance involving numerous periods of mild hypomanic and depressive symptoms that do not meet criteria for a major depressive episode	Over 2 years any symptom free intervals last no longer than 2 months
Bipolar disorder (not otherwise specified)	Disorders with bipolar features that do not meet criteria for any specific bipolar disorder	Examples: very rapid cycling (over days); recurrent hypomanias without depressive symptoms; indeterminate whether primary or secondary (due to a general medical condition or substance abuse)

Bulimia nervosa

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Unknown effectiveness

See glossary, p 1234

Key Messages

Antidepressants

- **Antidepressant medication (tricyclic antidepressants, monoamine oxidase inhibitors, and fluoxetine)** Systematic reviews and one subsequent RCT have found short term reduction in bulimic symptoms with tricyclic antidepressants, monoamine oxidase inhibitors, and fluoxetine. A further subsequent RCT found no significant difference in symptoms between moclobemide and placebo. One systematic review and one subsequent RCT found no significant difference in symptoms with antidepressants versus cognitive behavioural therapy.
- **Other antidepressants (venlafaxine, mirtazapine, and reboxetine)** We found no RCTs on the effects of venlafaxine, mirtazapine, and reboxetine.
- **Selective serotonin reuptake inhibitors (other than fluoxetine)** We found no good evidence on selective serotonin reuptake inhibitors other than fluoxetine.
- **Antidepressants as maintenance** We found insufficient evidence to assess the effects of antidepresssants for maintenance.

Psychotherapy

- **Cognitive behavioural therapy** One systematic review has found that cognitive behavioural therapy compared with remaining on a waiting list reduces specific symptoms of bulimia nervosa and improves non-specific symptoms such as depression. One systematic review found cognitive behavioural therapy compared with other psychotherapies improved abstinence from

binge eating and depression scores at the end of treatment. One RCT in the review found that cognitive behavioural therapy compared with interpersonal psychotherapy reduced binge eating in the short term, but there was no significant difference in the longer term. One systematic review and one subsequent RCT found no significant difference in symptoms with cognitive behavioural therapy compared with antidepressants.

- **Other psychotherapies** One systematic review has found that non-cognitive behavioural psychotherapy increases abstinence from binge eating compared with waiting list controls. The systematic review found that the combined result for four specific psychotherapies, other than cognitive behavioural therapy, reduced bulimic symptoms compared with specified control psychotherapies, but the review included RCTs with weak methods, and the result was significant in only one of the four individual results. One systematic review found cognitive behavioural therapy compared with other psychotherapies improved abstinence from binge eating and depression scores at the end of treatment. One RCT in the review found that cognitive behavioural therapy compared with interpersonal psychotherapy reduced binge eating in the short term, but there was no significant difference in the longer term.

Combination treatment

- **Combination treatment (antidepressants plus psychotherapy)** One systematic review and one subsequent RCT found no significant difference between combination treatment (antidepressants plus psychotherapy) and antidepressants alone in binge frequency, depressive symptoms, and remission rates. The systematic review found that, compared with psychotherapy alone, combination treatment improved short term remission, but there was no significant difference in binge frequency and depressive symptoms. The systematic review found that combination treatment was with psychotherapy were associated with higher withdrawal rates compared with psychotherapy alone. One subsequent RCT of cognitive behavioural therapy in a self help form plus fluoxetine found limited evidence that combined treatment reduced bulimic symptoms compared with cognitive behavioural therapy alone. A second subsequent RCT found no significant difference in symptoms between group based CBT, fluoxetine, and their combination.

DEFINITION Bulimia nervosa (see glossary, p 1234) is an intense preoccupation with body weight and shape, with regular episodes of uncontrolled overeating of large amounts of food (binge eating — see glossary, p 1234) associated with use of extreme methods to counteract the feared effects of overeating. If a person also meets the diagnostic criteria for anorexia nervosa, then the diagnosis of anorexia nervosa takes precedence.[1] Bulimia nervosa can be difficult to identify because of extreme secrecy about binge eating and purgative behaviour. Weight may be normal but there is often a history of anorexia nervosa or restrictive dieting. Some people alternate between anorexia nervosa and bulimia nervosa. Some RCTs included participants with subthreshhold bulimia nervosa or a related eating disorder, binge eating disorder. Where possible, only results relevant to bulimia nervosa are reported in this review.

INCIDENCE/ PREVALENCE In community based studies, the prevalence of bulimia nervosa is between 0.5% and 1.0% in young women, with an even social class distribution.[2–4] About 90% of people diagnosed with bulimia nervosa are women. The numbers presenting with bulimia nervosa in industrialised countries increased during the decade that followed

its recognition in the late 1970s and "a cohort effect" is reported in community surveys,[2,5,6] implying an increase in incidence. The prevalence of eating disorders such as bulimia nervosa is lower in non-industrialised populations,[7] and varies across ethnic groups. African-American women have a lower rate of restrictive dieting than white American women, but have a similar rate of recurrent binge eating.[8]

AETIOLOGY/ RISK FACTORS

Young women from the developed world who restrict their dietary intake are at greatest risk of developing bulimia nervosa and other eating disorders. One community based case control study compared 102 people with bulimia nervosa with 204 healthy controls and found higher rates of the following in people with the eating disorder: obesity, mood disorder, sexual and physical abuse, parental obesity, substance misuse, low self esteem, perfectionism, disturbed family dynamics, parental weight/shape concern, and early menarche.[9] Compared with a control group of 102 women who had other psychiatric disorders, women with bulimia nervosa had higher rates of parental problems and obesity.

PROGNOSIS

A 10 year follow up study (50 people with bulimia nervosa from a trial of mianserin treatment) found that 52% had fully recovered, and only 9% continued to experience full symptoms of bulimia nervosa.[10] A larger study (222 people from a trial of antidepressants and structured, intensive group psychotherapy) found that, after a mean follow up of 11.5 years, 11% still met criteria for bulimia nervosa, whereas 70% were in full or partial remission.[11] Short term studies found similar results: about 50% of people made a full recovery, 30% made a partial recovery, and 20% continued to be symptomatic.[12] There are few consistent predictors of longer term outcome. Good prognosis has been associated with shorter illness duration, a younger age of onset, higher social class, and a family history of alcohol abuse.[10] Poor prognosis has been associated with a history of substance misuse,[13] premorbid and paternal obesity,[14] and, in some studies, personality disorder.[15–18] One study (102 people) of the natural course of bulimia nervosa found that 31% still had the disorder at 15 months and 15% at 5 years.[19] Only 28% received treatment during the follow up period. In an evaluation of response to cognitive behavioural therapy, early progress (by session 6) best predicted outcome.[20] A subsequent systematic review of the outcome literature found no consistent evidence to support early intervention and a better prognosis.[21]

AIMS OF INTERVENTION

To reduce symptoms of bulimia nervosa; to improve general psychiatric symptoms; to improve social functioning and quality of life.

OUTCOMES

Frequency of binge eating, abstinence from binge eating, frequency of behaviours to reduce weight and counter the effects of binge eating, severity of extreme weight and shape preoccupation, severity of general psychiatric symptoms, severity of depression, improvement in social and adaptive functioning, remission rates, relapse rates, and withdrawal rates.

METHODS

Clinical Evidence search and appraisal December 2002 and hand search of reference lists from identified reviews.

QUESTION What are the effects of treatments for bulimia nervosa in adults?

OPTION COGNITIVE BEHAVIOURAL THERAPY

One systematic review has found that cognitive behavioural therapy compared with remaining on a waiting list reduces specific symptoms of bulimia nervosa and improves non-specific symptoms such as depression. One systematic review found cognitive behavioural therapy compared with other psychotherapies improved abstinence from binge eating and depression scores at the end of treatment. One RCT in the review found that cognitive behavioural therapy compared with interpersonal psychotherapy reduced binge eating in the short term, but there was no significant difference in the longer term. One systematic review and one subsequent RCT found no significant difference in symptoms with cognitive behavioural therapy compared with antidepressants.

Benefits: We found one systematic review (search date 2002, 34 RCTs).[22] It included RCTs of other binge eating disorders, although most studies were of people with bulimia nervosa (see glossary, p 1234) (18 RCTs in people with bulimia nervosa characterised by purging behaviour).[22] The review reported data separately for bulimia nervosa and other disorders of binge eating. Unless otherwise specified, results reported here refer only to analyses of people with bulimia nervosa. **Versus waiting list controls:** One systematic review (search date 2002; individual analyses included a maximum of 10 RCTs and 735 people) found that cognitive behavioural therapy (CBT — see glossary, p 1234) compared with remaining on a waiting list significantly increased the proportion of people abstaining from binge eating at the end of the trial (3 RCTs; RR 0.62, 95% CI 0.47 to 0.83), significantly reduced mean bulimic symptom scores (6 RCTs; SMD –0.85, 95% CI –1.14 to –0.57), and mean depression scores (3 RCTs; SMD –1.13, 95% CI –1.60 to –0.67).[22] It found no significant difference, in a mixed population, between CBT and remaining on the waiting list in weight at the end of treatment (3 RCTs, 1 with bulimia nervosa participants; SMD +0.12, 95% CI –0.23 to +0.46, 135 people). The review found insufficient evidence about other outcomes, such as social functioning. **Versus placebo medication:** One subsequent RCT (91 people) found no significant difference in efficacy between unguided manual based self help CBT and placebo medication.[23] **Versus other psychotherapies:** See table 1, p 1237. The systematic review (search date 2002) found that CBT compared with other psychotherapies significantly improved abstinence from binge eating (6 RCTs, 448 people; RR 0.78, 95% CI 0.70 to 0.87) and depression scores at the end of treatment (6 RCTs, 206 people; SMD –0.66, 95% CI –0.94 to –0.37).[22] For all RCTs (including both binge eating disorder and bulimia nervosa participants) CBT plus exposure therapy (see glossary, p 1234) was not significantly more effective than CBT alone (3 RCTs, 168 people; RR for abstinence from binge eating 0.87, 95% CI 0.65 to 1.16). Depression scores were significantly lower at the end of treatment with CBT plus exposure therapy compared with CBT alone (4 RCTs, 145 people;

SMD 0.45, 95% CI 0.11 to 0.79). CBT in a full or less intensive form was not significantly superior to CBT in a pure self help form (see glossary, p 1235) (5 RCTs, 264 people; RR 0.92, 95% CI 0.82 to 1.03). One RCT included in the review (220 people) compared classic CBT versus interpersonal psychotherapy (see glossary, p 1234) for bulimia nervosa that involved purging.[24] It found that CBT significantly improved abstinence from binge eating at the end of treatment (19 individual sessions conducted ≥ 20 weeks; intention to treat analysis; 29% with CBT *v* 6% with interpersonal psychotherapy; $P < 0.01$). However, the difference was not significant at 4, 8, and 12 months of follow up, with improvement in both groups from baseline. We found one subsequent RCT (125 people with bulimia nervosa), which compared four sessions of CBT versus motivational enhancement therapy (see glossary, p 1234).[25] It found no significant differences between CBT and motivational enhancement therapy in engaging participants or the chance of achieving a clinically significant reduction in binge frequency (17/25 [68%] *v* 23/43 [53%]; RR 1.3, 95% CI 0.9 to 1.9). However, results were reported only on the first 4 weeks of treatment, which was prior to all people receiving a further 8 weeks of individual or group CBT. **Versus antidepressants:** See benefits of antidepressants, p 1230. **Versus combination treatment:** See benefits of combination treatment, p 1233.

Harms: The systematic review (search date 2002) found that the RCTs did not report details of adverse effects.[22] It found no significant difference in completion rates between interventions,[22] suggesting no major difference in acceptability. However, it could not exclude infrequent serious adverse effects.[22] An observational study found that group psychotherapy offered very soon after presentation was sometimes perceived as threatening.[10]

Comment: We found a second systematic review in German, which is awaiting translation, and may be included in a future *Clinical Evidence* update.[26] One systematic review (search date 2002)[22] defined CBT as psychotherapy that uses the techniques and models specified by Wilson and Fairburn,[27] but it did not specify the number of sessions or specialist expertise (classical CBT for bulimia nervosa specifies 19 individual sessions over 20 weeks conducted by trained therapists[27]). Effect sizes for CBT were large, but over 50% of people were still binge eating at the end of treatment.[22] Further research is needed to evaluate the specific and non-specific effects of CBT and other psychotherapies, to explore individual characteristics (such as readiness to change) that may predict response, and to explore the long term effects of treatment. Waiting list or delayed treatment control groups are subject to bias because it is not possible to "blind" someone to the knowledge they are not in the active treatment group. It is difficult to interpret the clinical importance of the statistically significant changes in depression scores. Further limitations are that the quality of trials was variable (e.g. 57% were not blinded).[22] Sample sizes were often small. None of the studies measured harms rigorously. Two further analyses[28,29] found limited observational evidence that motivation and compliance factors may influence outcomes. One study[28] performed additional analyses in an RCT of CBT versus interpersonal psychotherapy.[24] It found that

"stage of change", or psychological motivation and greater readiness to change, was not related to non-completion, but was associated with a good outcome in those who completed interpersonal psychotherapy. The second RCT examined the effects of compliance on outcome in 62 people randomised to guided self help or to full CBT for 16 weeks.[29] At 6 months' follow up, but not the end of treatment, binge eating abstinence rates were greater in those who had completed two or more of the CBT exercises (P = 0.04; CI not reported). Stricter inclusion criteria in the review removed previously included RCTs in people with binge eating disorders other than bulimia nervosa.[22] **Versus antidepressants:** See antidepressants, p 1230.

OPTION OTHER PSYCHOTHERAPIES

One systematic review has found that non-cognitive behavioural psychotherapy increases abstinence from binge eating compared with waiting list controls. The systematic review found that the combined result for four specific psychotherapies, other than cognitive behavioural therapy, reduced bulimic symptoms compared with specified control psychotherapies. However, the review included RCTs with weak methods, and the result was significant in only one of the four individual results. One systematic review found cognitive behavioural therapy compared with other psychotherapies improved abstinence from binge eating and depression scores at the end of treatment. One RCT in the review found that CBT compared with interpersonal psychotherapy reduced binge eating in the short term, but there was no significant difference in the longer term.

