Key Messages

- We found no reliable direct evidence that one type of treatment (drug or non-drug) is superior to another in improving symptoms of depression. However, we found strong evidence that some treatments are effective, whereas the effectiveness of others remains uncertain. Of the interventions examined, prescription antidepressant drugs and electroconvulsive therapy are the only treatments for which there is good evidence of effectiveness in severe and psychotic depressive disorders. We found no RCTs comparing drug and non-drug treatments in severe depressive disorders.

Clin Evid 2004;11:1278–1301.

- **Befriending (in mild to moderate depression)** One small RCT provided insufficient evidence to assess befriending.
- **Bibliotherapy (in mild to moderate depression)** One systematic review of RCTs in younger and older adults recruited by advertisement found limited evidence that bibliotherapy may reduce mild depressive symptoms compared with waiting list control or standard care. Another systematic review in people with combined anxiety and depression, anxiety, or chronic fatigue found that bibliotherapy may improve symptoms over 2–6 months compared with standard care. It is unclear whether people in the RCTs identified by the reviews are clinically representative of people with depressive disorders.
- **Care pathways (in mild to moderate depression)** Five RCTs in people aged over 18 years found that the effectiveness of antidepressant treatment may be improved by several approaches, including collaborative working between primary care clinicians and psychiatrists plus intensive patient education, case management, telephone support, and relapse prevention programmes. One RCT found that a clinical practice guideline and practice based education did not improve either detection or outcome of depression compared with usual care.
- **Care pathways versus usual care for long term outcomes (in mild to moderate depression)** One RCT found that a multifaceted "quality improvement programme" significantly improved symptoms and increased the proportion of people who returned to work over 1 year compared with usual care, but found no significant difference in outcomes at 2 years.
- **Cognitive therapy (in mild to moderate depression)** One systematic review in younger and older adults has found that cognitive therapy significantly improves the symptoms of depression compared with no treatment.
- **Cognitive therapy versus antidepressants for long term outcomes (in mild to moderate depression)** One systematic review and one additional RCT in younger and older adults found limited evidence by combining relapse rates across different RCTs that cognitive therapy may reduce the risk of relapse over 1–2 years compared with antidepressants.
- **Combining prescription antidepressant drugs and psychological treatment (in mild to moderate and severe depression)** One non-systematic review of RCTs in people aged 18–80 years has found that, in people with severe depression, adding drug treatment to interpersonal psychotherapy or to cognitive therapy compared with either psychological treatment alone improves symptoms, but found no significant difference in symptoms in people with mild to moderate depression. Subsequent RCTs in younger and older adults with mild to moderate depression have found that combining antidepressants plus psychotherapy improves symptoms significantly more than either antidepressants or psychotherapy alone. One RCT in older adults with mild to moderate depression found that cognitive behavioural therapy plus desipramine improved symptoms significantly more than desipramine alone.
- **Continuation drug treatment in mild to moderate depression (reduces risk of relapse in mild to moderate depression)** One systematic review and subsequent RCTs in younger and older adults have found that continuation treatment with antidepressant drugs compared with placebo for 4–6 months after recovery significantly reduces the risk of relapse. One RCT in people aged over 60 years has found that continuation treatment with dosulepin (dothiepin) significantly reduces the risk of relapse over 2 years compared with placebo.

Depressive disorders

- **Electroconvulsive therapy (in severe depression)** Two systematic reviews and additional RCTs in people aged over 16 years have found that electroconvulsive therapy significantly improves symptoms in severe depression compared with simulated electroconvulsive therapy.
- **Exercise (in mild to moderate depression)** One systematic review found limited evidence from poor RCTs that exercise may improve symptoms compared with placebo, and may be as effective as cognitive therapy or antidepressants.
- **Interpersonal psychotherapy (in mild to moderate depression)** One large RCT has found that interpersonal psychotherapy significantly improves rates of recovery from depression after 16 weeks compared with antidepressants or standard care.
- **Non-directive counselling (in mild to moderate depression)** One systematic review in people aged over 18 years with recent onset psychological problems, including depression, found that brief, non-directive counselling significantly reduced symptom scores in the short term (< 6 months) compared with usual care, but found no significant difference in scores in the long term (> 6 months).
- **Prescription antidepressant drugs (in mild to moderate and severe depression)** Systematic reviews in people aged 16 years or over have found that antidepressant drugs are effective in acute treatment of all grades of depressive disorders compared with placebo. Systematic reviews have found no significant difference in outcomes with different kinds of antidepressant drug. One systematic review in people aged 55 years or over with all grades of depressive disorder has found that tricyclic antidepressants, selective serotonin reuptake inhibitors, or monoamine oxidase inhibitors significantly reduce the proportion of people who fail to recover over 26–49 days compared with placebo. We found no specific evidence on adverse effects in older adults. However, the drugs differ in their adverse event profiles.

    - **Monoamine oxidase inhibitors** One systematic review found that monoamine oxidase inhibitors were less effective than tricyclic antidepressants in people with severe depressive disorders, but may be more effective in atypical depressive disorders with biological features such as increased sleep, increased appetite, mood reactivity, and rejection sensitivity.
    - **Selective serotonin reuptake inhibitors and related drugs** One systematic review found that selective serotonin reuptake inhibitors were associated with a lower rate of adverse effects compared with tricyclic antidepressants, but the difference was small. Another systematic review and one retrospective cohort study found no strong evidence that fluoxetine was associated with increased risk of suicide compared with tricyclic antidepressants or placebo. One RCT and observational data suggest that abrupt withdrawal of selective serotonin reuptake inhibitors is associated with symptoms including dizziness, nausea, paraesthesia, headache, and vertigo, and that these symptoms are more likely with drugs with a short half life, such as paroxetine.
    - **Tricyclic antidepressants** One systematic review found that tricyclic antidepressants were associated with higher rates of adverse effects compared with selective serotonin reuptake inhibitors, but the difference was small.

- **Problem solving treatment (in mild to moderate depression)** RCTs have found that problem solving treatment significantly improves symptoms over 3–6 months compared with placebo or control, and have found no significant difference in symptoms between problem solving treatment and drug treatment.
- **Psychological treatments (cognitive therapy, interpersonal psychotherapy, and problem solving treatment) in severe depression** RCTs found insufficient evidence to assess psychological treatments in severe depression.
- **St John's Wort (in mild to moderate depression)** Systematic reviews in people with mild to moderate depressive disorders have found that St John's Wort (*Hypericum perforatum*) significantly improves depressive symptoms over 4–12 weeks compared with placebo, and have found no significant difference in symptoms with St John's Wort versus prescription antidepressant drugs. The results of the reviews should be interpreted with caution because the RCTs did not use standardised preparations of St John's Wort, and doses of antidepressants varied. One subsequent RCT in people aged over 18 years with major depressive disorder found no significant difference in depressive symptoms at 8 weeks between a standardised preparation of St John's Wort and placebo or sertraline, but it is likely to have been underpowered to detect a clinically important difference between groups.

DEFINITION

Depressive disorders are characterised by persistent low mood, loss of interest and enjoyment, and reduced energy. They often impair day to day functioning. Most of the RCTs assessed in this review classify depression using the *Diagnostic and statistical manual of mental disorders* (DSM IV)[1] or the *International classification of mental and behavioural disorders* (ICD-10).[2] DSM IV divides depression into major depressive disorder or dysthymic disorder. **Major depressive disorder** is characterised by one or more major depressive episodes (i.e. at least 2 wks of depressed mood or loss of interest accompanied by at least 4 additional symptoms of depression). **Dysthymic disorder** is characterised by at least 2 years of depressed mood for more days than not, accompanied by additional symptoms that do not reach the criteria for major depressive disorder.[1] ICD-10 divides depression into mild to moderate or severe depressive episodes.[2] **Mild to moderate depression** is characterised by depressive symptoms and some functional impairment. **Severe depression** is characterised by additional agitation or psychomotor retardation with marked somatic symptoms.[2] In this review, we use both DSM IV and ICD-10 classifications, but treatments are considered to have been assessed in severe depression if the RCT included inpatients. **Older adults:** Older adults are generally defined as people aged 65 years or older. However, some of the RCTs of older people in this review included people aged 55 years or over. The presentation of depression in older adults may be atypical: low mood may be masked and anxiety or memory impairment may be the principal presenting symptoms. Dementia should be considered in the differential diagnosis of depression in older adults.[3]

INCIDENCE/ PREVALENCE

Depressive disorders are common, with a prevalence of major depression between 5% and 10% of people seen in primary care settings.[4] Two to three times as many people may have depressive symptoms but do not meet DSM IV criteria for major depression.

Depressive disorders

Women are affected twice as often as men. Depressive disorders are the fourth most important cause of disability worldwide and they are expected to become the second most important cause by the year 2020.[5,6] **Older adults:** Between 10% and 15% of older people have depressive symptoms, although major depression is relatively rare in older adults.[7]

AETIOLOGY/ RISK FACTORS The causes are uncertain but include both childhood events and current psychosocial adversity.

PROGNOSIS About half of people suffering a first episode of major depressive disorder experience further symptoms in the next 10 years.[8] **Older adults:** One systematic review (search date 1996, 12 prospective cohort studies, 1268 people, mean age 60 years) found that the prognosis may be especially poor in elderly people with a chronic or relapsing course of depression.[9] Another systematic review (search date 1999, 23 prospective cohort studies in people aged ≥65 years, including 5 identified by the first review) found that depression in older people was associated with increased mortality (15 studies; pooled OR 1.73, 95% CI 1.53 to 1.95).[10]

AIMS OF INTERVENTION To improve mood, social and occupational functioning, and quality of life; to reduce morbidity and mortality; to prevent recurrence of depressive disorder; and to minimise adverse effects of treatment.

OUTCOMES Depressive symptoms rated by the depressed person and clinician; social functioning; occupational functioning; quality of life; admission to hospital; rates of self harm; relapse of depressive symptoms; rates of adverse events. Trials often use continuous scales to measure depressive symptoms (such as the Hamilton Depression Rating Scale and the Beck Depression Inventory). **Older adults:** The Hamilton Depression Rating Scale is not ideal for older people because it includes several somatic items that may be positive in older people who are not depressed. It has been the most widely used scale, although specific scales for elderly people (such as the Geriatric Depression Scale) avoid somatic items.

METHODS The contributors conducted a validated search for systematic reviews and RCTs between May and September 1998 from the Cochrane Database of Systematic Reviews and the Database of Abstracts of Reviews of Effectiveness, *Best Evidence* and *Evidence-Based Mental Health*, Medline, Psychlit, and Embase. Studies were included by using epidemiological criteria and relevance to the clinical question. A *Clinical Evidence* search and appraisal was conducted in July 2002, including a search for data on depression in older adults. In this review, studies are included under the heading older adults if they specifically included people aged over 55 years.

QUESTION What are the effects of treatments?

OPTION PRESCRIPTION ANTIDEPRESSANT DRUGS

Systematic reviews in people aged 16 years or over have found that antidepressant drugs (monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, or tricyclic antidepressants) improve symptoms in

acute treatment of all grades of depressive disorder compared with placebo. Two systematic reviews have found no significant difference in outcomes with different kinds of antidepressant drug, although one systematic review found that monoamine oxidase inhibitors were less effective than tricyclic antidepressants in people with severe depressive disorders, but may be more effective in atypical depressive disorders with reversed biological features such as increased sleep, increased appetite, mood reactivity, and rejection sensitivity. Systematic reviews have found that antidepressant drugs differ in their adverse event profiles. One systematic review has found that selective serotonin reuptake inhibitors were associated with fewer adverse effects compared with tricyclic antidepressants, but the difference was small. Another systematic review and one retrospective cohort study found no strong evidence that fluoxetine was associated with increased risk of suicide compared with tricyclic antidepressants or placebo. One RCT and observational data suggest that abrupt withdrawal of selective serotonin reuptake inhibitors is associated with symptoms including dizziness and rhinitis, and that these symptoms are more likely with drugs with a short half life, such as paroxetine. One systematic review in people aged 55 years or over with all grades of depressive disorder has found that tricyclic antidepressants, selective serotonin reuptake inhibitors, or monoamine oxidase inhibitors significantly reduce the proportion of people who fail to recover over 26–49 days compared with placebo. We found no specific evidence on adverse effects in older adults.

Benefits:

Antidepressants versus placebo: We found three systematic reviews.[11,12,13] The first review (search date 1995, 49 RCTs in people aged 18–70 years with mild to moderate or severe depressive disorders) included five RCTs in people admitted to hospital (probably with severe depressive disorders), 40 RCTs in a setting outside hospital, one in both settings, and three that did not specify the setting.[11] All RCTs identified by the review were of least 4 weeks' duration and included three way comparisons, including two antidepressant drugs (monoamine oxidase inhibitors [MAOIs], selective serotonin reuptake inhibitors [SSRIs], or tricyclic antidepressants [TCAs]) and placebo. The review only included RCTs that measured improvement in depressive symptoms using validated scales such as the Hamilton Depression Rating Scale and Montgomery-Asberg Depression Rating Scale. It found that the mean effect size (see glossary, p 1297) for change in score with antidepressants versus placebo was 0.5, which means that 69% of people taking placebo had worse outcomes than the average person taking antidepressants (see comment below).[11] The second review (search date 1997, 15 RCTs, 1871 people aged ≥ 18 years) compared antidepressants (SSRIs, TCAs, MAOIs, amisulpride, amineptine, or ritanserin) versus placebo in people with dysthymia (chronic mild depressive disorders).[12] It found that antidepressants versus placebo significantly increased the proportion of people who responded to treatment at 4–12 weeks (response defined as a 50% decrease in Hamilton Depression Rating Scale score or scoring 1 or 2 on item 2 of the Clinical Global Impression Score; RR 1.9, 95% CI 1.6 to 2.3; NNT 4, 95% CI 3 to 5). The third systematic review (search date 1998, 18 RCTs, 838 people aged > 18 years with depression and a physical illness [e.g. cancer, cardiovascular disorders, diabetes])

found that antidepressants versus placebo significantly reduced the proportion of people who failed to recover over 4–12 weeks (177/366 [48%] with antidepressant *v* 229/325 [70%] with placebo; RR 0.68, 95% CI 0.60 to 0.77; NNT 4, 95% CI 3 to 7).[13] People allocated to antidepressants were more likely to withdraw from the study than were those on placebo (NNH 10, 95% CI 5 to 43). **In older adults; antidepressants versus placebo:** We found one systematic review (search date 2000, 17 RCTs, 1326 people aged ≥ 55 years with mild to moderate or severe depression) comparing antidepressants versus placebo.[14] It found that TCAs, SSRIs, or MAOIs versus placebo significantly reduced the proportion of people who failed to recover over 26–49 days (125/245 [51%] with TCAs *v* 167/223 [75%] with placebo: RR 0.68, 95% CI 0.59 to 0.68, NNT 4, 95% CI 4 to 5; 261/365 [72%] with SSRIs *v* 310/372 [83%] with placebo: RR 0.86, 95% CI 0.79 to 0.93, NNT 9, 95% CI 9 to 10; 34/58 [59%] with MAOIs *v* 57/63 [90%] with placebo: RR 0.64, 95% CI 0.50 to 0.81, NNT 4, 95% CI 3 to 4).[14] **TCAs versus SSRIs:** We found three systematic reviews (search dates 1999,[15] 1997,[16] and 1998[17]) and one subsequent RCT[18] in people with mild to moderate or severe depression comparing SSRIs versus TCAs. The reviews found no significant difference in overall effectiveness between TCAs and SSRIs.[15,16] The second review (search date 1997, 95 RCTs, 10 533 people aged 18–80 years) found that SSRIs may be slightly more acceptable overall than TCAs, as measured by the number of people who withdrew from clinical trials for any cause (RR of withdrawal 0.88, 95% CI 0.83 to 0.93; NNH 26, 95% CI 18 to 46).[16] The third systematic review (search date 1998, 28 RCTs, 5940 people aged ≥ 18 years) compared the efficacy of newer antidepressants versus placebo or versus older antidepressants in primary care.[17] The average response rate was 63% for newer agents, 35% for placebo, and 60% for TCAs (RR for SSRIs versus placebo 1.6, 95% CI 1.2 to 2.1). The subsequent RCT (152 people with major depression) compared adherence on dosulepin (dothiepin) versus fluoxetine over 12 weeks and found no significant difference between the drugs.[18] However, the RCT was probably underpowered to detect a clinically important difference. **MAOIs versus TCAs:** We found one systematic review (search date not stated, 55 RCTs) comparing MAOIs versus TCAs in several subgroups of people with depression aged 18–80 years.[19] It found that MAOIs were less effective than TCAs in people with severe depressive disorders but may be more effective in atypical depressive disorders (depressive disorders with reversed biological features, e.g. increased sleep, increased appetite, mood reactivity, and rejection sensitivity). **Antidepressants plus benzodiazepines:** We found one systematic review (search date 1999, 8 RCTs, 679 people aged 18–65 years, 1 RCT in people aged 20–73 years with major depression) comparing combination treatment with antidepressants plus benzodiazepines versus antidepressants alone.[20] It found that combination treatment versus antidepressants alone was significantly more likely to produce a response within 1 week (RR of > 50% reduction on symptom rating scale 1.64, 95% CI 1.19 to 2.27), although this difference was not apparent at 6 weeks.

Harms:

Common adverse events with TCAs versus SSRIs: One systematic review (search date 1996) compared adverse events with TCAs versus SSRIs in people aged 18 years or over with all severities of depression (see table 1, p 1300).[21] **Adverse effects with different SSRIs:** One large cohort study of people receiving four different SSRIs (fluvoxamine [983 people], fluoxetine [692 people], sertraline [734 people], and paroxetine [13 741 people]) in UK primary care found that reports of common adverse events (nausea/vomiting, malaise/lassitude, dizziness, and headache/migraine) varied between SSRIs (fluvoxamine 78/1000 participant months; fluoxetine 23/1000 participant months; RR *v* fluvoxamine 0.29, 95% CI 0.27 to 0.32; paroxetine 28/1000 participant months; RR 0.35, 95% CI 0.33 to 0.37; sertraline 21/1000 participant months; RR 0.26, 95% CI 0.25 to 0.28).[22] Only 52% of people responded to the questionnaire, although this response rate was similar for all four drugs. A study of spontaneous reports to the UK Committee on Safety of Medicines found no difference in safety profiles between the same four SSRIs.[23] **Suicide with TCAs versus SSRIs:** One systematic review (search date not stated, which included RCTs completed by December 1989) pooled data from 17 double blind RCTs in people with depressive disorders aged 12–90 years comparing a TCA (731 people) versus fluoxetine (1765 people) or versus placebo (569 people).[24] It found no significant difference in the rate of suicidal acts between the groups (TCAs 0.4%, fluoxetine 0.3%, and placebo 0.2%), but development of suicidal ideation was less frequent in the fluoxetine group (1% fluoxetine *v* 3% placebo, P = 0.04; and *v* 4% TCAs, P = 0.001). One historical cohort study followed 172 598 people who had at least one prescription for 1/10 antidepressants during the study period in general practice in the UK.[25] The risk of suicide was higher in people who received fluoxetine (19/10 000 person years, 95% CI 9 to 34) than in those receiving dosulepin (RR of suicide *v* dosulepin 2.1, 95% CI 1.1 to 4.1). In a nested case controlled subanalysis in people with no history of suicidal behaviour or previous antidepressant prescription, the risk remained the same, although the confidence interval broadened to make the result non-significant (RR 2.1, 95% CI 0.6 to 7.9). Although the apparent association may be because of residual confounding, there remains uncertainty about the possible association between fluoxetine and suicide. However, any absolute increase in risk is unlikely to be large. **Withdrawal effects with SSRIs:** We found one RCT in people aged 18 years or over (average age 30–40 years) comparing abrupt discontinuation of fluoxetine (96 people) versus continued treatment (299 people) in people who had been taking the drug for 12 weeks.[26] Abrupt discontinuation was associated with increased dizziness (7% *v* 1%), dysmenorrhoea (3% *v* 0%), rhinitis (10% *v* 3%), and somnolence (4% *v* 0%). However, there was a high withdrawal rate in this study because of the return of symptoms of depression (39%), so these may be underestimates of the true rate of withdrawal symptoms. Between 1987 and 1995 the rate of spontaneous reports of suspected withdrawal reactions per million defined daily doses to the World Health Organization Collaborating Centre for International Drug Monitoring was higher for paroxetine than for sertraline and fluoxetine.[27] The most common withdrawal

effects were dizziness, nausea, paraesthesia, headache, and vertigo. **MAOIs versus TCAs:** The systematic review found that MAOIs were associated with a similar level of overall adverse effects as were TCAs.[19] Adverse effects associated with MAOIs included hypotension, dizziness, mydriasis, piloerection, oedema, tremor, anorgasmia, and insomnia. **During pregnancy:** One systematic review (search date 1999) assessing the risk of fetal harm of antidepressants in pregnancy found four small prospective studies published since 1993.[28] No evidence of increased risk was found, although the risk of adverse effects cannot be excluded. Decreased birth weights of infants exposed to fluoxetine during the third trimester were identified in one study, and direct drug effects and withdrawal syndromes were identified in some neonates. **In older adults:** We found no specific evidence on adverse effects in older adults.

Comment: **Antidepressants versus placebo:** The first review found that results were sensitive to the diagnostic criteria used; the mean effect size for antidepressants was 0.5 in those RCTs in which depressive disorders were diagnosed according to standard criteria (mainly *Diagnostic and statistical manual of mental disorders*, 3rd edition, revised) and 0.4 in those RCTs that did not use objective diagnostic criteria.[11] **In older adults:** The systematic review of antidepressants versus placebo in older people was limited by the diversity of populations included and by the brevity of the studies.[13] The reviewers recommended at least 6 weeks of antidepressant treatment in elderly people to achieve optimal effect. A systematic review is under way to examine adverse effects in elderly people. Metabolic and physical changes with age mean that older people may be more prone to adverse effects such as falls. Because older people often take more medications, they may be at greater risk of drug interactions.

OPTION CARE PATHWAYS

Five RCTs in people aged over 18 years found that the effectiveness of antidepressant treatment may be improved by several approaches, including collaborative working between primary care clinicians and psychiatrists plus intensive patient education, case management, telephone support, and relapse prevention programmes. One RCT found that a clinical practice guideline and practice based education did not improve either detection or outcome of depression compared with usual care.

Benefits: We found no systematic review but found six RCTs.[29–34] **Collaborative working between primary care clinicians and psychiatrists plus intensive patient education:** The first RCT (217 people aged 19–76 years with mild to moderate or major depression in primary care in the USA) found that, compared with standard treatment (including antidepressants), the addition of a multifaceted programme, including collaborative working between primary care physician and psychiatrist plus intensive patient education, improved outcomes over 12 months.[29] Improvement in depressive symptoms assessed using the Symptom Checklist-90 was significant only in the subgroup of people with major depressive

disorder (91 people; AR of clinical response of > 50% reduction in symptom checklist 74% *v* 44% with standard treatment; NNT 4, 95% CI 3 to 10).[29] **Care management:** The second RCT (613 people, mean age 46 years) in a Health Maintenance Organization in Seattle (USA) compared three interventions: usual care (antidepressants), usual care plus feedback (in which doctors received a detailed report on each person at 8 and 16 wks after randomisation), or usual care plus feedback plus care management (in which the care manager assessed people with depression by telephone at 8 and 16 wks, doctors received a detailed report, and care managers facilitated the follow up).[30] It found that feedback plus care management versus usual care significantly increased the proportion of people with a clinically important reduction in depressive symptoms at 6 months after randomisation (about 56% of people with care management *v* 40% with usual care [results presented graphically]; OR 2.22, 95% CI 1.31 to 3.75). **Clinical practice guideline and practice based education:** The third RCT (cluster randomised, based in UK primary care, people aged over 16 years) compared the effects of a clinical practice guideline and practice based education versus usual care.[31] It found that the intervention did not improve either detection or outcome of depression. **Telephone support:** The fourth RCT (302 people with major depressive disorder or dysthymia aged 19–90 years) compared usual physician care (selective serotonin reuptake inhibitor [SSRI]; 117 people), usual care plus nurse telehealth (SSRI plus 12–14 telephone support calls during 16 wks of treatment; 62 people), or usual care plus telehealth plus peer support (123 people).[32] Nurse telehealth versus usual clinician care significantly increased the proportion of people with a 50% reduction in symptoms at 6 months (57% with nurse telehealth *v* 38% with usual care; NNT 6, 95% CI 4 to 18). **Relapse prevention programme:** The fifth RCT (386 people aged > 18 with recurrent major depression or dysthymia who had largely recovered after 8 wks of antidepressant treatment) compared a relapse prevention programme (2 primary care visits and 3 telephone calls) versus usual care for 1 year.[33] It found that relapse prevention versus usual care significantly improved depressive symptoms over 1 year (results presented graphically; P = 0.04) but found no significant difference in relapse rates (35% in both groups). **Multifaceted quality improvement programme:** The sixth RCT compared a multifaceted "quality improvement programme" including antidepressants plus psychotherapy or plus cognitive behavioural therapy (see glossary, p 1296) versus usual care and assessed outcomes at 1 and 2 years (see which treatments are most effective at improving long term outcome, p 1295).[34] **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: The RCTs gave no information about adverse effects.[29–34]

Comment: None.

OPTION ST JOHN'S WORT (*HYPERICUM PERFORATUM*)

Two systematic reviews in people with mild to moderate depressive disorders have found that St John's Wort (*H perforatum*) significantly improves depressive symptoms over 4–12 weeks compared with placebo,

and have found no significant difference in symptoms between St John's Wort and prescription antidepressant drugs. The results of the reviews should be interpreted with caution because the RCTs did not use standardised preparations of St John's Wort, and doses of antidepressants varied. One subsequent RCT in people aged over 18 years major depressive disorder found no significant difference in depressive symptoms at 8 weeks between a standardised preparation of St John's Wort and placebo or sertraline, but it is likely to have been underpowered to detect a clinically important difference between groups.

Benefits: We found two systematic reviews[35,36] and one subsequent RCT.[37] The first review (search date 1998) identified 17 RCTs (1168 people aged > 18 years with mild to moderate depression) comparing St John's Wort versus placebo (16 RCTs using single preparations of hypericum, and 1 RCT using combinations of hypericum and 4 other plant extracts; see comment below).[35] It also identified 10 RCTs (1123 people) comparing St John's Wort versus other antidepressants or sedative drugs (8 RCTs using single preparations of hypericum, and 2 RCTs using combinations of hypericum and valeriana). It found that *H perforatum* preparations versus placebo significantly increased the proportion of people who responded over 4–12 weeks (response defined as a Hamilton Depression Rating Scale score of < 10 or < 50% of baseline score; 267/465 [57%] with hypericum *v* 122/485 [25%] with placebo; RR 2.47, 95% CI 1.69 to 3.61), and found no significant difference in the proportion of people who responded with St John's Wort versus antidepressants or sedatives (177/352 [50%] with single preparations of hypericum *v* 176/339 [52%] with placebo; 88/130 [68%] *v* 66/132 [50%]; RR 1.01, 95% CI 0.87 to 1.16; combinations RR 1.52, 95% CI 0.78 to 2.94). The second review (search date 2000, 23 RCTs, 2776 people with mild to moderate depression) included 14 RCTs identified by the first review, but applied different inclusion criteria for RCTs and excluded 13 of the RCTs included in the first review.[36] It identified 14 RCTs (1336 people) comparing St John's Wort versus placebo and nine RCTs (1394 people) comparing St John's Wort versus other antidepressants. It found that St John's Wort versus placebo significantly increased the proportion of people who responded over 4–8 weeks (390/690 [57%] *v* 184/646 [28%]; RR 1.98, 95% CI 1.49 to 2.62), but found no significant difference in depressive symptoms over 4–6 weeks with St John's Wort versus other antidepressants (422/694 [61%] *v* 423/700 [60%]; RR 1.00, 95% CI 0.91 to 1.11). These results did not change when only RCTs that met stricter methodological treatment were combined (6 RCTs; St John's Wort *v* placebo: 153/257 [60%] *v* 79/232 [34%]; RR 1.77, 95% CI 1.16 to 2.70; St John's Wort *v* other antidepressants: 260/440 [59%] *v* 261/468 [56%]; RR 1.04, 95% CI 0.94 to 1.15). The subsequent RCT (340 people aged over 18 years with major depressive disorder defined as a total score of ≥ 20 on the Hamilton Depression Rating Scale) compared St. John's Wort (standardised extract, hypericin 0.12%–0.28%, 900–1500 mg/day) versus placebo or sertraline (50–100 mg/day).[37] It found no significant difference in the proportion of people who responded at 8 weeks with St John's Wort compared with placebo (response defined as Clinical Global Impression Score of 1

[very much improved] or 2 [much improved] or a Hamilton Depression Rating Scale score of < 8: 24% with St John's Wort *v* 32% with placebo *v* 25% with sertraline; P = 0.21 for St John's Wort *v* placebo; P for St John's Wort *v* sertraline not stated). The RCT is likely to have been underpowered to detect a clinically important difference between groups.[37] **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: We found three systematic reviews that assessed adverse effects associated with St John's Wort.[35,36,38] The first review (search date 1998) found that adverse events were poorly reported in the trials.[35] Adverse effects were reported by 26% of people taking St John's Wort versus 45% of people taking standard antidepressants (RR 0.57, 95% CI 0.47 to 0.69), and by 15% of people taking combinations of hypericum and valeriana versus 27% taking amitriptyline or desipramine (RR 0.49, 95% CI 0.23 to 1.04). The second systematic review (search date 2000) found no significant difference in the proportion of people who had adverse effects (including gastrointestinal effects, headaches, restlessness, and fatigue) with St John's Wort versus placebo (43/236 [18%] *v* 29/177 [16%]; RR 1.04, 95% CI 0.68 to 1.58), and found that St John's Wort versus antidepressants significantly reduced the proportion of people with adverse effects (260/440 [59%] *v* 261/448 [58%]; RR 0.59, 95% CI 0.52 to 0.71).[36] The third systematic review (search date 1997) included RCTs and observational surveillance studies after marketing of St John's Wort.[38] It found that the most common adverse effects of St John's Wort in the included studies were gastrointestinal symptoms, dizziness/confusion, tiredness/sedation, and dry mouth, although all occurred less frequently than on conventional drugs. Findings from observational studies were consistent with these results. Photosensitivity is theoretically possible; however, only two cases have been reported.

Comment: The results of the systematic reviews must be interpreted with caution because the preparations and doses of *H perforatum* and types and doses of antidepressants varied widely.[35,36] More RCTs are needed using standardised preparations. Interactions with other drugs are possible and should be considered.

OPTION ELECTROCONVULSIVE THERAPY

Two systematic reviews and additional RCTs in people aged over 16 years have found that electroconvulsive therapy significantly improves symptoms in severe depression compared with simulated electroconvulsive therapy.

Benefits: We found two systematic reviews,[39,40] three additional RCTs,[41–43] and two subsequent RCTs.[44,45] The first review (search date not stated, 6 RCTs published between 1960 and 1978, 205 people with severe depressive disorder, age range not stated) compared electroconvulsive therapy (ECT) versus simulated ECT (in which people received everything but electric stimulation; see comment below).[39] It found that people given real versus simulated ECT were significantly more likely to respond to treatment (response defined as global clinical state or a "clinically significant" difference in

scores on depressive scales such as the Hamilton Depression Rating Scale: 73/109 [67%] *v* 33/96 [34%]; pooled RR 1.95, 95% CI 1.43 to 2.65; NNT 3, 95% CI 2 to 5; calculated by the author from data in the article). The second review (search date 1998, which included 11 additional RCTs published between 1987 and 1998) also found good evidence for the beneficial effects of ECT, but did not quantify its conclusions.[40] The results of the additional and subsequent RCTs are consistent with the findings of the review.[41–45] **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: The systematic reviews gave no information on adverse effects,[39,40] and we found no good evidence about possible adverse cognitive effects of ECT. However, people often complain of memory impairment after ECT. One of the main difficulties in studying the association between memory impairment and ECT is that depressive disorders also lead to cognitive impairment that usually improves during the course of treatment. For this reason, most of the small studies in this area find an average improvement in memory in people treated with ECT. This does not rule out the possibility of more subtle, subjective memory impairment secondary to ECT. Adverse memory effects may vary according to the dose and electrode location.

Comment: Because ECT may be unacceptable to some people and because it is a short term treatment, there is consensus that it should normally be reserved for people who cannot tolerate or have not responded to drug treatment, although it may be useful when a rapid response is required.

OPTION PSYCHOLOGICAL TREATMENTS

One systematic review in younger and older adults with mild to moderate depression has found that cognitive therapy significantly improves symptoms compared with no treatment. One systematic review in people aged over 18 years with recent onset psychological problems, including depression, found that brief, non-directive counselling significantly reduced symptom scores in the short term (< 6 months) compared with usual care, but found no significant difference in scores in the long term (> 6 months). RCTs in younger and older adults with mild to moderate depression found that problem solving treatment or interpersonal psychotherapy significantly improved depressive symptoms in the short term compared with placebo, and found no significant difference in symptoms with problem solving treatment or interpersonal psychotherapy compared with antidepressant treatment. RCTs found insufficient evidence to assess the relative efficacy of drug and non-drug treatment in severe depression. One systematic review in people aged over 55 years with mild to moderate depression found no significant difference in symptoms between psychological treatments (such as cognitive therapy or cognitive behaviour therapy) and no treatment. However, it also found no significant difference in symptoms between psychological treatments and similar but non-specific attention. This review was based on a small number of RCTs, the populations varied (although most were community samples), and many of the studies were short term. RCTs found limited evidence about the effects of psychological treatments in severe depression.

Benefits: The evidence comparing psychological treatments versus drug or no treatment is summarised in table 2 (see table 2, p 1301).[46–50] RCTs found insufficient evidence to assess the relative efficacy of drug and non-drug treatment in severe depression (see comment below). **Older adults:** We found one systematic review (search date 1995, 14 small RCTs, < 24 people, age > 55 years in an outpatient or community setting) of pharmacological and psychological treatments.[51] It found four RCTs in older adults that compared psychological treatments versus no treatment. None of the RCTs found a significant difference between treatment and no treatment, measured on the Hamilton Depression Rating Scale. It also found six RCTs comparing different psychological treatments. Five of six comparisons of "rational" treatments (such as cognitive therapy or cognitive behavioural therapy [see glossary, p 1297]) versus no treatment in older adults found significant benefit with treatment. Combined, the "rational" treatments performed significantly better than no treatment (mean difference in the Hamilton Depression Rating Scale score −7.3, 95% CI −10.1 to −4.4), but were not significantly different from the "non-specific attention" control. None of the RCTs found significant differences in effectiveness between psychological treatments.

Harms: The systematic review and RCTs gave no information on adverse effects.[46–50]

Comment: Large RCTs are needed in more representative people in a range of clinical settings, including primary care. Because of varying exclusion criteria, the generalisability of the studies is questionable (see table 2, p 1301). Other factors to be considered when psychological treatments are compared with drug treatment include whether serum concentrations of drugs reach therapeutic concentrations, whether changes in medication are allowed (reflecting standard clinical practice), and whether studies reflect the natural course of depressive disorders. It is difficult to conduct studies of psychological treatments for severe depression because of the ethics surrounding withholding a proved treatment (antidepressant drugs) in a group of people at risk of self harm or neglect.[52]

OPTION PSYCHOLOGICAL TREATMENTS PLUS PRESCRIPTION ANTIDEPRESSANT DRUGS

One non-systematic review of RCTs in people aged 18–80 years has found that, in people with severe depression, adding drug treatment to interpersonal psychotherapy or to cognitive therapy compared with either psychological treatment alone improves symptoms, but found no significant difference in symptoms in people with mild to moderate depression. Subsequent RCTs in younger and older adults with mild to moderate depression have found that combining antidepressants plus psychotherapy improves symptoms significantly more than either antidepressants or psychotherapy alone. One RCT in older adults with mild to moderate depression found that cognitive behavioural therapy plus desipramine improved symptoms significantly more than desipramine alone.