Benefits:

Versus waiting list controls: We found one systematic review (search date 2002),[22] which also included studies of other binge eating (see glossary, p 1234) syndromes. It found that, for bulimia nervosa (see glossary, p 1234) participants only, non-cognitive behavioural psychotherapies (e.g. hypnobehavioural therapy and interpersonal psychotherapy — see glossary, p 1234) compared with waiting list control significantly increased abstinence from binge eating (3 RCTs, 124 people; RR 0.67, 95% CI 0.55 to 0.81) and reduced the number of people who did not achieve remission (4 RCTs, 162 people; RR 0.63, 95% CI 0.53 to 0.75). **Versus a control therapy:** The systematic review included four RCTs in which psychotherapies other than cognitive behavioural therapy were compared with a control therapy.[22] One compared nutritional counselling with stress management; one compared guided imagery with self monitoring; one was a three-armed RCT comparing self psychology (the active treatment), cognitive orientation (see glossary, p 1234), and a control nutritional counselling therapy, and the fourth compared interpersonal psychotherapy with behavioural therapy alone. The combined results for psychotherapy, for participants with bulimia nervosa, significantly reduced bulimic symptoms compared with a control treatment (4 RCTs, 163 people; SMD –0.64 95% CI –1.00 to –0.29).[22] However, in only one trial was the individual result significant. **Versus antidepressants:** See antidepressants, p 1230. **Versus cognitive behavioural therapy:** See benefits of cognitive behavioural therapy, p 1227. **Versus combination treatment:** See combination treatment, p 1232. We found one subsequent RCT, which is awaiting translation.[30]

Bulimia nervosa

Harms: The systematic review (search date 2002) found that the RCTs did not report details of adverse effects.[22] It found no significant difference in completion rates between interventions,[22] suggesting no major difference in acceptability. However, it could not exclude infrequent serious adverse effects.[22] An observational study found that group psychotherapy offered very soon after presentation was sometimes perceived as threatening.[10] Non-cognitive behavioural psychotherapies include a large number of options, and it remains unclear which therapies are most effective.

Comment: The quality of trials was variable, few were blinded, sample sizes were small, and none of the studies measured harms rigorously (see comment under cognitive behavioural therapy, p 1228). Waiting list or delayed treatment control groups are subject to bias because it is not possible to "blind" someone to the knowledge they are not in the active treatment group. Stricter inclusion criteria in the review removed previously included RCTs in people with binge eating disorders other than bulimia nervosa.[22]

OPTION ANTIDEPRESSANTS

Systematic reviews and one subsequent RCT have found short term reduction in bulimic symptoms with tricyclic antidepressants, monoamine oxidase inhibitors, and fluoxetine. A further subsequent RCT found no significant difference in symptoms between moclobemide and placebo. One systematic review and one subsequent RCT found no significant difference in symptoms or relapse rates with antidepressants versus cognitive behavioural therapy. One systematic review and one subsequent RCT found no significant difference between combination treatment (antidepressants plus psychotherapy) and antidepressants alone in binge frequency, depressive symptoms, and remission rates. We found no RCTs on the effects of venlafaxine, mirtazapine, and reboxetine. We found no good evidence on selective serotonin reuptake inhibitors other than fluoxetine. We found insufficient evidence to assess the effects of antidepresssants for maintenance.

Benefits: We found two systematic reviews (search date 2001[31] and 2000[32]), three additional RCTs of longer term maintenance (not primary treatment studies),[33–35] and one subsequent RCT.[36]
Versus placebo: We found one systematic review comparing antidepressants with placebo.[31] It found that antidepressants reduced bulimic symptoms.[31] The review (search date 2001; antidepressants were imipramine [5 RCTs], amitriptyline [1 RCT], desipramine [5 RCTs], phenelzine [2 RCTs], isocarboxazid [1 RCT], brofaromine [1 RCT], fluoxetine [5 RCTs], mianserin [1 RCT], bupropion [1 RCT], and trazodone [1 RCT]) found significantly more frequent short term remission of bulimic episodes with antidepressants (9 RCTs, 777 people, 20% *v* 8% with placebo; pooled RR 0.87, 95% CI 0.81 to 0.93).[31] The review found no significant difference in effect between different classes of antidepressants, but there were too few RCTs to exclude a clinically important difference (see table 2, p 1237). Most RCTs were of tricyclic antidepressants or monoamine oxidase inhibitors; fluoxetine was the only selective serotonin reuptake inhibitor included in the reviews.[31] The first subsequent, four armed RCT (91 women)

compared fluoxetine 60 mg daily, placebo, self help cognitive behavioural therapy manual, and fluoxetine plus a self help manual.[23] It found a significantly greater reduction with fluoxetine compared with placebo in vomiting and binge eating symptoms at week 4 ($P < 0.05$). Remission rates after a 16 week treatment period with fluoxetine were 16%, and were not reported for placebo. The second subsequent RCT (78 women with bulimia nervosa [see glossary, p 1234]) compared moclobemide (a reversible monoamine oxidase inhibitor) 600 mg daily versus placebo.[36] It reported no significant differences in weekly binge and vomiting episodes, Hamilton depression scores, and scores on three self report measures of eating disorder symptoms between those randomised to active drug or placebo, among the 52 women who completed the RCT. It was not possible to provide quantified results, as insufficient data were provided. Remission rates were not reported. We found no RCTs on the effects of other selective serotonin reuptake inhibitors (sertraline, paroxetine, and citaopram), venlafaxine, mirtazapine, and reboxetine. **Versus psychotherapy:** We found one systematic review (search date 2000, 5 RCTs) of antidepressants versus psychotherapy (all CBT RCTs) and one subsequent RCT.[32,37] We found another trial comparing fluoxetine with psychotherapy, which is awaiting translation.[38] The systematic review found no significant difference in remission rates, bulimic symptom severity (4 RCTs), or depression symptom severity at the end of the trials (3 RCTs).[32] A subsequent RCT (53 people) compared three treatments: group based CBT, fluoxetine 60 mg daily, and CBT plus fluoxetine.[37] Completer only analysis found no significant differences in 1 month abstinence from binge eating at the end of treatment (5/19 with CBT *v* 2/16 with fluoxetine; RR 2.11, 95% CI 0.47 to 9.43) or in 1 month absence from self induced vomiting (7/19 with CBT, 1/16 with fluoxetine; RR 5.9, 95% CI 0.81 to 42.99).[37] **Versus combination treatment:** See combination treatment, p 1232. **Antidepressants as maintenance:** We found two small RCTs of maintenance treatment.[33,34] The first very small RCT (9 people who had responded well to despiramine over the previous 24 weeks) compared continuation of desipramine versus placebo.[33] It found no significant difference between treatments (relapse: 1/5 [20%] with desipramine *v* 2/4 [50%] with placebo; RR 0.4, 95% CI 0.1 to 3.0). The second very small RCT (9 women who had responded well to imipramine over the previous 10 weeks) compared continuation of imipramine versus placebo.[34] It found no significant difference in relapse (relapse: 2/3 [67%] with imipramine *v* 5/6 [83%] with placebo; RR 0.8, 95% CI 0.3 to 1.9).[34]

Harms: One systematic review (search date 2000) found that withdrawal significantly increased with antidepressants compared with psychotherapy (4 RCTs, 189 people; AR 40% *v* 18%; RR 2.18, 95% CI 1.09 to 4.35).[32] One subsequent RCT (53 people) found no significant difference in withdrawals with fluoxetine compared with CBT and with combined treatment (42% with CBT, 25% with fluoxetine; RR 1.68, 95% CI 0.62 to 4.57; and 33% with combined treatment; RR 1.33, 95% CI 0.46 to 3.89).[37] The authors thought this might be due to cultural differences because psychotherapy is rarely offered as part of a treatment trial in Germany. A second systematic review (search date 2001) found significantly increased

withdrawal in people taking antidepressants compared with placebo (12 RCTs, 1123 people, 10.5% with any antidepressant *v* 5.1% with placebo; RR 1.83, 95% CI 1.13 to 2.95; NNH 7, 95% CI 4 to 18).[31] It found no significant difference in withdrawal due to adverse effects between and within classes of antidepressants. It found that withdrawal due to any cause was more likely with tricyclic antidepressants than with placebo (6 RCTs, 277 people, 29% with tricyclic *v* 14% with placebo; RR 1.93, 95% CI 1.15 to 3.25), but was more likely with placebo than with selective serotonin reuptake inhibitors (3 RCTs, 706 people, 37% with a selective serotonin reuptake inhibitor *v* 40% with placebo; RR 0.83, 95% CI 0.68 to 0.99). We found one RCT examining specific adverse effects. One found significant increases in reclining and standing blood pulse rate, lying systolic and diastolic blood pressure, and greater orthostatic effects on blood pressure with desipramine versus placebo.[39] Cardiovascular changes were well tolerated and few people withdrew because of these effects. Meta-analyses of two double blind RCTs of fluoxetine versus placebo found no significant difference in the incidence of suicidal acts or ideation in people treated with fluoxetine versus placebo.[40] However, the overall incidence of events was low (suicide attempts 1.2%, none fatal; emergent suicidal ideation 3.1%). The third subsequent RCT did not report on withdrawal or adverse events.[23]

Comment: We found no consistent predictors of response to treatment. We found no good evidence for the efficacy of other selective serotonin reuptake inhibitors apart from fluoxetine of the "newer" antidepressants venlafaxine, reboxetine, and mirtazapine. One review commented on the lack of follow up.[31] The second subsequent RCT found no differences between active and placebo groups in withdrawal rates because of adverse events, and no changes in blood pressure in those on moclobemide despite reports in food diaries of a high consumption of tyramine-containing foods.[36] The RCTs of maintenance both made multiple randomisations and compared a number of different groups. This meant that there were very few people in the groups for maintenance treatment.

OPTION COMBINATION TREATMENT

One systematic review and one subsequent RCT found no significant difference between combination treatment (antidepressants plus psychotherapy) and antidepressants alone in binge frequency, depressive symptoms, and remission rates. The systematic review found that, compared with psychotherapy alone, combination treatment improved short term remission, but there was no significant difference in binge frequency and depressive symptoms. The systematic review found that combination treatment with psychotherapy was associated with higher withdrawal rates compared with psychotherapy alone. One subsequent RCT of cognitive behavioural therapy in a self help form plus fluoxetine found limited evidence that combined treatment reduced bulimic symptoms compared with cognitive behavioural therapy alone. A second subsequent RCT found no significant difference in symptoms between group based CBT, fluoxetine, and their combination.

Benefits: **Versus antidepressants alone:** We found one systematic review (search date 2000, 7 RCTs, 247 people)[32] and one subsequent RCT comparing combination treatment (antidepressants plus psychotherapy) versus antidepressants alone.[37] The systematic review found that combination treatment compared with antidepressants alone did not significantly improve binge frequency, depressive symptoms, and short term remission rates, although outcomes were better with combination treatment (binge frequency 4 RCTs; SMD +0.34, 95% CI −0.05 to +0.73; depressive symptoms 3 RCTs; SMD +0.24, 95% CI −0.14 to +0.62; short term remission rates 4 RCTs, 141 people, 42% with combined treatment *v* 23% with antidepressants alone; RR 1.40, 95% CI 0.98 to 1.99).[32] The subsequent RCT (53 people) compared three treatments: group based cognitive behavioural therapy (CBT); fluoxetine 60 mg daily; and CBT plus fluoxetine (see option, p 1230).[37] Completer only analysis found no significant difference in 1 month abstinence from binge eating (2/16 with fluoxetine *v* 3/18 with combination; RR 1.05, 95% CI 0.80 to 1.30) or in 1 month abstinence from self induced vomiting (1/16 with fluoxetine *v* 1/18 with combination; RR 0.99, 95% CI 0.84 to 1.18).
Versus psychotherapy alone: We found one systematic review (search date 2000, 7 RCTs, 343 people)[32] and two subsequent RCTs comparing combination treatment (antidepressants plus psychotherapy) versus antidepressants alone.[23,37] The systematic review found that combination treatment compared with psychotherapy alone significantly increased short term remission (6 RCTs, 257 people, 49% *v* 36%; RR 1.21, 95% CI 1.02 to 1.45) but found no significant difference in depressive symptoms or in frequency of binge eating (see glossary, p 1234) (6 RCTs; SMD +0.12, 95% CI −0.21 to +0.46).[32] The first subsequent RCT found that people who received both the self help manual and fluoxetine 60 mg daily had the greatest reduction in bulimic symptoms compared with those in the placebo, fluoxetine, or self help only arms, but significance was not reported.[23] Remission rates did not differ significantly across the three active treatment arms. The second subsequent RCT (53 people) compared three treatments: group based CBT; fluoxetine 60 mg daily; and CBT plus fluoxetine.[37] Completer only analysis found no significant difference in 1 month abstinence from binge eating (5/19 with CBT *v* 3/18 with combination; RR 1.58, 95% CI 0.44 to 5.67), or in 1 month abstinence from self induced vomiting (7/19 with CBT *v* 1/18 with combination; RR 6.63, 95% CI 0.90 to 48.69).

Harms: The review found no significant difference in withdrawal rates between combination treatment and antidepressants alone (4 RCTs, 196 people, 34% with combination treatment *v* 41% with antidepressants alone; RR 1.19, 95% CI 0.69 to 2.05).[32] Withdrawal rates were significantly lower with psychotherapy alone compared with combination treatments (6 RCTs, 295 people, 16% *v* 30%; RR 0.57, 95% CI 0.38 to 0.88).[32] The subsequent RCT[37] did not find higher non-completion rates when CBT was combined with fluoxetine.

Comment: Modest effect sizes in these analyses may be clinically relevant, but the small number and size of trials limit conclusions.

Bulimia nervosa

GLOSSARY

Binge eating Modified from DSM-IV.[1] Eating, in a discrete period (e.g. hours), a large amount of food, accompanied by a lack of control over eating during the episode.

Bulimia nervosa The American Psychiatric Association DSM-IV[1] criteria include recurrent episodes of binge eating; recurrent inappropriate compensatory behaviour to prevent weight gain; frequency of binge eating and inappropriate compensatory behaviour both, on average, at least twice a week for 3 months; self evaluation unduly influenced by body shape and weight; and disturbance occurring not exclusively during episodes of anorexia nervosa. Types of bulimia nervosa, modified from DSM-IV[1], are purging: using self induced vomiting, laxatives, diuretics, or enemas; non-purging: fasting, exercise, but not vomiting or other abuse as for the purging type. Many studies however evaluate efficacy for samples that may include participants with subthreshold bulimia nervosa or binge eating disorder. Where possible, only data of bulimia nervosa participants are reported in this review.

Cognitive behavioural therapy In bulimia nervosa this uses three overlapping phases. Phase one aims to educate the person about bulimia nervosa. People are helped to increase regularity of eating, and resist urge to binge or purge. Phase two introduces procedures to reduce dietary restraint (e.g. broadening food choices). In addition, cognitive procedures supplemented by behavioural experiments are used to identify and correct dysfunctional attitudes and beliefs, and avoidance behaviours. Phase three is the maintenance phase. Relapse prevention strategies are used to prepare for possible future set backs.[41]

Cognitive orientation therapy The cognitive orientation theory aims to generate a systematic procedure for exploring the meaning of a behaviour around themes, such as avoidance of certain emotions. Therapy for modifying behaviour focuses on systematically changing beliefs related to themes, not beliefs referring directly to eating behaviour. No attempt is made to persuade the people that their beliefs are incorrect or maladapative.[42]

Dialectical behaviour therapy A type of behavioural therapy that views emotional dysregulation as the core problem in bulimia nervosa, with binge eating and purging understood as attempts to influence, change, or control painful emotional states. Patients are taught a repertoire of skills to replace dysfunctional behaviours.[43]

Exposure therapy In bulimia nervosa this is a modification of the exposure and response prevention therapy developed for obsessive compulsive disorder. It involves exposure to food, for example, and then psychological prevention strategies to control weight behaviour, such as vomiting after eating until the urge or compulsion to vomit has receded.[44]

Hypnobehavioural psychotherapy Uses a combination of behavioural techniques, such as self monitoring to change maladaptive eating disorders, and hypnotic techniques to reinforce and encourage behaviour change.

Interpersonal psychotherapy In bulimia nervosa, this is a three phase treatment. Phase one analyses in detail the interpersonal context of the eating disorder. This leads to the formulation of an interpersonal problem area, which forms the focus of the second stage, which is aimed at helping the person make interpersonal changes. Phase three is devoted to the person's progress and an exploration of ways to handle future interpersonal difficulties. At no stage is attention paid to eating habits or body attitudes.[24]

Motivational enhancement therapy (MET) This is based on a model of change with focus on stages of change. Stages of change represent constellations of intentions and behaviours through which individuals pass as they move from having a problem to doing something to resolve it. People in "precontemplation" show no intention to change. People in "contemplation" acknowledge they have a problem

and are thinking about change, but have not yet made a commitment to change. People in the third "action" stage are actively engaged in overcoming their problem, and people in "maintenance" work to prevent relapse. Transition from one stage to the next is sequential, but not linear. The aim of MET is to help people move from earlier stages into "action, utilising cognitive and emotional strategies". There is an emphasis on the therapeutic alliance. With precontemplators, the therapist explores perceived positive and negative aspects of their behaviours. Open-ended questions are used to elicit client expression, and reflective paraphrase is used to reinforce key points of motivation. During a session following structured assessment, most of the time is devoted to explaining feedback to the client. Later in MET, attention is devoted to developing and consolidating a change plan.[45]

Pure self help cognitive behavioural therapy A modified form of cognitive behavioural therapy, in which a treatment manual is provided for people to proceed with treatment on their own, or with support from a non-professional. "Guided self help" usually implies that the support person may or may not have some professional training, but is usually not a specialist in eating disorders.

Self psychology therapy This approaches bulimia nervosa as a specific case of the pathology of the self. The treated person cannot rely on people to fulfil their needs such as self esteem. They rely instead on a substance, food, to fulfil personal needs. Therapy progresses when the people move to rely on humans, starting with the therapist.[42]

QUESTIONS

INTERVENTIONS

See glossary, p 1248

Key Messages

- We found little RCT evidence for any intervention in people with deliberate self harm. Most RCTs and meta-analyses of small RCTs are likely to have been underpowered to detect clinically important outcomes of interventions.
- **Continuity of care** One systematic review of one RCT found limited evidence that follow up after hospital treatment with the same compared with a different therapist may increase repetition of deliberate self harm over 3 months, although this may be explained by a higher level of risk factors for repetition in the group receiving same therapist follow up, despite randomisation.
- **Dialectal behaviour therapy** One RCT found limited and equivocal evidence that dialectical behaviour therapy may reduce the proportion of people who repeat deliberate self harm over 12 months compared with usual care.
- **Emergency card** One systematic review found no significant difference in the proportion of people who repeated deliberate self harm over 12 months between emergency card (allowing emergency admission or contact with a doctor) and usual care.
- **Flupentixol depot injection** One small RCT found that flupentixol depot injection reduced the proportion of people who repeated deliberate self harm over 6 months compared with placebo. However, we were unable to draw reliable conclusions from this small study. Typical antipsychotics such as flupentixol are associated with a wide range of adverse effects.
- **Hospital admission** One RCT found no significant difference between hospital admission and immediate discharge in the proportion of people who repeated deliberate self harm over 16 weeks, but it is likely to have been too small to exclude a clinically important difference.

- **Intensive outpatient follow up plus outreach** One systematic review found no significant difference in the proportion of people who repeated deliberate self harm over 4–12 months between intensive intervention plus outreach and usual care.
- **Mianserin** RCTs provided insufficient evidence to assess mianserin.
- **Nurse led case management** One RCT found no significant difference between nurse led case management and usual care in the proportion of people who were admitted to emergency departments for episodes of deliberate self harm over 12 months.
- **Paroxetine** One RCT in people with deliberate self harm receiving psychotherapy found no significant difference between paroxetine and placebo in the proportion of people who repeated self harm over 12 months. It found that paroxetine increased diarrhoea and tremor compared with placebo.
- **Problem solving therapy** One systematic review of small RCTs found no significant difference between problem solving therapy and usual care in the proportion of people who repeated deliberate self harm over 6–12 months. Another systematic review found that problem solving therapy reduced depression, anxiety, and hopelessness, and improved problems compared with usual care.
- **Psychodynamic interpersonal therapy** One RCT found that psychodynamic interpersonal therapy for 4 weeks reduced repetition of deliberate self harm, depression, and suicidal ideation over 6 months compared with usual care. However, we were unable to draw reliable conclusions from one RCT.
- **Same number of therapy sessions given over long term versus over short term** One systematic review of one RCT found no significant difference in the proportion of people who repeated deliberate self harm at 12 months with therapy given over 3 months compared with 12 months.
- **Telephone contact** One RCT found no significant difference between telephone contact at 4 and 8 months and usual care in repetition of deliberate self harm, global functioning, and suicidal ideation over 12 months.
- **General practice based guidelines** One large cluster randomised trial comparing the use of general practitioner guidelines for management of deliberate self harm versus usual care found no significant difference in the proportion of people who repeated deliberate self harm over 12 months or in the time to repetition of self harm.

DEFINITION Deliberate self harm is an acute non-fatal act of self harm carried out deliberately in the form of an acute episode of behaviour by an individual with variable motivation.[1] The intention to end life may be absent or present to a variable degree. Other terms used to describe this phenomenon are “attempted suicide” and “parasuicide”. The terms are not entirely satisfactory. Common methods of deliberate self harm include self cutting and self poisoning, such as overdosing on medicines. Some acts of deliberate self harm are characterised by high suicidal intent, meticulous planning (including precautions against being found out), and severe lethality. Other acts of deliberate self harm are characterised by no or low intention of suicide, lack of planning and concealing of the act, and low lethality of the method used. The related term of “suicide” is defined as an act with a fatal outcome that is deliberately initiated and performed by the person with the knowledge or expectation of its fatal outcome.[1] This review focuses on recent deliberate self harm as the main presenting problem and excludes RCTs in which deliberate self harm is

assessed as an outcome associated with other disorders, such as depression or borderline personality disorder. Deliberate self harm is not defined in the *Diagnostic and statistical manual of mental disorders* (DSM IV)[2] or the *International classification of mental and behavioural disorders* (ICD-10).[3]

INCIDENCE/ PREVALENCE

Based on data from 16 European countries between 1989–1992, the lifetime prevalence of deliberate self harm in people treated in hospital and other medical facilities, including general practice settings, is estimated at about 3% for women and 2% for men.[4] Over the last 50 years there has been a rise in the incidence of deliberate self harm in the UK.[4] A reasonable current estimate is about 400/100 000 population a year.[5] In two community studies in the USA, 3–5% of responders said that they had made an attempt at deliberate self harm at some time.[6] Self poisoning using organophosphates is particularly common in developing countries.[7] A large hospital (catering for 900 000 people) in Sri Lanka, reported 2559 adult hospital admissions and 41% occupancy of medical intensive care beds for deliberate self harm with organophosphates over 2 years.[8] An international survey using representative community samples of adults (aged 18–64 years) reported lifetime prevalence of self reported suicide attempts of 3.82% in Canada, 5.93% in Puerto Rico, 4.95% in France, 3.44% in West Germany, 0.72% in Lebanon, 0.75% in Taiwan, 3.2% in Korea, and 4.43% in New Zealand.[6]

AETIOLOGY/ RISK FACTORS

Familial, biological, and psychosocial factors may contribute to deliberate self harm. Evidence for genetic factors includes a higher risk of familial suicide and greater concordance in monozygotic than dizygotic twins for deliberate self harm and suicide.[9] Evidence for biological factors includes reduced cerebrospinal fluid 5-hydroxyindole acetic acid (5-HIAA) levels and blunted prolactin response to fenfluramine challenge test, indicating a reduction in the function of serotonin in the central nervous system.[10] People who deliberately self harm also show traits of impulsiveness and aggression, inflexible and impulsive cognitive style, and impaired decision making and problem solving (see glossary, p 1248).[11] Deliberate self harm is more likely in women, young adults, and people who are single or divorced, of low education level, unemployed, disabled, or suffering from a psychiatric disorder[12] particularly depression,[13] substance misuse,[14] borderline and antisocial personality disorders,[15] severe anxiety disorders,[16] and physical illness.[17]

PROGNOSIS

Suicide is highest during the first year after deliberate self harm.[18] One systematic review found median rates of repetition of deliberate self harm of 16.0% (interquartile range [IQR] 12.0% to 25.0%) within the first year, 21.0% (IQR 12.0% to 30.0%) within 1–4 years, and 23% (IQR 11% to 32%) within 4 years or longer. It found median mortality from suicide after deliberate self harm of 1.8% (IQR 0.8% to 2.6%) within the first year, 3.0% (IQR 2.0% to 4.4%) within 1–4 years, 3.4% (IQR 2.5% to 6.0%) within 5–10 years, and 6.7% (IQR 5.0% to 11.0%) within 9 years or longer.[18] Repetition of deliberate self harm is more likely in people aged 25–49 years, who are unemployed, divorced, from lower social class, or who suffer from substance misuse, depression, hopelessness, powerlessness,

personality disorders, have unstable living conditions or live alone, have a criminal record, previous psychiatric treatment, a history of stressful traumatic life events, or a history of coming from broken home or of family violence.[12] Factors associated with risk of suicide after deliberate self harm are age over 45 years, male sex, being unemployed, retired, separated, divorced, or widowed, living alone, poor physical health, psychiatric disorder (particularly depression, alcoholism, schizophrenia, and sociopathic personality disorder), high suicidal intent in current episode including leaving a written note, violent method used in current episode, and history of deliberate self harm.[19]

AIMS OF INTERVENTION To reduce repetition of deliberate self harm, desire to self harm, to prevent suicide, and improve social functioning and quality of life, with minimal adverse effects.

OUTCOMES Repetition of deliberate self harm, occurrence of suicide, admission to hospital, improvement in underlying psychiatric symptoms, improvement in coping, quality of life, and adverse effects. Some of the validated scales used for assessing psychiatric symptoms and deliberate self harm are: Symptom Checklist-90 (SCL-90), a self administered rating scale for assessing nine areas of psychopathology (somatisation, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic-anxiety, paranoid ideation, and psychoticism),[20–22] Beck Depression Inventory (a 21 item self administered Likert scale for measuring severity of depression),[23] Hospital Anxiety Depression Scale (a self administered 14 item Likert scale for measuring depression and anxiety),[24] Beck Scale for Suicidal Ideation (a 21-item self administered Likert scale covering thoughts and plans about suicide and aims at assessing the risk of a later suicide attempt),[25] Beck Hopelessness Scale (a 20 item true-false self administered items and aims at assessing hopelessness about the future),[26] and Global Severity Index (GSI; a mean of all items in SCL-90).[21]

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments for deliberate self harm in adults?

OPTION PAROXETINE

One RCT in people with deliberate self harm receiving psychotherapy found no significant difference between paroxetine and placebo in the proportion of people who repeated self harm over 12 months. It found that paroxetine increased diarrhoea and tremor compared with placebo.

Benefits: We found one systematic review (search date 1999),[27] which identified one RCT[28] (91 outpatients who had previously been admitted to hospital for deliberate self harm, without current depression, receiving psychotherapy) comparing paroxetine 40 mg daily versus placebo for 12 months. It found no significant difference between paroxetine and placebo in the proportion of people repeating deliberate self harm over 12 months (15/46 [33%] with paroxetine *v* 21/45 [47%] with placebo; RR 0.70, 95% CI 0.40 to 1.18).

Harms: The RCT found that, compared with placebo, paroxetine significantly increased the proportion of people with diarrhoea (10/46 [22%] with paroxetine *v* 1/45 [2%] with placebo; P = 0.007), tremor (8/46 [17%] with paroxetine *v* 1/46 [2%] with control; P = 0.03), and delayed orgasm (9/46 [19%] with paroxetine *v* 0/45 [0%] with placebo; P = 0.003).[28] It also found that paroxetine was associated with large bruises in two people.

Comment: The review did not report any other outcomes.[27]

OPTION MIANSERIN

RCTs provided insufficient evidence to assess mianserin.

Benefits: We found one systematic review (search date 1999),[27] which identified two RCTs.[29,30] The first RCT (38 people with borderline or histrionic personality disorder and a history of deliberate self harm, admitted to hospital after an episode of self harm) identified by the review found no significant difference between mianserin 30 mg daily and placebo in the proportion of people who repeated deliberate self harm over 6 months' treatment (8/17 [47%] with mianserin *v* 12/21 [57%] with placebo; RR 0.82, 95% CI 0.44 to 1.54), but it is likely to have been too small to detect a clinically important difference.[29] The second RCT (114 people admitted to hospital after deliberate self poisoning, history of deliberate self harm not stated) identified by the review compared mianserin 30–60 mg daily or nomifensine 75–150 mg daily versus placebo for 6 weeks' treatment (see comment below).[30] The RCT did not compare mianserin alone versus placebo. It found no significant difference between mianserin or nomifensine and placebo in the proportion of people who repeated deliberate self harm over 12 weeks (16/76 [21%] with mianserin or nomifensine *v* 5/38 [13%] with placebo; RR 1.60, 95% CI 0.63 to 4.04), but it is likely to have been too small to detect a clinically important difference.

Harms: The review[27] and RCTs[29,30] gave no information on adverse effects.

Comment: The review did not report any other outcomes.[27] Nomifensine was withdrawn worldwide in the 1980s because of association with immune haemolytic anaemia.[30]

OPTION FLUPENTIXOL DEPOT INJECTION

One small RCT found that flupentixol depot injection reduced the proportion of people who repeated deliberate self harm over 6 months compared with placebo. However, we were unable to draw reliable conclusions from this small study. Typical antipsychotics such as flupentixol are associated with a wide range of adverse effects.

Benefits: We found one systematic review (search date 1999), which identified one RCT (30 people with a history of deliberate self harm) comparing flupentixol decanoate (20 mg im once every 4 weeks) versus placebo for 6 months.[27] It found that flupentixol significantly reduced the proportion of people who repeated deliberate self harm over 6 months compared with placebo (3/14 [21%] with flupentixol *v* 12/16 [75%] with placebo; RR 0.29, 95% CI 0.10 to 0.81).

Harms: The review gave no information on adverse effects (see comment below).[27]

Comment: We found insufficient evidence about the adverse effects of flupentixol in people with deliberate self harm. Typical antipsychotics such as flupentixol are associated with a wide range of adverse effects.[31] The review did not investigate other outcomes.[27]

OPTION PROBLEM SOLVING THERAPY

One systematic review of small RCTs found no significant difference between problem solving therapy and usual care in the proportion of people who repeated deliberate self harm over 6–12 months. Another systematic review found that problem solving therapy reduced depression, anxiety, and hopelessness, and improved problems compared with usual care.