Benefits: We found no systematic review, but found one non-systematic review[52] and two subsequent RCTs.[53,54] The non-systematic review (6 RCTs, 595 people aged 18–80 years with major depression)

found that, in more severe depressive disorders, antidepressants plus interpersonal psychotherapy (see glossary, p 1297) or plus cognitive therapy (see glossary, p 1297) significantly increased the proportion of people who responded after 16 weeks of treatment compared with interpersonal psychotherapy or cognitive therapy alone (response defined as 4 wks with Hamilton Depression Rating Scale score < 7; P = 0.001).[52] It found no advantage in combining antidepressants and specific psychological treatments in mild to moderate depressive disorders (P = 0.10). The first subsequent RCT (681 adults with chronic depressive disorder, mean age 43 years) compared three interventions: nefazodone alone, cognitive behavioural therapy (see glossary, p 1296) alone, or nefazodone plus cognitive behavioural therapy.[53] It found that combined treatment significantly improved the proportion of people with a clinical response compared with either treatment alone (defined as at least 50% reduction in Hamilton Depression Rating Scale score and a score of ≤ 15; 152/226 [67%] with combined treatment *v* 92/220 [42%] with nefazodone alone *v* 90/226 [40%] with psychotherapy alone; combined treatment *v* either single intervention; P < 0.001; NNT 5, 95% CI 3 to 6). The second subsequent RCT (167 people with a major depressive episode) compared antidepressants (fluoxetine, amitriptyline, or moclobemide) plus short term psychodynamic supportive psychotherapy (see glossary, p 1297) versus antidepressants alone (see comment below).[54] It found that combined treatment versus antidepressants significantly increased the proportion of people who had improved after 24 weeks (improvement defined as Hamilton Depression Rating Scale score of ≤ 7, Clinical Global Impression score of 1 or 2, Symptom Checklist-90 or Quality of Life Depression Scale score of at least 1 standard deviation from baseline; mean success rate 41% *v* 59%; NNT 5, 95% CI 3 to 11). **Older adults:** We found one RCT (102 people aged > 60 years with major depressive disorder) that compared three interventions: desipramine plus cognitive behavioural therapy; desipramine alone; or cognitive behavioural therapy alone.[55] It found that all three groups showed a significant reduction in symptoms from baseline as assessed using the Hamilton Depression Rating Scale after 16–20 weeks of treatment (reduction of 0.20 with desipramine, 0.36 with cognitive behavioural therapy, and 0.41 with combined treatments; P < 0.05 for all comparisons). It found that combined treatments versus desipramine alone significantly improved symptoms over 16–20 weeks (P < 0.05). It found no significant difference among the three groups in the proportion of people who withdrew for any cause (desipramine 34%, cognitive behavioural therapy 23%, and combined treatments 33%; P = 0.52).

Harms: The non-systematic review and RCTs gave no information on adverse effects.[52–55]

Comment: A systematic review is needed to address this question. In the second subsequent RCT, 38/167 people initially randomised refused the proposed treatment: 27/84 (32%) of people offered antidepressants and 11/83 (13%) of people offered combined treatment.[54] This makes the results of the RCT very difficult to interpret.

OPTION EXERCISE

One systematic review found limited evidence from poor RCTs that exercise may improve symptoms compared with placebo, and may be as effective as cognitive therapy. One poor RCT in older adults identified by the review found limited evidence that exercise may be as effective as antidepressants in improving symptoms and may reduce relapse over 10 months.

Benefits: We found one systematic review (search date 1999, 14 RCTs, 851 people).[56] It found limited evidence that exercise versus no treatment may improve symptoms and found that exercise may be as effective as cognitive therapy (see glossary, p 1297). However, it suggested that these results were inconclusive because of methodological problems in all of the RCTs; randomisation was adequately concealed in only three of the RCTs, intention to treat analysis was undertaken in only two, and assessment of outcome was blinded in only one of the RCTs. **Older adults:** The systematic review[56] identified one RCT (156 people with major depression, mean age 57 years) comparing aerobic exercise, sertraline hydrochloride (a selective serotonin reuptake inhibitor), and combined treatment for 16 weeks.[57] It found that the proportion of people who recovered (those no longer meeting criteria for depression or with a Hamilton Depression Rating Scale score < 8) was not significantly different across the treatment groups (60% with exercise *v* 69% with sertraline *v* 66% with combined treatments). A 10 month follow up of this RCT found lower rates of relapse with exercise versus medication (30% with exercise *v* 52% with sertraline *v* 55% with combined treatment).[58] However, about half of the people in the medication group engaged in exercise during follow up, making it difficult to draw firm conclusions about effects of exercise. The clinical importance of the observed difference at 10 months remains unclear.

Harms: The review gave no information about adverse effects.[56]

Comment: There is a need for a well designed RCT of the effects of exercise in people with all grades of depression assessing clinical outcomes over an adequate time period.

OPTION BIBLIOTHERAPY

One systematic review of RCTs in younger and older adults recruited by advertisement found limited evidence that bibliotherapy may reduce mild depressive symptoms compared with waiting list control or standard care. Another systematic review in people with combined anxiety and depression, anxiety, or chronic fatigue found that bibliotherapy may improve symptoms over 2–6 months compared with standard care. It is unclear whether people in the RCTs identified by the reviews are clinically representative of people with depressive disorders.

Benefits: **Younger and older adults:** We found two systematic reviews (search date not stated[59] and search date 1999[60]). The first review identified six small short term RCTs of bibliotherapy (see glossary, p 1296) versus waiting list control in 273 people (described as adults in 4 RCTs and elderly in 2 RCTs; no age range provided)

recruited by advertisement through the media and probably with only mild depression (see comment below).[59] The mean effect size (see glossary, p 1297) of bibliotherapy was 0.82 (95% CI 0.50 to 1.15). This means that 79% of people in the waiting list control group had a worse outcome than the average person in the bibliotherapy group. The second systematic review identified eight randomised and non-randomised trials in younger and older people, but only one of them included people with depression.[60] It found that, in people with combined anxiety and depression, anxiety, or chronic fatigue, bibliotherapy may improve symptoms over 2–6 months compared with standard care. The RCT identified by the second review that included people with depression found that bibliotherapy versus standard care significantly improved symptoms of anxiety over 4 weeks as assessed using the Hamilton Depression Rating Scale, but found no significant difference in symptoms of depression at 4 or 12 weeks. **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: None reported.

Comment: The review did not clearly describe the characteristics of the people in the RCTs it identified, and it is unclear whether people were receiving interventions in addition to bibliotherapy.[59] Further RCTs are needed in clinically representative groups.

OPTION BEFRIENDING

One small RCT provided insufficient evidence to assess befriending.

Benefits: We found one small RCT (86 women with chronic depression, aged > 18 years, primarily aged 25–40 years, based in London, UK) of befriending (see glossary, p 1296) versus waiting list control.[61] Initial identification was by postal screening of women registered with, but not attending, primary care. It found that befriending versus waiting list control significantly increased the proportion of women with remission of symptoms at 13 months (65% with befriending *v* 39% with control; $P < 0.05$; NNT 4, 95% CI 2 to 18). **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: The RCT gave no information on harms.[61]

Comment: In the RCT, 14% of women in the befriending group were taking antidepressants and 12% of women in the waiting list control group.[61] Fewer than half of the women screened by post were interested in befriending as a treatment option.

QUESTION **What are the effects of continuation treatment with antidepressant drugs?**

OPTION **CONTINUATION TREATMENT WITH ANTIDEPRESSANT DRUGS**

One systematic review and subsequent RCTs in younger and older adults have found that continuation treatment with antidepressant drugs compared with placebo for 4–6 months after recovery significantly reduces the risk of relapse. One RCT in people aged over 60 years has found that continuation treatment with dosulepin significantly reduces the risk of relapse over 2 years compared with placebo.

Benefits: We found one systematic review (search date not stated, 6 RCTs, 312 people, age range not stated).[62] It found that continuation of antidepressant medication versus placebo for 4–6 months after acute treatment reduced the relapse rate by nearly half (RR 0.6, 95% CI 0.4 to 0.7). Several more recent RCTs confirmed this reduction in risk of early relapse with continuing antidepressant treatment for 6–12 months after acute treatment. **Older adults:** We found one RCT (69 people aged > 60 years with mild to moderate or severe depression who had recovered sufficiently and consented to enter a 2 year trial of continuation treatment [see glossary, p 1297]), which compared dosulepin (dothiepin) versus placebo.[63] It found that dosulepin versus placebo reduced the risk of relapse over 2 years by 55% (RR 0.45, 95% CI 0.22 to 0.96).

Harms: Adverse effects seem to be similar to those reported in trials of acute treatment.

Comment: We found no adequate systematic review of maintenance treatment (see glossary, p 1297), but several RCTs have found that maintenance treatment reduced recurrence compared with placebo in recurrent depressive disorder. However, they all have problems with their methods (e.g. high withdrawal rates)[64] and will be considered in future *Clinical Evidence* updates. A systematic review of antidepressant treatment duration is in progress.[65]

QUESTION **Which treatments are most effective at improving long term outcome (≥ 1 year)?**

OPTION **IMPROVING LONG TERM OUTCOMES**

One systematic review and one additional RCT in younger and older adults found limited evidence by combining relapse rates across different RCTs that cognitive therapy may reduce the risk of relapse over 1–2 years compared with antidepressants. One RCT found that a multifaceted "quality improvement programme" significantly improved symptoms and increased the proportion of people who returned to work over 1 year compared with usual care, but found no significant difference in outcomes at 2 years.

Benefits: **Cognitive therapy versus antidepressants:** We found one systematic review (search date not stated) comparing cognitive therapy (see glossary, p 1297) versus antidepressants in people

with mainly mild to moderate depressive disorders.[46] The review identified eight small RCTs (261 people, mean age 39.3 years) that assessed long term (1–2 year) relapse rates after treatment had stopped. Relapse was defined as a return of depressive symptoms (Beck Depression Inventory Score > 16) at 6–9 months after a 2 month remission. It found limited evidence by combining relapse rates across different RCTs that, overall, 30% of people treated with cognitive therapy relapsed compared with 60% of those treated with either antidepressants or antidepressants plus cognitive therapy. We found one small additional RCT (40 people) comparing cognitive therapy versus normal clinical management (antidepressants) for residual depressive symptoms in people who had responded to antidepressants. It also found that, at 2 years, fewer people relapsed with cognitive therapy than with antidepressants.[66]
Care pathways versus usual care: One RCT (1356 people aged > 18 years with mild to moderate or major depression in 46 primary care clinics in US Health Maintenance Organizations) compared a multifaceted "quality improvement programme" (including antidepressants plus psychotherapy or plus cognitive behavioural therapy [see glossary, p 1296]) versus usual care (including mailed practice guidelines).[34] It found that the quality improvement programme versus usual care significantly increased the proportion of people who improved on continuous depression rating scales over 1 year. It found that, among people initially employed, 90% of people in the quality improvement programme worked at 1 year versus 85% of the people receiving usual care (P = 0.05). For people initially not working, there was no difference in employment rates at 12 months with quality improvement versus usual care (17% *v* 18%). A 2 year follow up of this RCT found no significant difference in outcomes with quality improvement versus usual care.[67] **Older adults:** We found no systematic review or RCTs specifically in older adults.

Harms: See harms of prescription antidepressant drugs, p 1285.

Comment: The review did not present information on the proportion of people who recovered and continued to remain well after 2 years.[46] The largest RCT identified by the review found that only a fifth of people remained well over 18 months' follow up, and that there were no significant differences between interpersonal psychotherapy (see glossary, p 1297), cognitive therapy, or drug treatment.[46] It is possible that different people respond to different treatments. Further large scale comparative studies are needed of the long term effectiveness of treatments in people with all severities of depressive disorders.

GLOSSARY

Befriending Consists of a befriender meeting the person to talk and socialise for at least 1 hour a week, acting as a friend.

Bibliotherapy Advising people to read written material such as *Feeling good: the new mood therapy* by David Burns (New York: New American Library, 1980).

Brief, non-directive counselling Helping people to express feelings and clarify thoughts and difficulties; therapists suggest alternative understandings and do not give direct advice but try to encourage people to solve their own problems.

Cognitive behavioural therapy Brief (20 sessions over 12–16 wks) structured

treatment, incorporating elements of cognitive therapy and behavioural therapy. Behavioural therapy is based on learning theory and concentrates on changing behaviour.

Cognitive therapy Brief (20 sessions over 12–16 wks) structured treatment aimed at changing the dysfunctional beliefs and negative automatic thoughts that characterise depressive disorders. It requires a highly trained therapist.[68]

Continuation treatment Continuation of treatment after successful resolution of a depressive episode to prevent relapse.

Effect size This expresses the degree of overlap between the range of scores in the control and experimental groups. The effect size can be used to estimate the proportion of people in the control group who had a poorer outcome than the average person in the experimental group; a proportion of 50% indicates that the treatment has no effect.

Interpersonal psychotherapy Standardised form of brief psychotherapy (usually 12–16 weekly sessions) primarily intended for outpatients with unipolar non-psychotic depressive disorders. It focuses on improving the person's interpersonal functioning and identifying the problems associated with the onset of the depressive episode.[69]

Maintenance treatment Long term treatment of recurrent depressive disorder to prevent the recurrence of further depressive episodes.

Problem solving treatment Consists of three stages: (1) identifying the main problems for the person; (2) generating solutions; and (3) trying out the solutions. Potentially briefer and simpler than cognitive therapy and may be feasible in primary care.[48]

Psychodynamic supportive psychotherapy Aims to facilitate change by detecting and resolving underlying psychological conflicts. The treatment aims to be less challenging by incorporating supportive elements.

TABLE 1 **Adverse events (% of people) with selective serotonin reuptake inhibitors versus tricyclic antidepressants (see text, p 1285).[21]**

Adverse effects	SSRI event rates (%)	TCA event rates (%)
Dry mouth	21	55
Constipation	10	22
Dizziness	13	23
Nausea	22	12
Diarrhoea	13	5
Anxiety	13	7
Agitation	14	8
Insomnia	12	7
Nervousness	15	11
Headache	17	14

SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.

TABLE 2 **Effects of specific psychological treatments for depressive disorders (see text, p 1291).**

Intervention	Evidence	Benefits	Harms	Disadvantages
Cognitive therapy	1 SR (48 RCTs of psychological therapies [2765 people, mean age 39.3 y] mainly outpatients in secondary care; therefore, probably with mild to moderate depression; people with psychotic or bipolar symptoms were excluded); 20 RCTs compared CT with waiting list or placebo and 17 compared it with drug treatment[46]	79% of people receiving placebo were more symptomatic than the average person receiving CT ($P < 0.0001$).[43] 65% of people receiving CT were less symptomatic than the average person treated with antidepressant drugs ($P < 0.0001$)[46]	No harms reported	Requires extensive training. Limited availability. RCTs in primary care suggest limited acceptability to some people
Interpersonal psychotherapy	No SR. 1 large RCT (people with mild to moderate depression, mean age 35 y) compared interpersonal psychotherapy *v* either drug treatment, CT, or placebo plus clinical management for 16 wks[47]	Rates of recovery from depression: interpersonal psychotherapy (43%; NNT 5, 95% CI 3 to 19), imipramine (42%; NNT 5, 95% CI 3 to 22), placebo clinical management (21%)[47]	No harms reported	Requires extensive training. Limited availability
Problem solving therapy	No SR. 1 large RCT (452 people aged 18–65 y with mild to moderate depression or adjustment disorders) compared PS, group treatment, and control.[49] 1 RCT (91 people aged 18–65 y with mild to moderate depression) compared problem solving, placebo, and amitriptyline[48]	PS *v* control significantly increased the proportion of people who were not depressed at 6 mo, but no significant difference at 1 y.[49] PS *v* placebo significantly improved symptoms at 12 wks, and no significant difference in symptoms with PS *v* amitriptyline[48]	No harms reported	Requires some training. Limited availability
Non-directive counselling	1 SR (7 RCTs, 772 people aged over 18 y with recent onset psychological problems, including depression in UK primary care) compared counselling *v* standard physician care[50]	Counselling *v* standard care significantly improved symptons in the short term (1–6 mo; WMD –2.03, 95% CI –3.82 to –0.24), but no significant difference in the long term (> 6 mo; WMD –0.03, 95% CI –0.39 to +0.32)[50]	No harms reported	Requires some training. Limited availability

QUESTIONS

INTERVENTIONS

See glossary, p 1316

Key Messages

- **Buspirone** RCTs have found that buspirone improves symptoms over 4–9 weeks compared with placebo. RCTs found no significant difference in symptoms over 6–8 weeks between buspirone and antidepressants, diazepam, or hydroxyzine, but the studies may have lacked power to detect clinically important differences among treatments.
- **Certain antidepressants (imipramine, opipramol, paroxetine, and venlafaxine)** RCTs have found that antidepressants (imipramine, opipramol, paroxetine, and venlafaxine) improve symptoms over 4–28 weeks compared with placebo. RCTs found no significant difference among these antidepressants or between antidepressants and benzodiazepines or buspirone. RCTs and observational studies have found that antidepressants are associated with sedation, dizziness, nausea, falls, and sexual dysfunction.
- **Cognitive behavioural therapy** Two systematic reviews and two subsequent RCTs have found that cognitive behavioural therapy (using a combination of interventions, such as exposure, relaxation, and cognitive restructuring) improves anxiety and depression over 4–12 weeks compared with waiting list control, anxiety management alone, relaxation alone, or non-directive psychotherapy. Three subsequent RCTs, two in people aged ≥60 years, found no significant difference in symptoms at 13 weeks, 6 months, or 24 months between cognitive therapy and applied relaxation.
- **Hydroxyzine** Three RCTs comparing hydroxyzine versus placebo found different results. Two RCTs found that, compared with placebo, hydroxyzine improved symptoms of anxiety at 4 or 12 weeks, but a third RCT found no significant difference in the proportion of people with improved symptoms of anxiety at 5 weeks. One of the RCTs found that hydroxyzine increased somnolence and

headaches compared with placebo. One RCT found no significant difference between hydroxyzine and bromazepam in the proportion of people who responded after 6 weeks. Another RCT found no significant difference between hydroxyzine and buspirone in the proportion of people who responded after 4 weeks.

- **Benzodiazepines** One systematic review and one subsequent RCT found that benzodiazepines reduced symptoms over 2–9 weeks compared with placebo. RCTs found no significant difference in symptoms over 3–8 weeks between alprazolam and bromazepam or mexazolam, or between benzodiazepines and buspirone, hydroxyzine, abecarnil, or antidepressants. RCTs and observational studies found that benzodiazepines increased the risk of dependence, sedation, industrial accidents, and road traffic accidents and that, if used in late pregnancy or while breast feeding, benzodiazepines may cause adverse effects in neonates. One systematic review of poor quality RCTs provided insufficient evidence to assess long term treatment with benzodiazepines.
- **Kava** One systematic review in people with a variety anxiety disorders, including generalised anxiety disorder, found that kava reduced symptoms of anxiety over 1–24 weeks compared with placebo. It is unclear whether results of the review are generalisable to people with generalised anxiety disorder. Observational evidence suggests that kava may be associated with hepatotoxicity.
- **Trifluoperazine** One large RCT found that trifluoperazine reduced anxiety after 4 weeks compared with placebo, but caused more drowsiness, extrapyramidal reactions, and other movement disorders.
- **Abecarnil** One RCT found limited evidence that low dose abecarnil improved symptoms compared with placebo. Another RCT found no significant difference in symptoms at 6 weeks between abecarnil and placebo or diazepam. Both RCTs found that abecarnil increased drowsiness compared with placebo.
- **Applied relaxation** We found no RCTs comparing applied relaxation versus placebo or no treatment. Three RCTs found no significant difference in symptoms at 13 weeks, 6 months, or 24 months between applied relaxation and cognitive behavioural therapy.
- **β Blockers** We found no RCTs on the effects of β blockers in people with generalised anxiety disorder.

DEFINITION Generalised anxiety disorder (GAD) is defined as excessive worry and tension about every day events and problems, on most days, for at least 6 months, to the point where the person experiences distress or has marked difficulty in performing day-to-day tasks.[1] It may be characterised by the following symptoms and signs: increased motor tension (fatigability, trembling, restlessness, and muscle tension); autonomic hyperactivity (shortness of breath, rapid heart rate, dry mouth, cold hands, and dizziness); and increased vigilance and scanning (feeling keyed up, increased startling, and impaired concentration), but not panic attacks.[1] One non-systematic review of epidemiological and clinical studies found marked reduction of quality of life and psychosocial functioning in people with anxiety disorders (including GAD).[2] It also found that people with GAD had low overall life satisfaction and some impairment in ability to fulfil roles, social tasks, or both.[2]

INCIDENCE/ PREVALENCE One overview of observational studies found that the prevalence of GAD among adults in the community was 1.5–3.0%.[3] It found that 3–5% of adults had had GAD in the past year and 4–7% had had GAD during their lives. The US National Comorbidity Survey found that over 90% of people diagnosed with GAD had a co-morbid diagnosis,

Generalised anxiety disorder

including dysthymia (22%), depression (39–69%), somatisation, other anxiety disorders, bipolar disorder, or substance abuse.[4] The Harvard Brown Anxiety Research Program also found that only 30/180 people (17%) had GAD alone.[5] Subgroup analysis suggested that 46/122 people with GAD (38%) had co-morbid personality disorder.[6] A systematic review of the comorbidity of eating disorders and anxiety disorders (search date 2001, 2 observational studies, 55 people) found a lifetime prevalence of GAD among people with anorexia nervosa of 24% in one study and 31% in the other.[7] The lifetime prevalence of GAD in the control group of one of the studies (44 people) was 2%. The reliability of the measures used to diagnose GAD in epidemiological studies is unsatisfactory.[8,9] One US study, with explicit diagnostic criteria (DSM-III-R), estimated that 5% of people will develop GAD at some time during their lives.[9] A recent cohort study of people with depressive and anxiety disorders found that 49% of people initially diagnosed with GAD retained this diagnosis over 2 years.[10] The incidence of GAD in men is only half the incidence in women[11] and is lower in older people.[12] A non-systematic review (20 observational studies in younger and older adults) suggested that autonomic arousal to stressful tasks was decreased in older people, and that older people became accustomed to stressful tasks more quickly than younger people.[13]

AETIOLOGY/ RISK FACTORS

GAD is believed to be associated with an increase in the number of minor stressors, independent of demographic factors,[14,15] but this finding is also common in people with other diagnoses.[10] One non-systematic review (5 case control studies) of psychological sequelae to civilian trauma found that rates of GAD reported in four of the five studies were significantly increased compared with a control population (rate ratio 3.3, 95% CI 2.0 to 5.5).[16] One systematic review (search date 1997) of cross-sectional studies found that bullying (or peer victimisation) was associated with a significant increase in the incidence of GAD (effect size 0.21, CI not reported).[17] Genetic factors are also implicated. One systematic review (search date not reported, 2 family studies, 45 index cases, 225 first degree relatives) found a significant association between GAD in the index cases and in their first degree relatives (OR 6.1, 95% CI 2.5 to 14.9).[18] The review also identified three twin studies (13 305 people), which estimated that 32% (95% CI 24% to 39%) of the variance to liability to GAD was explained by genetic factors.

PROGNOSIS

One systematic review found that 25% of adults with GAD will be in full remission after 2 years, and 38% will have a remission after 5 years.[3] The Harvard-Brown anxiety research program reported 5 year follow up of 167 people with GAD.[19] In this period, the weighted probability for full remission was 38% and for at least partial remission was 47%: the probability of relapse from full remission was 27% and relapse from partial remission was 39%.

AIMS OF INTERVENTION

To reduce symptoms of anxiety; to minimise disruption of day-to-day functioning; and to improve quality of life, with minimum adverse effects.

OUTCOMES

Severity of symptoms and effects on quality of life, as measured by symptom scores on continuous rating scales, usually the Hamilton Anxiety Scale, State-Trait Anxiety Inventory, or Clinical Global

Impression Scale. Other continuous scales include the Penn State Worry Questionnaire and the GAD Severity Scale. Most RCTs define a 20% reduction in symptoms scores on the relevant scale as a clinical response. Where numbers needed to treat are given, these represent the number of people requiring treatment within a given time period (usually 6–12 weeks) for one additional person to achieve a certain improvement in symptom score. The method for obtaining numbers needed to treat was not standardised across studies. Some RCTs defined a reduction by, for example, 20 points in the Hamilton Anxiety Scale as a clinical response, others defined a clinical response as a reduction, for example, by 50% of the premorbid score. The authors have not attempted to standardise methods, but instead have used the response rates reported in each study to calculate numbers needed to treat. Similarly, the authors have calculated numbers needed to harm from original trial data.

METHODS *Clinical Evidence* search and appraisal June 2003. Recent changes in diagnostic classification make it hard to compare older studies with more recent ones. In the earlier classification system (DSM-III-R) the diagnosis was made only in the absence of other psychiatric disorders. In current systems (DSM-IV and ICD-10), GAD can be diagnosed in the presence of any comorbid condition.

QUESTION What are the effects of treatments?

OPTION COGNITIVE BEHAVIOURAL THERAPY

Two systematic reviews and two subsequent RCTs have found that cognitive behavioural therapy (using a combination of interventions such as exposure, relaxation, and cognitive restructuring) improves anxiety and depression over 4–12 weeks compared with waiting list control, anxiety management alone, relaxation alone, or non-directive psychotherapy. Three subsequent RCTs, two in people aged ≥ 60 years, found no significant difference in symptoms at 13 weeks, 6 months, or 24 months between cognitive therapy and applied relaxation.

Benefits: We found two systematic reviews[20,21] and five subsequent RCTs[22–26] comparing cognitive behavioural therapy (see glossary, p 1316) versus waiting list control (no treatment) or versus other psychotherapies in people with generalised anxiety disorder (GAD). The first systematic review (search date 1996, 13 RCTs, 722 people aged 18–60 years, 60% women) compared cognitive behavioural therapy (which involved, alone or in combination, cognitive restructuring, relaxation, exposure, and systematic desensitisation) versus control (remaining on a waiting list, anxiety management alone, relaxation alone, and non-directive psychotherapy).[20] It found that cognitive behavioural therapy significantly improved symptoms over 4–12 weeks compared with control (effect size for anxiety 0.70, 95% CI 0.57 to 0.83 and for depression 0.77, 95% CI 0.64 to 0.90; dichotomous data not reported). The second systematic review (search date not reported, 5 RCTs, 313 people aged 18–60 years) included three RCTs identified by the first review.[21] It found that cognitive behavioural therapy (including relaxation, cognitive therapy, behavioural therapy, and anxiety

management training, alone or in combination) or analytical psychotherapy were associated with an improvement in symptoms compared with waiting list control (median effect size 0.9; CI not reported).[21] The first subsequent RCT (75 people aged > 55 years) compared three interventions: cognitive therapy, attending a discussion group on worrying topics, and waiting list control for 12 weeks.[25] It found that, compared with waiting list control, either cognitive therapy or a discussion group significantly increased the proportion of people who no longer met criteria for GAD immediately after treatment (people without GAD: 54% with cognitive therapy *v* 50% with discussion group *v* 13% with control; $P < 0.01$ for either treatment *v* control; absolute numbers not reported). It found no significant difference between cognitive therapy and a discussion group in the proportion of people who no longer met criteria for GAD immediately after treatment ($P = 0.78$) or at 6 months (72% with cognitive therapy *v* 53% with discussion group; $P = 0.23$). The second subsequent RCT (80 people aged > 60 years) compared cognitive therapy versus minimal contact for 15 weeks.[24] Minimal contact involved one telephone call a week (see comment below). Symptoms were assessed by Hamilton Anxiety Scale (HAM-A), State-Trait Anxiety Inventory, Penn State Worry Questionnaire, and GAD Severity Scale. It found that cognitive therapy significantly increased the proportion of people who responded immediately after treatment compared with minimal contact (response defined as a 20% reduction in symptoms on 3 of the 4 assessment scales: 13/29 [45%] with cognitive therapy *v* 3/35 [8%] with minimal contact; RR 5.2, 95% CI 1.6 to 16.5; NNT 3, 95% CI 2 to 8). The third subsequent RCT (36 people aged 18–60 years) found no significant difference between 12 weekly sessions of cognitive therapy and applied relaxation (see glossary, p 1316) in the proportion of people who responded after 13 weeks (response defined as improvement to score 3 or 4 on Cognitive Global Impression Scale, 10/18 [56%] with cognitive therapy *v* 8/15 [53%] with applied relaxation; RR 1.04, 95% CI 0.55 to 1.95).[22] The fourth subsequent RCT (76 people aged mean 37 years, 69 people completed) compared 15 weekly sessions of cognitive therapy, applied relaxation, and a combination of these methods.[23] It found that similar proportions of people in each group no longer met criteria for GAD immediately after treatment and at 24 months (people without GAD at follow up: 8.7% in each group immediately after treatment; 14.3% with cognitive therapy *v* 19.1% with applied relaxation *v* 19.1% with combination of treatments at 24 months; P value not reported).[23] The fifth subsequent RCT (45 people aged 17–70 years) found no significant difference between cognitive therapy and applied relaxation for 12 weeks in the proportion of people who responded at 6 months (response defined as a score of ≤ 46 on the State-Trait Anxiety Inventory: 55% with cognitive therapy *v* 53.3% with applied relaxation; results not intention to treat, reported as non-significant, absolute numbers not reported).[26]

Harms: The reviews and subsequent RCTs gave no information on harms.[20–27]

Comment: In the second subsequent RCT, the control group received minimal contact rather than usual care without cognitive therapy; this may have overestimated the effect of cognitive therapy.[24] A third systematic review (search date 1998, 6 RCTs comparing cognitive therapy versus a variety of other psychological treatments, 404 people) did not compare treatments directly.[28] It reanalysed the raw data from individual RCTs to calculate the proportion of people who experienced a clinically important improvement in symptoms after treatment and maintained that improvement for 6 months. It found limited evidence that more people who had individual cognitive therapy maintained recovery after 6 months than people who had other psychological treatments, with the exception of applied relaxation (proportion of people who maintained improvement: 41% with individual cognitive therapy, 19% with non-directive treatment, 18% with group cognitive therapy, 12% with group behaviour therapy, 18% with individual behaviour therapy, 0% with analytical psychotherapy, and 52% with applied relaxation; P values not reported).[28] Many of the RCTs were small and were not analysed on an intention to treat basis.

OPTION APPLIED RELAXATION

We found no RCTs comparing applied relaxation versus placebo or no treatment. Three RCTs found no significant difference in symptoms at 13 weeks, 6 months, or 24 months between applied relaxation and cognitive therapy.

Benefits: **Versus placebo or no treatment:** We found no systematic review or RCTs. **Versus other psychological treatments:** See benefits of cognitive therapy, p 1305.

Harms: **Versus other psychological treatments:** See harms of cognitive therapy, p 1305.

Comment: We found one systematic review (search date 1998, 6 RCTs comparing cognitive therapy (see glossary, p 1316) versus a variety of other psychological treatments, 404 people), which did not compare treatments directly (see comment on cognitive therapy, p 1307).[28]

OPTION BENZODIAZEPINES

One systematic review and one subsequent RCT found that benzodiazepines reduced symptoms over 2–9 weeks compared with placebo. RCTs found no significant difference in symptoms over 3–8 weeks between alprazolam and bromazepam or mexazolam, or between benzodiazepines and buspirone, hydroxyzine, abecarnil, or antidepressants. RCTs and observational studies found that benzodiazepines increased the risk of dependence, sedation, industrial accidents, and road traffic accidents and that, if used in late pregnancy or while breast feeding, benzodiazepines may cause adverse effects in neonates. One systematic review of poor quality RCTs provided insufficient evidence to assess long term treatment with benzodiazepines.

Generalised anxiety disorder

Benefits:

Versus placebo: We found one systematic review (search date 1996, 17 RCTs, 2044 people)[20] and one subsequent RCT.[29] The review found that benzodiazepines significantly improved symptoms over 2–9 weeks compared with placebo (pooled mean effect size 0.70; CI not reported).[20] The subsequent RCT (310 people) compared three interventions: diazepam (15–35 mg/day), abecarnil (7.5–17.5 mg/day), and placebo.[29] It found that diazepam significantly increased the proportion of people with moderate improvement on the Clinical Global Impression (CGI) scores at 6 weeks compared with placebo (73% with diazepam *v* 56% with placebo; $P < 0.01$).[29] **Versus each other:** The systematic review did not compare different benzodiazepines directly.[20] We found two RCTs.[30,31] The first RCT (121 people) compared sustained release alprazolam versus bromazepam.[30] It found no significant difference in Hamilton Anxiety Scale scores or CGI scores over 5 weeks between alprazolam and bromazepam (reported as non-significant, results presented graphically).[30] The second RCT (64 people) comparing mexazolam versus alprazolam found no significant difference in the proportion of people who had "highly improved" or "moderately improved" CGI scores at 3 weeks (98% with "highly improved" *v* 87% "moderately improved"; $P > 0.05$; absolute numbers presented graphically).[31] **Long term treatment:** We found one systematic review (search date 1998, 8 RCTs, any benzodiazepine medication, > 2 months' duration).[32] It found that the weak methods of the RCTs prevented firm conclusions being made.[32] **Versus buspirone:** See benefits of buspirone, p 1309. **Versus hydroxyzine:** See benefits of hydroxyzine, p 1310. **Versus abecarnil:** See benefits of abecarnil, p 1311. **Versus antidepressants:** See benefits of antidepressants, p 1312.

Harms:

Versus placebo: The review gave no information on harms.[20] The subsequent RCT found that, compared with placebo, both diazepam and abecarnil significantly increased drowsiness (52% with diazepam *v* 47% with abecarnil *v* 14% with placebo; $P < 0.05$ for either drug *v* placebo) and dizziness (11% with diazepam *v* 16% with abecarnil *v* 3% with placebo; $P < 0.05$ for either drug *v* placebo).[29] **Dependence and sedation:** One non-systematic review of the harms of benzodiazepines found that rebound anxiety on withdrawal has been reported in 15–30% of people.[33] It also found that there is a high risk of substance abuse and dependence with benzodiazepines. Benzodiazepines have been found to cause impairment in attention, concentration, and short term memory. One RCT identified by the review found an increased rate of drowsiness (71% with diazepam *v* 13% with placebo; $P = 0.001$) and dizziness (29% with diazepam *v* 11% with placebo; $P = 0.001$).[20] Sedation can interfere with concomitant psychotherapy. **Memory:** Thirty one people with agoraphobia/panic disorder in an RCT comparing alprazolam versus placebo for 8 weeks were reviewed after 3.5 years.[34] Five people were still taking benzodiazepines and had significant impairment in memory tasks. There was no clear difference in memory performance between those who had been in the placebo group and those who had been given alprazolam but were no longer taking the drug.[34] **Road traffic accidents:** We found one systematic review (search date 1997) examining the relation between benzodiazepines and road traffic

accidents.[35] In the case control studies, the odds ratio for death or emergency medical treatment in those who had taken benzodiazepines compared with those who had not taken them was 1.45–2.40. The odds ratio increased with higher doses and more recent intake. In the police and emergency ward studies, benzodiazepine use was a factor in 1–65% of accidents (usually 5–10%). In two studies in which people had blood alcohol concentrations under the legal limit, benzodiazepines were found in 43% and 65% of people. For drivers over 65 years of age, the risk of being involved in reported road traffic accidents was higher if they had taken longer acting and larger quantities of benzodiazepines. These results are from case control studies and are, therefore, subject to confounding. **Pregnancy and breast feeding:** One systematic review (search date 1997) of 23 case series and reports found no association between cleft lip and palate and benzodiazepines in the first trimester of pregnancy.[36] However, case reports in one non-systematic review suggested that benzodiazepines taken in late pregnancy may be associated with neonatal hypotonia and withdrawal syndrome.[37] Benzodiazepines are secreted in breast milk, and there have been reports of sedation and hypothermia in infants.[38] **Other:** One non-systematic industry funded review (8 RCTs) comparing benzodiazepines versus placebo or buspirone found that recent use of benzodiazepines limited the effectiveness of buspirone in people with generalised anxiety disorder.[38]

Comment: All of the RCTs assessing benzodiazepines were short term (at most 12 weeks).[20,29,30]

OPTION BUSPIRONE

RCTs have found that buspirone improves symptoms over 4–9 weeks compared with placebo. RCTs found no significant difference in symptoms over 6–8 weeks between buspirone and antidepressants, diazepam, or hydroxyzine, but the studies may have lacked power to detect clinically important differences among treatments.