Benefits: We found one systematic review (search date 1999)[27] that assessed the effects of problem solving therapy (see glossary, p 1248) on repetition of deliberate self harm and one systematic review (search date not stated)[32] that assessed the effects of problem solving therapy on depression, anxiety, and hopelessness. The first review identified five RCTs (571 people) comparing problem solving therapy versus usual care (standard care [from psychiatrist, community psychiatric nurse, or social worker], marital counselling, or general practitioner counselling).[27] Four of the RCTs were in people who had been admitted to hospital for deliberate self poisoning and included people with both a history of deliberate self harm and experiencing their first episode; one RCT was in people admitted to hospital after deliberate self harm who had self harmed at least once before in the previous year. The duration of interventions for four RCTs was 2–8 sessions, and for one RCT 3 months; follow up ranged from 6–12 months. The review found no significant difference between problem solving therapy and usual care in the proportion of people who repeated deliberate self harm over 6–12 months (45/290 [15%] with problem solving therapy *v* 54/281 [19%] with usual care; RR 0.77, 95% CI 0.55 to 1.08).[27] The second review (6 RCTs, including 5 identified by the first review) found that, compared with usual care, problem solving therapy significantly reduced depression (assessed by Beck Depression Inventory and Hospital Anxiety Depression Scale, 4 RCTs, 158 people, SMD –0.36 95% CI –0.61 to –0.11) and hopelessness (assessed by Beck Hopelessness Scale, 3 RCTs, 63 people; WMD –2.97 95% CI –4.81 to –1.13) and "improved problems" (2 RCTs, 211 people; OR 2.31, 95% CI 1.29 to 4.13; see comment below).[32]

Harms: The reviews gave no information on adverse effects.[27,32]

Comment: The second review did not state how improvement in problems was assessed.[32] The reviews did not assess other outcomes.[27,32]

OPTION DIALECTICAL BEHAVIOUR THERAPY

One RCT found limited and equivocal evidence that dialectical behaviour therapy may reduce the proportion of people who repeat deliberate self harm over 12 months compared with usual care.

Deliberate self harm

Benefits: We found one systematic review (search date 1999)[27] which identified one RCT (39 women with borderline personality disorder and a history of deliberate self harm who had self harmed in the previous 8 weeks) comparing dialectical behaviour therapy (see glossary, p 1248) versus usual care (alternative therapy referrals). It found that dialectical behaviour therapy significantly reduced the proportion who repeated deliberate self harm over 1 year compared with usual care (5/19 [26%] with dialectical behaviour therapy *v* 12/20 [60%] with usual care; OR 0.24, 95% CI 0.06 to 0.93; see comment below).

Harms: The review gave no information on adverse effects.[27]

Comment: The results of the RCT are sensitive to the method of statistical calculation used; calculation of relative risk renders the difference between dialectical behaviour therapy and usual care non-significant (RR 0.44, 95% CI 0.19 to 1.01).[27] The review did not assess other outcomes.

OPTION CONTINUITY OF CARE

One RCT found limited evidence that follow up after hospital treatment with the same compared with a different therapist may increase repetition of deliberate self harm over 3 months, although this may be explained by a higher level of risk factors for repetition in the group receiving same therapist follow up, despite randomisation.

Benefits: We found one systematic review (search date 1999), which identified one RCT (141 people with a history of deliberate self harm who had been admitted to hospital for 3 day crisis intervention [see glossary, p 1248] after an episode of self harm) comparing follow up by the same therapist who assessed them in hospital versus different therapist follow up.[27] All participants also received a "motivational interview [see glossary, p 1248], letter, and assessment of motivation towards therapy". It found that follow up by the same therapist significantly increased the proportion of people who repeated deliberate self harm over 3 months compared with different therapist follow up (12/68 [18%] with same therapist *v* 4/73 [5%] with different therapist; RR 3.22, 95% CI 1.09 to 9.51; see comment below).

Harms: The review gave no information on adverse effects.[27]

Comment: The authors commented that the increase in deliberate self harm in people who had continuity of care may have been because of a higher prevalence of risk factors (unspecified) for repetition in the same therapist group despite randomisation.[27] The review and RCTs did not assess other outcomes.

OPTION SAME NUMBER OF SESSIONS OF THERAPY GIVEN OVER LONG TERM VERSUS OVER SHORT TERM

One systematic review of one RCT found no significant difference in the proportion of people who repeated deliberate self harm over 12 months with therapy given over 3 months compared with 12 months.

Benefits: We found one systematic review (search date 1999, 1 RCT, 80 people with deliberate self harm and a history of deliberate self harm) comparing 12 sessions of therapy given over 12 months versus the same number of session given over 3 months (see comment below).[27] It found no significant difference between longer and shorter duration of therapy in the proportion of people who repeated deliberate self harm over 12 months (9/40 [22%] with longer therapy *v* 9/40 [22%] with shorter therapy; RR 1.00, 95% 0.44 to 2.26).

Harms: The review gave no information on adverse effects.[27]

Comment: The RCT did not specify what type of therapy participants received.[27] The review did not assess other outcomes.

OPTION PSYCHODYNAMIC INTERPERSONAL THERAPY

One RCT found that, compared with usual care, psychodynamic interpersonal therapy for 4 weeks reduced repetition of deliberate self harm, depression, and suicidal ideation over 6 months. However, we were unable to draw reliable conclusions from one RCT.

Benefits: We found no systematic review. We found one RCT (119 people admitted to hospital after deliberate self poisoning, 60% with a history of "deliberate self harm") that compared psychodynamic interpersonal therapy (see glossary, p 1248) versus usual care (referral to usual services) for 4 weeks.[33] It found that, compared with usual care, brief psychodynamic interpersonal therapy significantly reduced repetition of deliberate self harm at 6 months (5/58 [9%] with psychodynamic interpersonal therapy *v* 17/61 [28%] with usual care; P = 0.009). It also found that brief psychodynamic interpersonal therapy significantly reduced depression (measured by Beck Depression Inventory, mean difference in score with interpersonal therapy *v* usual care –5.0, 95% CI –9.7 to –0.3) and suicidal ideation (measured by Beck Scale for Suicidal Ideation, mean difference in score –4.9, 95% CI –8.2 to –1.6).

Harms: The RCT gave no information on adverse effects.[33]

Comment: The RCT did not assess other outcomes.[33]

OPTION INTENSIVE OUTPATIENT FOLLOW UP PLUS OUTREACH

One systematic review found no significant difference in the proportion of people who repeated deliberate self harm over 4–12 months between outreach plus intensive intervention and usual care.

Benefits: We found one systematic review (search date 1999, 6 RCTs, 1161 people admitted to hospital after deliberate self harm, 30–100% with a history of deliberate self harm) comparing intensive intervention plus outreach versus usual care over 3–12 months.[27] Intensive outpatient follow up plus outreach varied but usually involved in person or phone contact of the person in the community, including encouragement to attend health services. Usual care involved treatment by various professionals, not involving outreach. It found

no significant difference between intensive intervention plus outreach and usual care in the proportion of people who repeated deliberate self harm over 4–12 months (92/580 [16%] with intensive intervention *v* 107/581 [18%] with usual care; RR 0.87, 95% CI 0.68 to 1.12).

Harms: The review gave no information on adverse effects.[27]

Comment: The review did not assess other outcomes.[27]

OPTION EMERGENCY CARD

One systematic review found no significant difference in the proportion of people who repeated deliberate self harm over 12 months between emergency card (allowing emergency admission or contact with a doctor) and usual care.

Benefits: We found one systematic review (search date 1999, 2 RCTs, 1 RCT in 212 adults admitted to hospital after their first episode of deliberate self harm, 1 RCT in 105 children admitted to hospital after deliberate self harm, history of self harm not stated).[27] It compared emergency card (indicating that a doctor was available and how to contact them or allowing readmission to a paediatric hospital ward) versus usual care (referral to and treatment from usual inpatient, outpatient, or primary care services as appropriate). It found no significant difference in the proportion of people who repeated deliberate self harm over 12 months between emergency card and usual care (8/148 [5%] with emergency card *v* 19/169 [11%] with usual care; RR 0.48, 95% CI 0.22 to 1.07; see comment below).

Harms: The review gave no information on adverse effects.[27]

Comment: The review pooled results from RCTs of heterogeneous populations (adults and children) to try to increase the power of its meta-analysis but it may not be appropriate to pool results in such different groups.[27] The review did not assess other outcomes.

OPTION HOSPITAL ADMISSION

One RCT found no significant difference between hospital admission and immediate discharge in the proportion of people who repeated deliberate self harm over 16 weeks, but it is likely to have been underpowered to detect a clinically important difference.

Benefits: We found one systematic review (search date 1999) which identified one RCT (77 people).[27] The RCT found no significant difference between hospital admission for a median of 17 hours and immediate discharge in the proportion of people who repeated deliberate self harm over 16 weeks (3/38 [8%] with hospital admission *v* 4/39 [10%] with immediate discharge; RR 0.77, 95% CI 0.18 to 3.21), but it is likely to have been underpowered to detect a clinically important difference.

Harms: The review gave no information on adverse effects.[27]

Comment: The review did not assess other outcomes.[27]

OPTION GENERAL PRACTICE BASED GUIDELINES

One large cluster randomised trial comparing the use of general practitioner guidelines for management of deliberate self harm versus usual care found no significant difference in the proportion of people who repeated deliberate self harm over 12 months or in the time to repetition of self harm.

Benefits: We found no systematic review. We found one cluster randomised trial (98 general practices, 2084 people who had attended hospital emergency departments after deliberate self harm, 11–14 with a recent recorded history of deliberate self harm).[34] It compared inviting people for consultation with their general practitioner who followed guidelines for managing self harm versus usual care (provided by general practitioner or referral to mental health or other services as appropriate). It found no significant difference between use of guidelines and usual care in repetition of deliberate self harm (211/964 [22%] with guidelines *v* 189/968 [20%] with usual care; OR 1.17, 95% CI 0.94 to 1.47), mean repeat episodes per person (mean 0.48 with guidelines *v* 0.37 with usual care; incident rate ratio 1.24, 95% CI 0.92 to 1.68), and mean days to first episode of self harm (mean 105 with guidelines *v* 110 with usual care; HR 1.15, 95% CI 0.94 to 1.42).

Harms: The RCT gave no information on adverse effects.[34]

Comment: The RCT did not assess other outcomes.[34]

OPTION NURSE LED CASE MANAGEMENT

One RCT found no significant difference between nurse led case management and usual care in the proportion of people who were admitted to emergency departments for episodes of deliberate self harm over 12 months.

Benefits: We found no systematic review. We found one RCT (467 people who had attended hospital emergency departments after deliberate self harm, 47% with a history of deliberate self harm) comparing nurse led case management (see glossary, p 1248) versus usual care (triage, psychiatric assessment, and inpatient care if appropriate) for 12 months.[35] It found no significant difference between groups in rates of readmission to hospital as a result of deliberate self harm over 12 months (19/220 [9%] with nurse led case management *v* 25/247 [10%] with usual care; OR 0.84, 95% CI 0.45 to 1.57).

Harms: The RCT gave no information on adverse effects.[35]

Comment: The RCT did not assess other outcomes.[35]

OPTION TELEPHONE CONTACT

One RCT found no significant difference between telephone contact at 4 and 8 months and usual care in repetition of deliberate self harm, global functioning, and suicidal ideation over 12 months.

Deliberate self harm

Benefits: We found one RCT (216 people admitted to hospital after deliberate self harm, 51–54% with a history of deliberate self harm) that compared telephone contact at 4 and 8 months aimed at increasing motivation versus usual care (undefined).[36] It found no significant difference between telephone contact and usual care in the proportion of people repeating deliberate self harm over 12 months (14/83 [17%] with telephone contact *v* 15/89 [17%] with usual care; reported as non-significant, CI not reported; results not intention to treat, 19% lost to follow up). It found similar rates in overall functioning between telephone contact and usual care (assessed by Global Assessment of Functioning Scale: mean score 61.4 with telephone contact *v* 58.6 with usual care; CI not reported). It also found similar scores on the scale for suicidal ideation (mean score 5.8 with telephone contact group *v* 4.0 with usual care; CI not reported) and on the Symptom Checklist-90 scale at 12 months (mean score 0.82 with telephone contact group *v* 0.88 with usual care; CI not reported).

Harms: The RCT gave no information on adverse effects.[36]

Comment: None.

GLOSSARY

Case management Involves a case manager managing an individual's care including comprehensive assessment of their needs, development of individualised package of care, the arrangement of access to services, monitoring of quality of services provided, and long term flexible support.

Crisis intervention Involves short term help with current and acute difficult life events using variety of counselling, problem solving, and practical measures.

Dialectical behaviour therapy Is a multimodal cognitive behaviour therapy used particularly in the treatment of people with borderline personality disorder who repeatedly engage in deliberate self harm. It involves helping to replace extremes of emotions and behaviour with behaviour that is a moderate synthesis of extremes.

Motivational interviewing Uses principles of motivational psychology and is aimed at helping people to change and engage in demanding treatments.

Problem solving therapy Uses a set of sequential steps in solving problems and aims at minimising negative emotion and maximising identification, evaluation, and implementation of optimal solutions.

Psychodynamic interpersonal therapy Is a psychotherapeutic intervention aimed at improving interpersonal problems using the model developed by Hobson.

QUESTIONS

INTERVENTIONS

See glossary, p 1273

Key Messages

- People in RCTs of treatments for dementia are often not representative of people with dementia. Few RCTs are conducted in primary care and few are conducted in people with types of dementia other than Alzheimer's disease.

Cognitive symptoms

- **Donepezil** One systematic review has found that donepezil improves cognitive function and global clinical state at up to 52 weeks compared with placebo in people with mild to moderate Alzheimer's disease. The review found no significant difference in patient rated quality of life at 12 or 24 weeks between donepezil and placebo. One large RCT identified by the review found that donepezil delayed the median time to "clinically evident functional decline" by 5 months compared with placebo. One open label RCT in people with mild to moderate Alzheimer's disease found no significant difference in cognitive function at 12 weeks between donepezil and rivastigmine, although fewer people taking donepezil withdrew from the trial for any cause.

- **Galantamine** RCTs have found that galantamine improves cognitive function and global clinical state over 6 months compared with placebo in people with Alzheimer's disease or vascular dementia.
- **Ginkgo biloba** RCTs found limited evidence that ginkgo biloba improved cognitive function over 24–26 weeks compared with placebo in people with Alzheimer's disease or vascular dementia.
- **Memantine** One systematic review has found that memantine improves cognitive function at 12–28 weeks compared with placebo in people with mild to moderate vascular dementia. Subsequent RCTs have found that memantine improves global clinical outcome and reduces care dependence at 12–28 weeks in people with more severe Alzheimer's disease or vascular dementia.
- **Reality orientation** One systematic review of small RCTs found that reality orientation improved cognitive function compared with no treatment in people with various types of dementia.
- **Oestrogen (in postmenopausal women)** One systematic review has found that, in postmenopausal women with mild to moderate Alzheimer's disease, oestrogen improves cognition over 7 weeks to 12 months' treatment compared with placebo or no treatment but there is concern that oestrogen treatment may increase the risk of developing breast cancer and cardiovascular events.
- **Physostigmine** One RCT in people with Alzheimer's disease found limited evidence that slow release physostigmine improved cognitive function over 12 weeks compared with placebo, but adverse effects, including nausea, vomiting, diarrhoea, dizziness, and stomach pain, were common.
- **Rivastigmine** One systematic review and one additional RCT have found that rivastigmine improves cognitive function compared with placebo in people with Alzheimer's disease or Lewy body dementia, but adverse effects such as nausea, vomiting, and anorexia are common. Subgroup analysis from one RCT in people with Alzheimer's disease suggests that people with vascular risk factors may respond better to rivastigmine than those without. One open label RCT in people with mild to moderate Alzheimer's disease found no significant difference in cognitive function at 12 weeks between rivastigmine and donepezil, although more people taking rivastigmine withdrew from the trial for any cause.
- **Tacrine** Two systematic reviews found limited evidence that tacrine improved cognitive function and global state at 3–36 weeks compared with placebo in people with Alzheimer's disease, but adverse effects, including nausea and vomiting, diarrhoea, anorexia, and abdominal pain, were common.
- **Lecithin** Small, poor RCTs identified by a systematic review provided insufficient evidence to assess lecithin in people with Alzheimer's disease.
- **Music therapy** Poor studies identified by a systematic review provided insufficient evidence to assess music therapy in people with dementia.
- **Nicotine** One systematic review found no RCTs of sufficient quality on the effects of nicotine in people with dementia.
- **Non-steroidal anti-inflammatory drugs** One RCT in people with Alzheimer's disease found no significant difference in cognitive function after 25 weeks' treatment with diclofenac plus misoprostol compared with placebo. Another RCT in people with Alzheimer's disease provided insufficient evidence to compare indometacin versus placebo in people with Alzheimer's disease.
- **Reminiscence therapy** One systematic review provided insufficient evidence to assess reminiscence therapy in people with dementia.

Dementia

- **Selegiline** One systematic review found that, in people with mild to moderate Alzheimer's disease, selegiline for 2–4 months improved cognitive function compared with placebo. It found no significant difference in global clinical state or activities of daily living. RCTs assessing outcomes beyond 4 months found no significant difference between selegiline and placebo.
- **Vitamin E** One RCT in people with moderate to severe Alzheimer's disease found no significant difference in cognitive function after 2 years' treatment with vitamin E compared with placebo. However, it found that vitamin E reduced mortality, institutionalisation, loss of ability to perform activities of daily living, and the proportion of people who developed severe dementia.

Behavioural and psychological symptoms

- **Carbamazepine** One RCT found that carbamazepine reduced agitation and aggression over 6 weeks compared with placebo in people with various types of dementia and behavioural and psychological symptoms.
- **Reality orientation** One systematic review of small RCTs found that reality orientation improved behaviour compared with no treatment in people with various types of dementia.
- **Haloperidol** One systematic review in people with various types of dementia plus behavioural and psychological symptoms found no significant difference in agitation at 6–16 weeks between haloperidol and placebo. However, it found that haloperidol may reduce aggression. It found that haloperidol increased the frequency and severity of extrapyramidal symptoms compared with placebo. Another systematic review in people with various types of dementia plus behavioural and psychological symptoms found limited evidence that haloperidol and risperidone were similarly effective in reducing agitation over 12 weeks but that haloperidol caused more frequent and more severe extrapyramidal symptoms. Two RCTs in people with agitated behaviour associated with dementia found no significant difference in agitation between trazodone and haloperidol, but may have been too small to exclude a clinically important difference.
- **Olanzapine** One RCT identified by a systematic review in nursing home residents with Alzheimer's disease or Lewy body dementia plus behavioural and psychological symptoms found that olanzapine reduced agitation, hallucinations, and delusions over 6 weeks compared with placebo. Olanzapine has been associated with cerebrovascular adverse effects.
- **Risperidone** One systematic review and one subsequent RCT in people with various types of dementia, primarily Alzheimer's disease, all with behavioural and psychological symptoms, found that risperidone improved symptoms over 12 weeks compared with placebo. Another systematic review in people with various types of dementia plus aggressive behaviours found limited evidence that risperidone and haloperidol were similarly effective in reducing agitation over 12 weeks but that risperidone caused fewer and less severe extrapyramidal symptoms. Risperidone has been associated with cerebrovascular adverse events.
- **Sodium valproate** One RCT found that sodium valproate reduced agitation over 6 weeks compared with placebo in people with dementia plus behavioural and psychological problems. Another RCT found no significant difference in aggressive behaviour over 8 weeks between sodium valproate and placebo.

- **Trazodone** We found no RCTs comparing trazodone versus placebo. One small RCT in people with agitated behaviour associated with dementia found no significant difference in agitation over 9 weeks between trazodone and haloperidol. Another small RCT in people with Alzheimer's disease and agitated behaviour found no significant difference in outcomes over 16 weeks among trazodone, haloperidol, behaviour management techniques, and placebo. The RCTs may have been underpowered to detect a clinically important difference.
- **Donepezil; galantamine** RCTs provided inconclusive evidence about the effects of donepezil or galantamine compared with placebo on behavioural and psychiatric symptoms in people with mild to moderate Alzheimer's disease.

DEFINITION

Dementia is characterised by chronic, global, non-reversible impairment of cerebral function. It usually results in loss of memory (initially of recent events), loss of executive function (such as the ability to make decisions or sequence complex tasks), and changes in personality. **Alzheimer's disease** is a type of dementia characterised by an insidious onset and slow deterioration, and involves speech, motor, personality, and executive function impairment. It should be diagnosed after other systemic, psychiatric, and neurological causes of dementia have been excluded clinically and by laboratory investigation. **Vascular dementia** is multi-infarct dementia involving a stepwise deterioration of executive function with or without language and motor dysfunction occurring as a result of cerebral arterial occlusion. It usually occurs in the presence of vascular risk factors (diabetes, hypertension, and smoking). Characteristically, it has a more sudden onset and stepwise progression than Alzheimer's disease. **Lewy body dementia** is a type of dementia involving insidious impairment of executive function with Parkinsonism, visual hallucinations, fluctuating cognitive abilities, and increased risk of falls or autonomic failure.[1,2] Careful clinical examination of people with mild to moderate dementia and the use of established diagnostic criteria accurately identifies 70–90% of cases confirmed at postmortem.[3,4]

INCIDENCE/ PREVALENCE

About 6% of people aged over 65 years and 30% of people aged over 90 years have some form of dementia.[5] Dementia is rare before the age of 60 years. Alzheimer's disease and vascular dementia (including mixed dementia) are each estimated to account for 35–50% of dementia, and Lewy body dementia is estimated to account for up to 20% of dementia in the elderly, varying with geographical, cultural, and racial factors.[1,5–10]

AETIOLOGY/ RISK FACTORS

Alzheimer's disease: The cause of Alzheimer's disease is unclear. A key pathological process is deposition of abnormal amyloid in the central nervous system.[11] Most people with the relatively rare condition of early onset Alzheimer's disease (before age 60 years) show an autosomal dominant inheritance owing to mutations on presenelin or amyloid precursor protein genes. Several genes (*APP*, *PS-1*, and *PS-2*) have been identified. Later onset dementia is sometimes clustered in families, but specific gene mutations have not been identified. Head injury, Down's syndrome, and lower premorbid intellect may be risk factors for Alzheimer's disease. **Vascular dementia** is related to cardiovascular risk factors, such as smoking, hypertension, and diabetes. **Lewy body dementia:** The cause of Lewy body dementia is unknown. Brain acetylcholine

activity is reduced in many forms of dementia, and the level of reduction correlates with cognitive impairment. Many treatments for Alzheimer's disease enhance cholinergic activity.[1,6]

PROGNOSIS

Alzheimer's disease: Alzheimer's disease usually has an insidious onset with progressive reduction in cerebral function. Diagnosis is difficult in the early stages. Average life expectancy after diagnosis is 7–10 years.[10] **Lewy body dementia:** People with Lewy body dementia have an average life expectancy of about 6 years after diagnosis.[5] Behavioural problems, depression, and psychotic symptoms are common in all types of dementia.[12,13] Eventually, most people with dementia find it difficult to perform simple tasks without help.

AIMS OF INTERVENTION

To improve cognitive function (memory, orientation, attention, and concentration); to reduce behavioural and psychological symptoms (wandering, aggression, anxiety, depression, and psychosis); to improve quality of life for both the individual and carer, with minimum adverse effects.

OUTCOMES

Primary outcomes are quality of life, time to institutionalisation or death, functional scores, and scales of cognitive function, global assessment of function and behavioural and psychological symptoms. **Quality of life** of the person with dementia or their carer and **time to institutionalisation or death** are rarely reported because of the short duration of most trials.[14] Functional scores include the Disability Assessment for Dementia, a 40 item scale assessing 10 domains of function,[15] the Instrumental Activities of Daily Living Scale, maximum score 14 (lower scores indicate worse function).[16]

Cognitive symptoms and global assessment of function: Quality of life of the person with dementia and their carer (rarely used in clinical trials). Comprehensive scales of cognitive function (e.g. Alzheimer's Disease Assessment Scale cognitive subscale [ADAS-cog], 70 point scale, lower scores indicate better function;[17] Mini Mental State Examination [MMSE], 30 point scale, lower scores indicate worse function;[18] Clinical Dementia Rating Scale [CDR], 3 point scale assessing six cognitive and functional parameters, higher scores indicate worse function;[14] Alzheimer's Disease Functional Assessment and Change Scale [ADFACS], 7 point scale, higher scores indicate worse function;[14] Severe Impairment Battery, 100 point scale used in people with severe Alzheimer's Disease, lower scores indicate worse function[19]). It has been suggested that ADAS-cog may be more sensitive than MMSE in assessing dementia, but neither scale directly reflects outcomes important to people with dementia or their carers. A 7 point change in the ADAS-cog has been regarded as clinically important. Measures of global state (e.g. Clinical Global Impression of Change [CGI-C] with caregiver input scale; Clinician's Interview Based Impression of Change-Plus [CIBIC-Plus], 7 point scale).

Behavioural and psychological symptoms: Measures of psychiatric symptoms (e.g. Neuropsychiatric Inventory, 120 point scale, higher scores indicate greater difficulties; 12 item caregiver rated scale, maximum score 144, higher scores indicate greater difficulties; Dementia Mood Assessment Scale and Brief Psychiatric Rating Scale, higher scores indicate greater difficulties; Behave-AD scale, scores 0–75, higher scores indicate greater difficulties).

METHODS *Clinical Evidence* search and appraisal June 2003. Dementia is often considered to have two domains of symptoms: cognitive impairment and non-cognitive symptoms (behavioural and psychological symptoms). We have separated the evidence into these two domains because they are often therapeutic targets at different stages of dementia and many RCTs focus on one or other domain of symptoms. In many RCTs, missing data were managed using "last observation carried forward", which does not account for the tendency of people with dementia to deteriorate with time. These RCTs may overestimate the benefit derived from interventions, especially when there are higher withdrawal rates in the intervention arm compared with controls. We found few RCTs in people with types of dementia other than Alzheimer's disease and most trials were placebo controlled rather than comparative.

QUESTION What are the effects of treatments on cognitive symptoms of dementia?

OPTION DONEPEZIL

One systematic review has found that donepezil improves cognitive function and global clinical state at up to 52 weeks compared with placebo in people with mild to moderate Alzheimer's disease. The review found no significant difference in patient rated quality of life at 12 or 24 weeks between donepezil and placebo. One large RCT identified by the review found that donepezil delayed the median time to "clinically evident functional decline" by 5 months compared with placebo. One open label RCT in people with mild to moderate Alzheimer's disease found no significant difference in cognitive function at 12 weeks between donepezil and rivastigmine, although fewer people taking donepezil withdrew from the trial for any cause.

Benefits: **Versus placebo:** We found one systematic review (search date 2003, 16 RCTs of 12, 24, and 52 weeks' duration, 4365 people, most with mild to moderate Alzheimer's disease) comparing donepezil versus placebo.[20] Nine RCTs identified by the review reported results using the Alzheimer's Disease Assessment Scale cognitive subscale (ADAS-cog) or the Clinician's Interview Based Impression of Change-Plus (CIBIC-Plus). The review found that donepezil 10 mg daily significantly improved cognitive function and global clinical state at 24 weeks compared with placebo (see table 1, p 1277). It found no significant difference in patient rated quality of life at 12 or 24 weeks (at 24 weeks: WMD +2.79, 95% CI −2.56 to +8.14).[20] One RCT (24 weeks, 290 people with more severe Alzheimer's disease aged 48–92 years, Mini Mental State Examination [MMSE] score 5–17) identified by the review compared donepezil 5–10 mg daily versus placebo.[21] It found that donepezil significantly improved CIBIC-Plus scores at 24 weeks compared with placebo (mean difference 0.54, CI not reported, results presented graphically; NNT 5, 95% CI 4 to 10 for improved or no change on CIBIC-Plus).[21] Another RCT (431 people with mild to moderate Alzheimer's disease aged 49–94 years, MMSE score 12–20) identified by the review compared donepezil 10 mg daily versus placebo for 1 year.[22] It found that donepezil delayed the

median time to "clinically evident functional decline" by 5 months compared with placebo (median: 357 days with donepezil *v* 208 days with placebo; CI not reported). It found that a significantly higher proportion of people had no "clinically evident functional decline" at 1 year with donepezil compared with placebo (no functional decline: 123/207 [59%] with donepezil *v* 92/208 [44%] with placebo; NNT 7, 95% CI 5 to 17). **Versus rivastigmine:** We found no systematic review. We found one open label RCT (111 people with mild to moderate Alzheimer's disease, MMSE score 10–26) comparing donepezil 5–10 mg daily versus rivastigmine (1.5–6.0 mg twice daily). It found no significant difference in cognitive function at 12 weeks between donepezil and rivastigmine (assessed by clinicians blind to intervention; mean difference in ADAS-cog –0.15, 95% CI –1.47 to +1.71).[23]

Harms: Adverse effects common to all cholinesterase inhibitors include anorexia, nausea, vomiting, and diarrhoea. **Versus placebo:** The RCTs identified by the review found that donepezil was associated with nausea, vomiting, and diarrhoea, which tended to be mild and transient.[20] The review found no difference between donepezil and placebo in the proportion of people who withdrew for any cause (see table 1, p 1277).[20] Long term follow up of people taking donepezil (≤ 10 mg; open label extension) found that 86% experienced at least one adverse effect, often occurring later in the study. Common adverse events included agitation (24%), pain (20%), insomnia (11%), and diarrhoea (9%).[24] **Versus rivastigmine:** The RCT found that fewer people had at least one adverse event with donepezil than with rivastigmine, but the difference was not significant (24/56 [43%] with donepezil *v* 32/55 [58%] with rivastigmine; RR 0.74, 95% CI 0.51 to 1.07). It found that, compared with rivastigmine, donepezil significantly reduced the proportion of people who withdrew from the trial for any cause (6/56 [11%] with donepezil *v* 17/55 [31%] with rivastigmine; RR of withdrawal 0.35, 95% CI 0.15 to 0.81; NNH 5, 95% CI 3 to 20).[23]

Comment: In the RCT identified by the review in people with moderate to severe dementia, "clinically evident functional decline" was defined as a decline of at least 1 point on the Alzheimer's Disease Functional Assessment and Change Scale (ADFACS) or an increase of at least 1 point on the Clinical Dementia Rating Scale.[22] An unblinded extension of one of the RCTs identified by the review observed 133 people taking donepezil 3–10 mg daily for up to 240 weeks.[24] It found that improved cognitive function compared with baseline was present for 38 weeks in people taking donepezil, and throughout the period of observation cognitive function remained above the level estimated had people not been treated. Donepezil is taken once daily; this is a potential advantage over other cholinesterase inhibitors for people with dementia. Improvement usually starts within 2–4 months of starting donepezil. Open label studies should be interpreted with caution but do suggest that the effect of continued treatment is sustained in the long term.[23] We found no RCTs of donepezil in people with Lewy body or vascular dementia.