Benefits: **Versus placebo:** We found one systematic review (search date 1996, 9 RCTs)[20] and two subsequent RCTs.[39,40] The systematic review found that buspirone significantly improved symptoms over 4–9 weeks compared with placebo (pooled mean effect size 0.39; CI not reported, withdrawal rate 17%).[20] The first subsequent RCT (162 people) comparing buspirone versus placebo found similar results (55% with buspirone *v* 35% with placebo; $P < 0.05$).[39] The second subsequent RCT (365 people) compared four interventions: buspirone (30 mg/day), venlafaxine (75 mg/day), venlafaxine (150 mg/day), and placebo over 8 weeks (see also benefits of antidepressants, p 1312).[39] It found that, compared with placebo, buspirone significantly increased the proportion of people who responded after 8 weeks of treatment (response defined as score of 1 or 2 on the Clinical Global Impression Scale; 52/95 [55%] with buspirone *v* 38/98 [39%] with placebo; $P = 0.03$).[39] **Versus benzodiazepines:** One large RCT (240 people) identified by the review[20] compared three interventions: buspirone, diazepam, and placebo.[41] It found that a similar proportion of people responded over 6 weeks with buspirone compared with diazepam (response

defined as ≥ 40% reduction in Hamilton Anxiety Scale score; 54% with buspirone *v* 61% with diazepam; P values not reported).[41] **Versus antidepressants:** See benefits of antidepressants, p 1312. **Versus hydroxyzine:** See benefits of hydroxyzine, p 1310.

Harms: The systematic review gave no information on harms.[20] One subsequent RCT found that, compared with placebo, buspirone significantly increased the proportion of people with nausea (27/80 [34%] with buspirone *v* 11/82 [13%] with placebo; RR 2.5, 95% CI 1.3 to 4.7; NNH 5, 95% CI 4 to 14), dizziness (51/80 [64%] with buspirone *v* 10/82 [12%] with placebo; RR 5.2, 95% CI 2.9 to 9.6; NNH 2, 95% CI 2 to 3), and somnolence (15/80 [19%] with buspirone *v* 6/82 [7%] with placebo; RR 2.6, 95% CI 1.0 to 6.3; NNH 9, 95% CI 5 to 104).[39] Diazepam was associated with more fatigue and weakness compared with buspirone but less headache and dizziness.[41] **Pregnancy and breast feeding:** We found no evidence on the effects of buspirone during pregnancy or breast feeding..

Comment: We found one non-systematic review (8 RCTs, 520 people) that was sponsored by pharmaceutical companies and had been included in regulatory submissions for buspirone.[42] It found that buspirone significantly increased the proportion of people "much or very much improved" as rated by their physician compared with placebo (54% with buspirone *v* 28% with placebo; P ≤ 0.001). Another non-systematic industry funded review (8 RCTs) comparing benzodiazepines versus placebo or buspirone found that recent use of benzodiazepines limited the effectiveness of buspirone in people with generalised anxiety disorder.[38]

OPTION HYDROXYZINE

Three RCTs comparing hydroxyzine versus placebo found different results. Two RCTs found that, compared with placebo, hydroxyzine improved symptoms of anxiety at 4 or 12 weeks, but a third RCT found no significant difference in the proportion of people with improved symptoms of anxiety at 5 weeks. One of the RCTs found that hydroxyzine increased somnolence and headaches compared with placebo. One RCT found no significant difference between hydroxyzine and bromazepam in the proportion of people who responded after 6 weeks. Another RCT found no significant difference between hydroxyzine and buspirone in the proportion of people who responded after 4 weeks.

Benefits: **Versus placebo:** We found one non-systematic review (2 RCTs, 354 people)[43] and one additional RCT.[44] The first RCT (110 people) identified by the review found that hydroxyzine (50 mg/day) significantly improved Clinical Global Impression Scale scores after 4 weeks compared with placebo (mean improvement 1.53 with hydroxyzine *v* 0.95 with placebo; P < 0.02).[43] The second RCT (244 people entered, 213 people analysed) identified by the review compared three interventions: hydroxyzine, buspirone, and placebo for 28 days, followed by placebo in all groups for 7 days. It found no significant difference between hydroxyzine 50 mg/day and placebo in the proportion of people with a Hamilton Anxiety Scale (HAM-A) score reduction of 50% or greater at 35 days (30/71 [42%] with

hydroxyzine *v* 20/70 [29%] with placebo; RR 1.50, 95% CI 0.93 to 2.23; not intention to treat).[43] The additional RCT (369 people) also compared three interventions: hydroxyzine, bromazepam, and placebo for 12 weeks, followed by placebo in all groups for 1 week.[44] It found that, compared with placebo, hydroxyzine significantly increased the proportion of people who responded at 42 days (response defined as ≥ 50% reduction in HAM-A scores from baseline; P = 0.022; absolute numbers presented graphically). **Versus benzodiazepines:** The additional RCT found no significant difference in the proportion of people who responded at 42 days between hydroxyzine and bromazepam (response defined as a HAM-A score reduction of ≥50%; reported as non-significant, no further data provided).[44] **Versus buspirone:** The second RCT identified by the non-systematic review also found no significant difference between hydroxyzine and buspirone in the proportion of people who responded at 28 days (response defined as HAM-A score reduction of ≥ 50%: 30/71 [42%] with hydroxyzine *v* 26/72 [36%] with buspirone; RR 1.20, 95% CI 0.78 to 1.80).[43]

Harms: **Versus placebo:** The second RCT (244 people) identified by the review found that, compared with placebo, more people taking hydroxyzine had somnolence (AR 10% with hydroxyzine *v* 0% with placebo) and headaches (AR 6% with hydroxyzine *v* 1% with placebo).[43] Overall adverse effects were reported in 40% of people taking hydroxyzine and 28% taking placebo.

Comment: None.

OPTION ABECARNIL

One RCT found limited evidence that low dose abecarnil improved symptoms compared with placebo. Another RCT found no significant difference in symptoms at 6 weeks between abecarnil and placebo or diazepam. Both RCTs found that abecarnil increased drowsiness compared with placebo.

Benefits: We found no systematic review, but found two multicentre RCTs of abecarnil (an anxiolytic).[29,45] The first RCT (129 people) compared 3 weeks of treatment with abecarnil (3–9, 7.5–15, and 15–30 mg/day) versus placebo.[45] Within each group the dose was escalated from the minimum to the maximum over the length of the trial. It found that lower doses of abecarnil (3–9 mg/day) significantly improved symptoms compared with placebo (outcome 50% reduction in Hamilton Anxiety Scale score 19/31 [61%] with abecarnil *v* 8/26 [31%] with placebo; RR 1.99, 95% CI 1.05 to 3.78), but found no significant difference in symptoms between higher doses of abecarnil and placebo. Results were not calculated by intention to treat (12/34 [35%] people withdrew with abecarnil 15–30 mg/day *v* 4/35 [11%] with abecarnil 7.5–15 mg/day *v* 1/32 [3%] with abecarnil 3–9 mg/day *v* 2/28 [7%] with placebo).[45] The second RCT (310 people) compared three interventions: abecarnil (7.5–17.5 mg/day), diazepam (15–35 mg/day), and placebo.[29] It found no significant difference between abecarnil and placebo or

diazepam in the proportion of people with moderate improvement on the Clinical Global Impression scores at 6 weeks (AR for moderate improvement 62% with abecarnil *v* 56% with placebo *v* 73% with diazepam; reported as non-significant; P values not reported).[29]

Harms: The first RCT found that abecarnil (3–9 mg/day) was associated with fatigue (4/32 [13%] with abecarnil *v* 0/28 [0%] with placebo), equilibrium loss (2/32 [6%] with abecarnil *v* 0/28 [0%] with placebo), and drowsiness (10/32 [31%] with abecarnil *v* 4/28 [14%] with placebo). Higher doses were associated with more adverse effects (62% of people taking abecarnil 15–30 mg experienced at least 1 adverse effect *v* 51% of people taking abecarnil 7.5–15 mg *v* 22% with abecarnil 3–9 mg *v* 21% with placebo).[45]

Comment: None.

OPTION ANTIDEPRESSANTS

RCTs have found that antidepressants (imipramine, opipramol, paroxetine, and venlafaxine) improve symptoms over 4–28 weeks compared with placebo. RCTs found no significant difference among these antidepressants or between antidepressants and benzodiazepines or buspirone. RCTs and observational studies have found that antidepressants are associated with sedation, dizziness, nausea, falls, and sexual dysfunction.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 8 RCTs, 2058 people),[46] one subsequent[47] and one additional RCT.[48] The review found that antidepressants (imipramine, paroxetine, and venlafaxine) significantly increased the proportion of people who responded at 8–28 weeks compared with placebo (4 RCTs, proportion of people who failed to respond 277/606 [46%] with antidepressants *v* 280/449 [62%] with placebo; RR of not responding 0.70, 95% CI 0.62 to 0.79; NNT 6, 95% CI 5 to 9).[46] It also found that each antidepressant significantly increased response rates compared with placebo: imipramine (1 RCT; RR 0.67, 95% CI 0.50 to 0.91; NNT 4, 95% CI 3 to 14), venlafaxine (2 RCTs; RR 0.68, 95% CI 0.46 to 0.99; NNT 5, 95% CI 4 to 9), and paroxetine (1 RCT; RR 0.72, 95% CI 0.56 to 0.92; NNT 7, 95% CI 4 to 25).[46] The subsequent RCT compared paroxetine (20 or 40 mg/day) versus placebo.[47] It found that, compared with placebo, paroxetine at either dose significantly increased response rates (response defined as Clinical Global Impression [CGI] scores ≤ 2: paroxetine 20 mg/day: 116/188 [62%] *v* 82/180 [45%]; RR 1.36, 95% CI 1.11 to 1.64; NNT 6, 95% CI 4 to 13; paroxetine 40 mg/day: 134/197 [68%] *v* 82/180 [45%]; RR 1.49, 95% CI 1.24 to 1.79; NNT 4, 95% CI 3 to 6).[47] The additional RCT (318 people) compared three treatments: opipramol (a tricyclic antidepressant with minimal serotonin reuptake blocking properties), alprazolam, or placebo over 28 days.[48] It found that opipramol significantly increased response rate after 28 days compared with placebo (response defined as CGI scale score of < 2; 63/100 [63%] with opipramol *v* 50/107 [47%] with placebo; RR 1.35, 95% CI 1.05 to 1.69; NNT 7; 95% CI 1 to 26). **Versus each other:** The systematic review[46] identified one RCT (56 people) that found no significant

difference between paroxetine and imipramine in the proportion of people who responded over 8 weeks of treatment (proportion who failed to respond 3/36 [8%] with paroxetine *v* 2/30 [7%] with imipramine; RR of failing to respond 1.73, 95% CI 0.31 to 9.57). **Versus benzodiazepines:** The systematic review[46] identified two RCTs[49,50] and we found one additional RCT.[48] The first RCT (230 people) identified by the review compared variable doses of four interventions: imipramine, trazodone, diazepam, and placebo.[49] It found similar improvements among groups in participant assessed global improvement after 8 weeks of treatment (results not intention to treat; 73% of people improved with imipramine *v* 67% with trazodone *v* 66% with diazepam).[49] The RCT did not directly compare the significance of differences between groups. The second RCT (81 people) identified by the review compared paroxetine, imipramine, and 2'-chlordesmethyldiazepam for 8 weeks.[50] It found that paroxetine and imipramine significantly improved anxiety after 8 weeks compared with 2'-chlordesmethyldiazepam (mean Hamilton Anxiety Scale score: 11.1 with paroxetine *v* 10.8 with imipramine *v* 12.9 with 2'-chlordesmethyldiazepam; P = 0.05 for either comparison *v* 2'-chlordesmethyldiazepam). The additional RCT found no significant difference between opipramol and alprazolam in response rate over 28 days (63/100 [63%] with opipramol *v* 67/105 [64%] with alprazolam; RR 1.01, 95% CI 0.79 to 1.25).[48] **Versus buspirone:** One RCT (365 people) identified by the review[46] compared four interventions: venlafaxine at two different doses (75 or 150 mg/day), buspirone (30 mg/day), and placebo over 8 weeks. It found similar response rates between venlafaxine and buspirone after 8 weeks of treatment (response defined as CGI score of 1 or 2; 54/87 [62%] with venlafaxine 75 mg *v* 44/89 [49%] with venlafaxine 150 mg *v* 52/95 [55%] with buspirone; P values not reported).[40]

Harms:

Withdrawals: The review found no significant difference between antidepressants and placebo in the proportion of people who withdrew for any cause (403/1273 [31%] with antidepressants *v* 240/678 [35%] with placebo; RR 0.95, 95% CI 0.73 to 1.24).[46] A survival analysis of the two RCTs of venlafaxine (767 people) identified by the review[46] found no significant difference between venlafaxine and placebo in the proportion of people who withdrew because of adverse effects over 6 months (36/253 [14%] with venlafaxine *v* 91/514 [18%] with placebo; RR 1.24, 95% CI 0.87 to 1.77).[51] **Common adverse events:** The review found that people taking venlafaxine were more likely to report nausea, dry mouth, insomnia, constipation, flatulence, anorexia, somnolence, and sexual dysfunction than people taking placebo.[46] One RCT found sedation, confusion, dry mouth, and constipation with both imipramine and trazodone.[49] RCTs reported nausea, somnolence, dry mouth, sweating, constipation, anorexia, and sexual dysfunction with venlafaxine. Most of the adverse effects (apart from dizziness and sexual dysfunction) decreased over 6 months in those who continued to take the medication. There have been case reports of nausea in people taking paroxetine.[50] **Adverse effects when discontinuing treatment:** Abrupt discontinuation of selective serotonin reuptake inhibitors has been associated with adverse effects including dizziness, headache, nausea, vomiting, diarrhoea,

movement disorders, insomnia, irritability, visual disturbance, lethargy, anorexia, and lowered mood. One RCT (120 people receiving maintenance selective serotonin reuptake inhibitors for depression) found that significantly more people had adverse effects when discontinuing paroxetine or sertraline compared with people discontinuing fluoxetine (60% with paroxetine *v* 66% with sertraline *v* 16% taking fluoxetine; $P < 0.01$ for paroxetine or sertraline *v* fluoxetine).[52] **Overdose:** In a series of 239 coroner directed necropsies from 1970–1989, tricyclic antidepressants were considered to be a causal factor in 12% of deaths and hypnosedatives (primarily benzodiazepines and excluding barbiturates) in 8% of deaths.[53] **Accidental poisoning:** Tricyclic antidepressants are a major cause of accidental poisoning.[54] A study estimated that there was one death for every 44 children admitted to hospital after ingestion of tricyclic antidepressants.[55] **Hyponatraemia:** One case series reported 736 incidents of hyponatraemia in people taking selective serotonin reuptake inhibitors; 83% of episodes were in hospital inpatients aged over 65 years.[56] It is not possible to establish causation from this type of data. **Falls:** One retrospective cohort study (2428 elderly residents of nursing homes) found an increased risk of falls in new users of antidepressants (665 people taking tricyclic antidepressants; adjusted RR 2.0, 95% CI 1.8 to 2.2; 612 people taking selective serotonin reuptake inhibitors; adjusted RR 1.8, 95% CI 1.6 to 2.0; and 304 people taking trazodone; adjusted RR 1.2, 95% CI 1.0 to 1.4).[57] The increased rate of falls persisted through the first 180 days of treatment and beyond. One case control study (8239 people aged ≥66 years, treated in hospital for hip fracture) found an increased risk of hip fracture in those taking antidepressants (adjusted OR, selective serotonin reuptake inhibitors 2.4, 95% CI 2.0 to 2.7; secondary amine tricyclic antidepressants such as nortriptyline 2.2, 95% CI 1.8 to 2.8; and tertiary amine tricyclic antidepressants such as amitriptyline 1.5, 95% CI 1.3 to 1.7).[58] This study could not control for confounding factors; people taking antidepressants may be at increased risk of hip fracture for other reasons. **In pregnancy:** We found no reports of harmful effects in pregnancy. One case control study found no evidence that imipramine or fluoxetine increased the rate of malformations in pregnancy.[59] **Sexual dysfunction:** A survey (1022 people mostly suffering from depression; 610 women) of people using antidepressants with acceptable sexual function before antidepressant treatment has reported the incidence of sexual dysfunction (decreased desire, delayed ejaculation, and anorgasmia) to be 71% with paroxetine, 67% with venlafaxine, and 63% with fluvoxamine.[60]

Comment: None.

OPTION ANTIPSYCHOTIC DRUGS

One large RCT found that trifluoperazine reduced anxiety after 4 weeks compared with placebo, but caused more drowsiness, extrapyramidal reactions, and other movement disorders.

Benefits: We found no systematic review. We found one RCT (415 people) comparing 4 weeks of trifluoperazine treatment (2–6 mg/day) versus placebo.[61] It found that trifluoperazine significantly reduced the total score on the Hamilton Anxiety Scale compared with placebo (difference 14 points; $P < 0.001$).

Harms: The RCT reported more cases of drowsiness (43% with trifluoperazine *v* 25% with placebo) and extrapyramidal reactions and movement disorders (17% with trifluoperazine *v* 8% with placebo) with trifluoperazine compared with placebo.[61] A cohort study found that in the longer term, rates of tardive dyskinesia are increased if trifluoperazine treatment is frequently interrupted.[62]

Comment: None.

OPTION β BLOCKERS

We found no RCTs on the effects of β blockers in people with generalised anxiety disorder.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION KAVA

One systematic review in people with a variety anxiety disorders, including generalised anxiety disorder, found that kava reduced symptoms of anxiety over 1–24 weeks compared with placebo. It is unclear whether results of the review are generalisable to people with generalised anxiety disorder. Observational evidence suggests that kava may be associated with hepatotoxicity.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 11 RCTs, 645 people with a variety of anxiety disorders, including generalised anxiety disorder, preoperative anxiety, and climacteric).[63] It found that kava significantly improved Hamilton Anxiety Scale scores over 1–24 weeks compared with placebo (6 RCTs, 345 people: WMD 4.97, 95% CI 1.14 to 8.81).

Harms: The review gave little information on adverse effects.[63] Eight RCTs identified by the review found that kava was associated with adverse effects, including stomach complaints, restlessness, drowsiness, tremor, headache, and tiredness.[63] We found one systematic review (search date 2000, 30 studies including 9 clinical trials) assessing adverse effects associated with kava.[64] Adverse effects in the clinical trials were gastrointestinal symptoms, tiredness, restlessness, tremor, and headache. Post-marketing surveillance (4049 adults taking 150 mg/day kava extract) found an adverse reaction rate of 1.5% (61/4094). Case reports included five cases of dermatological reactions, four cases of acute dyskinesias, nine cases of liver damage, and one case of myoglobulinuria (the incidence of these adverse effects was not reported).[64] One case was found where kava may have interacted with alprazolam, leading to decreased in level of consciousness.[64]

Generalised anxiety disorder

Comment: It is unclear whether results of the review are generalisable to people with generalised anxiety disorder as we were unable to ascertain how many people in the RCTs included in the review had generalised anxiety disorder.[63] The review found that, although research about kava has been published in languages other than English, there was a trend for positive results to be published in English and negative results in other languages and that this could lead to a bias when extracting data.[63] There have been concerns that kava may cause liver damage.[65]

GLOSSARY

Applied relaxation A technique involving training in relaxation techniques and self monitoring of symptoms without challenging beliefs.

Cognitive behavioural therapy Brief (20 sessions over 12–16 weeks) structured treatment incorporating elements of cognitive therapy and behavioural therapy. Covers a variety of techniques. *Behavioural therapy* is based on learning theory and concentrates on changing behaviour. *Cognitive therapy* is aimed at identifying anxiety associated thoughts and beliefs, changing over monitoring of physical symptoms, and minimising the catastophising that characterises generalised anxiety disorder. This is combined with relaxation, exercise, and testing the validity of beliefs in real life situations. *Cognitive restructuring* involves systematic challenging of thought processes and underlying assumptions related to the symptoms. *Exposure* entails being confronted (through visualisation, image, or the stimulus) with an anxiogenic stimulus in a repetitive and prolonged manner. *Relaxation* involves practising techniques that lead to muscular or bodily relaxation. *Systematic desensitisation* is a type of exposure.

Substantive changes

Antidepressants One RCT added;[47] conclusions unchanged.

Hydroxyzine One RCT found no significant difference between hydroxyzine and bromazepam in the proportion of people who responded after 6 weeks. Hydroxyzine recategorised as Likely to be beneficial.

Cognitive behavioural therapy Three RCTs added;[24–26] conclusions unchanged.

QUESTIONS

INTERVENTIONS

INITIAL TREATMENT

Beneficial

Behavioural therapy. 1326
Cognitive or cognitive behavioural therapy 1327
Serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline) 1322

Unknown effectiveness

Behavioural or cognitive therapy plus serotonin reuptake inhibitors (compared with behavioural or cognitive therapy alone) . . .1328
Electroconvulsive therapy. . . .1329
Venlafaxine. 1322

MAINTENANCE TREATMENT

Unknown effectiveness

Optimum duration of maintenance treatment with serotonin reuptake inhibitors 1329

IN PEOPLE WHO DO NOT RESPOND TO INITIAL TREATMENT WITH SEROTONIN REUPTAKE INHIBITORS

Likely to be beneficial

Addition of antipsychotics to serotonin reuptake inhibitors. 1330

To be covered in future updates

Deep brain stimulation
Other adjuvant/augmentation drug treatment
Other drug monotherapies
Other forms of psychotherapy
Psychosurgery
Transcranial magnetic stimulation

See glossary, p 1331

Key Messages

Initial treatment

- **Behavioural therapy** We found no RCTs comparing behavioural therapy versus no treatment. One systematic review and subsequent RCTs have found that behavioural therapy improves symptoms compared with relaxation. The review and one subsequent RCT found no significant difference in symptoms over 4–16 weeks between behavioural therapy and cognitive therapy. One subsequent RCT found limited evidence that group behavioural therapy improved symptoms after 12 weeks compared with group cognitive behavioural therapy.
- **Cognitive or cognitive behavioural therapy** We found no RCTs comparing cognitive therapy versus no treatment. One RCT found that cognitive behavioural group therapy improved symptoms and quality of life compared with no treatment after 12 weeks. One systematic review and one subsequent RCT

Obsessive compulsive disorder

found no significant difference in symptoms over 4–16 weeks between behavioural therapy and cognitive therapy. Another subsequent RCT found limited evidence that group behavioural therapy improved symptoms over 12 weeks compared with group cognitive behavioural therapy.

- **Serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline)** RCTs have found that selective and non-selective serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine) improve symptoms compared with placebo. Two systematic reviews found inconsistent results about the effects of sertraline compared with placebo. RCTs have found that selective and non-selective serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline) improve symptoms compared with tricyclic antidepressants or monoamine oxidase inhibitors. RCTs have found no consistent evidence of a difference in efficacy among serotonin reuptake inhibitors, but have found that the non-selective serotonin reuptake inhibitor clomipramine is associated with more adverse effects than selective serotonin reuptake inhibitors.
- **Behavioural or cognitive therapy plus serotonin reuptake inhibitors (compared with behavioural or cognitive therapy alone)** RCTs provided insufficient evidence to assess the effects of adding serotonin reuptake inhibitors to behavioural or cognitive therapy.
- **Electroconvulsive therapy** We found no RCTs of electroconvulsive therapy in people with obsessive compulsive disorder.
- **Venlafaxine** One RCT provided insufficient evidence to compare venlafaxine versus clomipramine.

Maintenance treatment

- **Optimum duration of treatment with serotonin reuptake inhibitors** RCTs provided insufficient evidence to define the optimum duration of treatment with serotonin reuptake inhibitors.

In people who do not respond to selective and non-selective serotonin reuptake inhibitors

- **Addition of antipsychotics in people who have not responded to serotonin reuptake inhibitors** Three small RCTs in people unresponsive to serotonin reuptake inhibitors found that the addition of antipsychotics improved symptoms compared with placebo.

DEFINITION Obsessive compulsive disorder involves obsessions, compulsions, or both, that are not caused by drugs or a physical disorder, and which cause significant personal distress or social dysfunction.[1,2] The disorder may have a chronic or an episodic course (see glossary, p 1331). **Obsessions** are recurrent and persistent ideas, images, or impulses that cause pronounced anxiety and that the person perceives to be self produced. **Compulsions** are repetitive behaviours or mental acts performed in response to obsessions or according to certain rules, which are aimed at reducing distress or preventing certain imagined dreaded events. People with obsessive compulsive disorder may have insight into their condition, in that obsessions and compulsions are usually recognised and resisted. There are minor differences in the criteria for obsessive compulsive disorder between the third, revised third, and fourth editions of the *Diagnostic and Statistical Manual* (DSM-III, DSM-III-R, and DSM-IV)[1] and *The ICD-10 Classification of Mental and Behavioural Disorders*.[2]

INCIDENCE/ PREVALENCE One national, community based survey of obsessive compulsive disorder in the UK (1993, 10 000 people) found that 1% of men and 1.5% of women reported symptoms in the past month.[3] An epidemiological catchment area (ECA) survey carried out in the USA in 1984 (about 10 000 people) found age and sex standardised annual prevalence of obsessive compulsive disorder in people aged 26–64 years of 1.3%, and lifetime prevalence of 2.3%.[4] Subsequent cross national surveys using methodology comparable to ECA found age and sex standardised annual and lifetime prevalence in people aged 26–64 years as follows: Canada (survey size about 2200 people), annual prevalence 1.4% (SE 0.25), and lifetime prevalence 2.3% (SE 0.32); Puerto Rico (survey size about 1200 people), annual prevalence 1.8% (SE 0.39), and lifetime prevalence 2.5% (SE 0.46); Germany (survey size 4811 people), annual prevalence 1.6% (SE 0.57), and lifetime prevalence 2.1% (SE 0.66); Taiwan (survey size about 7400 people), annual prevalence 0.4% (SE 0.07), and lifetime prevalence 0.7% (SE 0.10); Korea (survey size about 4000 people), annual prevalence 1.1% (SE 0.10), and lifetime prevalence 1.9% (SE 0.20); and New Zealand (survey size about 1200 people), annual prevalence 1.1% (SE 0.31), and lifetime prevalence 2.2% (SE 0.42).[4]

AETIOLOGY/ RISK FACTORS The cause of obsessive compulsive disorder is uncertain. Behavioural, cognitive, genetic, and neurobiological factors have been implicated.[5–11] Risk factors include a family history of obsessive compulsive disorder, being single (which could be a consequence of the disorder), and belonging to a higher socioeconomic class.[12] Other risk factors include cocaine abuse, female sex, not being in paid employment, past history of alcohol dependence, affective disorder, and phobic disorder.[4]

PROGNOSIS One study (144 people followed for a mean of 47 years) found that an episodic course of obsessive compulsive disorder was more common during the initial years (about 1–9 years), but a chronic course was more common afterwards.[13] Over time, the study found that 39–48% of people had symptomatic improvement. A 1 year prospective cohort study found that 46% of people had an episodic course and 54% had a chronic course.[14]

AIMS OF INTERVENTION To improve symptoms, and to reduce the impact of illness on social functioning and quality of life, with minimal adverse effects of treatment.

OUTCOMES Severity of symptoms; social functioning; and adverse effects of treatment. Commonly used instruments for measuring symptoms include the Hamilton Anxiety Rating scale; the Hamilton Depression Rating scale; and the Yale-Brown Obsessive Compulsive Scale, which is observer rated and well validated. It rates severity of both obsessions and compulsions across five dimensions (time spent, interference with functioning, distress, resistance, and control), each on a five point scale from 0–4 (0 means that the dimension is absent and 4 means that the dimension is present to extremely

severe degree). The total score range of obsessions and compulsions combined is 0–40 (the higher the score the more severe the condition).[15–17] Most trials use a 25% reduction in Yale-Brown scale scores from baseline as indicative of clinically important improvement, but some studies use a 35% reduction.[17]

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION **What are the effects of initial treatments in adults?**

OPTION **SEROTONIN REUPTAKE INHIBITORS (CITALOPRAM, CLOMIPRAMINE, FLUOXETINE, FLUVOXAMINE, PAROXETINE, SERTRALINE)**

RCTs have found that selective and non-selective serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine) improve symptoms compared with placebo. Two systematic reviews found inconsistent results about the effects of sertraline compared with placebo. RCTs have found that selective and non-selective serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline) improve symptoms compared with tricyclic antidepressants or monoamine oxidase inhibitors. One RCT found no significant difference in symptoms between clomipramine and venlafaxine, but it is likely to have been underpowered to detect a clinically important difference. RCTs have found no consistent evidence of a difference in efficacy among serotonin reuptake inhibitors, but have found that the non-selective serotonin reuptake inhibitor clomipramine is associated with more adverse effects than selective serotonin reuptake inhibitors.

Benefits:

Versus placebo: We found two systematic reviews (search dates 1994[18] and not reported[19]) and three subsequent RCTs.[20–22] The two systematic reviews and three subsequent RCTs found that selective or non-selective serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine) significantly improved symptoms compared with placebo (see comment below).[18–22] One of the reviews found that sertraline significantly improved symptoms compared with placebo,[18] and the other review found no significant difference in symptoms (see table 1, p 1334).[19] **Versus each other:** We found two systematic reviews[18,19] and five subsequent RCTs.[23–27] All found no significant difference in symptoms between different selective and non-selective serotonin reuptake inhibitors.[18,19,23–27] The first review (search date 1994, 85 people, 3 RCTs) found no significant difference in symptoms among clomipramine, fluoxetine and fluvoxamine (SMD –0.04, 95% CI –0.43 to +0.35).[18] The second review (search date not reported) found no significant difference in symptoms between clomipramine and fluvoxamine (4 RCTs, including 2 RCTs from the first review; change in Yale-Brown scale score; SMD +1.23, 95% CI –1.11 to +3.56).[19] It also found no significant difference in symptoms between clomipramine and fluoxetine (1 RCT, not included in the first review, 55 people; change in Yale-Brown scale score; SMD +1.40, 95% CI –5.74 to +2.94) or clomipramine and paroxetine (1 RCT not included in the first review, 300 people; change in Yale-Brown scale score; SMD 0.00, 95% CI –1.94 to +1.94).[19] The first subsequent RCT (170 people) found

that sertraline significantly improved symptoms compared with clomipramine (8% greater mean reduction in Yale-Brown scale score, P = 0.036; see comment below).[23] The second subsequent RCT (133 people) found no significant difference in symptoms between clomipramine and fluvoxamine (change in Yale-Brown scale score, 12.6 with clomipramine *v* 12.3 with fluvoxamine; reported as non-significant, no further data reported).[24] The third subsequent RCT (227 people, double blind) found no significant difference between clomipramine (150–300 mg) and fluvoxamine (150–300 mg) in severity of symptoms after 10 weeks (mean reduction in Yale-Brown scale score about 12 in both groups; P value not reported; proportion of people achieving at least 35% reduction in Yale-Brown scale score 65% with clomipramine *v* 62% with fluvoxamine, reported as non-significant).[25] The fourth subsequent RCT (150 people) compared sertraline (50–200 mg) versus fluoxetine (20–80 mg).[26] It found similar symptom severity at 24 weeks between sertraline and fluoxetine (reduction in Yale-Brown scale score 9.6 with sertraline *v* 9.7 with fluoxetine, CI not reported). The fifth subsequent RCT (30 people, observer blinded) compared three interventions: fluvoxamine, paroxetine, and citalopram.[27] It found no significant difference in symptoms among drugs, but was too small to exclude a clinically important difference.

Versus tricyclic antidepressants and monoamine oxidase inhibitors: We found one systematic review[18] and two subsequent RCTs.[28,29] These found that serotonin reuptake inhibitors significantly improved symptoms compared with tricyclic antidepressants or monoamine oxidase inhibitors. The systematic review (search date 1994, 7 RCTs, 147 people with obsessive compulsive disorder, including 67 children/adolescents) found that, compared with tricyclic antidepressants (desipramine, imipramine, nortripytyline) or monoamine oxidase inhibitors (clorgiline, phenelzine), clomipramine significantly improved symptoms (SMD 0.65, 95% CI 0.36 to 0.92).[18] The first subsequent RCT (54 people) compared three interventions: fluoxetine, phenelzine (a monoamine oxidase inhibitor), and placebo.[28] It found that fluoxetine significantly improved symptoms over 10 weeks compared with phenelzine or placebo (mean reduction in Yale-Brown scale score 2.8 with fluoxetine *v* 1.7 with phenelzine *v* 0.2 with placebo; P < 0.05 for fluoxetine *v* either comparator). The second subsequent RCT (164 people with concurrent obsessive compulsive disorder and major depressive disorder) found that sertraline significantly increased the proportion of people who had a clinically important reduction in obsessive compulsive symptoms compared with desipramine (> 40% improvement on Yale-Brown scale, 38/79 [48%] with sertraline *v* 26/85 [31%] with desipramine; P = 0.01) and significantly increased the proportion of people with remission of depressive symptoms (< 7 on Hamilton Depression Rating Scale, 39/79 [49%] with sertraline *v* 30/85 [35%] with desipramine; P = 0.04).[29] **Versus venlafaxine:** We found one RCT (73 people), which compared clomipramine (150–225 mg daily, 47 people) versus venlafaxine (225–350 mg daily, 26 people).[30] It found no significant difference in response at 12 weeks between clomipramine and venlafaxine (response defined as ≥ 35% reduction in Yale-Brown scale score and Clinical Global Impression Scale score of ≥ 2, 9/25 [36%] *v* 20/40 [50%]; RR 1.39,

95% CI 0.76 to 2.55). **Versus behavioural therapy:** We found one systematic review (search date 1997, number of studies and people not reported).[31] It found no significant difference in symptoms among serotonin reuptake inhibitors, behavioural therapy (see glossary, p 1331), and placebo, but these conclusions must be treated with caution as the review made indirect comparisons of effect sizes (standardised mean differences).[31] **Plus behavioural or cognitive therapy:** See behavioural or cognitive therapy plus serotonin reuptake inhibitors, p 1328.