OPTION GALANTAMINE

RCTs have found that galantamine improves cognitive function and global clinical state over 6 months compared with placebo in people with Alzheimer's disease or vascular dementia.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 7 RCTs)[25] in people with mild to moderate Alzheimer's disease and one additional RCT[26] in people with vascular dementia (see comment below). The review found that, compared with placebo, galantamine (12 or 16 mg twice daily) significantly improved cognitive function (measured by Alzheimer's Disease Assessment Scale cognitive subscale [ADAS-cog] score) and improved global status (measured by Clinician's Interview Based Impression of Change-Plus [CIBIC-Plus] score) over 6 months (see table 1, p 1277). The additional RCT (592 people with vascular dementia or Alzheimer's disease plus cerebrovascular disease) compared galantamine 24 mg daily (396 people) versus placebo (196 people) for 6 months.[26] It found that galantamine significantly improved cognitive function from baseline at 6 months compared with placebo (4 point improvement in ADAS-cog: 35% with galantamine *v* 22% with placebo; NNT 8, 95% CI 5 to 17, absolute numbers not reported). It also found that galantamine significantly improved global clinical state at 6 months compared with placebo (CIBIC-Plus score "improved" or "no change": 74% with galantamine *v* 59% with placebo; NNT for "no change" 7, 95% CI 5 to 15).[26]

Harms: Adverse effects common to all cholinesterase inhibitors include anorexia, nausea, vomiting, and diarrhoea. **Versus placebo:** The review found that galantamine 12–16 mg daily significantly increased the proportion of people who withdrew for any cause over 6 months compared with placebo (see table 1, p 1277). It also found that adverse effects were more frequent with higher doses of galantamine, including nausea (42% with galantamine 16 mg twice daily *v* 25% with placebo: OR 2.2, 95% CI 1.7 to 2.9) and vomiting (21% with galantamine 16 mg twice daily *v* 7% with placebo; OR 3.2, 95% CI 2.1 to 4.5). It also found that higher doses of galantamine increased the proportion of people who discontinued treatment because of adverse effects over 6 months (27% with galantamine 16 mg twice daily *v* 15% with galantamine 12 mg twice daily *v* 8% with placebo; 16 mg twice daily *v* placebo: OR 3.3, 95% CI 2.5 to 4.3).[25] The additional RCT comparing galantamine versus placebo in people with vascular dementia found that more people taking galantamine withdrew because of adverse effects (20% with galantamine *v* 8% with placebo; CI not reported).[26]

Comment: We found no RCTs of galantamine in people with Lewy body dementia.

OPTION RIVASTIGMINE

One systematic review and one additional RCT have found that rivastigmine improves cognitive function in people with Alzheimer's disease or Lewy body dementia compared with placebo, but adverse

effects such as nausea, vomiting, and anorexia are common. Subgroup analysis from one RCT in people with Alzheimer's disease suggests that people with vascular risk factors may respond better to rivastigmine than those without. One open label RCT in people with mild to moderate Alzheimer's disease found no significant difference in cognitive function at 12 weeks between rivastigmine and donepezil, although more people taking rivastigmine withdrew from the trial for any cause.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 4 RCTs, 12 or 26 weeks' duration, 3370 people with mild to moderate Alzheimer's disease)[27] and one additional RCT[28] in people with Lewy body dementia (see comment below). The review found that rivastigmine (6–12 mg twice daily) produced small but significant improvements in cognitive function global clinical state over 26 weeks compared with placebo (see table 1, p 1277). A subgroup analysis of an RCT[29] identified by the review[27] (699 people with Alzheimer's disease) comparing rivastigmine 1–4 mg daily or 6–12 mg daily versus placebo over 26 weeks found that people with vascular risk factors responded better than those without (mean Alzheimer's Disease Assessment Scale cognitive subscale difference –2.3). The additional RCT (120 people with Lewy body dementia) found that rivastigmine (dose titrated to 6 mg twice daily) significantly improved a computerised psychometric measure of cognitive function at 20 weeks compared with placebo (intention to treat analysis; P = 0.05; no further data reported) and improved a global measure of behavioural function (NNT for at least 30% improvement on Neuropsychiatric Inventory score 3, 95% CI 2 to 6).[28] **Versus donepezil:** See benefits of donepezil, p 1255.

Harms: Adverse effects common to all cholinesterase inhibitors include anorexia, nausea, vomiting, and diarrhoea. **Versus placebo:** The systematic review in people with Alzheimer's disease found that rivastigmine increased the proportion of people who discontinued treatment for any cause compared with placebo (see table 1, p 1277).[27] The RCT in people with Lewy body dementia found that rivastigmine increased the proportion of people who had nausea compared with placebo (37% with rivastigmine *v* 22% with placebo), vomiting (25% with rivastigmine *v* 15% with placebo), anorexia (19% with rivastigmine *v* 10% with placebo), and somnolence (9% with rivastigmine *v* 5% with placebo; no further data reported).[28] **Versus donepezil:** See harms of donepezil, p 1256.

Comment: We found no RCTs of rivastigmine in people with vascular dementia.

OPTION PHYSOSTIGMINE

One RCT in people with Alzheimer's disease found limited evidence that slow release physostigmine improved cognitive function over 12 weeks compared with placebo but adverse effects, including nausea, vomiting, diarrhoea, dizziness, and stomach pain, were common.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 15 RCTs) comparing physostigmine versus placebo in people mild to severe Alzheimer's disease (see comment below).[30] The RCTs differed widely in the preparations of physostigmine used, and most had weak reporting methods so the review could not perform

a meta-analysis. Four were small trials of intravenous physostigmine, which did not report quantitative results. Seven were small trials (131 people, 6 crossover design) of standard oral preparation. The crossover trials did not provide results before crossover. One RCT (16 people) found no significant difference in cognition between oral physostigmine and placebo but it is likely to have been too small to exclude a clinically important difference. Four RCTs (1456 people) used controlled release preparations, but three of these reported results only for people who responded to physostigmine in a prestudy titration phase (see comment below). One RCT (170 people) found that slow release physostigmine 27 mg daily significantly improved cognition after 12 weeks compared with placebo (Alzheimer's Disease Assessment Scale cognitive subscale: WMD–2.0, 95% CI –3.6 to –0.5). It did not significantly improve activities of daily living or Clinician Based Impression of Change.

Harms: **Versus placebo:** Common adverse effects of physostigmine include nausea, vomiting, diarrhoea, dizziness, and stomach pain. In RCTs that randomised all people with Alzheimer's disease rather than selecting those who tolerated and responded to physostigmine, withdrawals were more common with physostigmine (234/358 [65%] with physostigmine *v* 31/117 [26%] with placebo; OR 4.80, 95% CI 3.17 to 7.33).[30]

Comment: We found no RCTs of physostigmine in people with Lewy body or vascular dementia. Physostigmine is a sympathomimetic drug and has a short half life. Screening out non-responders to a drug before the trial is likely to overestimate its effectiveness.

OPTION TACRINE

Two systematic reviews found limited evidence that tacrine improved cognitive function and global state at 3–36 weeks compared with placebo in people with Alzheimer's disease, but adverse effects, including nausea and vomiting, diarrhoea, anorexia, and abdominal pain, were common.

Benefits: **Versus placebo:** We found two systematic reviews comparing tacrine versus placebo in people with Alzheimer's disease (search date not reported, 12 RCTs, 1984 people;[31] search date 1997, 21 RCTs, including all 12 RCTs identified by the first review, 3555 people[32]). Various doses of tacrine were used in the RCTs, and the duration of treatment varied from 3–36 weeks. The first review found that, compared with placebo, tacrine significantly increased the proportion of people with overall clinical improvement (OR 1.58, 95% CI 1.18 to 2.11) and improved cognition (Mini Mental State Examination [MMSE] at 12 weeks: SMD 0.77, 95% CI 0.35 to 1.20; Alzheimer's Disease Assessment Scale cognitive subscale [ADAS-cog] at 12 weeks: SMD –2.7, 95% CI –1.36 to –2.78).[31] A subsequent subgroup analysis indicated that the five non-industry sponsored studies found no significant effect between tacrine and placebo, but most (6/7 [86%]) manufacturer supported studies found clinical benefit (1 RCT could not be located for inclusion in the

subgroup analysis).[33] The second review assessed the methods and quality of tacrine RCTs and did not perform a meta-analysis.[32] It suggested that tacrine improved cognitive function in about 20% of people (improvement of 3–4 points in MMSE Scale score or ADAS-cog).

Harms: **Versus placebo:** The first review found that tacrine significantly increased the proportion of people who withdrew because of adverse effects, primarily elevated liver enzymes, compared with placebo (OR for withdrawal 3.6, 95% CI 2.8 to 4.7).[31] One RCT identified by the reviews found that tacrine 40–180 mg daily significantly increased withdrawals because of adverse events compared with placebo (265/479 [55%] with tacrine *v* 20/184 [11%] with placebo; RR 5.1, 95% CI 3.3 to 7.7; NNH 3, 95% CI 2 to 3), and that reversible elevation of liver enzymes was found in 133/265 (50%) of people taking tacrine.[34] Common adverse events included nausea and vomiting (35% with 160 mg daily), diarrhoea (18%), anorexia (12%), and abdominal pain (9%).

Comment: The reviews suggested that the quality of tacrine RCTs was generally poor.[31,32] We found no RCTs of tacrine in people with Lewy body or vascular dementia.

OPTION LECITHIN

Small, poor RCTs identified by a systematic review provided insufficient evidence to assess lecithin in people with Alzheimer's disease.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 12 RCTs, 265 people with Alzheimer's disease, 21 with Parkinsonian dementia, 90 with subjective memory problems) comparing lecithin versus placebo (see comment below).[35] It found no significant difference between lecithin and placebo in cognition (1 RCT, 37 people, OR 0.91, 95% CI 0.25 to 3.34), functional performance (1 RCT, 30 people, WMD +0.76, 95% CI –0.91 to +2.43), or global impression (2 RCTs, 17/24 [71%] with lecithin *v* 12/28 [43%] with placebo; OR 3.01, 95% CI 0.92 to 9.81; see comment below).[35]

Harms: **Versus placebo:** The review found that adverse effects were more common with lecithin (14/34 [41%] with lecithin *v* 3/29 [10%] with placebo; OR 6.1, 95% CI 1.5 to 24.0).[35] The specific nature of the adverse effects was not stated.

Comment: One RCT (included in the systematic review) comparing lecithin versus placebo in people with minimal cognitive impairment found that some components of cognition were significantly better in the placebo group.[35] Most studies of lecithin were small and weak. Meta-analysis in the systematic review was hampered by diverse outcome criteria and it is likely that the meta-analyses were underpowered to detect a clinically important difference in outcomes. We found no RCTs of lecithin in people with Lewy body or vascular dementia.

OPTION NICOTINE

One systematic review found no RCTs of sufficient quality on the effects of nicotine in people with dementia.

Benefits: One systematic review (search date 2001) found no RCTs of sufficient quality.[36]

Harms: We found no RCTs.

Comment: None.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One RCT in people with Alzheimer's disease found no significant difference in cognitive function after 25 weeks' treatment with diclofenac plus misoprostol compared with placebo. Another RCT in people with Alzheimer's disease provided insufficient evidence to compare indometacin versus placebo in people with Alzheimer's disease.

Benefits: **Versus placebo:** We found two RCTs in people with Alzheimer's disease (see comment below).[37,38] The first RCT (41 people with Alzheimer's disease) found no significant difference in cognitive function after 25 weeks' treatment with diclofenac plus misoprostol compared with placebo (Alzheimer's Disease Assessment Scale cognitive subscale [ADAS-cog] score: mean difference +1.14, 95% CI −2.90 to +5.20) or global status (Clinician's Interview Based Impression of Change score: +0.24, 95% CI −0.26 to +0.74).[37] The second RCT (44 people with mild to moderate Alzheimer's disease) found that indometacin (indomethacin) (≤ 150 mg daily) for 6 months significantly improved cognitive function compared with placebo (assessed by averaging percentage changes in scores on Mini Mental State Examination Scale, ADAS-cog, Boston Naming Test, and Token Test; mean increase 1.3% with indometacin *v* mean reduction 8.4% with placebo; results not intention to treat, 16/44 [36%] withdrew from the trial).[38]

Harms: See non-steroidal anti-inflammatory drugs, p 1551. In one RCT, more people withdrew by week 25 with diclofenac plus misoprostol than with placebo (12/24 [50%] with diclofenac plus misoprostol *v* 2/17 [12%] with placebo).[37] No serious drug related adverse events were reported.[37] In the RCT of indometacin, 21% of people on indometacin withdrew because of gastrointestinal symptoms.[38]

Comment: We found one systematic review of aspirin for vascular dementia (search date 2000), which identified no RCTs.[39] Earlier versions of a systematic review of aspirin in vascular dementia included one RCT (70 people), which was subsequently removed because of inadequate quality, including a lack of placebo control.[39] We found no RCTs of NSAIDs in people with Lewy body dementia.

OPTION OESTROGEN

One systematic review has found that, in postmenopausal women with mild to moderate Alzheimer's disease, oestrogen improves cognition over 7 weeks to 12 months' treatment compared with placebo or no treatment but there is concern that oestrogen treatment may increase the risk of developing breast cancer and cardiovascular events.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 8 RCTs, 313 women with mild to moderate Alzheimer's disease aged over 56 years) comparing oestrogen 0.625–1.25 mg

daily versus placebo or no treatment for 7 weeks to 12 months (see comment below).[40] The review found that oestrogen improved cognitive function compared with placebo or no treatment (5 RCTs, Mini Mental State Examination: WMD 2.3, 95% CI 1.7 to 3.4).

Harms: There is concern that oestrogen treatment may increase the risk of developing breast cancer and cardiovascular events (see harms of hormone replacement therapy under secondary prevention of ischaemic cardiac events, p 197).

Comment: Most RCTs in the review were small and heterogeneity may have distorted the results of the meta-analysis. We found no RCTs of oestrogen in people with Lewy body or vascular dementia. A meta-analysis of 14 observational studies (5990 people, length of follow up not stated) found that hormone replacement therapy is associated with a lower risk of developing dementia (dementia in 13% with hormone replacement therapy *v* 21% with controls; RR 0.56, 95% CI 0.46 to 0.68).[40] Observational studies provide only indirect evidence; the observed association may be explained by confounders (e.g. educational level, lifestyle factors).

OPTION SELEGILINE

One systematic review found that, in people with mild to moderate Alzheimer's disease, selegiline for 2–4 months improved cognitive function compared with placebo. It found no significant difference in global clinical state or activities of daily living. RCTs assessing outcomes beyond 4 months found no significant difference between selegiline and placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 17 RCTs) comparing selegiline versus placebo in people with mild to moderate Alzheimer's disease.[41] It found that, compared with placebo, selegiline 10 mg daily for 2–4 months significantly improved cognitive function (measured by various parameters: 11 RCTs, 866 people: WMD 2.40, 95% CI 0.06 to 4.74). It found no significant difference in global clinical state (5 RCTs, 275 people: WMD –0.03, 95% CI –0.13 to +0.07) or in activities of daily living (7 RCTs, 810 people: WMD –0.17, 95% CI –0.35 to 0). RCTs assessing outcomes beyond 4 months found no significant difference between selegiline and placebo.

Harms: **Versus placebo:** The RCTs identified by the first review found a similar proportion of adverse effects (anxiety, agitation, dizziness, nausea, dyspepsia) between selegiline and placebo.[41]

Comment: Many of the RCTs identified by the review were small and brief.[41] They used a variety of outcomes, making meta-analysis and comparison with other treatments difficult. Although selegiline may cause short term improvement, the improvement in cognition seems marginal and may not be of clinical importance. There is no evidence of long term benefit. We found no RCTs of selegiline in people with Lewy body or vascular dementia.

OPTION **MEMANTINE** New

One systematic review has found that memantine improves cognitive function at 12–28 weeks compared with placebo in people with mild to moderate vascular dementia. Subsequent RCTs have found that memantine improves global clinical outcome and reduces care dependence at 12–28 weeks in people with more severe Alzheimer's disease or vascular dementia.

Benefits:

Versus placebo: We found one systematic review[42] and two subsequent RCTs[43,44] comparing memantine versus placebo. The review (search date 2002, 7 RCTs, 1532 people) did not meta-analyse many results because of differences in people included and in dose of memantine taken in the RCTs.[42] Two RCTs (154 people) included in the review were of poor quality and data are not reported here (see comment below). The review identified two RCTs (900 people with mild to moderate vascular dementia, Mini Mental State Examination [MMSE] score 10–22). They found that, compared with placebo, memantine significantly improved cognitive function at 28 weeks (measured by Alzheimer's Disease Assessment Scale cognitive subscale [ADAS-cog]: WMD –2.19, 95% CI –1.21 to –3.16; results not intention to treat). They found no significant difference in global clinical state (measured by Gottsfries-Brane-Steen scale: 2 RCTs, 595 people: WMD –1.81, 95% CI –4.21 to +0.58). Subgroup analysis in one of the RCTs identified by the review suggested that the largest treatment effect occurred in people with baseline MMSE scores of less than 15 (mean difference 3.17 points, P = 0.04) and in people without cerebrovascular macrolesions (mean difference 2.29 points; P = 0.002).[45] The first subsequent RCT (166 people with Alzheimer's disease [49%] or vascular dementia [51%], MMSE < 10, Global Deterioration Scale stages 5–7) found that memantine 10 mg daily significantly increased the proportion of people with improved global clinical outcome at 12 weeks compared with placebo (measured by Clinical Global Impression of Change; 60/82 [73%] with memantine *v* 38/84 [45%] with placebo; RR 1.62, 95% CI 1.24 to 2.12; NNT 4, 95% CI 3 to 7). It also found that memantine significantly reduced care dependence compared with placebo (measured by a Behavioural Rating Scale for Geriatric Patients [BGP] care dependence subscore: mean difference 2.0 points, CI not reported; P = 0.016).[43] The second subsequent RCT (252 people with moderate to severe Alzheimer's disease) found that memantine 20 mg daily for 28 weeks significantly improved cognitive function compared with placebo (measured by the Severe Impairment Battery [SIB]; WMD 6.10, 95% CI 2.99 to 9.21), and activities of daily living (measured by the Activities of Daily Living Scale: WMD 2.1, 95% CI 0.5 to 3.7; results not intention to treat; 71 [28%] people withdrew from the trial).[44] A resource utilisation analysis based on this RCT found that people taking memantine required significantly less caregiver time compared with people taking placebo (mean difference –52 hours/month, 95% CI –95 hours/month to –7 hours/month).[46]

Harms: The review found no significant difference between memantine and placebo in the proportion of people who had at least one adverse effect (2 RCTs, 351/460 [76%] with memantine *v* 327/440 [74%] with placebo; OR 1.11, 95% CI 0.82 to 1.51).[42] The subsequent RCTs also found that a similar proportion of people taking memantine and placebo had adverse effects.[44,46]

Comment: The methods of two memantine RCTs identified by the review were poor (follow up of 6 weeks, lack of blinding, unclear randomisation procedures, lack of intention to treat analysis, lack of ethics approval) and we have not reported the data here.[47,48] Memantine is a partial N-methyl-D-aspartate antagonist and has a different mechanism of action to cholinesterase inhibitors. Current evidence suggests it is well tolerated and may improve outcomes, especially in people with more severe dementia. However, it is difficult to compare memantine with cholinesterase inhibitors as most memantine RCTs are in people with more severe dementia and report different outcomes. Evidence for its use in mild to moderate dementia is inconclusive and more high quality trials are needed. We found no RCTs of memantine in people with Lewy body dementia.

OPTION GINKGO BILOBA

RCTs found limited evidence that ginkgo biloba improved cognitive function over 24–26 weeks compared with placebo in people with Alzheimer's disease or vascular dementia.

Benefits: **Versus placebo:** We found one systematic review (search date 2002) comparing ginkgo biloba versus placebo in people with cognitive impairment, Alzheimer's disease, or vascular dementia (see comment below).[49] Trial duration ranged from 3–53 weeks, doses and preparations of ginkgo biloba varied widely, and diverse outcomes were assessed, making meta-analysis difficult.[49] The review included two large RCTs in people with Alzheimer's disease or vascular dementia. The first large RCT (216 people with mild to moderate Alzheimer's disease or vascular dementia) found that ginkgo biloba (≥ 200 mg daily) significantly increased the proportion of people who were rated as improved at 24 weeks (completer analysis: improvement in Clinician's Interview Based Impression of Change [criteria for improvement not defined] 57/79 [72%] with ginkgo biloba *v* 42/77 [55%] with placebo; RR 1.32, 95% CI 1.03 to 1.69).[49] The second large RCT (327 people, 236 people with Alzheimer's disease) had a high withdrawal rate; 137/309 (44%) people withdrew from the trial.[50] However, it provided an intention to treat analysis. It found that, in people with Alzheimer's disease, ginkgo biloba significantly improved cognition (intention to treat analysis for people with Alzheimer's disease, change in Alzheimer's Disease Assessment Scale cognitive subscale score [ADAS-cog]: –1.7, 95% CI –3.1 to –0.20; NNT for 4 point change in ADAS-cog: 8, 95% CI 5 to 50) and caregiver assessed improvement over 26 weeks compared with placebo (change in Geriatric Evaluation by Relative's Rating Instrument score: –0.16, 95% CI –0.25 to –0.06). It found no significant difference in mean Clinician's Global Impression of Change score (change in score: +0.1, 95% CI –0.1 to +0.2).[50]

Harms: The review found no significant difference between ginkgo biloba and placebo in the proportion of people who had at least one adverse effect (adverse effects not specified; 5 RCTs, 1070 people; 117/591 [19.7%] with ginkgo biloba *v* 59/471 [12.5%] with placebo; RR 0.95, 95% CI 0.72 to 1.26).[49]

Comment: Many of the RCTs in the review included people with memory and cognitive impairment other than dementia so the results of the meta-analysis may not be fully generalisable to people with Alzheimer's disease or vascular dementia. We found no RCTs of ginkgo biloba in people with Lewy body dementia. Preparations of ginkgo biloba available without prescription differ in terms of purity and concentration of active ingredients compared with high purity extract (EGb 761) used in most RCTs.

OPTION VITAMIN E

One RCT in people with moderate to severe Alzheimer's disease found no significant difference in cognitive function between vitamin E and placebo after 2 years' treatment. However, it found that vitamin E reduced mortality, institutionalisation, loss of ability to perform activities of daily living, and the proportion of people who developed severe dementia.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 1 multicentre RCT, 169 people with moderate to severe Alzheimer's disease; see comment below).[51] The RCT compared four treatments: vitamin E (α-tocopherol; 2000 IU daily); selegiline; vitamin E plus selegiline; or placebo.[52] It found no significant difference in cognitive function with high dose vitamin E alone for 2 years compared with placebo (measured by the cognitive portion of the Alzheimer's Disease Assessment Scale, lower scores indicate worse function: mean reduction in score 8.3 with vitamin E *v* 6.7 with placebo; reported as non-significant; no further details reported; see comment below). It found that vitamin E significantly increased event free survival compared with placebo (defined as death, survival until institutionalisation, loss of ability to perform activities of daily living, or severe dementia [clinical dementia rating of 3]; OR 0.49, 95% CI 0.25 to 0.96).[52]

Harms: **Versus placebo:** The RCT found no significant difference in adverse effects between placebo and vitamin E.[52] Other studies have found weak evidence of associations between high dose vitamin E and bowel irritation, headache, muscular weakness, visual complaints, vaginal bleeding, bruising, thrombophlebitis, deterioration of angina pectoris, worsening of diabetes, syncope, and dizziness.[53]

Comment: The groups in the RCT identified by the review were not matched evenly at baseline: the placebo group had a higher mean Mini Mental State Examination score, and these baseline scores were a significant predictor of outcome.[52] Attempts to correct for this imbalance suggested that vitamin E might increase mean survival, but the need for statistical adjustments weakens the strength of this conclusion. We found no RCTs of vitamin E in people with Lewy body or vascular dementia.

OPTION MUSIC THERAPY

Poor studies identified by a systematic review provided insufficient evidence to assess music therapy in people with dementia.

Benefits: **Versus control:** We found one systematic review of music therapy (search date 1998, 21 studies, 336 people with various types of dementia).[54] It included studies with weak methods and found that music therapy significantly improved cognitive and behavioural outcomes compared with control interventions (mean effect size 0.79, 95% CI 0.62 to 0.95; see comment below). Significant effects were noted with different types of music therapy (active *v* passive, taped *v* live).

Harms: **Versus control:** The systematic review gave no information on harms.[54]

Comment: The primary studies lacked adequate controls, had potential for bias, used diverse interventions, and used inadequate outcome measures. Although one meta-analysis found significant benefits for music therapy on pooling the results of many studies, further high quality studies are needed to clarify whether the results are explained by a true effect or by bias. A previous Cochrane systematic review of music therapy has been withdrawn.[55]

OPTION REALITY ORIENTATION

One systematic review of small RCTs found that reality orientation improved cognitive function compared with no treatment in people with various types of dementia.

Benefits: **Versus no treatment:** We found one systematic review (search date 2000, 6 RCTs, 125 people with various types of dementia).[56] The RCTs compared reality orientation (see glossary, p 1273) versus no treatment and used different measures of cognition. The review found that reality orientation significantly improved cognitive function score compared with no treatment (SMD –0.59, 95% CI –0.95 to –0.22). No separate analysis was done for specific types of dementia.

Harms: **Versus no treatment:** The RCTs gave no information on adverse effects.[56]

Comment: The RCTs did not use standardised interventions or outcomes.[56]

OPTION REMINISCENCE THERAPY

RCTs provided insufficient evidence to assess reminiscence therapy in people with dementia.

Benefits: We found one systematic review of reminiscence therapy (see glossary, p 1273) (search date 2000, 2 RCTs, 42 people).[57] Analysis of pooled data was hindered by poor trial methods, diverse outcomes, and no separation of data for different types of dementia.

Harms: We found no RCTs.

Comment: None.

QUESTION **What are the effects of treatments on behavioural and psychological symptoms of dementia?**

OPTION **HALOPERIDOL**

One systematic review in people with various types of dementia plus behavioural and psychological symptoms found no significant difference in agitation at 6–16 weeks between haloperidol and placebo. However, it found that haloperidol may reduce aggression. It found that haloperidol increased the frequency and severity of extrapyramidal symptoms compared with placebo. Another systematic review in people with various types of dementia plus behavioural and psychological symptoms found limited evidence that haloperidol and risperidone were similarly effective in reducing agitation over 12 weeks but that haloperidol caused more frequent and more severe extrapyramidal symptoms. Two RCTs in people with agitated behaviour associated with dementia found no significant difference in agitation between trazodone and haloperidol, but may have been too small to exclude a clinically important difference.

Benefits:

Versus placebo: We found one systematic review (search date 2000, 5 RCTs) comparing haloperidol versus placebo in people with various types of dementia, including Alzheimer's disease and vascular dementia, all with behavioural and psychological symptoms.[58] It found no significant difference in agitation at 6–16 weeks between haloperidol and placebo (4 RCTs, 369 people, change in symptoms from baseline measured by the Cohen-Mansfield Agitation Inventory or the psychomotor score of the Behavioural Symptoms Scale for Dementia [BSSD]; WMD −0.45, 95% CI −1.43 to +0.53). However, it found that haloperidol significantly reduced aggression from baseline at 3–6 weeks compared with placebo (4 RCTs, 489 people, change in symptoms from baseline measured by Multidimensional Observation Scale for Elderly Subjects aggression subscore, Behave-AD scale, aggression subscore, or the physical aggression score of the BSSD; WMD −0.92, 95% CI −1.75 to −0.09).[58] **Versus risperidone:** We found one systematic review (search date 2002, 2 RCTs, 402 people with Alzheimer's disease, vascular dementia, or mixed dementia, all with behavioural and psychological symptoms) comparing haloperidol versus risperidone for 12 weeks.[59] The reviewers could not perform a meta-analysis because of differences in outcomes assessed and people included in the trials (outpatients and people in hospital). The first RCT (58 people) identified by the review found no significant difference in agitation over 12 weeks between haloperidol and risperidone (measured by Cohen-Mansfield Agitation Inventory and Behave-AD scale; reported as non-significant; no further data reported). The second RCT (344 people) identified by the review compared three interventions: haloperidol, risperidone, and placebo. It found that a similar proportion of people taking haloperidol or risperidone had improvements in agitation (63% with haloperidol *v* 54% with risperidone; CI not reported). **Versus trazodone:** See benefits of trazodone, p 1271.