Harms:

Versus placebo: One systematic review (search date 1995, 16 RCTs) found that serotonin reuptake inhibitors significantly increased overall adverse effects (unspecified) compared with placebo (RRI *v* placebo: 54% with clomipramine, 11% with fluoxetine, 19% with fluvoxamine, and 27% with sertraline).[32] The other systematic reviews gave no information on adverse effects.[18,19] The first subsequent RCT found that fluoxetine significantly increased tremor ($P < 0.001$), dry mouth ($P < 0.001$), and nausea ($P < 0.01$) compared with placebo (absolute numbers presented graphically).[20] The second subsequent RCT found that citalopram significantly increased nausea, insomnia, fatigue, sweating, dry mouth, and ejaculatory failure compared with placebo ($P < 0.05$).[21] The third subsequent RCT (253 people) found that more people withdrew because of adverse effects with controlled release fluvoxamine than with placebo (20% with fluvoxamine *v* 7% with placebo; P value not reported).[22] Compared with placebo, fluvoxamine increased insomnia (35% with fluvoxamine *v* 20% with placebo), somnolence (27% *v* 11%), asthenia (25% *v* 8%, nausea (34% *v* 13%), diarrhoea (18% *v* 8%), anorexia (13% *v* 5%), and decreased libido (7% *v* 3%). **Versus each other:** The systematic reviews gave no information on adverse effects.[18,19] Three subsequent RCTs found that clomipramine increased adverse effects compared with selective serotonin reuptake inhibitors,[23–25] and one subsequent RCT[26] found no significant difference in adverse effects between the selective serotonin reuptake inhibitors sertraline and fluoxetine. The first subsequent RCT (170 people) found that significantly more people withdrew because of adverse effects with clomipramine than with sertraline ($P < 0.05$).[23] Clomipramine was associated with dry mouth, nausea, tremor, anxiety, and constipation, whereas sertraline was associated with nausea and diarrhoea. The second subsequent RCT (133 people) found that clomipramine significantly increased dry mouth (38% *v* 10%) and constipation (26% *v* 10%) compared with fluvoxamine ($P < 0.05$).[24] The third subsequent RCT comparing clomipramine versus fluvoxamine (227 people) found that more people stopped clomipramine prematurely (16% withdrew with clomipramine *v* 8% with fluvoxamine; CI not reported), and found that clomipramine significantly increased the proportion of people who had anticholinergic adverse effects (dry mouth 43% with clomipramine *v* 10% with fluvoxamine; constipation 25% *v* 9%; tremor 22% *v* 9%; and dizziness 18% *v* 7%; $P = 0.05$ for frequency of all anticholinergic adverse effects with clomipramine *v* fluvoxamine).[25] The fourth subsequent RCT found no significant difference in adverse effects between sertraline and fluoxetine.[26] The fifth subsequent RCT gave no information on adverse effects.[27] One systematic review (search date 1997) of

controlled and uncontrolled studies found that the withdrawal rate because of adverse effects was 11% with clomipramine, 10% with fluoxetine, 13% with fluvoxamine, 9% with sertraline, and 11% with paroxetine.[31] One non-systematic review of three prospective cohort studies and five surveys found that fluoxetine during pregnancy did not increase the risk of spontaneous abortion or major malformation (numerical values not provided).[33] The review included one prospective cohort study (174 people) and three surveys that found similar outcomes with other selective serotonin reuptake inhibitors (sertraline, paroxetine, and fluvoxamine). One prospective cohort study of 55 preschool children exposed to fluoxetine *in utero* found no significant difference from unexposed children in global IQ, language, or behaviour. It included no information on long term harms for the other selective serotonin reuptake inhibitors. The non-systematic review of effects in pregnancy did not describe how articles were selected.[33] **Versus tricyclic antidepressants and monoamine oxidase inhibitors:** The systematic review gave no information on adverse effects.[18] The second subsequent RCT (164 people) found that significantly more people discontinued treatment because of adverse effects with desipramine than with sertraline (26% *v* 10%; P = 0.009).[29] One systematic review comparing the harms of selective serotonin reuptake inhibitors versus tricyclic antidepressants found that selective serotonin reuptake inhibitors were associated with fewer anticholinergic adverse effects but more nausea, diarrhoea, anxiety, agitation, insomnia, and headache.[34] **Versus venlafaxine:** The RCT (73 people) found that significantly more people had overall adverse effects with clomipramine than with venlafaxine (43/47 [92%] with clomipramine *v* 16/26 [62%] with venlafaxine; P = 0.002).[30] It found that, compared with venlafaxine, clomipramine significantly increased the proportion of people who had dry mouth (16/47 [34%] with clomipramine *v* 3/26 [12%] with venlafaxine; P = 0.036) and constipation (17/47 [36%] *v* 2/26 [8%]; P = 0.008).

Comment: One of the reviews found that sertraline was more effective than placebo,[18] whereas the other did not.[19] This may have been due to different methods of meta analysis. The reviews found heterogeneity in the selection of participants and duration of treatment in the RCTs identified; the first review[18] found that this heterogeneity reached significance in RCTs comparing clomipramine versus placebo. Two RCTs comparing clomipramine versus placebo in the first review included 73 children, but the review did not analyse these RCTs separately.[18] Some RCTs identified by the reviews included people with depression associated with obsessive compulsive disorder. The first systematic review performed a subgroup analysis in people with obsessive compulsive disorder without depression and found that, compared with placebo, clomipramine improved symptoms of obsessive compulsive disorder in people without depression (5 RCTs, 594 people, standardised mean differences 1.37, 95% CI 1.19 to 1.55).[18] This suggests that the effect of serotonin reuptake inhibitors on obsessive compulsive symptoms is independent of their effect on symptoms of depression. In the first subsequent RCT comparing sertraline versus clomipramine, people taking clomipramine received very low doses (median 90 mg/day). This makes the results of the RCT difficult to interpret. **Factors**

predicting outcome: Four RCTs found that people who did not respond to serotonin reuptake inhibitors had younger age of onset, longer duration of the condition, higher frequency of symptoms, coexisting personality disorders, and a greater likelihood of previous hospital admission. Predictors of good response were older age of onset, history of remissions, no previous drug treatment, more severe obsessive compulsive disorder, and either high or low score on the Hamilton Depression Rating Scale.[35–38] Two cohort studies of people with obsessive compulsive disorder found that poor response to serotonin reuptake inhibitors was predicted by concomitant schizotypal personality disorder, by tic disorder (see glossary, p 1331), and also by severe obsessive compulsive disorder with cleaning rituals (OR 4.9, 95% CI 1.1 to 21.2).[39,40]

OPTION BEHAVIOURAL THERAPY

We found no RCTs comparing behavioural therapy versus no treatment. One systematic review and subsequent RCTs have found that behavioural therapy improves symptoms compared with relaxation. The review and one subsequent RCT found no significant difference in symptoms over 4–16 weeks between behavioural therapy and cognitive therapy. Another subsequent RCT found limited evidence that group behavioural therapy may improve symptoms over 12 weeks compared with group cognitive behavioural therapy.

Benefits:

Versus no treatment: We found no systematic review or RCTs. **Versus relaxation:** We found one systematic review (search date 1995, 2 RCTs, 121 people), which found that behavioural therapy (see glossary, p 1331) significantly improved symptoms over 4–16 weeks of treatment compared with relaxation (standardised mean differences 1.18, CI not reported; $P < 0.01$).[32] One subsequent RCT (218 people with DSM-IV obsessive compulsive disorder, 49% of whom were also taking a serotonin reuptake inhibitor) compared three treatments: behavioural therapy guided by a computer, behavioural therapy guided by a clinician, and relaxation.[41] It found that both types of behavioural therapy significantly improved Yale-Brown scale score after 10 weeks of treatment compared with relaxation (mean reduction 5.6 with computer guided behavioural therapy *v* 8.0 with clinician guided behavioural therapy *v* 1.7 with relaxation; $P = 0.001$ for relaxation *v* either type of behavioural therapy; $P = 0.035$ for clinician guided *v* computer guided behavioural therapy; analysis not by intention to treat).[41] **Versus cognitive or cognitive behavioural therapy:** We found one systematic review[32] and two subsequent RCTs.[42,43] The systematic review (search date 1995, 4 RCTs, 92 people) found no significant difference in symptoms over 4–16 weeks between behavioural therapy and cognitive therapy (see glossary, p 1331) (SMD −0.19; reported as $P > 0.05$, no further data reported).[32] The first subsequent RCT (76 people) found no significant difference between group behavioural therapy (exposure with response prevention) and group cognitive behavioural therapy in recovery (defined as ≥6 point Yale-Brown scale score reduction and score ≤12) immediately after 12 weeks of treatment (AR 12/32 [38%] with behavioural therapy *v* 5/31 [16%] with cognitive behavioural therapy;

P = 0.09), but found that behavioural therapy significantly improved recovery at 3 months follow up compared with cognitive behavioural therapy (AR 14/31 [45%] with behavioural therapy *v* 4/31 [13%] with cognitive behavioural therapy; P = 0.01; analysis not by intention to treat). The second subsequent RCT (63 people) found no significant difference between behavioural therapy and cognitive therapy in the proportion of people achieving at least 25% improvement in Yale-Brown scale score after 16 weeks of treatment (OR 0.7, 95% CI 0.2 to 2.0).[43] **Versus serotonin reuptake inhibitors:** See benefits of serotonin reuptake inhibitors, p 1322. **Plus serotonin reuptake inhibitors:** See behavioural therapy or cognitive therapy plus serotonin reuptake inhibitors, p 1328.

Harms: We found no evidence from RCTs or cohort studies of adverse effects from behavioural therapy. Case reports have described unbearable and unacceptable anxiety in some people receiving behavioural therapy.

Comment: **Factors predicting outcome:** We found two RCTs of behavioural therapy (total 96 people, duration 2.5 months and 32 weeks) and two retrospective cohort studies (total 346 people, duration 1 year and 11 weeks), which assessed factors predicting outcome.[44–47] These found that poorer outcome was predicted by initial severity, depression, longer duration, poorer motivation, and dissatisfaction with the therapeutic relationship. Good outcome was predicted by early adherence to exposure homework (see glossary, p 1331), employment, living with one's family, no previous treatment, having fear of contamination, overt ritualistic behaviour, and absence of depression.[44–46] Good outcome for women was predicted by having a co-therapist (someone, usually related to the woman concerned, who is enlisted to help with treatment outside regular treatment sessions; OR 19.5, 95% CI 2.7 to 139).[47] Two systematic reviews of drug, behavioural, cognitive, and combination treatments for obsessive compulsive disorder are being prepared. **Maintenance of improvement:** A prospective follow up (20 people with obsessive compulsive disorder, specific diagnostic criteria not provided) after a 6 month RCT of behavioural therapy found that 79% maintained improvement in obsessive compulsive symptoms at 2 years follow up.[48] A prospective non-inception cohort study of behavioural therapy in 21 people with obsessive compulsive disorder (specific diagnostic criteria not provided) found that, after 2 weeks of treatment, 68–79% maintained complete or much improvement in symptoms at 3 months follow up.[49] In both RCTs, some people received additional behavioural therapy during follow up.

OPTION COGNITIVE OR COGNITIVE BEHAVIOURAL THERAPY

We found no RCTs comparing cognitive therapy versus no treatment. One RCT found that cognitive behavioural group therapy improved symptoms and quality of life compared with no treatment after 12 weeks. One systematic review and one subsequent RCT found no significant difference in symptoms over 4–16 weeks between behavioural therapy and cognitive therapy. Another subsequent RCT found limited evidence that group behavioural therapy improved symptoms over 12 weeks compared with group cognitive behavioural therapy.

Obsessive compulsive disorder

Benefits: **Versus no treatment:** We found one RCT (47 people with DSM-IV obsessive compulsive disorder, 45% of whom were also taking a serotonin reuptake inhibitor), which compared cognitive behavioural group therapy versus no therapy. [50] It found that cognitive behavioural group therapy significantly increased the proportion of people achieving at least 35% improvement in Yale-Brown scale score after 12 weeks treatment, and significantly improved quality of life compared with no treatment (16/23 [69.6%] with cognitive behavioural group therapy *v* 1/24 [4.2%] with no treatment; OR 16.7, 95% CI 2.2 to 115.9; mean reduction in Yale-Brown scale score 11.6 with cognitive behavioural group therapy *v* 1.5 with no treatment, P value not reported; difference in quality of life: $P < 0.04$ in favour of cognitive behavioural therapy).[50] **Versus behavioural therapy:** See behavioural therapy, p 1326. **Plus serotonin reuptake inhibitors:** See behavioural therapy or cognitive therapy plus serotonin reuptake inhibitors, p 1328.

Harms: **Versus no treatment:** The RCT reported that one person withdrew from the treatment group owing to to severe anxiety during response prevention and exposure homework (see glossary, p 1331) exercises.[50]

Comment: None.

OPTION BEHAVIOURAL OR COGNITIVE THERAPY PLUS SEROTONIN REUPTAKE INHIBITORS

RCTs provided insufficient evidence to assess the effects of adding serotonin reuptake inhibitors to behavioural or cognitive therapy.

Benefits: We found one systematic review[31] and two subsequent RCTs.[51,52] The systematic review (search date 1997, 77 studies, number of people not reported) did not make direct comparisons between treatments.[31] It included all types of study with the exception of case control studies. In indirect comparisons, it found similar reductions in symptoms with behavioural therapy alone versus placebo, behavioural therapy plus serotonin reuptake inhibitors (clomipramine, fluoxetine, fluvoxamine, paroxetine, or sertraline) versus placebo, and serotonin reuptake inhibitors alone versus placebo. One subsequent RCT (99 people in an outpatient setting) compared four interventions: behavioural therapy, cognitive therapy (see glossary, p 1331), behavioural therapy plus fluvoxamine (a selective serotonin reuptake inhibitor), and cognitive therapy plus fluvoxamine. It found no significant difference among interventions in symptoms after 16 weeks of treatment (mean reduction in Yale-Brown scale score 17.1 with behavioural therapy *v* 13.5 with cognitive therapy *v* 12.6 with behavioural therapy plus fluvoxamine *v* 15.6 with cognitive therapy plus fluvoxamine, reported as non-significant, no further data reported).[51] Another subsequent RCT (49 people in a hospital setting) found that behavioural therapy plus fluvoxamine significantly increased the proportion of people with improved symptoms after 9 weeks of treatment compared with behavioural therapy plus pill placebo (number of people with > 35% reduction of Yale-Brown scale score 21/24 [88%] *v* 15/25 [60%]; RR 1.46, 95% CI 1.02 to 2.08).[52]

Harms: We found no evidence from RCTs or cohort studies of adverse effects from behavioural therapy. Case reports have described unbearable and unacceptable anxiety in some people receiving behavioural therapy. See harms of serotonin reuptake inhibitors, p 1324. See harms of cognitive therapy, p 1328.

Comment: None.

OPTION ELECTROCONVULSIVE THERAPY

We found no RCTs of electroconvulsive therapy in people with obsessive compulsive disorder.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: People with obsessive compulsive disorder who also have depression may be treated with electroconvulsive therapy. The evidence for the effects of electroconvulsive therapy in depression is summarised elsewhere in *Clinical Evidence* (see depressive disorders in adults, p 1278).

QUESTION What are the best forms of maintenance treatment in adults?

OPTION OPTIMUM DURATION OF MAINTENANCE TREATMENT WITH SEROTONIN REUPTAKE INHIBITORS

RCTs provided insufficient evidence to define the optimum duration of treatment with serotonin reuptake inhibitors.

Benefits: Most RCTs lasted only 10–12 weeks.[53] We found two RCTs that assessed maintenance of serotonin reuptake inhibitors for 1 year in people who had responded to treatment.[54,55] The first RCT (70 people who had responded to a 20 week course of fluoxetine) found no significant difference between maintenance of fluoxetine and replacement by placebo for 1 year in relapse rate over 1 year (21% with fluoxetine *v* 32% with placebo; P = 0.137).[54] The second RCT compared sertraline versus placebo in 223 people with obsessive compulsive disorder, who had all previously responded to 1 year's treatment with sertraline (response defined as at least 25% reduction in Yale-Brown scale score from baseline).[55] People continuing on sertraline were prescribed their previous dose (mean 183 mg). The RCT found that, compared with placebo, sertraline significantly reduced the proportion of people who withdrew because of relapse or insufficient clinical response over 24 weeks (9% with sertraline *v* 24% with placebo; P = 0.006). It found that sertraline reduced the proportion of people who had worsening of symptoms compared with placebo (12% with sertraline *v* 35% with placebo; P = 0.001), but found no significant difference in relapse rate over 24 weeks (2.7% with sertraline *v* 4.4% with placebo; P = 0.34).[55]

Harms: The first RCT found no significant difference between fluoxetine and placebo in overall adverse effects (reported as non-significant, adverse effects not specified, absolute numbers and CI not reported) or in the proportion of people who withdrew from the trial

for any cause over 52 weeks (16/36 [44%] with fluoxetine *v* 23/35 [66%] with placebo; P = 0.072).[54] The second RCT found that upper respiratory infection, headache, and malaise were reported in ≥ 10% of people taking sertraline, and that people taking placebo had dizziness and depression (no further data reported).[55] It found that fewer people taking sertraline withdrew because of adverse effects than people taking placebo (5/109 [5%] with sertraline *v* 12/114 [11%] with placebo; P value not reported).

Comment: One prospective, 1 year study found further improvement after a 40 week open label extension of the study, with continuing adverse effects.[56] One observational study found that 16/18 (89%) of people relapsed within 7 weeks of replacing clomipramine with placebo treatment.[57]

QUESTION **What are the effects of treatments in adults who have not responded to initial treatment with serotonin reuptake inhibitors?**

OPTION **ADDITION OF ANTIPSYCHOTICS TO SEROTONIN REUPTAKE INHIBITORS**

Three small RCTs in people unresponsive to serotonin reuptake inhibitors found that the addition of antipsychotics improved symptoms compared with placebo.

Benefits: We found no systematic review, but found three small RCTs that assessed combined antipsychotics and serotonin reuptake inhibitors in people who did not respond to serotonin reuptake inhibitors alone.[58–60] The first RCT (34 people with obsessive compulsive disorder who had not responded to 8 weeks of treatment with fluvoxamine) compared fluvoxamine (a selective serotonin reuptake inhibitor) plus haloperidol (an antipsychotic; maximum dose of haloperidol 10 mg/day) versus fluvoxamine plus placebo.[58] It found that fluvoxamine plus haloperidol significantly increased the proportion of people who met two out of three different response criteria compared with fluvoxamine plus placebo (11/17 [65%] *v* 0/17 [0%]; NNT 2, 95% CI 2 to 3; P < 0.0002). The second RCT (36 people with obsessive compulsive disorder who did not respond to 12 weeks of treatment with a serotonin reuptake inhibitor) found that, compared with addition of placebo, addition of 6 weeks of risperidone (an antipsychotic) to the prior serotonin reuptake inhibitor significantly improved symptoms of obsessive compulsive disorder (reduction in the Yale-Brown scale score 36% *v* 9%; P = 0.001), depression (reduction in the Hamilton Depression Rating Scale 35% *v* 20%; P = 0.002), and anxiety (reduction in the Hamilton Anxiety Rating Scale 31% *v* 12%; P = 0.007).[59] People taking risperidone were more likely to have met two of the response criteria (8/18 [44%] with serotonin reuptake inhibitor plus risperidone *v* 0/15 [0%] with serotonin reuptake inhibitor plus placebo; NNT 2, 95% CI 2 to 3; P < 0.005). The third RCT (27 people who did not respond to 3 months of treatment with fluoxetine, fluvoxamine, or clomipramine in an open label trial) compared a serotonin reuptake inhibitor plus quetiapine (an atypical antipsychotic 50–200 mg daily) versus a serotonin reuptake inhibitor plus placebo for 8

weeks.[60] People received the same serotonin reuptake inhibitors in the RCT as they had in the open label phase of the study. The RCT found that a serotonin reuptake inhibitor plus quetiapine significantly increased the proportion of people who responded compared with a serotonin reuptake inhibitor plus placebo (response defined as 30% or greater reduction in the Yale-Brown scale score; 10/14 [71%] with a serotonin reuptake inhibitor plus quetiapine *v* 0/14 [0%] with a serotonin reuptake inhibitor plus placebo; $P < 0.0001$).

Harms: Extrapyramidal adverse effects are common with haloperidol, which can also cause prolactinaemia. The RCT of serotonin reuptake inhibitors plus risperidone found that sedation, restlessness, increased appetite, dry mouth, or tinnitus were experienced by at least 10% of people taking serotonin reuptake inhibitors plus risperidone, and that blurred vision, excessive perspiration, headache, increased appetite, lightheadedness, restlessness, and sedation were experienced by at least 10% of people taking placebo.[59] Risperidone is commonly associated with hypotension and prolactinaemia. The RCT of serotonin reuptake inhibitors plus quetiapine found that people taking a serotonin reuptake inhibitor plus quetiapine had nausea (6/14), sedation (3/14), and dizziness (1/14), and people taking a serotonin reuptake inhibitor plus placebo had sedation (2/13), headache (1/13), and nervousness (1/13).[60]

Comment: None.

GLOSSARY

Behavioural therapy Consists of exposure to the anxiety provoking stimuli and prevention of ritualistic behaviour (engaging in compulsions).
Chronic obsessive compulsive disorder Continuous course without periods of remission since first onset.
Cognitive therapy Aims to correct distorted thoughts (such as exaggerated sense of harm and personal responsibility) by Socratic questioning, logical reasoning, and hypothesis testing.
Episodic obsessive compulsive disorder Episodic course with periods of remission since first onset.
Exposure homework Tasks involving contact with anxiety provoking situations to be carried out outside regular psychotherapy sessions.
Schizotypal personality disorder Characterised by discomfort in close relationships, cognitive and perceptual distortions, and eccentric behaviour.
Tic disorder Characterised by motor tics, vocal tics, or both.

Substantive changes

Serotonin reuptake inhibitors (citalopram, clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline) One RCT added;[22] categorisation unchanged.
Cognitive and cognitive behavioural therapy One RCT added;[50] categorisation unchanged.

TABLE 1 **Serotonin reuptake inhibitors (clomipramine, citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) versus placebo (see text, p 1322).**

Intervention and reference	Study design	Symptom improvement
Citalopram**		
21	RCT (401 people)	AR 57% with citalopram 20 mg v 52% with 40 mg v 65% with 60 mg v 37% with placebo; NNT for 20 mg citalopram v placebo 5, 95% CI 3 to 14
Clomipramine*¶		
18	SR (9 RCTs; 668 people)	SMD 1.31 (95% CI 1.15 to 1.47)
19	SR (7 RCTs; 808 people)	SMD –8.19 (95% CI –10.53 to –5.85)
Fluoxetine†¶		
18	SR (1 RCT; 287 people)	SMD 0.57 (95% CI 0.33 to 0.81)
19	SR (3 RCTs; 329 people)	SMD –1.61 (95% CI –2.18 to –1.04)
20	RCT (350 people)	Mean reduction in score 4.6 with fluoxetine 20 mg, 5.5 with 40 mg, 6.5 with 60 mg v 0.9 with placebo ($P < 0.001$ for all doses v placebo)
Fluvoxamine‡		
18	SR	SMD 0.57 (95% CI 0.37 to 0.77)
19	SR	SMD –4.84 (95% CI –7.78 to –1.83) (measured as a change in raw score of Yale Brown)
22	RCT (253 people)	Mean reduction in score 8.5 with fluvoxamine controlled release 100–300 mg v 5.6 with placebo ($P = 0.001$)
Paroxetine¶		
19	SR (1 RCT; 300 people)	SMD –3.00 (95% CI –4.91 to –1.09)
Sertraline§¶		
18	SR (3 RCTs; 270 people)	SMD 0.52 (95% CI 0.27 to 0.77)
19	SR (4 RCTs; 598 people)	SMD –2.57 (95% CI –6.13 to +1.20 [NS])

QUESTIONS

INTERVENTIONS

See glossary, p 1341

Key Messages

- **Selective serotonin reuptake inhibitors** Systematic reviews and one additional RCT have found that selective serotonin reuptake inhibitors improve symptoms in panic disorder compared with placebo. One subsequent RCT found that discontinuation of sertraline in people with a good response increased exacerbation of symptoms. A second subsequent RCT found that paroxetine plus cognitive behavioural therapy improved symptoms compared with placebo plus cognitive behavioural therapy.
- **Tricyclic antidepressants (imipramine)** One systematic review, one subsequent RCT, and one additional RCT have found that imipramine improves symptoms compared with placebo. One subsequent RCT found that imipramine reduced relapse rates over 12 months.
- **Benzodiazepines** One systematic review and one additional RCT have found that alprazolam reduces the number of panic attacks and improves symptoms compared with placebo. However, benzodiazepines are associated with a wide range of adverse effects, both during and after treatment.
- **Buspirone** We found insufficient evidence to assess the effects of buspirone.
- **Monoamine oxidase inhibitors** We found no RCTs on the effects of monoamine oxidase inhibitors.

Panic disorder

DEFINITION A panic attack is a period in which there is sudden onset of intense apprehension, fearfulness, or terror often associated with feelings of impending doom. Panic disorder occurs when there are recurrent, unpredictable attacks followed by at least 1 month of persistent concern about having another panic attack, worry about the possible implications or consequences of the panic attacks, or a significant behavioural change related to the attacks.[1] The term panic disorder excludes panic attacks attributable to the direct physiological effects of a general medical condition, a substance, or another mental disorder. Panic disorder is sometimes categorised as being with or without agoraphobia.[1] Alternative categorisations focus on phobic anxiety disorders and specify agoraphobia with or without panic disorder.[2]

INCIDENCE/ PREVALENCE Panic disorder often starts at around 20 years of age (between late adolescence and the mid-30s).[3] Lifetime prevalence is 1–3%, and panic disorder is more common in women than in men.[4] An Australian community study found 1 month prevalence rates for panic disorder (with or without agoraphobia) of 0.4% using International Classification of Diseases (ICD)-10 diagnostic criteria, and of 0.5% using Diagnostic and Statistical Manual (DSM)-IV diagnostic criteria.[5]

AETIOLOGY/ RISK FACTORS Stressful life events tend to precede the onset of panic disorder,[6,7] although a negative interpretation of these events in addition to their occurrence has been suggested as an important causal factor.[8] Panic disorder is associated with major depression,[9] social phobia, generalised anxiety disorder, obsessive compulsive disorder,[10] and a substantial risk of drug and alcohol abuse.[11] It is also associated with avoidant, histrionic, and dependent personality disorders.[10]

PROGNOSIS The severity of symptoms in people with panic disorder fluctuates considerably, and patients commonly experience periods of no attacks, or only mild attacks with few symptoms. There is often a long delay between the initial onset of symptoms and presentation for treatment. Recurrent attacks may continue for several years, especially if associated with agoraphobia. Reduced social or occupational functioning varies among people with panic disorder and is worse in people with associated agoraphobia. Panic disorder is also associated with an increased rate of attempted, but unsuccessful, suicide.[12] One study analysing data from RCTs and systematic reviews found that co-existence of anxiety and depressive features adversely affected treatment response at 12 years compared with treatment of panic disorder alone.[13]

AIMS OF INTERVENTION To reduce the severity and frequency of panic attacks, phobic avoidance, and anticipatory anxiety; to improve social and occupational functioning, with minimal adverse effects of treatment.

OUTCOMES Measures of panic attacks, agoraphobia, and associated disability (self reported and clinician rated, before and after treatment, and longer term) using general or specific scales for panic disorder (e.g. the panic and agoraphobia scale, the mobility inventory for agoraphobia).

METHODS *Clinical Evidence* search and appraisal September 2003. Studies with follow up periods of less than 6 months were excluded.

QUESTION **What are the effects of drug treatments for panic disorder?**

OPTION **TRICYCLIC ANTIDEPRESSANTS**

One systematic review, one subsequent RCT, and one additional RCT have found that imipramine improves symptoms in people with panic disorder compared with placebo. One subsequent RCT found that imipramine reduced relapse rates after 12 months in people with panic disorder compared with placebo.

Benefits: We found one systematic review (search date not reported, 27 RCTs, 2348 people),[14] one additional RCT,[15] and two subsequent RCTs.[16,17] The systematic review compared imipramine, selective serotonin reuptake inhibitors (SSRIs; paroxetine, fluvoxamine, zimelidine, and clomipramine; see comment below), and alprazolam verssu placebo and versus each other (see benefits of SSRIs, p 1338 and benzodiazepines, p 1340).[14] It found that imipramine significantly increased the proportion of people judged to have improved compared with placebo ($P < 0.0001$; see comment below). The additional RCT (181 people with panic disorder with or without agoraphobia) compared three treatments: oral imipramine (maximum dose 225 mg; see comment below), oral alprazolam (maximum dose 10 mg; see comment below), and placebo (see benefits of benzodiazepines, p 1340).[15] It found that imipramine reduced the number of panic attacks after 8 months compared with placebo (results presented graphically, significance not calculated). The first subsequent RCT (56 adults with panic disorder and agoraphobia in stable remission after 24 weeks' treatment with oral imipramine) comparing oral imipramine 2.25 mg/kg daily versus placebo found that significantly fewer people taking imipramine relapsed after 12 months (see comment below; 1/29 [3%] with imipramine *v* 10/27 [37%] with placebo; RR 0.09, 95% CI 0.01 to 0.68; NNT 5, 95% CI 3 to 14).[16] The second subsequent RCT (312 people) compared five groups: oral imipramine (maximum dose 300 mg/day; see comment below), cognitive behavioural therapy (see glossary, p 1341), placebo, cognitive behavioural therapy plus oral imipramine (maximum dose 300 mg/day; see comment below), and cognitive behavioural therapy plus placebo.[17] It found that imipramine significantly increased the proportion of people judged to have responded (using the panic disorder severity scale) compared with placebo after 6 months (response rate: 38% with imipramine *v* 13% with placebo; absolute numbers not provided; $P = 0.02$).

Harms: Adverse effects associated with imipramine treatment included blurred vision, tachycardia, palpitations, blood pressure changes, insomnia, nervousness, malaise, dizziness, headache, nausea, vomiting, and reduced appetite (see harms of prescription antidepressant drugs under depressive disorders, p 1278).[15,18]

Comment: The review included clomipramine as an SSRI. This drug is also often described as a tricyclic antidepressant.[14] The review used improvement as an outcome measure without a clear definition of this term. In the additional RCT and the second subsequent RCT, flexible dosing was used according to tolerance and therapeutic need.[15,17] In the subsequent RCT comparing imipramine versus placebo, relapse rate was not clearly defined.[16] **Short term effects:** We found one systematic review (search date 1999, 43 studies including 34 RCTs, 2367 people, drop-out rate 24%, analysis based on completers) that compared the short term efficacy of SSRIs (fluoxetine, fluvoxamine, paroxetine, citalopram, and sertraline) versus tricyclic antidepressants (imipramine, desipramine, nortryptiline, and clomipramine) and analysed effect size within treatment group rather than within studies.[19] It found no significant difference between treatments in the proportion of people who were free of panic attacks at 6–10 weeks, but found that tricyclic antidepressants significantly increased drop-out rates (free of panic attacks: 60% with tricyclic antidepressants *v* 55% with SSRIs, P value not reported; drop-outs: 31% with tricyclic antidepressants *v* 18% with SSRIs, $P < 0.001$).

OPTION SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Systematic reviews and one additional RCT have found that selective serotonin reuptake inhibitors improve symptoms compared with placebo in panic disorder. One subsequent RCT found that discontinuation of sertraline in people with a good response increased exacerbation of symptoms. A second subsequent RCT found that paroxetine plus cognitive behavioural therapy improved symptoms compared with placebo plus cognitive behavioural therapy.

Benefits: **Versus placebo:** We found two systematic reviews (see benefits of tricyclic antidepressants, p 1337 and benzodiazepines, p 1340),[14,20] one additional RCT,[21] and two subsequent RCTs.[22,23] The first systematic review (search date not reported, 27 RCTs, 2348 people) found that selective serotonin reuptake inhibitors (SSRIs; paroxetine, fluvoxamine, zimelidine, and clomipramine; see comment below) significantly increased the proportion of people who improved compared with placebo ($P < 0.0001$; see comment below).[14] The second systematic review (search date not reported, 12 RCTs, 1741 people) only reported combined results as an effect size against placebo (effect size 0.55), and did not report statistical significance.[20] The additional RCT (279 people) compared five groups: oral citalopram 10 or 15 mg daily, oral citalopram 20 or 30 mg daily, oral citalopram 40 or 60 mg daily, oral clomipramine 60 or 90 mg daily, and placebo.[21] It found that citalopram (at all doses) significantly increased the proportion of people who responded (defined as no panic attacks and either no episodic increases in anxiety or only slight increases in anxiety precipitated by definite events or activities) compared with placebo after 12 months (citalopram 10 or 15 mg/day *v* placebo, $P = 0.05$; citalopram 20 or 30 mg/day *v* placebo, $P = 0.001$; citalopram 40 or 60 mg/day *v* placebo, $P = 0.003$; results presented graphically). The first subsequent RCT (182 people who had responded to open label sertraline for 52 weeks) compared double blind placebo

(discontinuation of sertraline) versus sertraline for 28 weeks.[22] It found that significantly more people on placebo had exacerbation of symptoms (33% with placebo *v* 13% with sertraline; P = 0.005; CI not reported). The second subsequent RCT (43 people with panic disorder with or without agoraphobia who had been unsuccessfully treated with 15 sessions of manual guided cognitive behavioural therapy [CBT; see glossary, p 1341] alone) compared paroxetine 40 mg plus CBT versus placebo plus CBT (see comment below).[23] Success was defined as no panic attacks for a 2 week period or achieving cut-off scores or lower on panic disorder scales. It found that combined treatment significantly increased success compared with placebo plus CBT (12/19 [63%] with combined treatment *v* 5/19 [26%] with placebo plus CBT; RR 2.4, 95% CI 1.1 to 5.6; NNT 3, 95% CI 2 to 21).

Harms: The additional RCT reported that harms associated with citalopram included headache, tremor, dry mouth, and somnolence (see harms of prescription antidepressant drugs under depressive disorders, p 1278).[21] The first subsequent RCT found the highest incidence of adverse events with sertraline in the first 12 weeks of the study, and tolerability seemed to improve with time.[22] The most common adverse events over the 52 week trial period were headache, malaise, insomnia, upper respiratory infection, diarrhoea, nausea, and dizziness. The second subsequent RCT did not report on adverse events.[23]

Comment: The first review included clomipramine as an SSRI, although this drug is often described as a tricyclic antidepressant.[14] It also included the SSRI zimelidine, which is rarely used these days. In addition, the review used improvement as an outcome measure, without defining this term clearly. In the additional RCT, only 28/54 (52%) completed the trial; analysis was by intention to treat and people who withdrew from the trial were counted as treatment failures.[21] The RCT used flexible dosing according to tolerance and therapeutic need. SSRIs can cause initial increased anxiety, which can exacerbate a tendency to focus on internal sensations and to avoid situations that trigger these sensations (catastrophise somatic sensations). Education about this event is likely to improve adherence with medication. The second systematic review found that smaller RCTs were associated with larger effect sizes, suggesting the possibility of publication bias.[20] The second subsequent RCT only used 8 weeks of medication as opposed to a more common 12 weeks, it only used clinician rated outcomes, and most people in both the placebo and paroxetine groups guessed correctly which treatment they had been allocated (62% with placebo *v* 79% with paroxetine).[23] **Tricyclic antidepressants versus selective serotonin reuptake inhibitors:** See comment under tricyclic antidepressants, p 1338.

OPTION MONOAMINE OXIDASE INHIBITORS

We found no RCTs on the effects of monoamine oxidase inhibitors in panic disorder.

Benefits: We found no systematic review and no RCTs.

Panic disorder

Harms: We found no evidence of harms associated specifically with the use of monoamine oxidase inhibitors in the long term treatment of panic disorder.

Comment: Our search strategy excluded studies with follow up of less than 6 months.

OPTION BUSPIRONE

We found insufficient evidence to assess the effects of buspirone in people with panic disorder.