Harms: **Versus placebo:** The review found that haloperidol (> 2 mg daily) significantly increased the proportion of people who had at least one extrapyramidal symptom or who withdrew because of adverse effects over 3–6 weeks (extrapyramidal symptom: OR 2.34, 95% CI 1.25 to 4.38; withdrawal: OR 2.99, 95% CI 1.26 to 7.10).[58] One study (2 year prospective, longitudinal, 71 people with dementia) found that the mean decline in cognitive scores in 16 people who took antipsychotics was twice that of people who did not (expanded Mini Mental State Examination: 21 with antipsychotics *v* 9 with no antipsychotics; P = 0.002).[60] **Versus risperidone:** The first RCT identified by the review did not compare adverse effects between haloperidol and risperidone directly. The second RCT found that haloperidol significantly increased frequency and severity of extrapyramidal symptoms compared with risperidone (frequency: 22% with risperidone *v* 15% with risperidone; P = 0.023; severity: measured by Extrapyramidal Symptoms Rating Scale score: mean +1.6 with haloperidol *v* –0.3 with risperidone; P < 0.05).[59] **Versus trazodone:** See harms of trazodone, p 1271.

Comment: High response rates with placebo indicate that many behavioural problems resolve spontaneously in the short term. Most people with dementia are sensitive to adverse effects from antipsychotics, especially sedation and extrapyramidal symptoms. People with Lewy body dementia are particularly sensitive to these adverse effects,[61] suggesting that antipsychotics have a poor balance of benefits and harms in people with Lewy body dementia. More studies are needed to determine whether newer atypical antipsychotics have a better ratio of benefits to harms than older antipsychotics.

OPTION OLANZAPINE

One RCT identified by a systematic review in nursing home residents with Alzheimer's disease or Lewy body dementia plus behavioural and psychological symptoms found that olanzapine reduced agitation, hallucinations, and delusions over 6 weeks compared with placebo. Olanzapine has been associated with cerebrovascular adverse effects.

Benefits: **Versus placebo:** We found one systematic review[59] (search date 2002), which identified one RCT[62] (double blind, 6 weeks' duration, 206 elderly US nursing home residents with Alzheimer's disease [177 people] or Lewy body dementia [29 people], all with psychotic or behavioural symptoms). The RCT compared olanzapine (given as a fixed dose of 5, 10, or 15 mg daily) versus placebo.[62] It found that agitation, hallucinations, and delusions were improved by the two lower doses but not by the highest dose of olanzapine compared with placebo (subscale of the Neuropsychiatric Inventory [nursing home version; higher scores indicate worse function]: –7.6 with olanzapine 5 mg *v* –6.1 with olanzapine 10 mg *v* –4.9 with olanzapine 15 mg *v* –3.7 with placebo).

Harms: **Versus placebo:** The RCT found that olanzapine increased sedation (25% with olanzapine 5 mg *v* 26% with olanzapine 10 mg *v* 36% with olanzapine 15 mg *v* 6% with placebo) and gait disturbance compared with placebo (20% with olanzapine 5 mg *v* 14% with olanzapine 10 mg *v* 17% with olanzapine 15 mg *v* 2% with placebo).[62]

Comment: See comment of haloperidol, p 1268. Following the suggestion of an association between olanzapine and cerebrovascular adverse events, the Food and Drugs Administration in the USA and the Committee on Safety of Medicines in the UK have issued an alert that risperidone has not been shown to be safe in people with psychosis associated with dementia.[65,74]

OPTION RISPERIDONE

One systematic review and one subsequent RCT in people with various types of dementia, primarily Alzheimer's disease, all with behavioural and psychological symptoms, found that risperidone improved symptoms over 12 weeks compared with placebo. Another systematic review in people with various types of dementia plus aggressive behaviours found limited evidence that risperidone and haloperidol were similarly effective in reducing agitation over 12 weeks but that risperidone caused fewer and less severe extrapyramidal symptoms. Risperidone has been associated with cerebrovascular adverse events.

Benefits: **Versus placebo:** We found one systematic review[59] and one subsequent RCT.[63] The review (search date 2002, 2 RCTs, 969 people with Alzheimer's disease [67–73%], vascular dementia, or mixed dementia, all with behavioural symptoms, 56–68% women) compared risperidone versus placebo for 12 weeks.[59] It found that risperidone modestly but significantly improved behavioural and psychological symptoms over 12 weeks compared with placebo (measured by Behave-AD scale: mean difference with risperidone *v* placebo –1.80, 95% CI –3.22 to –0.38).[59] The subsequent RCT (167 people with Alzheimer's disease, vascular dementia, or mixed dementia, all with aggressive behaviours, mean age 83 years, 72% women) compared risperidone (mean 0.95 mg daily) versus placebo over 12 weeks.[63] It also found that risperidone significantly improved behavioural and psychological symptoms over 12 weeks compared with placebo (mean difference with risperidone *v* placebo measured by Behave-AD scale –4.50, 95% CI –6.45 to –2.46; measured by the Cohen-Mansfield Agitation Inventory aggression subscale –4.4, 95% CI –6.75 to –2.07). **Versus haloperidol:** See benefits of haloperidol, p 1267.

Harms: **Versus placebo:** The review found that risperidone was associated with increases in extrapyramidal symptoms, somnolence, and mild peripheral oedema (no further data reported).[59] Adverse effects increased with higher doses. Data from four RCTs (1230 elderly people with dementia) of risperidone suggested that risperidone was associated with an increase in cerebrovascular adverse events (including strokes and transient ischaemic attacks, some of which were fatal) compared with placebo (29/764 [4%] with risperidone *v* 7/466 [2%] with placebo; CI not reported; see comment below).[64] **Versus haloperidol:** See harms of haloperidol, p 1268.

Comment: See comment of haloperidol, p 1268. Following the suggestion of an association between risperidone and cerebrovascular adverse events, the Food and Drugs Administration in the USA and the Committee on Safety of Medicines in the UK have issued an alert that risperidone has not been shown to be safe in people with psychosis associated with dementia.[65,74]

OPTION CARBAMAZEPINE

One RCT found that carbamazepine reduced agitation and aggression over 6 weeks compared with placebo in people with various types of dementia and behavioural and psychological symptoms.

Benefits: **Versus placebo:** We found no systematic review but found one RCT (single blind, 51 nursing home patients with agitation and Alzheimer's disease, vascular dementia, or mixed Alzheimer's disease and vascular dementia, 6 weeks' duration) comparing carbamazepine (individualised doses; modal dose 300 mg; mean serum level 5.3 μg/mL) versus placebo.[66] It found that carbamazepine significantly improved a measure of agitation and aggression (assessed by change in mean total Brief Psychiatric Rating Scale score: mean reduction 7.7 with carbamazepine *v* 0.9 with placebo; P = 0.03).

Harms: **Versus placebo:** The RCT found that adverse effects were significantly more common with carbamazepine than with placebo (16/27 [59%] with carbamazepine *v* 7/24 [29%] with placebo; P = 0.003). These were considered clinically important in two cases: one person with tics and one person with ataxia. Carbamazepine in the elderly may cause cardiac toxicity. See also epilepsy, p 1655.

Comment: We found no RCTs of carbamazepine in people with Lewy body dementia.

OPTION SODIUM VALPROATE

One RCT found that sodium valproate reduced agitation over 6 weeks compared with placebo in people with dementia plus behavioural and psychological problems. Another RCT found no significant difference in aggressive behaviour over 8 weeks between sodium valproate and placebo.

Benefits: **Versus placebo:** We found no systematic review but found two RCTs.[67,68] The first RCT (single blind, 56 people in nursing homes with Alzheimer's disease or vascular dementia, all with agitation) compared sodium valproate versus placebo for 6 weeks.[67] It found that when several covariates were taken into account, sodium valproate significantly improved agitation and aggression compared with placebo (measured by Brief Psychiatric Rating Scale score; P = 0.05 only after adjustment) and a measure of global status (Clinical Global Impression rating: 68% with sodium valproate *v* 52% with placebo; P = 0.06). The second RCT (43 people with various types of dementia plus behavioural problems, crossover design) comparing sodium valproate 480 mg daily versus placebo

for 3 weeks found no significant difference in aggressive behaviour over 8 weeks after crossover (mean change in Social Dysfunction and Aggression Scale-9 score –0.72 with sodium valproate *v* –0.72 with placebo; P = 0.99).[68] The RCT did not report results before crossover.

Harms: **Versus placebo:** The first RCT found that adverse effects, generally rated as mild, were significantly more common with sodium valproate than with placebo (68% with sodium valproate *v* 33% with placebo; P = 0.003).[67] See also epilepsy, p 1655.

Comment: The need to perform adjustments for covariates in the first RCT weakens the findings.[67]

OPTION TRAZODONE

We found no RCTs comparing trazodone versus placebo. One small RCT in people with agitated behaviour associated with dementia found no significant difference in agitation over 9 weeks between trazodone and haloperidol. Another small RCT in people with Alzheimer's disease and agitated behaviour found no significant difference in outcomes over 16 weeks among trazodone, haloperidol, behaviour management techniques, and placebo. The RCTs may have been underpowered to detect a clinically important difference.

Benefits: **Versus placebo:** We found not RCTs. **Versus haloperidol:** We found no systematic review but found two RCTs.[69,70] The first RCT (double blind, 28 elderly people with agitated behaviour associated with Alzheimer's disease, vascular dementia, or mixed Alzheimer's disease and vascular dementia, 9 weeks' duration) compared trazodone 50–250 mg daily versus haloperidol 1–5 mg daily.[69] It found no significant difference in agitation between the groups, but the trial was too small to exclude a clinically important difference. The second RCT (double blind, 149 people with Alzheimer's disease and agitated behaviours, 16 weeks' duration) compared four treatments: haloperidol (mean dose 1.1 mg daily); trazodone (mean dose 200 mg daily); behaviour management techniques; or placebo.[70] It found no significant difference in outcome (Alzheimer's Disease Co-operative Study Clinical Global Impression of Change) between the four interventions, but it may have been too small to exclude a clinically important difference.

Harms: **Versus haloperidol:** In the first RCT, adverse effects were more common in the group treated with haloperidol than trazodone.[69] In the second RCT, no significant differences in adverse events were seen between the trazodone group and the placebo group.[70]

Comment: None.

OPTION DONEPEZIL

One RCT found that donepezil improved functional and behavioural symptoms at 24 weeks compared with placebo. Two RCTs found no significant difference in psychiatric symptoms at 6 months to 1 year between donepezil and placebo. Many of the people included in the RCTs did not have behavioural and psychological problems.

Benefits: **Versus placebo:** We found one systematic review (search date 2001)[71] and two additional RCTs.[21,72] The review did not report results for donepezil alone. It identified one RCT (286 people with mild to moderate Alzheimer's disease, Mini Mental State Examination [MMSE] score 10–26, at least 1 symptom on the Neuropsychiatric Inventory Score [NPI]) comparing donepezil (5 mg daily for 28 days, followed by 10 mg daily) versus placebo over 1 year.[73] It found no significant difference in psychiatric symptoms at 1 year (measured by NPI; reported as non-significant; no further data reported). The first additional RCT (208 people with mild to moderate Alzheimer's disease, at least 1 symptom on the Neuropsychiatric Inventory Score, Nursing Home version and living in a nursing home) found no significant difference in psychiatric symptoms after 24 weeks of treatment between donepezil and placebo (change in mean Neuropsychiatric Inventory Nursing Home version Q scores –4.9 with donepezil *v* –2.3 with placebo; reported as non-significant; no further data reported).[72] The second additional RCT (290 people with moderate to severe Alzheimer's disease aged 48–92 years, MMSE score 5–17, Disability Assessment for Dementia [DAD] score 2.5–100, at least 1 symptom on the NPI score) compared donepezil (5–10 mg daily) versus placebo.[21] It found that donepezil significantly improved functional and behavioural symptoms at 24 weeks compared with placebo (Disability Assessment for Dementia score; mean difference 8.23, $P < 0.001$; NPI score; mean difference 5.64; $P < 0.0001$).

Harms: See harms of donepezil, p 1256.

Comment: Cholinesterase inhibitors improve cognitive function and are well tolerated in older people. Only one of the RCTs assessed behavioural and psychological problems as a primary outcome.[72] Many of the people included in the RCTs did not have behavioural and psychological problems.[21,72,73] Some people took sedatives, which may have affected the results.

OPTION GALANTAMINE

RCTs provided inconclusive evidence about the effects of galantamine compared with placebo on behavioural and psychiatric symptoms in people with mild to moderate Alzheimer's disease.

Benefits: **Versus placebo:** We found one systematic review (search date 2002), which identified two RCTs that assessed the effects of galantamine on behavioural and psychological symptoms.[25] A meta-analysis was not performed because of differences in length of follow up between the trials. Both trials used the Neuropsychiatric Inventory (NPI) scale. The first RCT (386 people with mild to moderate Alzheimer's disease; Mini Mental State Examination score 10–22) found no significant difference in psychiatric symptoms at 3 months between galantamine (12–16 mg twice daily) and placebo (mean reduction in NPI score –0.30 with galantamine *v* +0.50 with placebo; WMD –0.80, 95% CI –2.67 to +1.07). The second RCT (978 people with mild to moderate Alzheimer's disease; Mini Mental State Examination score 12–24) found that

galantamine 16 mg daily significantly reduced psychiatric symptoms at 6 months compared with placebo (mean reduction in NPI score –0.10 with galantamine *v* +2.00 with placebo; WMD –2.10, 95% CI –4.04 to –0.16). However, it found no significant difference with galantamine (8 or 24 mg daily).[25]

Harms: See harms of galantamine, p 1257.

Comment: Neither RCT assessed behavioural and psychological problems as a primary outcome.[25] Many of the people included in the RCTs did not have behavioural and psychological problems. Some people took sedatives, which may have affected the results.

OPTION REALITY ORIENTATION

One systematic review found that reality orientation improved behaviour compared with no treatment in people with various types of dementia.

Benefits: **Versus no treatment:** We found one systematic review (search date 2000, 6 RCTs, 125 people with various types of dementia).[56] It found that reality orientation (see glossary, p 1273) significantly improved behavioural symptom score compared with no treatment (SMD –0.66, 95% CI –1.27 to –0.05). No separate analysis was done for specific types of dementia.

Harms: **Versus no treatment:** The RCTs gave no information on adverse effects.[56]

Comment: The RCTs did not use standardised interventions or outcomes.[56]

GLOSSARY

Reality orientation Involves presenting information that is designed to reorient a person in time, place, or person. It may range in intensity from a board giving details of the day, date, and season, to staff reorienting a patient at each contact.

Reminiscence therapy Involves encouraging people to talk about the past in order to enable past experiences to be brought into consciousness. It relies on remote memory, which is relatively well preserved in mild to moderate dementia.

Substantive changes

Tacrine Evidence reassessed. Recategorised as Trade off between benefits and harms.

Oestrogen Evidence on adverse effects reassessed. Recategorised as Trade off between benefits and harms.

Selegiline One systematic review updated;[41] Recategorised as Unknown effectiveness.

Haloperidol One systematic review comparing haloperidol versus risperidone added;[59] recategorised as Trade off between benefits and harms.

Olanzapine One systematic review added;[59] categorisation unchanged.

Risperidone One systematic review[59] and one subsequent RCT added.[63] One meta-analysis of the adverse effects of risperidone found that risperidone increased the risk of cerebrovascular adverse effects.[64] Recategorised as Trade off between benefits and harms.

Donepezil One systematic review added;[71] categorisation unchanged.