Benefits: We found no systematic review but found two RCTs.[24,25] The first RCT (48 people) compared oral buspirone (maximum 60 mg/day) plus (CBT; see glossary, p 1341) versus placebo plus CBT for 16 weeks.[24] It found that oral buspirone plus CBT significantly improved self rated panic and agoraphobia scores after 1 year (using a 90 point symptom scale where each symptom was graded from 0 = not present to 4 = severe; P = 0.03; absolute numbers not reported).[24] The second RCT (41 people with panic disorder and agoraphobia) compared 16 weeks of oral buspirone 30 mg daily plus CBT versus 16 weeks of placebo plus CBT.[25] It found no significant difference in the proportion of people who had a reduction of at least 50% in their agoraphobic symptoms after 68 weeks (44% with buspirone plus CBT *v* 68% with placebo plus CBT; absolute numbers of people not provided).

Harms: The RCTs did not report harms (see harms of buspirone under generalised anxiety disorder, p 1302).

Comment: The first RCT used a flexible dosing regimen with maximum dose adjustment according to tolerance and therapeutic need.[24]

OPTION BENZODIAZEPINES

One systematic review and one additional RCT have found that alprazolam reduces the number of panic attacks and improves symptoms compared with placebo. However, benzodiazepines are associated with a wide range of adverse effects, both during and after treatment.

Benefits: We found one systematic review (search date not reported, 27 RCTs, 2348 people; see benefits of tricyclic antidepressants, p 1337 and selective serotonin reuptake inhibitors, p 1338)[14] and one additional RCT.[15] The review found that alprazolam significantly increased the proportion of people judged to have improved compared with placebo ($P < 0.0001$; see comment below).[14] The additional RCT (181 people with panic disorder with or without agoraphobia) compared three treatments: oral alprazolam (maximum 10 mg/day; see comment below), oral imipramine (maximum 225 mg/day; see comment below), and placebo (see benefits of tricyclic antidepressants, p 1337 and selective serotonin reuptake inhibitors, p 1338).[15] It found that alprazolam was associated with fewer panic attacks after 8 months compared with placebo (results presented graphically; significance not calculated).

Harms: The systematic review did not report harms.[14] Adverse effects associated with alprazolam include sedation, insomnia, memory lapses, nervousness, irritability, dry mouth, tremor, impaired coordination, constipation, urinary retention, altered libido, and altered appetite (see harms of benzodiazepines under generalised anxiety disorder, p 1302).[15] We found one non-systematic review of the effects of benzodiazepines in anxiety disorder in people with a history of substance abuse or dependence.[26] The review reported that the mortality of long term benzodiazepine users was no higher than that of matched controls. It reported that the most pronounced adverse effects followed sudden withdrawal and included tinnitus, paraesthesia, vision disturbance, depersonalisation, seizures, withdrawal psychosis, and persistent discontinuation syndrome.

Comment: The review used improvement as an outcome measure without clearly defining this term.[14] The additional RCT used flexible dosing according to tolerance and therapeutic need.[15] Many RCTs of psychological and pharmacological treatments (even those not involving benzodiazepines) allowed people to receive small amounts of anxiolytic drugs during the study because benzodiazepine abuse is quite prevalent in people who suffer from panic disorder.

GLOSSARY

Cognitive behavioural therapy (CBT) Brief structured treatment using relaxation and exposure procedures, and aimed at changing dysfunctional beliefs and negative automatic thoughts (typically 20 sessions over 12–16 weeks).

Competing interests: SK was reimbursed by Eli-Lilly, the manufacturers of Prozac (fluoxetine), for attending several conferences. MOB has been paid by GlaxoSmithKline for contributing to educational sessions for general practitioners. The programme topic was “the recognition and management of generalised anxiety disorder”. MOB has received reimbursement from Pfizer for attending a symposium.

Post-traumatic stress disorder

Search date May 2003

Jonathan Bisson

QUESTIONS

INTERVENTIONS

See glossary, p 1358

Key Messages

Prevention

- The evidence about the effects of interventions in preventing post-traumatic stress disorder is generally inconclusive.
- **Multiple session cognitive behavioural therapy in people with acute stress disorder** Two small RCTs in people with acute stress disorder after a traumatic event (accident or non-sexual assault) found that five sessions of cognitive behavioural therapy reduced the proportion of people with post-traumatic stress disorder after 6 months compared with supportive counselling.

Post-traumatic stress disorder

- **Hydrocortisone** One small RCT in people in intensive care with septic shock provided insufficient evidence to assess hydrocortisone in preventing post-traumatic stress disorder.
- **Multiple session cognitive behavioural therapy in all people exposed to a traumatic event** One RCT in bus drivers who had been attacked in the past 5 months found that cognitive behavioural therapy improved measures of anxiety and intrusive symptoms at 6 months compared with standard care. It found no significant difference in measures of depression or avoidance symptoms. Another RCT provided insufficient evidence to assess cognitive behavioural therapy plus educational techniques in preventing post-traumatic stress disorder in road traffic accident survivors. A third small RCT provided insufficient evidence to compare memory structuring versus supportive listening in road traffic accident survivors.
- **Multiple session education** One RCT provided insufficient evidence to assess educational techniques plus cognitive behavioural therapy in preventing post-traumatic stress disorder in road traffic accident survivors.
- **Multiple session trauma support** Two RCTs provided insufficient evidence to assess collaborative care interventions involving emotional, social, and practical support in people exposed to a traumatic event in the past 1 day to 1 week.
- **Propranolol** One small RCT provided insufficient evidence to assess propranolol in preventing post-traumatic stress disorder in people with early symptoms of post-traumatic stress disorder after a traumatic event.
- **Temazepam** One small RCT provided insufficient evidence to assess temazepam in preventing post-traumatic stress disorder in people with acute stress disorder or early symptoms of post-traumatic stress disorder after road traffic accident, industrial accident, or non-sexual assault.
- **Single session psychological interventions ("debriefing") in all people exposed to a traumatic event** RCTs in people who had been exposed to a traumatic event in the previous month found no significant difference between a single session of psychological debriefing and no debriefing in the incidence of post-traumatic stress disorder at 3 months or 1 year. One RCT found that debriefing within 10 hours reduced post-traumatic stress disorder compared with debriefing after 48 hours.

Treatment

- **Cognitive behavioural therapy** RCTs have found that cognitive behavioural therapy improves post-traumatic stress disorder symptoms, anxiety, and depression immediately after treatment and at up to 1 year compared with no treatment or supportive counselling.
- **Eye movement desensitisation and reprocessing** RCTs have found that eye movement desensitisation and reprocessing improves symptoms compared with no treatment. RCTs have found no significant difference in symptoms between eye movement desensitisation and reprocessing and cognitive behavioural therapy.
- **Paroxetine** One systematic review and subsequent RCTs found that paroxetine reduced symptoms at 3 months compared with placebo.
- **Sertraline** RCTs found that sertraline reduced symptoms at 3–7 months compared with placebo.
- **Fluoxetine** Two RCTs found that fluoxetine may reduce symptoms at 3 months compared with placebo.

- **Affect management; benzodiazepines; carbamazepine, drama therapy; eclectic psychotherapy; group therapy; hypnotherapy; inpatient programmes; interapy; lamotrigine; mirtazapine; monoamine oxidase inhibitors (brofaromine, phenelzine); nefazodone; propranolol; psychodynamic psychotherapy; risperidone; supportive counselling; tricyclic antidepressants (amitriptyline, imipramine)** We found insufficient evidence about the effects of these interventions in improving symptoms.

DEFINITION **Post-traumatic stress disorder (PTSD)** can occur after any major traumatic event. Symptoms include upsetting thoughts and nightmares about the traumatic event, avoidance behaviour, numbing of general responsiveness, increased irritability, and hypervigilance.[1] To fulfil the *Diagnostic and statistical manual of mental disorders* (DSM-IV) criteria for PTSD, an individual must have been exposed to a traumatic event, have at least one re-experiencing, three avoidance and two hyperarousal phenomena, have had the symptoms for at least 1 month, and the symptoms must cause clinically important distress or reduced day to day functioning.[1] People with **sub-syndromal PTSD** have all the criteria for PTSD except one of the re-experiencing, avoidance, or hyperarousal phenomena. **Acute stress disorder** occurs within the first month after a major traumatic event and requires the presence of symptoms for at least 2 days. It is similar to PTSD but dissociative symptoms (see glossary, p 1359) are required to make the diagnosis.

INCIDENCE/ PREVALENCE One large cross-sectional study in the USA found that 1/10 women and 1/20 men experience PTSD at some stage in their lives.[2]

AETIOLOGY/ RISK FACTORS Risk factors include major trauma, such as rape, a history of psychiatric disorders, acute distress and depression after the trauma, lack of social support, and personality factors.[3]

PROGNOSIS One large cross-sectional study in the USA found that over a third of sufferers continued to satisfy the criteria for a diagnosis of PTSD 6 years after diagnosis.[2] However, cross-sectional studies provide weak evidence about prognosis.

AIMS OF INTERVENTION To reduce initial distress after a traumatic event; to prevent PTSD and other psychiatric disorders; to reduce levels of distress in the long term; to improve function and quality of life.

OUTCOMES Presence or absence of PTSD and severity of symptoms assessed by continuous measures. Continuous measures for assessing changes in symptoms include Impact of Event Scale, Post-traumatic Stress Diagnostic Scale (range 0–51), Clinician Administered PTSD Scale, Trauma Symptom Checklist 40 (range 0–160), Post-Traumatic Stress Disorder Checklist, and Clinical Global Impression Scale (a composite measure of symptoms and everyday functioning). Symptoms assessed include anxiety, depression, intrusion, and avoidance. Changes in continuous measures are often expressed as effect sizes. It is difficult to interpret effect sizes in terms of clinical importance rather than statistical significance. Some categorise effect sizes of less than 0.5 as small, 0.5–0.8 as medium, and greater than 0.8 as large.

METHODS *Clinical Evidence* search and appraisal May 2003. The prevention question includes RCTs on any intervention commenced within 1 month of a traumatic event.

QUESTION What are the effects of preventive interventions?

OPTION SINGLE SESSION DEBRIEFING

RCTs in people who had been exposed to a traumatic event in the past month found no significant difference between a single debriefing session and no debriefing in the incidence of post-traumatic stress disorder at 3 months or 1 year. One RCT found that debriefing within 10 hours reduced post-traumatic stress disorder compared with debriefing after 48 hours.

Benefits: We found one systematic review (search date 2001, 11 RCTs, 1759 people)[4] and one subsequent RCT[5] comparing early (within 1 month) single session interventions ("debriefing") versus no intervention. The RCTs in the review used psychological debriefing (see glossary, p 1359) or similar techniques after traumatic events. The review found no significant difference between debriefing and no debriefing in the risk of post-traumatic stress disorder at 3 months and 1 year, although the risk of post-traumatic stress disorder was higher in people receiving debriefing (OR at 3 months 1.1, 95% CI 0.6 to 2.5; OR at 12 months 2.0, 95% CI 0.9 to 4.5).[4] The subsequent RCT (77 people who had been robbed) compared early group debriefing (within 10 hours) versus delayed group debriefing (after > 48 hours).[5] It found that early debriefing significantly reduced symptom severity measured on the Post-traumatic Stress Diagnostic Scale at 2 weeks compared with delayed debriefing (mean score 6.94 with early debriefing *v* 33.10 with delayed debriefing; $P < 0.001$).

Harms: Two RCTs included in the systematic review found an increased risk of subsequent psychological problems in people receiving the intervention.[4] However, initial traumatic exposure had been higher in these people.

Comment: The systematic review of single session debriefing found that the overall quality of RCTs was poor.[4] Problems included lack of blinding, failure to state loss to follow up, and lack of intention to treat analysis despite high withdrawal rates.

OPTION MULTIPLE SESSION COGNITIVE BEHAVIOURAL THERAPY

We found no systematic review or RCT comparing cognitive behavioural therapy alone versus no treatment. One RCT provided insufficient evidence to assess cognitive behavioural therapy plus educational techniques in preventing post-traumatic stress disorder in road traffic accident survivors. One RCT in bus drivers who had been attacked in the past 5 months found that cognitive behavioural therapy improved measures of anxiety and intrusive symptoms at 6 months compared with standard care, but found no significant difference in measures of depression or avoidance symptoms. Another small RCT provided insufficient evidence to compare memory structuring versus supportive listening in road traffic accident survivors. Two RCTs in people with acute stress disorder after a traumatic event (road traffic accident or

non-sexual assault) found that five sessions of either cognitive behavioural therapy or prolonged exposure reduced the proportion of people with post-traumatic stress disorder after 6 months compared with supportive counselling.

Benefits:

Versus no treatment: We found no systematic review or RCT comparing cognitive behavioural therapy (see glossary, p 1358) alone versus no treatment. **Cognitive behavioural therapy plus education versus no treatment:** We found one RCT (151 people who had been involved in a road traffic accident in the past month) that compared 3–6 sessions of cognitive behavioural therapy plus educational techniques versus no psychological intervention (see comment below).[6] The RCT found that people in the treatment group had a significantly higher baseline risk of post-traumatic stress disorder compared with the no intervention group, which makes the results difficult to interpret. The RCT found no significant difference between groups in rates of post-traumatic stress disorder at 6 months. **Versus standard care:** One RCT (132 bus drivers who had been attacked in the past few days) comparing 1–6 sessions of cognitive behavioural therapy versus standard care found that cognitive behavioural therapy significantly improved measures of anxiety and intrusive symptoms at 6 months, but found no significant difference in measures of depression or avoidance symptoms.[7] **Versus supportive counselling:** We found two RCTs.[8,9] The first RCT (24 people with acute stress disorder 2 weeks after a road traffic accident or industrial accident) compared five sessions of cognitive behavioural therapy versus five sessions of supportive counselling (see glossary, p 1359).[8] It found that cognitive behavioural therapy significantly reduced the proportion of people who met Post-traumatic Stress Disorder Diagnostic Scale criteria immediately after treatment compared with supportive counselling (AR 8% with cognitive behavioural therapy *v* 83% with supportive counselling; $P < 0.001$) and at 6 months (AR 17% with cognitive behavioural therapy *v* 67% with supportive counselling; $P < 0.05$). The second RCT (45 survivors of road traffic accidents or non-sexual assault with acute stress disorder) compared three treatments: five 90 minute sessions of prolonged exposure (see glossary, p 1358) therapy alone, prolonged exposure therapy plus anxiety management (see glossary, p 1358); or supportive counselling.[9] It found that, immediately after completion of treatment, both prolonged exposure alone and prolonged exposure plus anxiety management significantly reduced rates of post-traumatic stress disorder compared with supportive counselling (measured by Clinician Administered PTSD Scale: AR 2/14 [14%] with prolonged exposure *v* 3/15 [20%] with prolonged exposure plus anxiety management *v* 9/16 [56%] with supportive counselling; $P < 0.05$ for either group *v* supportive counselling). The differences remained significant at 6 months' follow up (AR 2/13 [15%] with prolonged exposure *v* 3/13 [23%] with anxiety management *v* 10/15 [67%] with supportive counselling; $P < 0.05$ for each group *v* supportive counselling). **Memory structuring versus supportive listening:** We found one RCT (17 survivors of a road traffic accident in the past

24–48 hours) comparing two sessions of memory structuring versus supportive listening (see glossary, p 1358).[10] It found that memory structuring significantly reduced mean scores on the Post-traumatic Stress Diagnostic Scale at 3 months compared with supportive listening (mean score 8.1 with memory structuring *v* 18.5 with supportive listening; $P < 0.05$).[10]

Harms: The RCTs gave no information on adverse effects.[6–10]

Comment: The overall quality of RCTs was poor.[6–10] Problems included lack of blinding, failure to state loss to follow up, and lack of intention to treat analysis despite high withdrawal rates. The RCT comparing cognitive behavioural therapy plus educational techniques versus no psychological intervention included multiple types of intervention (help, information, support, and reality testing/confrontation) in the treatment group.[6]

OPTION MULTIPLE SESSION TRAUMA SUPPORT

Two RCTs provided insufficient evidence to assess collaborative care interventions involving emotional, social, and practical support in people exposed to a traumatic event in the past 1 day to 1 week.

Benefits: We found no systematic review but found two RCTs.[11,12] The first RCT (70 people who had been admitted to hospital after a road traffic accident in the past week) compared three treatments: a social work intervention (emotional, practical, and social support for 2–10 hours in the first 3 months); immediate review (a single debriefing intervention); and no intervention.[11] It found that emotional, practical and social support significantly reduced the risk of a poor outcome (based on Traumatic Neurosis Symptoms) compared with immediate review, although both interventions reduced the risk of a poor outcome compared with no intervention (AR for a poor outcome 30% with social work intervention *v* 60% with immediate review *v* 87% with no intervention; ARR for social work *v* no intervention 57%, NNT 2; ARR for immediate review *v* no intervention 27%, NNT 4; CI not reported; $P < 0.001$ for either intervention group *v* no intervention; $P < 0.05$ for comparison between the intervention groups). The second RCT (34 survivors of road traffic accidents or assault in the past 24 hours) compared a 4 month collaborative care (see glossary, p 1359) intervention (emotional, practical, and social support from a trauma support specialist) versus no intervention.[12] After 4 months, the risk of developing post-traumatic stress disorder was lower with collaborative care than with no intervention, but the difference was not significant (AR for post-traumatic stress disorder assessed by Post-Traumatic Stress Disorder Checklist: 17% with collaborative care *v* 43% with no intervention; CI not reported; $P > 0.1$). The RCT might have lacked power to exclude a clinically important difference in outcomes.

Harms: The RCTs gave no information on adverse effects.[11,12]

Comment: The overall quality of RCTs was poor.[11,12] Problems included lack of blinding, failure to state loss to follow up, and lack of intention to treat analysis despite high withdrawal rates.

OPTION MULTIPLE SESSION EDUCATION

One RCT provided insufficient evidence to assess educational techniques plus cognitive behavioural therapy in preventing post-traumatic stress disorder in road traffic accident survivors.

Benefits: **Multiple episode education alone:** We found no systematic review or RCTs. **Multiple session education plus cognitive behavioural therapy:** See benefits of multiple session cognitive behavioural therapy, p 1347. See glossary, p 1358.

Harms: **Multiple session education alone:** We found no systematic review or RCTs. **Multiple session education plus cognitive behavioural therapy:** See harms of multiple session cognitive behavioural therapy, p 1348.

Comment: None.

OPTION SUPPORTIVE COUNSELLING

Two RCTs in people with acute stress disorder after a traumatic event (road traffic accident or non-sexual assault) found that supportive counselling was less effective than five sessions of either cognitive behavioural therapy or prolonged exposure in reducing the proportion of people with post-traumatic stress disorder after 6 months.

Benefits: **Versus no treatment:** We found no systematic review or RCTs comparing supportive counselling (see glossary, p 1359) versus no treatment. **Versus cognitive behavioural therapy:** See benefits of cognitive behavioural therapy, p 1351. See glossary, p 1358.

Harms: **Versus no treatment:** We found no RCTs. **Versus cognitive behavioural therapy:** See harms of cognitive behavioural therapy, p 1351.

Comment: None.

OPTION HYDROCORTISONE New

One small RCT in people in intensive care with septic shock provided insufficient evidence to assess hydrocortisone in preventing post-traumatic stress disorder.

Benefits: We found no systematic review but found one small RCT (20 people in an intensive care unit with septic shock) comparing intravenous hydrocortisone versus saline.[13] It found that hydrocortisone significantly reduced the proportion of people with post-traumatic stress disorder at 31 months compared with saline (assessed by Structured Clinical Interview using DSM-IV criteria for PTSD: 1/9 [11%] with hydrocortisone *v* 7/11 [64%] with placebo; RR 0.07, 95% CI 0.01 to 0.80).

Harms: The RCT gave no information on adverse effects.[13]

Comment: None.

OPTION PROPRANOLOL New

One small RCT provided insufficient evidence to assess propranolol in preventing post-traumatic stress disorder in people with early symptoms of post-traumatic stress disorder after a traumatic event.

Benefits: We found no systematic review but found one RCT (41 people with early symptoms of post-traumatic stress disorder 6 hours after a traumatic event) comparing propranolol 40 mg four times daily versus placebo for 10 days.[14] It found no significant difference between propranolol and placebo in the proportion of people with post-traumatic stress disorder at 1 month (measured by Clinician Administered PTSD Scale 2/11 [18%] with propranolol *v* 6/20 [30%] with placebo; RR 0.52, 95% CI 0.09 to 3.16) or 3 months (1/11 [9%] with propranolol *v* 2/15 [13%] with placebo; RR 0.65, 95% CI 0.05 to 8.23; results were not intention to treat).

Harms: The RCT gave no information on adverse effects.[14]

Comment: The RCT had a high withdrawal rate, and results are not intention to treat, which makes them difficult to interpret.[14]

OPTION TEMAZEPAM New

One small RCT provided insufficient evidence to assess temazepam in preventing post-traumatic stress disorder in people with acute stress disorder or early symptoms of post-traumatic stress disorder after road traffic accident, industrial accident, or non-sexual assault.

Benefits: We found no systematic review but found one RCT (22 people with post-traumatic stress disorder symptoms and sleep initiation difficulties a mean 14 days after road traffic accident, industrial accident, or non-sexual assault, 7 with acute stress disorder) comparing temazepam 30 mg daily for 5 days followed by 15 mg daily for 2 days versus placebo.[15] It found no significant difference in the proportion of people with post-traumatic stress disorder at 6 weeks (assessed by Structured Clinical Interview using DSM-IV criteria for PTSD: 6/11 [54%] with temazepam *v* 3/11 [27%] with placebo; RR 3.2, 95% CI 0.54 to 18.98). It found that temazepam significantly improved sleep after one night compared with placebo ($P < 0.04$), but found similar total sleep patterns after 1 week (P value not reported). The RCT is likely to have been underpowered to detect clinically important differences in outcomes.

Harms: The RCT gave no information on adverse effects.[15]

Comment: The RCT was published as a letter to the editor.[15]

QUESTION What are the effects of treatments?

OPTION COGNITIVE BEHAVIOURAL THERAPY

RCTs have found that cognitive behavioural therapy improves post-traumatic stress disorder symptoms, anxiety, and depression immediately after treatment and at up to 1 year compared with no treatment or supportive counselling. RCTs have found no significant difference in symptoms between cognitive behavioural therapy and eye movement desensitisation and reprocessing.

Benefits: **Versus supportive counselling or no treatment:** We found one systematic review (search date not reported)[16] and five subsequent RCTs of cognitive behavioural therapy (see glossary, p 1358).[17–21] The review compared a range of specific psychological treatments versus supportive counselling (see glossary, p 1359) or no treatment.[16] It identified 17 RCTs (690 people), including six RCTs (232 people) of cognitive behavioural therapy. All RCTs identified by the review found that psychological treatments were associated with a greater improvement immediately after treatment (using a composite score of post-traumatic stress disorder [PTSD] symptoms, anxiety, and depression) compared with supportive counselling or no treatment (17 RCTs, 690 people: overall effect size immediately after treatment 0.54, 95% CI 0.39 to 0.68). The difference was still evident at 1 year (overall effect size from 12 RCTs with long term follow up 0.53, 95% CI 0.37 to 0.69). The first subsequent RCT (87 people) compared exposure, cognitive therapy, or both, versus relaxation treatment (see glossary, p 1359).[17] It found that all cognitive behavioural therapies reduced symptoms of PTSD more than relaxation treatment, immediately after treatment and at 3 months (53 people evaluated; no intention to treat analysis performed). The second subsequent RCT (72 people) found no significant difference in symptoms at 1 year between 16 1-hour sessions of imaginal exposure therapy (see glossary, p 1358) and cognitive therapy (results not intention to treat; 54 people analysed; effect size 0.88 with imaginal exposure *v* 1.06 with cognitive therapy; reported as non-significant). It found that overall 21/54 (39%) of people continued to suffer from PTSD at 1 year.[18] The third subsequent RCT (168 female victims of sexual assault or childhood sexual abuse with PTSD and chronic nightmares) compared three sessions of imagery rehearsal therapy (see glossary, p 1359) versus no treatment over 5 weeks.[19] It found that imagery rehearsal therapy significantly improved PTSD symptoms at 3 or 6 months compared with no treatment (AR for symptoms improving by at least 1 level of clinical severity 65% with imagery rehearsal *v* 31% with no treatment; ARR 34%; NNT 3, CI not reported; $P < 0.001$). The fourth subsequent RCT (171 female victims of sexual assault) compared three treatments: cognitive processing therapy; prolonged exposure (see glossary, p 1358); or minimal attention (telephone call every 2 weeks) for 6 weeks.[20] It found that, immediately after treatment, both cognitive processing therapy and prolonged exposure significantly reduced rates of PTSD compared with minimal attention (AR of not having PTSD assessed by several measures including Clinician Administered PTSD Scale: 33/62 [53%] with cognitive processing *v* 33/62 [53%] with prolonged exposure *v* 1/45 [2%] with minimal attention; $P < 0.001$ for either intervention *v* placebo). The fifth subsequent RCT (78 people with PTSD or severe sub-syndromal PTSD 6 months after a road traffic accident) compared three interventions: 8–12 sessions of cognitive behavioural therapy, 8–12 sessions of supportive psychotherapy (see glossary, p 1359), and waiting list control.[21] It found that, immediately after treatment, cognitive behavioural therapy significantly increased the proportion of people who responded compared with supportive psychotherapy or waiting list control (20/27 [74%] with cognitive behavioural therapy *v* 14/27 [52%] with supportive

psychotherapy *v* 4/24 [17%] with waiting list control; P < 0.05 for cognitive behavioural therapy *v* either comparison). These results were maintained at 3 months' follow up. **Versus eye movement desensitisation and reprocessing:** See benefits of eye movement desensitisation and reprocessing, p 1352.

Harms: The systematic review[16] and subsequent RCTs[17–21] gave no information on adverse effects. Overall, cognitive behavioural therapy seems well tolerated. However, there have been case reports of worsening symptoms in some people receiving imaginal flooding (see glossary, p 1358), leading to calls for caution when evaluating people for treatment.[22]

Comment: None.

OPTION EYE MOVEMENT DESENSITISATION AND REPROCESSING

RCTs have found that eye movement desensitisation and reprocessing improves symptoms compared with no treatment, and have found no significant difference in symptoms between eye movement desensitisation and reprocessing and cognitive behavioural therapy.

Benefits: **Versus no treatment:** We found one systematic review (search date 2000), which identified nine RCTs (number of people not reported) in people with post-traumatic stress disorder.[23] It found that eye movement desensitisation and reprocessing (EMDR) (see glossary, p 1359) was significantly more effective than no treatment in reducing symptoms of post-traumatic stress disorder (effect size 0.39, CI not reported; P < 0.05; see comment below). **Versus cognitive behavioural therapy:** We found one systematic review[23] and one subsequent RCT.[24] The review found no significant difference between EMDR and cognitive behavioural therapy (see glossary, p 1358) (effect size for EMDR *v* cognitive behavioural therapy –0.44, CI not reported; reported as non-significant) or between EMDR with eye movements and EMDR without eye movements (effect size 0.22, CI not reported; reported as non-significant; see comment below).[23] The subsequent RCT (24 people with PTSD) found no significant difference between stress inoculation training plus prolonged exposure and eye movement desensitisation and reprocessing (see glossary, p 1359) in the proportion of people with PTSD immediately after 8–12 weeks' treatment (assessed by structured interview: 9/12 [75%] with stress inoculation training plus prolonged exposure *v* 10/12 [83%] with eye movement desensitisation and reprocessing; RR 0.60, 95% CI 0.08 to 4.45) or at 3 months' follow up (10/12 [83%] in each group; RR 1.00, 95% CI 0.12 to 8.56).[24]

Harms: The systematic review and subsequent RCT gave no information on adverse effects. [23,24]

Comment: The review did not report duration of treatment or state when the outcome of improvement in symptoms was measured.[23]

OPTION **OTHER PSYCHOLOGICAL TREATMENTS**

RCTs provided insufficient evidence to assess affect management, eclectic psychotherapy, group therapy, interapy, or psychodynamic psychotherapy. We found no RCTs of drama therapy or inpatient treatment programmes.

Benefits:

Affect management: We found no systematic review, but found one RCT (48 women) comparing 15 weeks of affect management (see glossary, p 1358) treatment (in addition to drug treatment) versus waiting list control.[25] It found that, compared with waiting list control, affect management improved post-traumatic stress disorder symptoms (assessed by the Davidson Trauma Scale: 45.8 with affect management *v* 73.1 with waiting list control; P = 0.02) and dissociative symptoms (see glossary, p 1359) from baseline (assessed by the Dissociative Experiences Scale: 11.9 with affect management *v* 25.2 with waiting list control; P = 0.02). **Eclectic psychotherapy:** We found no systematic review but found one RCT (42 police officers) comparing brief eclectic psychotherapy (combining components of cognitive behavioural therapy and psychodynamic psychotherapy [see glossary, p 1359]) versus waiting list control over 16 sessions of treatment.[26] It found that eclectic psychotherapy significantly reduced the proportion of people with post-traumatic stress disorder immediately after treatment (AR for post-traumatic stress disorder assessed by assessed by Structured Clinical Interview using DSM-IV criteria for PTSD: 9% with eclectic psychotherapy *v* 50% with waiting list control; P < 0.01) and at 3 months (AR 4% with eclectic psychotherapy *v* 65% with waiting list control; P < 0.01). **Group therapy:** We found no systematic review but found one RCT (55 female survivors of childhood sexual abuse with post-traumatic stress disorder) comparing three treatments: trauma focused group therapy; present focused group therapy (see glossary, p 1359); or waiting list control.[27] Group therapy was undertaken in 90 minute sessions for 24 weeks. The RCT found that either type of group therapy significantly improved symptoms of dissociation and sexual abuse trauma (P < 0.05 for both outcomes) compared with waiting list control. It found no significant difference in overall symptoms (symptoms assessed using the Trauma Symptom Checklist 40: mean difference in score 8.1 with group therapy *v* 3.8 with wait list control; reported as non-significant; no further data reported). The RCT prospectively defined three groups, but combined results for both active treatment groups in its analysis. This makes the results difficult to interpret. It is likely to have been underpowered to detect a clinically important difference in outcomes. **Interapy:** We found no systematic review but found one RCT (25 people) that compared interapy (see glossary, p 1359) versus waiting list control for 5 weeks.[28] It found that, at 5 weeks, interapy significantly improved intrusive symptom score from baseline compared with waiting list control (mean reduction 11.0 with interapy *v* 3.6 with waiting list control; P < 0.04) and reduced avoidance score (mean reduction 9.6 with interapy *v* 2.9 with waiting list control; P < 0.03). **Psychodynamic psychotherapy:** The systematic review of a range of psychological treatments[16] identified one RCT (112 people, search date not

stated) that compared four interventions: psychodynamic psychotherapy, prolonged exposure, hypnotherapy (see glossary, p 1359), and waiting list control.[29] It found that symptoms were improved from baseline significantly more within all active groups compared with waiting list control. However, the trial did not test the significance of comparative results. **Drama therapy; inpatient treatment programmes; supportive psychotherapy:** See glossary, p 1359. We found no RCTs.

Harms: The systematic review[16] and RCTs[25–29] gave no information on adverse effects.

Comment: None.

OPTION SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND RELATED ANTIDEPRESSANTS

RCTs found that sertraline or paroxetine reduced symptoms at 3–7 months compared with placebo. RCTs found more limited evidence from the systematic review and one subsequent RCT that fluoxetine may reduce symptoms at 3 months compared with placebo. RCTs provided insufficient evidence to compare mirtazapine versus placebo or sertraline versus nefazodone.

Benefits: **Versus placebo:** We found one systematic review (search date 1999)[30] and seven subsequent RCTs (3 evaluating sertraline,[31–33] 2 evaluating paroxetine,[34,35] 1 evaluating fluoxetine,[36] and one evaluating mirtazapine.[37] The review identified 4 RCTs (375 people) comparing selective serotonin reuptake inhibitors versus placebo that used the Clinical Global Impression Scale change item or close equivalent as the primary outcome measure.[30] Response was defined as a Clinical Global Impression Scale score of 1 [very much improved] or 2 [much improved]. Two RCTs (183 people) found that sertraline significantly increased the proportion of people who responded after 3 months (OR 0.44, 95% CI 0.24 to 0.78). One RCT (280 people) found no significant difference between paroxetine and placebo in the proportion of people who responded after 3 months (OR 0.64, 95% CI 0.40 to 1.02) and another RCT (53 people) found no significant difference between fluoxetine and placebo in the proportion of people who reponded after 3 months (OR 0.30, 95% CI 0.09 to 1.02).[30] Five of the subsequent placebo-controlled RCTs found improved symptoms with selective serotonin reuptake inhibitors. The first subsequent RCT (208 people) found that sertraline 50–200 mg daily significantly improved symptoms at 12 weeks compared with placebo (mean reduction in post-traumatic stress disorder [PTSD] symptom score on the Clinician Administered PTSD Scale –33.0 with sertraline *v* –26.2 with placebo; $P = 0.04$).[31] The second subsequent RCT (96 people who had previously responded to sertraline for acute treatment of PTSD) found that sertraline significantly reduced PTSD relapse after 28 weeks compared with placebo (AR 5% with sertraline *v* 26% with placebo; ARR 21%; NNT 5; CI not reported; $P < 0.02$).[32] The third subsequent RCT (42 veteran male soldiers) found no significant difference between sertraline 50–200 mg daily and placebo in symptoms of PTSD after 10 weeks of treatment (mean reduction in Clinician Administered PTSD score –18.7 with sertraline *v* –13.5

with placebo; P = 0.53; see comment below).[33] The fourth subsequent RCT (307 people) found that paroxetine 20–50 mg daily significantly increased response rate at 12 weeks compared with placebo (response defined as "very much improved" or "much improved" on the Clinical Global Impression Scale; AR 59% with paroxetine *v* 38% with control; ARR 21%; NNT 5; CI not reported; P = 0.008).[34] The fifth subsequent RCT (551 people) found that paroxetine 20 or 40 mg daily significantly improved response rate (using the same definition) at 12 weeks compared with placebo (AR for response 62% with 20 mg paroxetine *v* 54% with 40 mg paroxetine *v* 37% with placebo; P < 0.001 for both paroxetine groups compared with placebo).[35] The sixth subsequent RCT (301 people, primarily male soldiers) found that fluoxetine 50–80 mg daily significantly improved symptoms compared with placebo after 12 weeks' treatment (mean reduction in Clinician Administered PTSD score –34.6 with fluoxetine *v* –29.6 with placebo; P = 0.021).[36] The clinical importance of this difference in symptoms is unclear. The seventh subsequent RCT (26 people with PTSD) compared mirtazapine 45 mg daily (17 people) versus placebo (9 people) for 8 weeks' treatment.[37] It found no significant difference in the proportion of people with global improvement in symptoms immediately after treatment (as assessed by the Short PTSD Rating Interview: 11/17 [65%] with mirtazapine *v* 2/9 [22%] with placebo; RR 6.42, 95% CI 0.99 to 41.21; results not intention to treat). The RCT is likely to have been underpowered to detect clinically important differences in outcomes. **Versus each other:** We found one systematic review[30] and one subsequent RCT.[38] Two RCTs identified by the review found no significant difference in response at 10–12 weeks between sertraline, paroxetine, or fluoxetine (sertraline, 42 people: OR 0.44, 95% CI 0.12 to 1.60; paroxetine, 280 people: OR 0.64, 95% CI 0.40 to 1.02; fluoxetine, 53 people: OR 0.30, 95% CI 0.09 to 1.02). These RCTs may have been underpowered to detect a clinically important difference in outcomes. The subsequent RCT compared sertraline 50–100 mg daily versus nefazodone 200–400 mg daily.[38] It found no significant difference in symptoms at 5 months (mean total eight item PTSD scale [TOP-8] score 5.23 with sertraline *v* 4.35 with nefazodone; P = 0.36). However, the results of that RCT should be interpreted with caution because, despite randomisation, people taking sertraline had significantly higher baseline TOP-8 scores than people taking nefazodone.

Harms: The systematic review gave no information on adverse effects, although it found no significant difference between antidepressants and placebo in the proportion of people who withdrew for any cause (7 RCTs; 712 people; RR 0.85, 95% CI 0.63 to 1.14).[30] The first subsequent RCT found that, compared with placebo, sertraline significantly increased insomnia (35% with sertraline *v* 22% with placebo; P = 0.04), diarrhoea (28% with sertraline *v* 11% with placebo; P = 0.003), and nausea (23% with sertraline *v* 11% with placebo; P = 0.03), and decreased appetite (12% with sertraline *v* 1% with placebo; P = 0.001).[31] The fourth subsequent RCT comparing paroxetine versus placebo found that adverse effects with an incidence of at least 10% and twice that of placebo were nausea (19.2% with paroxetine *v* 8.3% with placebo), somnolence (17.2%

with paroxetine *v* 3.8% with placebo), dry mouth (13.9% with paroxetine *v* 4.5% with placebo), asthenia (13.2% with paroxetine *v* 5.2% with placebo), and abnormal ejaculation (11.8% with paroxetine *v* 3.7% with placebo).[34] In the seventh subsequent RCT four people taking mirtazapine withdrew because of adverse effects, including sedation, panic attacks, increased anxiety, and irritability.[37] One person taking placebo withdrew because of pain. The RCT found that significantly more people taking placebo had palpitations (3/9 [33%] with placebo *v* 0/17 [0%] with mirtazapine; P = 0.03) and more people taking mirtazapine had increased appetite (6 with mirtazapine *v* 1 with placebo; P value not reported). A further RCT (65 people) assessing the harms of fluoxetine in people with PTSD found that fluoxetine was associated with significantly higher rates of nausea, diarrhoea, and thirst compared with placebo (P < 0.05 for all outcomes).[39] Known adverse effects of selective serotonin reuptake inhibitors include nausea and headache (see harms of prescription antidepressant drugs under depressive disorders, p 1278).

Comment: The veteran soldiers in the third subsequent RCT evaluating sertraline had higher baseline Clinician Administered PTSD scores (mean baseline score 94.3) than people in the other RCTs of sertraline (mean baseline score about 74); this may explain the lack of significant improvement in symptoms between sertraline and placebo.[33]

OPTION TRICYCLIC ANTIDEPRESSANTS

RCTs provided insufficient evidence to assess imipramine or amitriptyline in people with post-traumatic stress disorder.

Benefits: We found one systematic review (search date 1999) of antidepressant drugs for post-traumatic stress disorder.[30] The review identified two RCTs (81 people) comparing tricyclic antidepressants versus placebo that used the Clinical Global Impression Scale change item or close equivalent as the primary outcome measure.[30] One RCT (41 people) identified by the review found that the proportion of non-responders at 2 months was significantly lower with imipramine than with placebo (response defined as Clinical Global Impression score of 1 [very much improved] or 2 [much improved]; OR 0.21, 95% CI 0.05 to 0.78). The other RCT (40 people) identified by the review found no significant difference between amitriptyline and placebo in the proportion of people who responded after 2 months (OR 0.41, 95% CI 0.12 to 1.42).[30]

Harms: The systematic review gave no information on adverse effects, although it found no significant difference between antidepressants and placebo in the proportion of people who withdrew for any cause (7 RCTs; 712 people; RR 0.85, 95% CI 0.63 to 1.14).[30] Known adverse effects of tricyclic antidepressants include anticholinergic effects (see harms of prescription antidepressant drugs under depressive disorders, p 1278).

Comment: None.

OPTION MONOAMINE OXIDASE INHIBITORS

RCTs provided insufficient evidence to assess brofaromine or phenelzine in people with post-traumatic stress disorder.

Benefits: We found one systematic review (search date 1999) of antidepressant drugs for post-traumatic stress disorder.[30] The review identified three RCTs (247 people) comparing monoamine oxidase inhibitors versus placebo that used the Clinical Global Impression Scale change item or close equivalent as the primary outcome measure.[30] Two RCTs found no significant difference between brofaromine and placebo in the proportion of non-responders at 14 weeks (response defined as Clinical Global Impression Scale of 1 [very much improved] or 2 [much improved]: 114 people: OR 0.94, 95% CI 0.45 to 1.99; 64 people: OR 0.40, 95% CI 0.15 to 1.08). One RCT (37 people) found that phenelzine significantly increased the proportion of responders at 2 months compared with placebo (OR 0.21, 95% CI 0.06 to 0.73).[30]

Harms: The systematic review gave no information on adverse effects, although it found no significant difference between antidepressants and placebo in the proportion of people who withdrew for any cause (7 RCTs; 712 people; RR 0.85, 95% CI 0.63 to 1.14).[30] Known adverse effects of monoamine oxidase inhibitors include possible hypertensive crisis. Monoamine oxidase inhibitors may also require a need for dietary restriction (see harms of prescription antidepressant drugs under depressive disorders, p 1278).

Comment: None.

OPTION CARBAMAZEPINE

We found no RCTs of carbamazepine in people with post-traumatic stress disorder.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION RISPERIDONE New

We found no RCTs of risperidone in people with post-traumatic stress disorder.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION LAMOTRIGINE

One RCT provided insufficient evidence to assess lamotrigine in people with post-traumatic stress disorder.

Post-traumatic stress disorder

Benefits: We found one systematic review (search date 1999), which identified one small RCT (14 people) comparing lamotrigine versus placebo that used the Clinical Global Impression Scale change item or close equivalent as the primary outcome measure.[30] The RCT found no significant difference between lamotrigine and placebo in the proportion of non-responders at 2 months (response defined as Clinical Global Impression Scale score of 1 [very much improved] or 2 [much improved]; OR 0.39, 95% CI 0.04 to 3.71). However, it is likely to have been underpowered to detect a clinically important difference between groups.

Harms: The systematic review gave no information on adverse effects, although it found no significant difference between antidepressants and placebo in the proportion of people who withdrew for any cause (7 RCTs; 712 people; RR 0.85, 95% CI 0.63 to 1.14).[30]

Comment: None.

OPTION BENZODIAZEPINES

One systematic review identified no RCTs of sufficient quality in people with post-traumatic stress disorder.

Benefits: We found one systematic review (search date 1999), which identified no RCTs of sufficient quality.[30]

Harms: We found no RCTs.

Comment: None.

OPTION PROPRANOLOL

We found no RCTs of propranolol in people with post-traumatic stress disorder.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Affect management A type of group treatment focusing on regulation of mood.

Anxiety management Involves teaching techniques to reduce anxiety levels. Examples include muscular relaxation in which individuals are taught to alternatively tense and relax specific muscle groups and breathing retraining to avoid overbreathing.

Cognitive behavioural therapy Covers a variety of techniques. *Imaginal exposure* entails exposure to a detailed account or image of what happened. *Real life exposure* involves confronting real life situations that have become associated with the trauma and cause fear and distress. *Cognitive therapy* entails challenging distorted thoughts about the trauma, the self, and the world. *Imaginal flooding* involves the intense reliving of the traumatic experience. *Memory structuring* involves listening to and clarifying the individual's narrative and structuring it for them to repeat to friends and family. *Prolonged exposure* entails repeated exposure

to memories of the trauma, and to non-dangerous real life situations that are avoided because of trauma related fear. *Stress inoculation* entails instruction in coping skills and some cognitive techniques such as restructuring. *Supportive listening* involves actively listening to the individual's narrative and clarifying factual, sensory, and affective details.

Cognitive processing therapy Includes elements of cognitive therapy and writing and reading about the traumatic event.

Collaborative care Entails counselling, liaison, and coordination of care after discharge.

Dissociative symptoms Involve a disruption to memory or perception of the environment, e.g. an inability to recall details of a traumatic event that cannot be accounted for by ordinary forgetfulness or an organic cause such as head injury.

Drama therapy Entails using drama as a form of expression and communication.

Eye movement desensitisation and reprocessing (EMDR) Entails asking the person to focus on the traumatic event, a negative cognition associated with it, and the associated emotions.[40] The person is then asked to follow the therapist's finger as it moves from side to side.

Hypnotherapy Entails hypnosis to allow people to work through the traumatic event.

Imagery rehearsal therapy Involves encouraging participants to practice pleasant imagery exercises and employ cognitive behavioural tools to deal with unpleasant images.

Interapy A protocol driven treatment delivered through the internet, which includes psychoeducation and cognitive reappraisal. For further information, see http://www.interapy.nl.

Present focused group therapy A group intervention that involves identifying and modifying patterns of behaviour that have arisen from their past traumatic experience.

Psychodynamic psychotherapy Entails analysis of defence mechanisms, interpretations, and pre-trauma experiences.

Psychological debriefing A technique that entails detailed consideration of the traumatic event and the normalisation of psychological reactions.

Relaxation treatment A technique involving imagination of relaxing situations to induce muscular and mental relaxation.

Supportive counselling A non-directive intervention dealing with current issues rather than the trauma itself.

Supportive psychotherapy A non-directive intervention that involves helping an individual to explore their thoughts, feelings, and behaviour with the aim of achieving clearer understanding of self and the ability to cope with situations more effectively.

Trauma focused group therapy A group intervention that involves reconstructing a past traumatic event, identifying and modifying negative self images associated with it, and integrating memories of the event into the individual's conscious awareness of self and others.

Substantive changes

Cognitive behavioural therapy to treat post-traumatic stress disorder One RCT added;[21] conclusions unchanged.

Eye movement desensitisation and reprocessing One RCT added;[22] conclusions unchanged.

Selective serotonin reuptake inhibitors and related antidepressants One RCT provided insufficient evidence to compare mirtazapine versus placebo.[37]

QUESTIONS

INTERVENTIONS

See glossary, p 1387

Key Messages

- Most evidence is from systematic reviews of RCTs that report disparate outcomes. There is a need for larger RCTs, over longer periods, with well designed end points, including standardised, validated symptom scales. No intervention has been found to consistently reduce negative symptoms.

- **Continuation of antipsychotic drugs for 6–9 months after an acute episode to reduce relapse rates** Systematic reviews have found that continuing antipsychotic drugs for at least 6 months after an acute episode reduces relapse rates compared with no treatment or placebo, and that some benefit of continuing antipsychotics is apparent for up to 2 years.
- **Multiple session family interventions to reduce relapse rates** One systematic review found that multiple session family interventions reduced relapse rates at 12 months compared with usual care, single session family interventions, or psychoeducational interventions.
- **Psychoeducational interventions to reduce relapse rates** One systematic review has found that psychoeducation reduces relapse rates at 9–18 months compared with a control intervention.
- **Behavioural therapy to improve adherence** One RCT found that behavioural interventions improved adherence to antipsychotic medication over 3 months compared with usual treatment. Two RCTs found limited evidence that behavioural interventions may improve adherence more than psychoeducational therapy.
- **Compliance therapy to improve adherence** Two RCTs found limited evidence that compliance therapy may increase adherence to antipsychotic drugs at 6 and 18 months compared with non-specific counselling.
- **Psychoeducational interventions to improve adherence** One systematic review found limited evidence that psychoeducation improved adherence to antipsychotic medication compared with usual care. Two RCTs found limited evidence that psychoeducational may improve adherence less than behavioural therapy.
- **Chlorpromazine** One systematic review has found that, compared with placebo, chlorpromazine reduces the proportion of people who have no improvement, or have marked or worse severity of illness at 6 months on a psychiatrist rated scale. The review found that chlorpromazine caused more adverse effects, such as sedation, acute dystonia, and parkinsonism, than placebo.
- **Clozapine** Two systematic reviews found that clozapine improved symptoms over 4–10 weeks compared with standard antipsychotic drugs. However, RCTs found that clozapine may be associated with blood dyscrasias. Three systematic reviews of small RCTs provided insufficient evidence to compare clozapine versus other new antipsychotic drugs. One systematic review in people resistant to standard treatment found that clozapine improved symptoms after 12 weeks and after 2 years compared with standard antipsychotic drugs. RCTs provided insufficient evidence to compare clozapine versus other newer antipsychotics in people resistant to standard antipsychotic drugs.
- **Depot bromperidol decanoate** RCTs found no significant difference in the proportion of people who needed additional medication, left the trial early, or had movement disorders over 6–12 months between depot bromperidol decanoate and haloperidol or fluphenazine decanoate.
- **Depot haloperidol decanoate** One systematic review of one small RCT found no significant difference in global clinical state at 4 months between depot haloperidol decanoate and oral haloperidol, but it may have been too small to exclude a clinically important difference. Haloperidol is associated with acute dystonia, akathisia, and parkinsonism.
- **Haloperidol** One systematic review has found that haloperidol increases physician rated global improvement at 6 and 24 weeks compared with placebo but is associated with acute dystonia, akathisia, and parkinsonism.

Schizophrenia

- **Thioridazine** One systematic review has found that thioridazine improves global mental state over 3–12 months compared with placebo.
- **Cognitive behavioural therapy to reduce relapse rates** Limited evidence from a systematic review of two RCTs found no significant difference in relapse rates between cognitive behavioural therapy plus standard care and standard care alone.
- **Multiple session family interventions to improve adherence** One systematic review found that "compliance with medication" over 9–24 months was higher in people who received multiple family interventions compared with usual care, single family interventions, or psychoeducational interventions, but the difference did not quite reach significance.
- **Perazine** RCTs provided insufficient evidence to assess perazine.
- **Social skills training to reduce relapse rates** One systematic review of small RCTs provided insufficient evidence to assess social skills training.
- **Amisulpride; loxapine; molindone; olanzapine; pimozide; quetiapine; risperidone; sulpiride; ziprasidone; zotepine** Systematic reviews have found that these newer antipsychotic drugs are as effective in improving symptoms as standard antipsychotic drugs, and have different profiles of adverse effects.

DEFINITION Schizophrenia is characterised by the positive symptoms (see glossary, p 1387) of auditory hallucinations, delusions, and thought disorder, and by the negative symptoms (see glossary, p 1387) of demotivation, self neglect, and reduced emotion.[1] People are defined as being resistant to standard antipsychotic drugs if, over the preceding 5 years, they have not had a clinically important improvement in symptoms after 2–3 regimens of treatment with standard antipsychotic drugs for at least 6 weeks (from at least 2 classes at doses equivalent to or greater than 1000 mg/day chlorpromazine) and they have had no period of good functioning.[2,3] Approximately 30% (10–45%) of people with schizophrenia meet these criteria.[3]

INCIDENCE/ PREVALENCE Onset of symptoms typically occurs in early adult life (average age 25 years) and is earlier in men than in women.[4,5] Prevalence worldwide is 2–4/1000. One in 100 people will develop schizophrenia in their lifetime.

AETIOLOGY/ RISK FACTORS Risk factors include a family history (although no major genes have been identified), obstetric complications, developmental difficulties, central nervous system infections in childhood, cannabis use, and acute life events.[4] The precise contributions of these factors and ways in which they may interact are unclear.

PROGNOSIS About three quarters of people suffer recurrent relapse and continued disability, although the proportion of people who improved significantly increased after the mid-1950s (mean 48.5% from 1956–1985 *v* 35.4% from 1895–1956).[6] Outcome may be worse in people with insidious onset and delayed initial treatment, social isolation, or a strong family history; in people living in industrialised countries; in men; and in people who misuse drugs.[5] Drug treatment is generally successful in treating positive symptoms, but up

to a third of people derive little benefit and negative symptoms are notoriously difficult to treat. About half of people with schizophrenia do not adhere to treatment in the short term. The figure is even higher in the longer term.[7]

AIMS OF INTERVENTION To relieve symptoms and to improve quality of life, with minimal adverse effects of treatment.

OUTCOMES Severity of positive and negative symptoms; global clinical improvement; global clinical impression (a composite measure of symptoms and everyday functioning); rate of relapse; adherence to treatment; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal December 2002. Most RCTs were small, short term, with high withdrawal rates, and employed many different outcome measures.[8] There were a large number of good systematic reviews. Therefore, if possible, we focused primarily on systematic reviews and included only the outcomes that we thought were the most clinically relevant. Because each treatment is associated with different benefits and harms, we used estimates of global effectiveness if they were available. We searched for placebo controlled RCTs of standard antipsychotic medication and comparative RCTs of newer antipsychotic drugs.

QUESTION What are the effects of drug treatments?

OPTION CHLORPROMAZINE

One systematic review has found that, compared with placebo, chlorpromazine reduces the proportion of people who have no improvement, or marked or worse severity of illness at 6 months on a psychiatrist rated scale. The review found that chlorpromazine caused more adverse effects, such as sedation, acute dystonia, and parkinsonism, than placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 45 RCTs, 3116 people, mean dose 511 mg/day, range 25–2000 mg/day).[9] It found that, compared with placebo, chlorpromazine significantly reduced the proportion of people who had no improvement on a psychiatrist rated global impression scale at 6 months (13 RCTs; 583/921 [63%] with chlorpromazine *v* 609/790 [77%] with placebo; RR of failing to improve 0.72, 95% CI 0.62 to 0.83; NNT 7, 95% CI 5 to 10) and significantly reduced the proportion of people who had marked or worse severity of illness on a psychiatrist rated scale at 1 week to 6 months (5 RCTs; 323/493 [66%] with chlorpromazine *v* 231/285 [81%] with placebo; RR of increased severity of illness 0.77, 95% CI 0.71 to 0.84; NNT 5, 95% CI 4 to 8).

Harms: **Versus placebo:** The systematic review found that, compared with placebo, chlorpromazine caused significantly higher rates of sedation (218/698 [31%] with chlorpromazine *v* 65/490 [13%] with placebo; RR 2.4, 95% CI 1.7 to 3.3; NNH 6, 95% CI 4 to 8), acute dystonia (28/439 [6%] with chlorpromazine *v* 5/234 [2%] with placebo; RR 3.1, 95% CI 1.3 to 7.6; NNH 24, 95% CI 14 to 77), parkinsonism (123/723 [17%] with chlorpromazine *v* 40/542 [7%]

with placebo; RR 2.6, 95% CI 1.2 to 5.4; NNH 10, 95% CI 8 to 16), weight gain (31/75 [41%] with chlorpromazine *v* 7/90 [8%] with placebo; RR 4.4, 95% CI 2.1 to 9.0; NNH 3, 95% CI 2 to 5), skin photosensitivity (81/496 [16%] with chlorpromazine *v* 9/303 [3%] with placebo; RR 5.2, 95% CI 3 to 10; NNH 7, 95% CI 6 to 10), dizziness caused by hypotension (112/688 [16%] with chlorpromazine *v* 38/504 [7%] with placebo; RR 1.9, 95% CI 1.3 to 2.6; NNH 12, 95% CI 8 to 20), and dry mouth (32/473 [7%] with chlorpromazine *v* 4/283 [1%] with placebo; RR 4.0, 95% CI 1.6 to 10.0; NNH 19, 95% CI 12 to 37).[9] Chlorpromazine was also associated with higher rates of seizures (19/450 [4%] with chlorpromazine *v* 4/245 [2%] with placebo; RR 2.4, 95% CI 0.4 to 16) and blood dyscrasias (10/207 [5%] with chlorpromazine *v* 2/187 [1%] with placebo; RR 2.0, 95% CI 0.7 to 6.0), although the differences did not reach significance. We found no long term data on the risk of tardive dyskinesia or the rare but potentially fatal neuroleptic malignant syndrome. Despite the frequent adverse effects, the review found that people taking chlorpromazine were more likely to stay in RCTs in both the short and the medium term than people taking placebo.

Comment: The review did not categorise symptoms as positive or negative because this information was rarely available from included RCTs.[9] It found significant heterogeneity among RCTs, but found that the analysis of global improvement over 9 weeks to 6 months remained significant after removal of the heterogeneous RCTs (RR 0.65, 95% CI 0.5 to 0.9).

OPTION HALOPERIDOL

One systematic review has found that haloperidol increases the proportion of people with psychiatrist rated global improvement at 6 and 24 weeks compared with placebo, but is associated with acute dystonia, akathisia, and parkinsonism.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 20 RCTs, 1001 people).[10] It found that haloperidol (over a wide range of doses) significantly increased psychiatrist rated global improvement at 6 weeks (3 RCTs, 159 people; 61/88 [69%] with haloperidol *v* 23/71 [32%] with placebo; RR 2.3, 95% CI 1.7 to 3.3; NNT 3, 95% CI 2 to 5) and at 24 weeks (8 RCTs; 72/163 [44%] *v* 21/150 [14%]; RR 3.5, 95% CI 2.3 to 5.6; NNT 3, 95% CI 3 to 5) compared with placebo.

Harms: **Versus placebo:** The systematic review found that, compared with placebo, haloperidol significantly increased the risk of acute dystonia (2 RCTs; RR 4.7, 95% CI 1.7 to 44; NNH 5, 95% CI 3 to 9), akathisia (3 RCTs: RR 6.5, 95% CI 1.5 to 28; NNH 6, 95% CI 4 to 14), and parkinsonism (4 RCTs; RR 8.9, 95% CI 2.6 to 31; NNH 3, 95% CI 2 to 5).[10] People taking haloperidol were significantly more likely to be treated with anticholinergic drugs than people taking placebo (4 RCTs; RR 4.9, 95% CI 1.01 to 24; NNH 2, 95% CI 1 to 3).

Comment: The median size of RCTs in the review was 38 people, but the quality of the RCTs was higher than average for schizophrenia trials.[10] Although the dose range was very wide, most RCTs used 4–20 mg daily and adjusted dose according to need. The review found evidence of publication bias for the 6–24 months global outcome ratings.[10]

OPTION THIORIDAZINE

One systematic review has found that thioridazine improves global mental state over 3–12 months compared with placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 11 RCTs, 560 people).[11] It found that thioridazine significantly reduced the proportion of people who were "no better or worse" in global clinical impression at 3–12 months compared with placebo (5 RCTs; 27/84 [32%] with thioridazine *v* 57/81 [70%] with placebo; RR 0.5, 95% CI 0.37 to 0.68; NNT 3, 95% CI 3 to 5).

Harms: **Versus placebo:** The review found no significant difference in adverse effects between thioridazine and placebo, but may have lacked power to detect a clinically important difference.[11]

Comment: None.

OPTION DEPOT BROMPERIDOL DECANOATE

RCTs found no significant difference in the proportion of people who needed additional medication, left the trial early, or had movement disorders over 6–12 months between depot bromperidol decanoate and haloperidol or fluphenazine decanoate.

Benefits: **Versus standard antipsychotic drugs:** One systematic review (search date 1999, 3 RCTs, 97 people) found no significant difference between depot bromperidol and haloperidol or fluphenazine decanoate in the proportion of people who needed additional antipsychotics or benzodiazepines over 6–12 months (19/48 [39%] with bromperidol *v* 18/49 [37%] with haloperidol or fluphenazine; RR 1.08, 95% CI 0.68 to 1.70) or who left the trial early (10/48 [21%] with bromperidol *v* 5/49 [10%] with haloperidol or fluphenazine; RR 1.92, 95% CI 0.80 to 4.60).[12]

Harms: **Versus standard antipsychotic drugs:** The review found no significant difference in movement disorders over 6–12 months between bromperidol and haloperidol or fluphenazine (2 RCTs: 16/38 [42%] with bromperidol *v* 22/39 [56%] with haloperidol or fluphenazine; RR 0.74, 95% CI 0.47 to 1.17).[12]

Comment: None.

OPTION DEPOT HALOPERIDOL DECANOATE

One systematic review of one small RCT found no significant difference in global clinical state at 4 months between depot haloperidol decanoate and oral haloperidol, but it may have been too small to exclude a clinically important difference. Haloperidol is associated with acute dystonia, akathisia, and parkinsonism.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1998) that identified one small RCT (22 people) comparing depot haloperidol versus oral haloperidol.[13] It found no significant difference in the proportion of people with "no improvement" in global clinical impression at 4 months (8/11 [73%] with depot haloperidol *v* 9/11 [82%] with oral haloperidol; RR of no improvement 0.89, 95% CI 0.56 to 1.40). The RCT may have been too small to detect a clinically important difference.

Harms: **Versus standard antipsychotic drugs:** The RCT found no significant difference between depot and oral haloperidol in the proportion of people who needed anticholinergic drugs for movement disorders (3/11 [27%] with depot haloperidol *v* 1/11 [9%] with oral haloperidol; RR 3.00, 95% CI 0.37 to 24.58).[13] Also see harms of haloperidol, p 1366.

Comment: Depot injection is believed to ensure adherence, but we found no evidence from RCTs to support this.

OPTION CLOZAPINE

One systematic review found that clozapine improved symptoms over 4–10 weeks compared with standard antipsychotic drugs. However, RCTs found that clozapine may be associated with blood dyscrasias. One systematic review of small RCTs provided insufficient evidence to compare clozapine versus other newer antipsychotic drugs.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1999, 31 RCTs, 2589 people), which compared clozapine versus standard antipsychotic drugs, such as chlorpromazine and haloperidol.[14] It found that clozapine significantly reduced the proportion of people with no clinical improvement over 4–10 weeks compared with standard antipsychotic drugs (14 RCTs; 267/561 [48%] with clozapine *v* 377/570 [66%] with standard antipsychotics; RR of no important improvement 0.75, 95% CI 0.66 to 0.84). This means that, on average, six people will need to be treated for one to improve (NNT 6, 95% CI 5 to 7). The review found that, despite the requirement for regular blood tests, significantly fewer people withdrew from treatment with clozapine over 7–24 months compared with standard antipsychotic drugs (111/750 [15%] with clozapine *v* 140/763 [18%] with standard antipsychotics; RR 0.76, 95% CI 0.66 to 0.92). **Versus other new antipsychotic drugs:** We found one systematic review (search date 1999, 8 RCTs, 795 people).[15] Five of the RCTs identified by the review were in people with treatment resistant schizophrenia (see benefits of clozapine in people who are resistant to standard antipsychotic drugs, p 1389).

Harms: **Versus standard antipsychotic drugs:** The review found that, compared with standard antipsychotic drugs, clozapine was significantly more likely to cause hypersalivation (351/699 [50%] with clozapine *v* 161/720 [22%] with standard antipsychotics; RR 2.23, 95% CI 1.95 to 2.57; NNH 3, 95% CI 3 to 4), increased temperature (129/560 [23%] with clozapine *v* 86/587 [15%] with standard antipsychotics; RR 1.57, 95% CI 1.27 to 1.98; NNH 11, 95% CI 7

to 25), and sedation (392/751 [52%] with clozapine *v* 332/776 [43%] with standard antipsychotics; RR 1.23, 95% CI 1.13 to 1.34; NNH 10, 95% CI 6 to 22), but that it was less likely to cause dry mouth (40/397 [10%] with clozapine *v* 111/402 [28%] with standard antipsychotics; RR 0.36, 95% CI 0.26 to 0.51; NNT 6, 95% CI 4 to 8) and extrapyramidal adverse effects (202/614 [33%] with clozapine *v* 304/621 [49%] with standard antipsychotics; RR 0.67, 95% CI 0.58 to 0.77; NNT 6, 95% CI 5 to 9).[14] A large case series found leucopenia in 3% of 99 502 people taking clozapine over 5 years.[16] However, it found that monitoring white cell (neutrophil) counts was associated with a lower rate of cases of agranulocytosis in people taking clozapine (382 *v* 995; AR 0.38% *v* 1%) and deaths (12 *v* 149).[16] The review found that clozapine significantly increased blood problems, including leucopenia and neutropenia compared with standard antipsychotic drugs (24/637 [4%] with clozapine *v* 12/656 [2%] with standard antipsychotics; RR 1.85, 95% CI 0.99 to 3.47).[14] We found one systematic review (search date 1996, 12 RCTs, all included in the first review) that performed a meta-regression analysis combining results with various new antipsychotic drugs and comparing them with results with haloperidol.[17] It found that the difference in withdrawal rates did not persist after controlling for dose of haloperidol.

Comment: Some of the benefits of clozapine were more apparent in the long term, depending on which drug was used for comparison in the RCTs.

OPTION AMISULPRIDE

Three systematic reviews found limited evidence that amisulpride may improve symptoms more than standard antipsychotic drugs, although one of the reviews suggested that effects may be attributable to differences in dose. The reviews found that extrapyramidal adverse effects were less likely with amisulpride than with standard antipsychotic drugs. RCTs found no significant difference in symptoms between amisulpride and olanzapine or risperidone.

Benefits: **Versus standard antipsychotic drugs**: We found three systematic reviews.[17–19] The first systematic review (search date 2000) identified four RCTs (651 people), which compared amisulpride versus a standard antipsychotic (haloperidol [3 RCTs] or flupentixol [1 RCT]), and used the Clinical Global Impression scale to assess outcomes.[18] It found that amisulpride significantly reduced the proportion of people who were less than "much improved" in global clinical impression compared with standard antipsychotic drugs (107/324 [33%] with amisulpride *v* 163/327 [50%] with standard antipsychotics; RR of failing to improve 0.66, 95% CI 0.55 to 0.80; NNT 6, 95% CI 5 to 11). It also found that amisulpride significantly reduced the proportion of people who left the study early (14 RCTs; 282/881 [32%] with amisulpride *v* 242/631 [38%] with standard antipsychotics; RR 0.72, 95% CI 0.62 to 0.83; NNT 9, 95% CI 7 to 16). The second systematic review (search date 1998, 4 RCTs, including 2 RCTs identified by the first review, duration 4–6 weeks, 683 people) compared amisulpride versus standard antipsychotic drugs, usually haloperidol.[17] It is unclear whether allocation concealment was adequately performed in all included RCTs. It found

that symptom reduction was greater with amisulpride than with standard antipsychotic drugs (standardised effect size –0.35, 95% CI –0.52 to –0.18), indicating that about 64% (95% CI 57% to 70%) of people do worse with standard antipsychotic drugs than with amisulpride. It also found that, compared with standard antipsychotic drugs, amisulpride significantly reduced the proportion of people who withdrew from the trial (NNH 9, 95% CI 5 to 22). All four short term RCTs identified by the review included people randomised to relatively high doses of amisulpride (estimated equivalent to 20 mg haloperidol), which may have exaggerated results in favour of amisulpride.[17] The review performed a meta-regression analysis and found that, after adjustment for dose differences in standard antipsychotics (usually haloperidol or chlorpromazine), newer antipsychotic drugs (amisulpride, olanzapine, quetiapine, risperidone) lose their therapeutic advantage over standard antipsychotic drugs. Meta-regression was not available for amisulpride alone. The third systematic review (11 RCTs, 6 of which were included in the first or second review) found that amisulpride improved Brief Psychiatric Rating Scale (BPRS) scores compared with haloperidol or flupentixol (mean effect size 0.11; CI not stated; no further data provided).[19] It also found that people taking amisulpride were less likely to withdraw from the study early. **Versus olanzapine:** We found no systematic review but found one RCT (377 people) comparing amisulpride versus olanzapine for 2 months' treatment.[20] It found no significant difference in symptoms at 2 months assessed by BPRS score (mean reduction 17.6 with amisulpride *v* 16.3 with olanzapine; reported as non-significant; CI not stated). **Versus risperidone:** The first review identified one RCT (228 people), which found no significant difference between amisulpride and risperidone in BPRS symptom scores.[18]

Harms:

Versus standard antipsychotic drugs: The first review found that, compared with standard antipsychotic drugs, amisulpride significantly reduced the proportion of people who had at least one adverse effect (6 RCTs; 261/373 [70%] with amisulpride *v* 308/378 [81%] with standard antipsychotics; RR 0.85, 95% CI 0.79 to 0.92; NNT 9, 95% 5% CI 6 to 17).[18] It also found that people taking amisulpride were significantly less likely to experience at least one extrapyramidal symptom (7 RCTs; 161/383 [42%] with amisulpride *v* 234/388 [60%] with standard antipsychotics; RR 0.68, 95% CI 0.60 to 0.79; NNT 5, 95% CI 4 to 8). The second review found that movement disorders, measured by the Simpson Angus scale, were significantly less frequent with amisulpride compared with standard antipsychotic drugs (SMD –0.44, 95% CI –0.26 to –0.61).[17] The reduction in extrapyramidal adverse effects remained significant despite adjustment for dose differences in standard antipsychotics.[17] The third systematic review found that people taking amisulpride experienced fewer movement disorders than people taking standard antipsychotic drugs.[19] It found that amisulpride significantly reduced the use of antiparkinsonian medication compared with standard antipsychotic drugs (effect size 0.25, 95% CI 0.17 to 0.32). **Versus olanzapine:** The RCT found that significantly fewer people had clinically important weight gain (more than 7% total body weight) with amisulpride than with olanzapine (27/

189 [14%] with amisulpride *v* 48/188 [25%] with olanzapine; P = 0.007).[20] **Versus risperidone:** The RCT identified by the first review found no significant difference in adverse effects, extrapyramidal symptoms, or withdrawal rate between amisulpride and risperidone.[18]

Comment: None.

OPTION LOXAPINE

One systematic review comparing loxapine versus standard antipsychotic drugs found no significant difference in global improvement or adverse effects.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1999, 22 RCTs, 1073 people), which compared loxapine (dose range 25–250 mg/day) versus standard antipsychotic drugs, primarily chlorpromazine.[21] It found no significant difference in clinical global improvement between loxapine and standard antipsychotic drugs (9 RCTs; 59/206 [29%] with loxapine *v* 65/205 [32%] with standard antipsychotics; RR of no improvement 0.82, 95% CI 0.52 to 1.31).

Harms: The review found no significant difference in adverse effects between loxapine and standard antipsychotic drugs (11 RCTs; 164/255 [64%] with loxapine *v* 166/251 [66%] with standard antipsychotics; RR 0.90, 95% CI 0.57 to 1.41).[21]

Comment: All of the RCTs identified by the review were conducted in the USA or India and none lasted longer than 12 weeks.[21]

OPTION MOLINDONE

One systematic review found no significant difference in global clinical improvement or in the proportion of people who had adverse effects over 4–12 weeks between molindone and standard antipsychotic drugs.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1999, 9 RCTs, 4 CCTs, 150 people) comparing molindone versus standard antipsychotic drugs, primarily haloperidol or chlorpromazine.[22] It found no significant difference between molindone and standard antipsychotic drugs in global clinical improvement over 4–12 weeks as assessed by a physician (4 RCTs; 25/84 [29.8%] with molindone *v* 20/66 [30.3%] with standard antipsychotics; RR of no improvement 1.10, 95% CI 0.68 to 1.78).

Harms: **Versus standard antipsychotic drugs:** The review found no significant difference between molindone and standard antipsychotic drugs in movement disorders (rigidity, tremor, akasthesia, use of antiparkinsonian medication) or in the proportion of people who had adverse effects (2 RCTs, 1 CCT; 24/42 [57%] with molindone *v* 25/42 [59%] with standard antipsychotics; RR 0.96, 95% CI 0.73 to 1.27).[22] One RCT identified by the review found that significantly more people taking molindone compared with standard antipsychotic drugs experienced confusion (9/14 [64%] with molindone *v* 6/30 [20%] with standard antipsychotics; RR 3.21, 95% CI 1.42 to 7.26). The review also found that significantly more

people had weight loss with molindone than with standard antipsychotic drugs (2 RCTs; 12/30 [40%] with molindone *v* 4/30 [13%] with standard antipsychotics; RR 2.78, 95% CI 1.10 to 6.99) and that fewer people had weight gain with molindone than with standard antipsychotic drugs (2 RCTs; 4/30 [13%] with molindone *v* 11/30 [37%] with standard antipsychotics; RR 0.39, 95% CI 0.95 to 1.00).

Comment: None.

OPTION OLANZAPINE

Systematic reviews found limited evidence that olanzapine may improve symptoms more than standard antipsychotic drugs and good evidence that olanzapine has fewer adverse effects, although one of the reviews suggested that effects may be attributable to differences in dose. Systematic reviews found no clear difference in symptoms or adverse effects among olanzapine, amisulpride, risperidone, and clozapine.

Benefits: **Versus standard antipsychotic drugs:** We found three systematic reviews.[17,23,24] The first review (search date 1999, 15 RCTs, 3282 people) compared olanzapine versus standard antipsychotic drugs, usually haloperidol.[23] It found no significant difference in psychotic symptoms over 6–8 weeks between olanzapine (2.5–25 mg/day) and standard antipsychotic drugs (4 RCTs; 1056/1926 [55%] with olanzapine *v* 596/852 [70%] with standard antipsychotics; RR for no important response [defined as a 40% reduction on any scale] 0.90, 95% CI 0.76 to 1.06). The second review (search date 1998, 4 RCTs, all included in the first review, 2846 people) performed a meta-regression analysis comparing newer versus standard antipsychotics, which adjusted for dose of standard antipsychotic (see benefits of amisulpride, p 1369).[17] Meta-regression analysis was not available for olanzapine alone. The third review (search date 1998, 3 RCTs, all included in the previous review, 2606 people) also found no significant difference in the mean change on a combined rating of positive and negative symptoms (Positive and Negative Syndrome Scale [PANSS]) between olanzapine and haloperidol.[24] However, it conducted a subsequent meta-regression analysis to control for confounding variables (e.g. age and duration of illness, among others) and found limited evidence that olanzapine significantly improved mean PANSS rating scale score compared with standard antipsychotics (WMD –5.9, 95% CI –11.1 to –0.6). The meta-regression analysis did not appear to take account of the dose of haloperidol.[24] **Versus clozapine:** See benefits of clozapine, p 1368. **Versus amisulpride:** See benefits of amisulpride, p 1369. **Versus risperidone:** We found two systematic reviews[25,26] and one subsequent RCT.[27] The first review (search date 1999, 3 RCTs) found that olanzapine improved mean PANSS scores at 28–30 weeks compared with risperidone (2 RCTs, 392 people; WMD 7.5 points, 95% CI 2.9 to 12.0 on a scale of 210 points), although it found no significant difference at 54 weeks (1 RCT, 435 people; WMD 6.1, 95% CI 1.9 to 10.3).[25] Olanzapine was also associated with significantly fewer withdrawals for any cause at 28–30 weeks than risperidone (2 RCTs; 85/204 [42%] with olanzapine *v* 109/200 [54%]

with risperidone; RR 0.76, 95% CI 0.62 to 0.94).[25] The second review (search review 2000, 2 RCTs, including 1 RCT identified by the first review) found similar results but did not quantify its conclusions.[26] The subsequent RCT (377 people) found no significant difference between olanzapine and risperidone in the proportion of people who responded at 8 weeks (response defined as a < 20% reduction in PANSS score: 48% with olanzapine *v* 51% with risperidone; reported as non-significant; no further data provided).[27]

Harms:

Versus standard antipsychotic drugs: The first review found no significant difference between olanzapine and standard antipsychotic drugs in the proportion of people who withdrew from the trial for any cause at 4–8 weeks (9 RCTs; 744/2068 [36%] with olanzapine *v* 464/952 [49%] with standard antipsychotics; RR 0.85, 95% CI 0.65 to 1.10) or at 1 year (4 RCTs; 1577/1905 [83%] *v* 748/833 [90%]; RR 0.90, 95% CI 0.75 to 1.08).[23] It found that, compared with standard antipsychotic drugs, olanzapine significantly reduced the proportion of people who required anticholinergic drugs for extrapyramidal adverse effects (293/1884 [15%] with olanzapine *v* 401/810 [49%] with standard antipsychotics; RR 0.26, 95% CI 0.17 to 0.40) and caused significantly less nausea (174/1576 [11%] with olanzapine *v* 117/771 [15%] with standard antipsychotics; RR 0.74, 95% CI 0.59 to 0.92; NNT 25, 95% CI 14 to 85), vomiting (97/1336 [7%] with olanzapine *v* 81/660 [12%] with standard antipsychotics; RR 0.59, 95% CI 0.45 to 0.78; NNT 20, 95% CI 12 to 46), or drowsiness (443/1576 [28%] with olanzapine *v* 268/771 [34%] with standard antipsychotics; RR 0.82, 95% CI 0.72 to 0.92; NNT 15, 95% CI 9 to 38). Olanzapine was associated with a significantly greater increase in appetite (1 RCT; 343/1336 [26%] with olanzapine *v* 103/660 [16%] with standard antipsychotics; RR 1.65, 95% CI 1.35 to 2.01; NNH 10, 95% CI 7 to 15) and weight gain than standard antipsychotic drugs.[23] The second review found that fewer people withdrew from the trial with olanzapine than with haloperidol, but the difference did not persist after adjustment for dose.[17] It found that dystonia and akathisia were significantly less frequent with olanzapine than with haloperidol, even after adjustment for dose (ARR for dystonia with olanzapine *v* haloperidol 14%, 95% CI 11% to 17%; ARR for akathisia with olanzapine *v* haloperidol 4.8%, 95% CI 3.1% to 6.5%). Olanzapine was associated with a 12% (95% CI 8% to 15%) increase in excessive appetite compared with haloperidol.[17] **Versus clozapine:** See harms of clozapine, p 1368. **Versus amisulpride:** See harms of amisulpride, p 1370. **Versus risperidone:** The first review found that olanzapine was associated with significantly fewer extrapyramidal adverse effects compared with risperidone (1 RCT; 32/172 [19%] with olanzapine *v* 52/167 [31%] with risperidone; RR 0.60, 95% CI 0.41 to 0.88; NNT 8, 95% CI 5 to 28), less parkinsonism (1 RCT; 22/172 [13%] with olanzapine *v* 37/167 [22%] with risperidone; RR 0.58, 95% CI 0.37 to 0.94; NNT 11, 95% CI 6 to 77), and less need for antiparkinsonian medication (1 RCT; 34/172 [20%] with olanzapine *v* 55/167 [33%] with risperidone; RR 0.60, 95% CI 0.41 to 0.87; NNT 8, 95% CI 4 to 25).[25] People taking olanzapine had greater weight gain, but the difference was not significant either at 28–30 weeks (2 RCTs: WMD

+2.86, 95% CI −0.68 to +6.34) or at 54 weeks (WMD +3.56, 95% CI −0.20 to +6.90). The second review found similar results but did not perform a meta-analysis.[26] The subsequent RCT found no significant difference between olanzapine and risperidone in severity of extrapyramidal adverse effects, need for anticholinergics, or withdrawals from the trial.[27] Fewer people on risperidone experienced clinically important weight gain (AR for ≥ 7% weight gain 27.3% with olanzapine *v* 11.6% with risperidone).

Comment: **Versus standard antipsychotic drugs:** The results of the reviews are dominated by one large multicentre RCT reported by drug company employees. [17,23,24] Benefits seem to be highest at a dose of 15 mg daily, and higher doses may be associated with more harms. Results depended on the statistical test used, and their reliability may be compromised by heterogeneity.

OPTION PERAZINE

Two weak RCTs found no significant difference in global clinical impression over 28 days between perazine and haloperidol. Two RCTs provided insufficient evidence to assess perazine compared with zotepine, and one RCT found no significant difference in mental state at 28 days between perazine and amisulpride. Three RCTs found no significant difference in extrapyramidal effects over 28 days between perazine and zotepine or amisulpride.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 2001), which identified two RCTs (71 people) comparing perazine versus haloperidol.[28] It could not perform a meta-analysis because of poor reporting in one of the RCTs. One of the RCTs (32 people) found no significant difference between perazine and haloperidol in the proportion of people who were "no better or worse" in global clinical impression at 28 days (8/17 [47%] with perazine *v* 6/15 [60%] with haloperidol; RR 1.18, 95% CI 0.53 to 2.62). **Versus other new antipsychotic drugs:** The review identified two RCTs comparing perazine versus zotepine.[28] It could not perform a meta-analysis because of methodological differences between the RCTs. The first RCT (34 people) found that perazine was significantly less effective than zotepine in improving symptoms as assessed by mean Brief Psychiatric Rating Scale score at 28 days (WMD 7.9, 95% CI 1.1 to 14.7). The second RCT (40 people), which used a different method to calculate mean Brief Psychiatric Rating Scale score, found that perazine was significantly more effective than zotepine in improving symptoms at the end of the trial (trial duration not specified: WMD −0.4, 95% −0.7 to −0.1). One RCT identified by the review found no significant difference between perazine and amisulpride in the proportion of people whose mental state was "no better or worse" at 28 days (4/15 [27%] with perazine *v* 3/15 [20%] with amisulpride; RR 1.33, 95% CI 0.36 to 4.97).[28]

Harms: **Versus standard antipsychotic drugs:** The review gave no information about the adverse effects of perazine compared with haloperidol.[28] **Versus other new antipsychotic drugs:** The review (3 RCTs) found no significant difference between perazine and

zotepine or amisulpride in the risk of akathesia (3/56 [5%] with perazine *v* 10/55 [18%] with zotepine or amisulpride; RR 0.30, 95% CI 0.09 to 1.00), dyskinesia (1/56 [2%] *v* 3/55 [5%]; RR 0.42, 95% CI 0.06 to 2.74), or parkinsonism over 28 days (10/41 [24%] with perazine *v* 8/40 [20%] with zotepine or amisulpride; RR 1.22, 95% CI 0.54 to 2.78).[28]

Comment: None.

OPTION PIMOZIDE

One systematic review comparing pimozide versus standard antipsychotic drugs found no significant difference in global clinical impression, and found that pimozide decreased sedation but increased tremor. It found no overall difference in cardiovascular adverse effects such as rise or fall in blood pressure or dizziness between pimozide and standard antipsychotic drugs.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1999) comparing pimozide (mean dose 7.5 mg/day, range 1–75 mg/day) versus standard antipsychotic drugs, including chlorpromazine, haloperidol, fluphenazine, and carpipramine.[29] It found no significant difference in global clinical impression between pimozide and standard antipsychotics at 1–3 months (3 RCTs; 18/50 [36%] with pimozide *v* 22/50 [44%] with standard antipsychotics; RR 0.82, 95% CI 0.52 to 1.29) or at 4–6 months (6 RCTs; 57/104 [55%] with pimozide *v* 55/102 [54%] with standard antipsychotics; RR 1.01, 95% CI 0.80 to 1.28).

Harms: **Versus standard antipsychotic drugs:** The review found that, over 1–3 months, pimozide caused significantly less sedation than standard antipsychotic drugs (53/117 [45%] with pimozide *v* 68/115 [59%] with standard antipsychotics; RR 0.77, 95% CI 0.61 to 0.98; NNT 7, 95% CI 4 to 61), but that it was more likely to cause tremor (43/97 [44%] with pimozide *v* 27/95 [28%] with standard antipsychotics; RR 1.57, 95 CI 1.07 to 2.29; NNH 6, 95% CI 3 to 44).[29] It found similar cardiovascular symptoms such as rise or fall in blood pressure and dizziness between pimozide and standard antipsychotic drugs. There was little usable ECG data. One RCT in the review found no significant difference in ECG changes between pimozide and standard antipsychotic drugs, but it may have been too small to detect a clinically important difference (2/28 [7%] with pimozide *v* 3/28 [11%] with standard antipsychotics; RR 0.67, 95% CI 0.1 to 3.7).

Comment: Sudden death has been reported in a number of people taking pimozide at doses over 20 mg daily, but we found no evidence from RCTs that pimozide is more likely to cause sudden death than other antipsychotic drugs.[29] The manufacturer recommends periodic ECG monitoring in all people taking more than 16 mg daily pimozide and avoidance of other drugs known to prolong the QT interval on an ECG or cause electrolyte disturbances (other antipsychotic drugs, antihistamines, antidepressants, and diuretics).

OPTION QUETIAPINE

Three systematic reviews comparing quetiapine versus standard antipsychotic drugs found no significant difference in symptoms, but two of the reviews found that quetiapine reduced akathisia, parkinsonism, and the proportion of people who left the trial early.

Benefits: **Versus standard antipsychotic drugs:** We found two systematic reviews.[17,30] The first review (search date 2000, 7 RCTs) compared quetiapine (50–800 mg/day) versus standard antipsychotic drugs (usually haloperidol).[30] It found no significant difference in mental state over 6 weeks between quetiapine and standard antipsychotic drugs (Brief Psychiatric Rating Scale or Positive and Negative Syndrome Scale score not improved, 4 RCTs; 367/723 [51%] with quetiapine *v* 283/524 [54%] with standard antipsychotics; RR 0.91, 95% CI 0.73 to 1.13). The second review (search date 1998, 2 RCTs, both included in the first review, 511 people) performed a meta-regression analysis comparing newer versus standard antipsychotics, which adjusted for dose of standard antipsychotic (see benefits of amisulpride, p 1369).[17] Meta-regression was not available for quetiapine alone.

Harms: **Versus standard antipsychotic drugs:** The first review found that, compared with standard antipsychotic drugs, quetiapine was associated with significantly fewer people leaving trials early for any cause over 6 weeks (6 RCTs; 334/913 [36.5%] with quetiapine *v* 254/711 [35.7%] with standard antipsychotics; RR 0.86, 95% CI 0.75 to 0.98), less dystonia (3 RCTs; 4/580 [0.69%] with quetiapine *v* 19/379 [5%] with standard antipsychotics; RR 0.24, 95% CI 0.04 to 0.49), less akathisia (3 RCTs; 19/580 [3%] with quetiapine *v* 68/379 [18%] with standard antipsychotics; RR 0.24, 95% CI 0.15 to 0.38), and less parkinsonism (2 RCTs; 31/479 [6%] with quetiapine *v* 92/279 [33%] with standard antipsychotics; RR 0.22, 95% CI 0.15 to 0.33), but more dry mouth (2 RCTs: 31/322 [10%] with quetiapine *v* 11/327 [3%] with standard antipsychotics; RR 2.85, 95% CI 1.46 to 5.57).[30]

Comment: The RCTs in the review had substantial withdrawal rates and did not conduct intention to treat analyses.[30]

OPTION RISPERIDONE

Systematic reviews found limited evidence that risperidone may improve symptoms more than standard antipsychotic drugs (mainly haloperidol) and found good evidence that, at lower doses, risperidone has fewer adverse effects, although one of the reviews suggested that effects may be attributable to differences in dose. Systematic reviews found no significant difference in symptoms between risperidone and other new antipsychotic drugs.

Benefits: **Versus standard antipsychotic drugs:** We found three systematic reviews[17,24,31] and one additional RCT.[32] The first review (search date 1997, 14 RCTs, 3401 people) found that, at 12 weeks, risperidone (mean dose range 6.1–12 mg/day) significantly increased the proportion of people who had "clinical improvement" compared with standard antipsychotic drugs, usually haloperidol.[31]

"Clinical improvement" was variably defined but usually as a 20% reduction in symptoms (11 RCTs; 894/2088 [43%] with risperidone *v* 482/893 [54%] with standard antipsychotics; RR of no clinical improvement 0.81, 95% CI 0.75 to 0.88; NNT 10, 95% CI 7 to 16). The review did not find significant heterogeneity among RCTs. The second review (search date 1998, 8 RCTs, all included in the first review) found "substantial heterogeneity" among six RCTs of 4–12 weeks' treatment.[17] It found that risperidone improved symptom scores over 12 months compared with standard antipsychotic drugs (2 RCTs; WMD –0.40, 95% CI –0.27 to –0.54, indicating that about 66% of people taking standard antipsychotics had worse composite symptom scores than with risperidone). Meta-regression analysis suggested that this difference did not persist after controlling for dose of standard antipsychotic (see benefits of amisulpride, p 1369). The third review (search date 1998, 11 RCTs, including 8 identified by the first review, 1208 people) found that risperidone significantly improved negative and positive symptoms, as measured using the Positive and Negative Syndrome Scale, compared with haloperidol (WMD –8.3, 95% CI –13.8 to –2.7).[24] The additional RCT (99 people) comparing a range of doses of risperidone versus haloperidol found no significant difference in the proportion of people who responded over 8 weeks (response defined as ≥ 20% reduction in Positive and Negative Syndrome Scale; reported as non-significant; results presented graphically).[32] **Versus olanzapine:** See benefits of olanzapine, p 1372. **Versus amisulpride:** see benefits of amisulpride, p 1369. **Versus clozapine:** see benefits of clozapine, p 1368.

Harms:

Versus standard antipsychotic drugs: The first review found no significant difference between risperidone and standard antipsychotic drugs in the proportion of people who withdrew from treatment because of adverse effects (139/1585 [9%] with risperidone *v* 70/591 [12%] with standard antipsychotics; RR 0.78, 95% CI 0.58 to 1.05).[31] It found that, compared with people taking standard antipsyschotic drugs, people taking risperidone developed significantly fewer extrapyramidal effects (347/1728 [20%] with risperidone *v* 234/551 [42%] with standard antipsychotics; RR 0.63, 95% CI 0.55 to 0.72; NNT 5, 95% CI 5 to 10), required less antiparkinsonian medication (444/1810 [24%] with risperidone *v* 274/626 [44%] with standard antipsychotics; RR 0.64, 95% CI 0.57 to 0.73; NNT 7, 95% CI 5 to 10), and were less likely to develop daytime somnolence (481/1509 [32%] with risperidone *v* 197/589 [33%] with standard antipsychotics; RR 0.87, 95% CI 0.76 to 0.99; NNT 22, 95% CI 11 to 500). However, it found that risperidone was associated with significantly more weight gain than standard antipsychotics (398/1290 [31%] with risperidone *v* 71/362 [20%] with standard antipsychotics; RR 1.37, 95% CI 1.10 to 1.71; NNH 13, 95% CI 8 to 36). The second review found no significant difference between risperidone and haloperidol in the proportion of people who withdrew from treatment, but found that risperidone reduced symptoms of dystonia (WMD –0.26, 95% CI –0.39 to –0.12), parkinsonism (WMD –0.39, 95% CI –0.51 to –0.27), and dyskinesia (WMD –0.16, 95% CI –0.28 to –0.04).[17] Differences persisted after controlling for dose. The third review found that, compared with haloperidol, risperidone significantly

reduced the proportion of people who required medication for extrapyramidal side effects (OR 0.42, 95% CI 0.19 to 0.96; absolute numbers presented graphically).[24] The additional RCT found no significant difference in the rate of overall adverse effects between risperidone and haloperidol.[32] **Versus olanzapine:** See harms of olanzapine, p 1373 **Versus amisulpride:** See harms of amisulpride, p 1370. **Versus clozapine:** See harms of clozapine, p 1368.

Comment: The first review found evidence of publication bias.[31] Sensitivity analyses found that benefits in clinical improvement and continuing treatment of risperidone compared with standard antipsychotic drugs were no longer significant if RCTs using more than 10 mg haloperidol daily were excluded. This could be because of loss of power. Exclusion of the higher dosage RCTs did not remove the difference in rate of extrapyramidal adverse effects.[31]

OPTION SULPIRIDE

One systematic review found no significant difference in global clinical impression over 4–10 weeks between sulpiride and standard antipsychotic drugs. The review found that the use of antiparkinson drugs over 4–10 weeks was less frequent with sulpiride compared with standard antipsychotic drugs.

Benefits: **Versus standard antipsychotic drugs:** One systematic review (search date 1998, 7 RCTs, 366 people) found no significant difference in the proportion of people who had no improvement in global clinical impression over 4–10 weeks between sulpiride and standard antipsychotic drugs, usually haloperidol chlorpromazine, or perphenazine (74/248 [30%] with sulpiride *v* 96/266 [36%] with standard antipsychotics; RR of no important improvement 0.82, 95% CI 0.64 to 1.05).[33]

Harms: **Versus standard antipsychotic drugs:** The review found that the use of antiparkinson drugs over 4–10 weeks was significantly less frequent with sulpiride compared with standard antipsychotic drugs (84/253 [33%] *v* 115/258 [44%]; RR 0.73, 95% CI 0.59 to 0.90).[33]

Comment: The review stated that the other two RCTs it identified reported improvement in mental state with sulpiride compared with placebo, but that no raw data could be obtained because of poor reporting in the RCTs.[33] Observational evidence and clinical experience suggest that sulpiride may be associated with galactorrhoea, but RCT data did not quantify the risk.[34]

OPTION ZIPRASIDONE

One systematic review found no significant difference in mental state improvement between ziprasidone and haloperidol, and found that ziprasidone reduced akathisia and acute dystonia but increased nausea and vomiting.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review comparing ziprasidone versus standard antipsychotic drugs.[35] The review (search date 1999, 4 RCTs, 690 people)

identified one RCT (301 people) that provided sufficient data to assess clinically important improvement in mental state (≥20% reduction in Positive and Negative Syndrome Scale score). It found no significant difference in mental state between ziprasidone and haloperidol (95/148 [64%] with ziprasidone *v* 114/153 [74%] with haloperidol; RR of no important improvement in mental state 0.86, 95% CI 0.74 to 1.00).

Harms: **Versus standard antipsychotic drugs:** The review found no clear difference in overall adverse effects between ziprasidone and haloperidol.[35] It found that, compared with haloperidol, ziprasidone was significantly less likely to cause akathisia over 1 week (2 RCTs; 19/296 [6%] with ziprasidone *v* 27/142 [19%] with haloperidol; RR 0.34, 95% CI 0.20 to 0.59; NNH 8, 95% CI 5 to 18) and over 28 weeks (1 RCT; 7/148 [5%] with ziprasidone *v* 25/153 [16%] with haloperidol; RR 0.3, 95% CI 0.1 to 0.7; NNH 9, 95% CI 5 to 21), and that it was less likely to cause acute dystonia over 1 week (2 RCTs; 13/296 [4%] with ziprasidone *v* 15/142 [10%] with haloperidol; RR 0.42, 95% CI 0.20 to 0.85; NNH 16, 95% CI 9 to 166). Ziprasidone was associated with significantly more nausea and vomiting both over 1 week (59/206 [29%] with ziprasidone *v* 8/100 [8%] with haloperidol; RR 3.58, 95% CI 1.78 to 7.20; NNH 5, 95% CI 4 to 8) and over 28 weeks (1 RCT; 31/148 [21%] with ziprasidone *v* 15/153 [10%] with haloperidol; RR 2.14, 95% CI 1.20 to 3.79; NNH 9, 95% CI 5 to 33) compared with haloperidol.

Comment: The duration of RCTs in the review was less than 6 weeks.[35] Most RCTs reported a withdrawal rate of over 20% and no RCT clearly described adequate precautions for the blinding of treatment allocation.

OPTION ZOTEPINE

One systematic review found weak evidence that zotepine increased the proportion of people with a clinically important improvement in symptoms compared with standard antipsychotic drugs, and reduced akasthesia, dystonia, and rigidity. This finding was not robust because removal of a single RCT from the analysis meant that the difference between zotepine and standard antipsychotics was no longer significant.

Benefits: **Versus standard antipsychotic drugs:** We found one systematic review (search date 1999, 8 RCTs, 356 people) comparing zotepine (75–450 mg/day) versus standard antipsychotic drugs, usually haloperidol.[36] It found that zotepine was significantly more likely than standard antipsychotic drugs to bring about "clinically important improvement" at 4–12 weeks, as defined by a pre-stated cut off point on the Brief Psychiatric Rating Scale (4 RCTs; 89/179 [50%] with zotepine *v* 62/177 [35%] with standard antipsychotics; RR 1.25, 95% CI 1.1 to 1.4; NNT 7, 95% CI 4 to 22; see comment below).

Harms: The review found that, compared with standard antipsychotic drugs, zotepine caused significantly less akathisia (67/199 [34%] with zotepine *v* 91/197 [46%] with standard antipsychotics; RR 0.73, 95% CI 0.58 to 0.93; NNT 8, 95% CI 5 to 34), dystonia (7/35 [20%] with zotepine *v* 15/35 [43%] with standard antipsychotics;

RR 0.47, 95% CI 0.24 to 0.93; NNT 4, 95% CI 2 to 56), and rigidity (19/83 [23%] with zotepine *v* 30/81 [37%] with standard antipsychotics; RR 0.63, 95% CI 0.40 to 0.98; NNT 7, 95% CI 4 to 360).[36] Two RCTs found abnormal ECG results in people taking zotepine, but few additional details were given.

Comment: All but one RCT identified by the review were of 12 weeks' or less duration and all were conducted in Europe.[36] Only one RCT favoured zotepine over standard antipsychotic drugs, and removal of this RCT from the analysis renders the results non-significant.

QUESTION Which interventions reduce relapse rates?

OPTION CONTINUED TREATMENT WITH ANTIPSYCHOTIC DRUGS

Systematic reviews have found that continuing antipsychotic drugs for at least 6 months after an acute episode reduces relapse rates compared with no treatment or placebo, and that some benefit of continuing antipsychotics is apparent for up to 2 years. Eight systematic reviews found no significant difference in relapse rates among antipsychotic drugs. One systematic review found that clozapine reduces relapse rates over 12 weeks compared with standard antipsychotic drugs. Another review found that fewer people taking depot zuclopenthixol decanoate relapsed over 12 weeks to 1 year compared with people taking other depot preparations. A third review found that bromperidol increased the proportion of people who relapsed compared with haloperidol or fluphenazine. One additional RCT found that risperidone reduced relapse over 2.2 years compared with haloperidol.

Benefits: **Versus no treatment or placebo:** We found three systematic reviews.[9,10,37] The first review (search date not stated, 66 studies, 4365 people taking antipsychotic drugs, mean dose 630 mg chlorpromazine equivalents daily, mean follow up of 6.3 months) included 29 controlled trials with a mean follow up of 9.7 months (see comment below).[37] It found that continuing compared with withdrawing antipsychotic drugs significantly reduced the proportion of people who relapsed (28 controlled studies, 2448 people; 16% with continued treatment *v* 51% with withdrawing treatment; ARR 35%, 95% CI 33% to 38%; NNT 3, 95% CI 3 to 4). Over time, the relapse rate in people maintained on antipsychotic treatment approached that in those withdrawn from treatment, but was still lower in those on treatment at 2 years. The second review (search date 1997, 5 RCTs, 2 included in the first review) found that continuing chlorpromazine significantly reduced relapse rates over 6–24 months compared with placebo (3 RCTs; 106/264 [40%] with chlorpromazine *v* 176/248 [71%] with placebo; RR 0.57, 95% CI 0.48 to 0.67; NNT 3, 95% CI 3 to 4).[9] The third review (search date 1998, 2 RCTs, neither included in the previous reviews, 70 people currently in remission) compared haloperidol versus placebo over 1 year.[10] It found that haloperidol significantly reduced relapse over 1 year compared with placebo (32/47 [68%] with haloperidol *v* 23/23 [100%] with placebo; RR 0.67, 95% CI 0.54 to 0.83, NNT 4, 95% CI 2 to 7). **Choice of drug:** We found 11 systematic reviews[12–14,23,29,38-43] and one additional RCT[44] evaluating the

effects of newer versus older antipsychotics, newer antipsychotics versus each other, and oral versus intramuscular administration of antibiotics on relapse rates (see table 1, p 1391). Eight reviews found no significant difference between antipsychotics in relapse rates,[13,23,29,38–42] but in two of the reviews[23,29] the number of people studied was too small to rule out a clinically important difference. A ninth review (search date 1998) found that clozapine significantly reduced relapse rates over 12 weeks compared with standard antipsychotics (19 RCTs; RR 0.6, 95% CI 0.5 to 0.8).[14] A tenth review (search date 1998) found that significantly fewer people taking depot zuclopenthixol decanoate relapsed over 12 weeks to 1 year compared with people taking other depot preparations (3 RCTs; 296 people: RR 0.7, 95% CI 0.6 to 1.0; NNT 9, 95% CI 5 to 53).[43] An eleventh review (search date 1999) found that bromperidol significantly increased the proportion of people who relapsed compared with haloperidol or fluphenazine (2 RCTs; RR 3.92, 95% CI 1.05 to 14.6; NNH 5, 95% CI 3 to 28).[12] The additional RCT (365 people) found that risperidone versus haloperidol significantly reduced relapse over 2.2 years (NNT 5, 95% CI 4 to 10).[44]

Harms: **Versus no treatment or placebo:** The first review found that mild transient nausea, malaise, sweating, vomiting, insomnia, and dyskinesia were reported in an unspecified number of people after sudden drug cessation, but were usually acceptable with gradual dose reduction.[37] The other reviews gave no information on adverse effects of continuing treatment with antipsychotic drugs.[9,10] **Choice of drug:** The review comparing different depot antipsychotic drugs found that the annual incidence of tardive dyskinesia was 5%.[43]

Comment: In the systematic review of continued treatment versus withdrawal of treatment, meta-analysis of the 29 controlled trials gave similar results to those obtained when all 66 studies were included.[37] A commentary of the review suggested that it was weakened because all RCT results were used rather than weighted comparisons, no length of time was given since the last acute episode, and no distinction was made between people experiencing a first episode and those with chronic illness.[45] Some clinicians use depot antipsychotic drugs in selected people to ensure adherence to medication. We found no evidence from RCTs to support this practice.

OPTION COGNITIVE BEHAVIOURAL THERAPY

Limited evidence from a systematic review of two RCTs found no significant difference in relapse rates between cognitive behavioural therapy plus standard care and standard care alone.

Benefits: We found one systematic review (search date 2001), which identified two RCTs (123 people) comparing the effects of cognitive behavioural therapy plus standard care versus standard care alone on relapse rates.[46] Both RCTs identified by the review incorporated challenging key beliefs, problem solving, and enhancement of coping. The review found no significant difference between cognitive behavioural therapy plus standard care and standard care alone

in relapse or readmission to hospital over 10 weeks (1 RCT; 0/33 [0%] with cognitive behavioural therapy plus standard care *v* 4/28 [14%] with standard care alone; RR 0.09, 95% CI 0.01 to 1.69) or over 9–24 months (2 RCTs; 36/63 [57%] with cognitive behavioural therapy plus standard care *v* 31/60 [52%] with standard care alone; RR 1.13, 95% CI 0.82 to 1.56).[46]

Harms: The systematic review gave no information on harms.[46]

Comment: None.

OPTION FAMILY INTERVENTIONS

One systematic review found that multiple session family interventions reduced relapse rates at 12 months compared with usual care, single session family interventions, or psychoeducational interventions.

Benefits: We found one systematic review (search date 1999) that compared multiple family interventions versus usual care, single family interventions, or psychoeducational interventions.[47] Family interventions consisted mainly of education about the illness and training in problem solving over at least six weekly sessions. The review found that multiple family interventions significantly reduced relapse rates at 12 months compared with other interventions (11 RCTs, 729 people; OR 0.52, 95% CI 0.31 to 0.89; absolute numbers not provided). On average, eight families would have to be treated to avoid one additional relapse (and likely hospitalisation) at 12 months in the family member with schizophrenia (NNT 8, 95% CI 6 to 18).[47]

Harms: The review gave no information on harms.[47]

Comment: These results may overestimate the effect of family interventions because of the difficulty of blinding people and investigators.[47] Although no harms were reported, illness education could possibly have adverse consequences on morale and outlook. The mechanism for the effects of family intervention remains unclear. It is thought to work by reducing "expressed emotion" (hostility and criticism) in relatives of people with schizophrenia. The time consuming nature of this intervention, which must normally take place at evenings or weekends, can limit its availability. It cannot be applied to people who have little contact with home based carers.

OPTION PSYCHOEDUCATIONAL INTERVENTIONS

One systematic review has found that psychoeducation reduces relapse rates at 9–18 months compared with usual care.

Benefits: **Versus usual treatment:** We found one systematic review (search date 2002), which identified one RCT of a brief individual intervention (10 sessions or less), six RCTs of brief group psychoeducational interventions, and four RCTs of standard length group psychoeducational interventions (11 sessions or more).[48] It found that standard length group psychoeducational interventions were significantly more effective than usual care in preventing relapse without readmission over 9–18 months (2 RCTs; 14/57 [24%] with psychoeducation *v* 24/57 [42%] with usual care; RR 0.58, 95% CI 0.34 to

0.99). It also found that brief group psychoeducational interventions were significantly more effective than usual care in preventing relapse or readmission over 1 year (5 RCTs; 153/326 [47%] with psychoeducation *v* 162/296 [55%] with usual care; RR 0.85, 95% CI 0.74 to 0.98; NNT 12, CI 6 to 83). The review found that any form of psychoeducation significantly reduced relapse with or without readmission to hospital over 9–18 months compared with usual care (6 RCTs; 176/383[46%] with psychoeducation *v* 192/337 [57%] with usual care; RR 0.78, 95% CI 0.62 to 0.98; NNT 9, 95% CI 6 to 22; see comment below).

Harms: The systematic review gave no information on harms.[48]

Comment: The systematic review found few good RCTs.[48] There was significant heterogeneity of both interventions and outcomes.

OPTION SOCIAL SKILLS TRAINING

One systematic review of small RCTs provided insufficient evidence to assess social skills training.

Benefits: We found one systematic review (search date not stated 1999), which identified nine RCTs (471 people) comparing the effect of social skills training versus standard care or psychoeducational interventions on relapse rates.[49] It found no significant difference in relapse rates over 1 year of treatment between social skills training and other interventions (4 RCTs, 125 people; OR 0.74, 95% CI 0.43 to 1.29; absolute numbers not provided), but found that social skills training reduced relapse over 2 years of treatment (2 RCTs, 264 people; OR 3.03, 95% CI 1.11 to 8.33; absolute numbers not provided).

Harms: The review gave no information on harms.[49]

Comment: None.

QUESTION Which interventions are effective in people who are resistant to standard antipsychotic drugs?

OPTION INTERVENTIONS IN PEOPLE WHO ARE RESISTANT TO STANDARD ANTIPSYCHOTIC DRUGS

Systematic reviews in people resistant to standard antipsychotic drugs found that clozapine or olanzapine improved symptoms after 12 weeks and after 2 years compared with standard antipsychotic drugs. RCTs provided insufficient evidence to compare newer antipsychotics in people resistant to standard antipsychotic drugs.

Benefits: **Clozapine versus standard antipsychotic drugs:** We found one systematic review (search date 1999, 6 RCTs) comparing clozapine versus standard antipsychotic drugs in people who were resistant to standard treatment.[14] It found that, compared with standard antipsychotic drugs, clozapine significantly increased the proportion of people who improved at 6–12 weeks (4 RCTs, 370 people; RR for no improvement compared with standard antipsychotic drugs 0.7, 95% CI 0.6 to 0.8) and at 12–24 months (2 RCTs, 648 people;

RR 0.8, 95% CI 0.6 to 1.0). It found no difference in relapse rates at 12 weeks. **Clozapine versus other new antipsychotic drugs:** We found one systematic review (search date 1988, 8 RCTs, 5 in people with treatment resistant schizophrenia, 595 people), which compared clozapine versus olanzapine, risperidone, and zotepine.[15] It found no significant difference between clozapine and other new antipsychotics in global clinical impression (Clinical Global Impression [CGI] score: WMD −0.09, 95% CI −0.34 to +0.15) or mental state (Brief Psychiatric Rating Scale or Positive and Negative Syndrome Scale < 20% improved: 83/173 [48%] with clozapine *v* 81/178 [45%] with olanzapine or risperidone; RR 1.05, 95% CI 0.84 to 1.32). However, the number of people studied was too small to rule out a clinically important difference. **Olanzapine versus standard antipsychotic drugs:** One systematic review (search date 1999, 1 RCT, 84 people) found no significant difference in psychotic symptoms over 8 weeks between olanzapine (25 mg/day) and chlorpromazine (39/42 [93%] with olanzapine *v* 42/42 [0%]; RR for no important response defined as a 40% reduction on the CGI scale 0.93, 95% CI 0.85 to 1.01).[23] The RCT is likely to have been too small to exclude a clinically important difference. **Olanzapine versus other new antipsychotic drugs:** We found one systematic review (search date 1999, 1 RCT, 180 people) comparing olanzapine versus clozapine, which found no significant difference in psychotic symptoms over 8 weeks (45/90 [50%] with olanzapine *v* 55/90 [0%] with clozapine; RR for no important response [defined as a 40% reduction on the CGI scale] 0.82, 95% CI 0.63 to 1.07).[23] The RCT is likely to have been too small to exclude a clinically important difference. **Other interventions:** We found no RCTs examining the effects of other interventions in people resistant to standard treatment.

Harms: **Clozapine versus standard antipsychotic drugs:** See harms of clozapine, p 1368. **Clozapine versus other new antipsychotic drugs:** The review found that, compared with other new antipsychotic drugs (mainly olanzapine and risperidone), clozapine was significantly less likely to cause extrapyramidal adverse effects (305 people; RR 0.3, 95% CI 0.1 to 0.6; NNT 6, 95% CI 4 to 9).[15] It also found that clozapine may be less likely to cause dry mouth and more likely to cause fatigue, nausea, dizziness, hypersalivation, and hypersomnia than other new antipsychotic drugs, but these findings were from one or at most two RCTs. It found that people taking clozapine tended to be more satisfied with their treatment than those taking other new antipsychotic drugs, but also tended to withdraw from RCTs more often. It found no significant difference in rates of blood dyscrasias between clozapine and other new antipsychotic drugs, but the number of people studied was too small (558) to rule out a clinically important difference.[15]

Comment: Some RCTs in the reviews included people who were partial responders to neuroleptic drugs and people unable to take some neuroleptic medication because of adverse effects.[14,15,23] The reviews did not specify the duration of treatment resistant illness of the participants in the RCTs. RCTs are underway to clarify the mode of action of cognitive behavioural therapy and establish its effects in people who are resistant to standard treatments.

QUESTION **Which interventions improve adherence to antipsychotic medication?**

OPTION BEHAVIOURAL THERAPY

One RCT found that behavioural interventions improved adherence to antipsychotic medication compared with usual treatment. Two RCTs found limited evidence that behavioural interventions may improve adherence more than psychoeducational therapy.

Benefits: We found no systematic review. **Versus usual treatment:** We found one RCT (36 men).[50] The behavioural training method comprised being told the importance of adhering to antipsychotic medication and instructions on how to take medication. Each participant was given a self monitoring spiral calendar, which featured a dated slip of paper for each dose of antipsychotic. Adherence was estimated by pill counts (see comment below). After 3 months fewer people had high pill adherence after usual treatment compared with behaviour therapy (figures not provided). **Versus psychoeducational therapy:** See benefits of psychoeducational interventions, p 1386.

Harms: None reported.

Comment: Assessing adherence by pill count has potential confounders in that people may throw pills away.[50]

OPTION COMPLIANCE THERAPY

Two RCTs found limited evidence that compliance therapy may increase adherence to antipsychotic drugs at 6 and 18 months compared with non-specific counselling.

Benefits: We found no systematic review, but found two RCTs.[51,52] The first RCT (47 people with acute psychoses, most of whom fulfilled criteria for schizophrenia or had been admitted with the first episode of a psychotic illness) compared compliance therapy (see glossary, p 1387) versus supportive counselling.[51] It found that, compared with non-specific counselling, compliance therapy significantly increased the proportion of people with improved adherence at 4–6 weeks (improved adherence defined as a score ≥ 5 on a scale from 1–7, where 1 is complete refusal and 7 active participation, ready acceptance, and taking some responsibility for adhering to antipsychotic medication; OR 6.3, 95% CI 1.6 to 24.6) and at 6 month follow up (OR 5.2, 95% CI 1.5 to 18.3; absolute numbers not provided; see comment below).[51] The second RCT (74 people with acute psychoses, most of whom fulfilled criteria for schizophrenia and had been admitted to hospital with relapse of symptoms) found that compliance therapy significantly improved compliance over 18 months measured on a 7 point scale of medication adherence compared with non-specific counselling (mean difference 1.4, 95% CI 0.9 to 1.6).[52]

Harms: The RCTs gave no information on harms.[51,52]

Comment: Other trials have examined the potential benefits of compliance therapy but either did not employ a standardised measure of adherence or did not assess adherence in a blind fashion. In the first RCT, about a third of each group did not complete the RCT, and missing data are estimated from the mean scores in each group.[51]

OPTION FAMILY INTERVENTIONS

One systematic review found that "compliance with medication" over 9–24 months was higher in people who received multiple family interventions compared with usual care, single family interventions, or psychoeducational interventions, but the difference did not quite reach significance.

Benefits: We found one systematic review (search date 1999) that compared multiple family interventions versus usual care, single family interventions, or psychoeducational interventions.[47] Family interventions consisted mainly of education about the illness and training in problem solving over at least six weekly sessions. The review found that "compliance with medication" over 9–24 months was higher in people who received multiple family interventions compared with other interventions, but the difference did not quite reach significance (5 RCTs, 393 people; OR 0.63, 95% CI 0.40 to 1.01; no further data provided).[47]

Harms: The review gave no information on harms.[47]

Comment: Although no harms were reported, illness education could possibly have adverse consequences on morale and outlook. The mechanism for the effects of family intervention remains unclear. It is thought to work by reducing "expressed emotion" (hostility and criticism) in relatives of people with schizophrenia. The time consuming nature of this intervention, which must normally take place at evenings or weekends, can limit its availability. It cannot be applied to people who have little contact with home based carers.

OPTION PSYCHOEDUCATIONAL INTERVENTIONS

One systematic review found limited evidence that psychoeducation improved adherence to antipsychotic medication compared with usual care. Two RCTs found limited evidence that psychoeducation may improve adherence less than behavioural therapy.

Benefits: **Versus usual treatment:** We found one systematic review (search date 2002), which identified four RCTs that assessed adherence with medication.[48] The RCTs compared individual or group psychoeducation of either standard length (11 sessions or more) or brief length (10 sessions or less) versus usual care. The first RCT (67 people) found no significant difference in adherence between brief individual psychoeducation and usual care measure on a continuous scale of medication compliance. The second RCT (82 people) found no significant difference in adherence over 18 months between standard length group interventions and usual care. However, two further RCTs identified by the review comparing brief group psychoeducational interventions versus control suggested that psychoeducation was more effective in improving adherence. The third

RCT (236 people) found that a brief group psychoeducational intervention significantly improved adherence compared with control (measured on a continuous scale of "medication concordance"; WMD –0.4, 95% CI –0.6 to –0.2). The fourth RCT (46 people) comparing a brief psychoeducational intervention versus usual care found limited evidence that psychoeducational interventions may improve adherence over 1 year (mean number of non-compliant episodes 0.38 with psychoeducation *v* 1.14 with usual care).[48]

Versus behavioural therapy: We found two RCTs.[50,53] The first RCT (36 men) compared three interventions: psychoeducation, behavioural therapy, or usual treatment.[50] The behavioural training method comprised being told the importance of complying with antipsychotic medication and instructions on how to take medication. Each participant was given a self monitoring spiral calendar, which featured a dated slip of paper for each dose of antipsychotic. Adherence was estimated by pill counts (see comment below). The RCT found that, after 3 months, fewer people had high pill adherence after psychoeducation compared with behavioural therapy, but the difference was not significant (3/11 [27%] with psychoeducation *v* 8/11 [72%] with behavioural therapy had pill adherence scores of 80% measured by pill counts; RR of high pill adherence score 0.37, 95% CI 0.13 to 1.05). The RCT is likely to have been too small to detect a clinically important difference.[50] The second RCT (39 people) compared a psychoeducational intervention, a behavioural intervention given individually, and a behavioural intervention involving the person with schizophrenia and their family.[53] The individual behavioural intervention consisted of specific written guidelines, and oral instructions given to people to use a pill box consisting of 28 compartments for every medication occasion during a week. The behavioural intervention, when given to the individual and their family, contained additional instructions for the family members to compliment the person with schizophrenia for taking their prescribed medication. The primary outcome measure was pill count at 2 months (see comment below). The RCT found that medication adherence was significantly more likely with behavioural interventions than with psychoeducation (> 90% adherence at 2 months, 25/26 [96%] with behavioural interventions *v* 6/13 [46%] with psychoeducation; RR 2.08, 95% CI 1.15 to 3.77, NNT 2, 95% CI 2 to 5).

Harms: None reported.

Comment: Assessing adherence by pill count has potential confounders in that people may throw pills away.[50,53] Each psychoeducational intervention varied in the protocol used and few employed the same outcome measurements.

GLOSSARY

Compliance therapy A treatment based on cognitive behavioural therapy and motivational interviewing techniques with a view to improving adherence to medication.

Negative symptoms This generally refers to qualities that are abnormal by their absence (e.g. loss of drive, motivation, and self care).

Positive symptoms This refers to symptoms that characterise the onset or relapse of schizophrenia, usually hallucinations and delusions, but sometimes including thought disorder.

Key Messages

- **Functional treatment** One systematic review and one subsequent RCT found limited evidence that functional treatment reduced the risk of the ankle giving way compared with minimal treatment. One systematic review and one subsequent RCT found that, compared with immobilisation, functional treatment improved symptoms and functional outcomes at short (< 6 weeks), intermediate (6 weeks to 1 year), or long term (> 1 year) follow up. However, effects were to be less marked at long term follow up, or if only results from high quality trials were analysed. One systematic review and one subsequent RCT provided insufficient evidence to compare functional treatment versus surgery. One systematic review and three additional RCTs provided insufficient evidence to compare different functional treatments.
- **Immobilisation** There is consensus that immobilisation is more effective than no treatment, however one systematic review and one subsequent RCT found that, compared with functional treatment, immobilisation was associated with less improvement in symptoms and functional outcomes at either short (< 6 weeks), intermediate (6 weeks to 1 year), or long term (> 1 year) follow up. However, effects were less marked at long term follow up, or if only results from high quality trials were analysed. One systematic review found no significant difference between immobilisation and surgery in pain or subjective instability. One systematic review found insufficient evidence to compare immobilisation versus physiotherapy.
- **Surgery** One systematic review found no significant difference between surgery and immobilisation in pain or subjective instability. Other systematic reviews and one subsequent RCT provided insufficient evidence to compare surgery versus functional treatment or versus conservative treatment (including both immobilisation and functional treatment).
- **Diathermy** One systematic review found insufficient evidence on the effects of diathermy versus placebo on walking ability and reduction in swelling.

- **Homeopathic ointment** One systematic review of one small RCT found limited evidence that homeopathic ointment improved outcome on a "composite criteria of treatment success" compared with placebo.
- **Cold pack compression** Two RCTs found no significant difference in symptoms between cold pack placement and placebo or control. One RCT found less oedema with cold pack placement compared with heat or a contrast bath at 3–5 days after injury.
- **Ultrasound** One systematic review found no significant difference between ultrasound and sham ultrasound in the general improvement of symptoms or the ability to walk or bear weight at 7 days. Three RCTs provided insufficient evidence to compare ultrasound versus other treatments.

DEFINITION Ankle sprain is an injury of the lateral ligament complex of the ankle joint. Such injury can range from mild to severe and is graded on the basis of severity.[1–5] Grade I is a mild stretching of the ligament complex without joint instability; grade II is a partial rupture of the ligament complex with mild instability of the joint (such as isolated rupture of the anterior talofibular ligament); and grade III involves complete rupture of the ligament complex with instability of the joint. Practically, this gradation may be considered as purely theoretical, because it has no therapeutic or prognostic consequences.[9] Unless otherwise stated, studies included in this topic did not specify the grades of injury included, or included a wide range of grades.

INCIDENCE/ PREVALENCE Ankle sprain is a common problem in acute medical care, occurring at a rate of about one injury/10 000 population a day.[6] Injuries of the lateral ligament complex of the ankle form a quarter of all sports injuries.[6]

AETIOLOGY/ RISK FACTORS The usual mechanism of injury is inversion and adduction (usually referred to as supination) of the plantar flexed foot. Predisposing factors are a history of ankle sprains and specific malalignment, like crus varum (see glossary, p 1401) and pes cavo-varus (see glossary, p 1401).

PROGNOSIS Some sports (e.g. basketball, football/soccer, and volleyball) are associated with a particularly high incidence of ankle injuries. Pain is the most frequent residual problem, often localised on the medial side of the ankle.[4] Other residual complaints include mechanical instability, intermittent swelling, and stiffness. People with more extensive cartilage damage have a higher incidence of residual complaints.[4] Long term cartilage damage can lead to degenerative changes, especially if there is persistent or recurrent instability. Every further sprain has the potential to add new damage.

AIMS OF INTERVENTION To reduce swelling and pain; to restore the stability of the ankle joint.

OUTCOMES Return to pre-injury level of sports; return to pre-injury level of work; pain; swelling; subjective instability; objective instability; recurrent injury; ankle mobility; complications; patient satisfaction.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION What are the effects of treatment strategies for acute ankle ligament ruptures?

OPTION IMMOBILISATION

There is consensus that immobilisation is more effective than no treatment, however one systematic review and one subsequent RCT found that, compared with functional treatment, immobilisation was associated with less improvement in symptoms and functional outcomes at either short (< 6 weeks), intermediate (6 weeks to 1 year), or long term (> 1 year) follow up. However, effects were less marked at long term follow up, or if only results from high quality trials were analysed. One systematic review found no significant difference between immobilisation and surgery in pain or subjective instability. One systematic review found insufficient evidence to compare immobilisation versus physiotherapy.

Benefits:

Versus functional treatment: We found one systematic review (search date 2000, 21 RCTs, 2184 people)[7] and one subsequent RCT.[8] The systematic review included any inpatient, outpatient, or home based intervention programme that was composed of immobilisation (see glossary, p 1401) with or without a plaster cast.[7] It included any trials comparing immobilisation versus either another type or duration of immobilisation or a functional treatment (see glossary, p 1401) for injuries to the lateral ligament complex of the ankle and it reported outcomes at short, intermediate, or long term follow up (see comment below). The review analysed a variety of different forms of functional treatment, including strapping, bracing, use of an orthosis, tubigrips, bandages, elastic bandages, and special shoes for at least 5 weeks. It found that functional treatment significantly improved seven outcomes measured at different follow up times compared with immobilisation. At short term follow up, it found that functional treatment significantly reduced the proportion of people with persistent swelling compared with immobilisation (3 RCTs; RR 1.7, 95% CI 1.2 to 2.6) and significantly decreased the proportion of people not returning to work (2 RCTs; RR 5.75, 95% CI 1.01 to 32.71). At intermediate term follow up, it found that immobilisation significantly increased objective instability, as assessed with stress x ray, compared with functional treatment (1 RCT; WMD 2.6°, 95% CI 1.2° to 4.0°) and found that significantly more people were satisfied with functional treatment compared with immobilisation (2 RCTs; RR 4.2, 95% CI 1.1 to 16.1). At long term follow up, it found that compared with immobilisation, functional treatment significantly decreased the proportion of people not returning to sports (5 RCTs; RR 1.9, 95% CI 1.2 to 2.9), the time taken to return to work (6 RCTs; WMD 8.2 days, 95% CI 6.3 days to 10.2 days), and the time taken to return to sports (3 RCTs; WMD 4.9 days, 95% CI 1.5 days to 8.3 days). At longer term follow up, differences in outcomes for persistent swelling, objective instability, proportion of people not returning to work, and patient satisfaction were no longer significant. A subgroup analysis using only 11 "high quality" RCTs (defined as scoring 50% or above on a recognised quality evaluation tool) found only one significant difference between groups: that functional treatment significantly

reduced the time taken to return to work compared with immobilisation (2 RCTs; WMD 12.9 days, 95% CI 7.1 days to 18.7 days). The subsequent RCT (121 semiprofessional sports people with acute grade III lateral ankle ligament) compared 3 weeks of functional treatment versus immobilisation in a plaster cast.[8] Functional treatment was composed of strapping plus early controlled mobilisation. It found that functional treatment significantly reduced time taken to return to normal physical training and reduced pain, swelling, and subjective instability at 3 months compared with immobilisation (mean time to return to normal training: 5.4 weeks with functional treatment *v* 6.3 weeks with immobilisation; $P = 0.02$; pain: 35% with functional treatment *v* 61% with immobilisation, $P = 0.008$); swelling: 16% with functional treatment *v* 49% with immobilisation, $P < 0.01$; subjective instability: 22% with functional treatment *v* 54% with immobilisation, $P = 0.001$; CI for differences in outcomes not reported). However, the RCT found no significant differences between treatments for pain, swelling, or subjective instability at 12 months ($P \geq 0.3$ for all comparisons).[8]
Versus surgery: We found one systematic review (search date 2000, 17 RCTs, 1950 people).[9] The review compared surgery (anatomic reconstruction) versus any conservative treatment (including both immobilisation and functional treatments) for acute injuries to the lateral ligament complex of the ankle. It included 12 RCTs comparing surgery versus immobilisation alone (see comment below). It found that surgery significantly reduced the proportion of people who did not return to sports compared with immobilisation (3 RCTs; RR 0.48, 95% CI 0.31 to 0.76) and who had objective instability (6 RCTs; RR 0.35, 95% CI 0.21 to 0.60). It found no significant difference between surgery and immobilisation in recurrence (8 RCTs; RR 0.86, 95% CI 0.63 to 1.18), pain (8 RCTs; RR 0.64, 95% CI 0.33 to 1.23), subjective instability (8 RCTs; RR 0.77, 95% CI 0.43 to 1.37), or swelling (9 RCTs; RR 0.67, 95% CI 0.38 to 1.18). **Versus physiotherapy:** One systematic review identified one RCT, but was unable to calculate outcomes because of insufficient data.[9] **Different forms of immobilisation:** One systematic review identified two RCTs.[9] The first RCT found that a semirigid cast significantly reduced the time taken to return to work compared with a rigid cast (WMD 3.80 days, 95% CI 1.16 days to 6.44 days). It found no significant difference in pain, swelling, or objective instability at short term follow up. The review was unable to calculate outcomes from the second RCT.

Harms: Two RCTs found fewer cases of deep venous thrombosis after cast immobilisation than after surgery (deep venous thrombosis: 2/47 [4%] after cast immobilisation *v* 3/34 [9%] after surgery;[10] 0/33 [0%] after cast immobilisation *v* 1/32 [3%] after surgery),[9] and one RCT found an equal occurrence of deep vein thrombosis in both groups (1/50 [2%] after cast immobilisation *v* 1/50 [2%] after surgery).[9] Other RCTs did not specifically address harms. Other known harms of immobilisation include pain and impairment in activities of daily living.[10]

Comment: There is a consensus that immobilisation is more effective in the treatment of ankle sprain than no treatment. **Versus functional treatment:** In the systematic review, follow up periods for outcome

measures were categorised as short term (within 6 weeks of randomisation), intermediate term (6 weeks to 1 year), or long term (1–2 years after treatment).[7] The review excluded trials that focused on the treatment of chronic instability or post-surgical treatment unless such injuries occurred in under 10% of the whole study population. The subsequent study only included semiprofessional sports people so the results may not be applicable to the general population.[8] **Versus surgery:** The systematic review noted that all included RCTs had methodological flaws, and there was insufficient evidence to determine the relative effectiveness of surgical and conservative treatment (see comment under surgery, p 1399).[9]

OPTION FUNCTIONAL TREATMENT

One systematic review and one subsequent RCT found limited evidence that functional treatment reduced the risk of the ankle giving way compared with minimal treatment. One systematic review and one subsequent RCT found that, compared with immobilisation, functional treatment improved symptoms and functional outcomes at short (< 6 weeks), intermediate (6 weeks to 1 year), or long term (> 1 year) follow up. However, effects were to be less marked at long term follow up, or if only results from high quality trials were analysed. One systematic review and one subsequent RCT provided insufficient evidence to compare functional treatment versus surgery. One systematic review and three additional RCTs provided insufficient evidence to compare different functional treatments.

Benefits:

Versus minimal treatment: We found one systematic review[11] and one subsequent RCT.[12] The systematic review (search date 1998, 3 RCTs, 214 people) compared functional treatment (see glossary, p 1401) versus a minimal treatment policy.[11] It found that functional treatment significantly reduced the risk of the ankle giving way (RR 0.34, 95% CI 0.17 to 0.71). Although pain scores were better with functional treatment, the difference was not significant (RR 0.53, 95% CI 0.27 to 1.02). The subsequent RCT (30 people with subacute or chronic ankle sprain without gross mechanical instability) compared the mortise separation adjustment (see glossary, p 1401) versus detuned ultrasound.[12] It found that mobilisation significantly reduced pain, increased ankle range of motion, and improved ankle function at 1 month (results presented graphically). **Versus immobilisation:** See benefits of immobilisation, p 1394. **Versus surgery:** We found one systematic review (search date 2000, 17 RCTs, 1950 people)[9] and one subsequent RCT.[13] The review (search date 2000, 17 RCTs, 1950 people) compared any surgical treatment (tenodesis [see glossary, p 1402] or anatomic reconstruction) versus any conservative treatment (including both immobilisation [see glossary, p 1401] and functional treatments) for acute injuries to the lateral ligament complex of the ankle.[9] It included eight RCTs comparing surgery versus functional treatment alone (see comment below). The review found no significant difference between surgery and functional treatment in return to sports (2 RCTs; RR 0.6, 95% CI 0.3 to 1.3), recurrence (5 RCTs; RR 1.2, 95% CI 0.8 to 1.8), pain (5 RCTs; RR 1.0, 95% CI 0.7 to 1.6), subjective instability (5 RCTs; RR 0.9,

95% CI 0.7 to 1.3), objective instability (4 RCTs; RR 0.6, 95% CI 0.3 to 1.2), and swelling (5 RCTs; RR 0.9, 95% CI 0.6 to 1.5; see comment below). The subsequent RCT (370 people with rupture of at least 1 lateral ankle ligament) compared functional treatment with surgery (anatomic reconstruction).[13] Functional treatment consisted of a non-weight bearing cast for 5 days followed by elastic bandaging or taping for 6 weeks. People in both groups received a standard rehabilitation programme. The RCT found that functional treatment was less effective than surgery for residual pain, subjective instability, and recurrent sprains after 6–11 years' follow up (317 people analysed; pain: 25% with functional treatment *v* 16% with surgery, RR 1.56, 95% CI 1.00 to 2.44; subjective instability: 32% with functional treatment *v* 20% with surgery, RR 1.61, 95% CI 1.09 to 2.38; recurrent sprains: 34% with functional treatment *v* 22% with surgery, RR 1.51, 95% CI 1.06 to 2.22). **Different types of functional treatment:** We found one systematic review[14] and three additional RCTs.[15–17] The review (search date 2000, 9 RCTs, 892 people) compared four types of functional treatment (elastic bandage, tape, lace-up ankle support, and semirigid ankle support) and included RCTs comparing two different types of functional treatments in people with an acute injury to the lateral ligament complex of the ankle. It reported outcomes at short, intermediate, and long term follow up (see comment below). At short term follow up, it found that lace-up ankle support significantly reduced persistent swelling compared with semirigid ankle support (1 RCT; RR 4.2, 95% CI 1.3 to 14.0), elastic bandage (1 RCT; RR 5.5, 95% CI 1.7 to 17.8), and tape (1 RCT; RR 4.1, 95% CI 1.2 to 13.7). A semirigid ankle support significantly reduced the proportion of people with subjective instability compared with an elastic bandage (1 RCT; RR 8.00, 95% CI 1.03 to 62.07). It found no significant differences between different types of functional treatments at intermediate or long term follow up. It found that a semirigid ankle support significantly reduced the time taken to return to work compared with an elastic bandage (2 RCTs; WMD 4.2 days, 95% CI 2.4 days to 6.0 days) and the time taken to return to sports (1 RCT; WMD 9.6 days, 95% CI 6.3 days to 12.8 days). It found no other significant differences in outcomes between treatments (see comment below).[14] The first additional RCT (61 people without previous fractures in the ankle joint or clinically demonstrable ankle instability; mean follow up of 230 days) found that elastic bandage plus propriocepsis training reduced the risk of recurrent sprains compared with elastic bandage alone (RR 0.46, 95% CI 0.20 to 1.00).[16] Thirteen people withdrew from the RCT and were not included in the analysis. The remaining two additional RCTs found no significant differences in outcomes between treatments.[15,17] One RCT (116 people with all grades of ankle sprain) compared a semirigid device versus tape and found similar rates of recurrent sprains (recurrent sprains were found in 4% with semirigid device *v* 0% with tape).[15] The other RCT (119 people not requiring surgery, treated within 24 hours of injury) compared two types of tape treatment with follow up of 5–7 days and found similar outcomes between groups (short term pain 8% *v* 5%; swelling 58% *v* 47%; limited range of movement 36% *v* 47%).[17]

Harms: Allergic reactions and skin problems have been recorded with tape.[18] In the systematic review comparing different functional treatments, tape treatment resulted in significantly more complications compared with elastic bandage (2 RCTs; 0/104 [0%] with elastic bandage *v* 8/104 [8%] with tape; RR 0.11, 95% CI 0.01 to 0.86).[14] Most of these complications were skin problems (absolute numbers with skin problems not reported).

Comment: **Versus surgery:** The review noted that all included RCTs had methodological flaws, and there was insufficient evidence to determine the relative effectiveness of surgical and conservative treatment (see comment under surgery, p 1399).[9] **Different types of functional treatment:** The systematic review reported follow up periods for outcome measures as short term (< 6 weeks of treatment), intermediate term (6 weeks to 1 year), or long term (1–2 years after treatment).[14] It noted that definitive conclusions were hampered by the variety of treatments used and the inconsistency of reported follow up times, and no definite conclusions concerning the optimal functional treatment strategy could be drawn.[14]

OPTION SURGERY

One systematic review found no significant difference between surgery and immobilisation in pain or subjective instability. Other systematic reviews and one subsequent RCT provided insufficient evidence to compare surgery versus functional treatment or versus conservative treatment (including both immobilisation and functional treatment).

Benefits: **Versus immobilisation:** See benefits of immobilisation, p 1394. **Versus functional treatment:** See benefits of functional treatment, p 1396. **Versus conservative (immobilisation and functional) treatment:** One systematic review (search date 2000, 17 RCTs, 1950 people) compared surgery (anatomical reconstruction and tenodesis [see glossary, p 1402]) versus conservative treatment (including both immobilisation and functional treatments [see glossary, p 1401]) for acute injuries to the lateral ligament complex of the ankle.[9] Significant results were often not robust to sensitivity analysis (see comment below). When data from one quasi-randomised trial were excluded, the review found that surgery significantly decreased the proportion of people with objective instability compared with conservative treatment (4 RCTs; RR 0.4, 95% CI 0.2 to 0.7) and surgery significantly increased the proportion of people with ankle stiffness compared with conservative treatment (2 RCTs; RR 1.9, 95% CI 1.2 to 3.1). It found no significant difference between groups in recurrence (10 RCTs; RR 0.96, 95% CI 0.70 to 1.20), pain on activity (8 RCTs; RR 0.9, 95% CI 0.7 to 1.2), swelling (9 RCTs; RR 0.83, 95% CI 0.60 to 1.10), or people not returning to sports (3 RCTs; RR 0.7, 95% CI 0.4 to 1.2; see comment below).[9]

Harms: Neurological injuries, infections, bleeding, osteoarthritis, and death are known harms of surgery.[10,19,20] Two RCTs found fewer cases of deep venous thrombosis after cast immobilisation than with surgery (deep venous thrombosis: 2/47 [4%] with cast immobilisation *v*

3/34 [9%] with surgery;[10] 0/33 [0%] with cast immobilisation *v* 1/32 [3%] with surgery[9]) and one RCT found an equal occurrence of deep vein thrombosis in both groups (1/50 [2%] with cast immobilisation *v* 1/50 [2%] with surgery[9]). Other RCTs have found dysaesthesia (see glossary, p 1401) in 4–12% of all people after surgery.[21–26] Wound necrosis after surgery was reported in two RCTs (2/73 [3%] with surgery;[24] 3/45 [7%] with surgery[25]). Tenderness of the scar was reported in six RCTs after surgical intervention, occurring in 2–19% of people.[22,23,26–29]

Comment: The systematic review comparing surgery versus conservative treatment noted that all RCTs had methodological flaws.[9] Data for pooling for individual outcomes were available for a maximum of 11 trials, and quality assessment ranged from 6 to 13 out of a possible 22 using a recognised quality evaluation tool.[9] Included trials were often heterogeneous, and significant results were often sensitive to the method of analysis used (random or fixed effects meta-analysis) or when data from quasi-randomised trials were excluded. The review concluded that "there is insufficient evidence available from randomised controlled trials to determine the relative effectiveness of surgical and conservative treatment for acute injuries of the lateral ligament complex of the ankle."[9]

OPTION ULTRASOUND

One systematic review found no significant difference between ultrasound and sham ultrasound in the general improvement of symptoms or the ability to walk or bear weight at 7 days. Three RCTs provided insufficient evidence to compare ultrasound versus other treatments.

Benefits: We found one systematic review (search date 2001, 5 RCTs, 572 people; see comment below).[30] **Versus placebo:** Four RCTs in the review compared ultrasound versus a sham ultrasound treatment.[30] None of the RCTs found a significant difference for any outcome measure. The review found no significant difference in general improvement between ultrasound and sham ultrasound at 7 days (3 RCTs; 121/169 [72%] with ultrasound *v* 116/172 [68%] with sham ultrasound; RR 1.04, 95% CI 0.92 to 1.17). It found no significant difference in functional disability (the ability to walk or bear weight) between ultrasound and sham ultrasound at 7 days (2 RCTs; 69/95 [73%] with ultrasound *v* 61/92 [66%] with sham ultrasound; RR 1.09, 95% CI 0.92 to 1.30).[30] **Versus other treatments:** Three RCTs in the review compared ultrasound versus other treatment modalities.[30] The largest RCT (72 people in the smallest group) compared ultrasound plus placebo gel, ultrasound plus felbinac gel, and sham ultrasound plus felbinac gel over about 7 days. The comparison between ultrasound and felbinac gel resulted in small and non-significant differences. The second RCT (20 people in the smallest group) compared ultrasound versus electrotherapy. It found no significant difference in swelling, ability to walk, and recovery. The third low quality RCT (40 people in the smallest group) compared ultrasound versus immobilisation (see glossary, p 1401) with Elastoplast over 2 weeks' follow up. It found no significant difference in the proportion of people who recovered

with ultrasound compared with immobilisation after 7 days (46% with ultrasound *v* 27% with immobilisation; ARR +19%, 95% CI −2% to +40%), but a significant difference after 14 days (86% with ultrasound *v* 59% with immobilisation; ARR 27%, 95% CI 8% to 46%).

Harms: Two included RCTs addressed adverse reactions.[31,32] One RCT found none.[31] The systematic review reported that in the other RCT, 8/73 (11%) people in the ultrasound group (plus placebo gel) reported 11 non-serious adverse reactions, including gastrointestinal events and skin reactions, and in one person treatment was discontinued because of skin reactions and the person was withdrawn from the RCT.[32]

Comment: In the review, the quality of four of the included RCTs was described as "modest" and one as "good".[30] The review reported RCTs in which one or more of pain, swelling, and functional disability because of an acute ankle sprain were present, and in which at least one group was treated with active ultrasound treatment. All the RCTs included follow up of less than 4 weeks.

OPTION COLD PACK COMPRESSION

Two RCTs found no significant difference in symptoms between cold pack placement and placebo or control. One RCT found less oedema with cold pack placement compared with heat or a contrast bath at 3–5 days after injury.

Benefits: We found one systematic review (search date 1994, 3 RCTs, 203 people).[33] The first RCT (143 people) identified by the review compared cryotherapy versus placebo (simulated) treatment.[34] The second RCT (30 people) identified by the review compared ice treatment plus physiotherapy versus no ice plus physiotherapy.[35] In both RCTs, no significant differences were found. The third RCT (30 people) identified by the review found significantly less oedema with cold than with heat or a contrast bath (see comment below) at 3–5 days after injury ($P < 0.05$).[36]

Harms: None of the RCTs addressed harms from cold pack placement.

Comment: The systematic review was narrative in character and no data were pooled.[33] The systematic review did not report the grade of injuries. In the third RCT, the injured ankle in the contrast bath group was submerged in warm water for 3 minutes and then in cold water for 1 minute. This was continued until the ankle had been given five heat and four cold treatments beginning and ending with heat.[36]

OPTION DIATHERMY

One systematic review found insufficient evidence on the effects of diathermy versus placebo on walking ability and reduction in swelling.

Benefits: We found one systematic review (search date 1994, 5 RCTs, 490 people).[33] The review included a range of severity of ankle sprains but excluded the most severe injuries (avulsion and osteochondral fractures). The largest high quality RCT (300 people with time from injury to treatment of ≤4 days) compared two forms of pulsating

short wave treatment versus placebo.[37] The RCT found that high frequency electromagnetic pulsing significantly improved walking ability more quickly compared with placebo ($P < 0.01$). The difference was not significant with low frequency electromagnetic pulsing. However, low frequency pulsing significantly reduced swelling compared with placebo. There was no significant difference between the high frequency group compared with placebo (change in circumference of ankle: 4.5 mm with high frequency *v* 5.0 mm with low frequency *v* 2.6 mm with placebo; $P < 0.01$ for low frequency *v* placebo). A second RCT (50 people) found that pulsating short wave diathermy significantly reduced oedema compared with placebo ($P < 0.01$).[38] The other RCTs (73,[39] 37,[40] and 30[41] people) found no significant differences for pain, oedema, or range of motion compared with placebo. The first RCT presented results graphically.[39] From these RCTs the grades of injuries were not clear. No other outcome measures were reported and no results were pooled.

Harms: No evidence of any harm was reported.

Comment: None.

OPTION HOMEOPATHIC OINTMENT

One systematic review of one small RCT found limited evidence that homeopathic ointment improved outcome based on a "composite criteria of treatment success" compared with placebo.

Benefits: We found one systematic review (search date 1998),[42] which included one small RCT in German (69 people with acute ankle sprains).[43] The review found that people treated with a homeopathic ointment had a significantly better outcome based on a "composite criteria of treatment success" compared with people treated with placebo. The review did not provide specific numerical results or timescale of outcome measurement but described a P value of 0.028.[42] People initially randomised in the RCT and losses to follow up were not reported.

Harms: Harms were not addressed in the review.

Comment: The RCT included in the systematic review will be translated and further details included in future *Clinical Evidence* updates.

GLOSSARY

Anatomic reconstruction Surgical reconstruction of lateral ankle ligament complex through suturing of the ligaments.
Crus varum Varus of the lower leg (O-leg).
Dysaesthesia Decreased sensitivity of the skin for stimuli.
Functional treatment Diverse functional treatments have been used. The main differences are the types of external device applied for treatment. The supports can be divided according to rigidity into elastic bandage, tape, lace-up ankle support, and semirigid ankle support. Propriocepsis training (to enhance joint stability) has also been used.
Immobilisation Limiting the mobility of a joint complex to zero degrees.
Mortise separation adjustment An adjustment technique involving special manual manipulation of the foot and ankle.[12]
Pes cavo-varus Severe high arched, varus foot.

Tenodesis Surgical reconstruction of lateral ankle ligament complex using tendon graft.

Substantive changes

Immobilisation One RCT added;[8] categorisation unchanged.
Functional treatment One RCT added;[13] categorisation unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 1414

Key Messages

Conservative treatments

- **Night splints** We found no RCTs about the effects of night splints compared with other treatments or no treatment.
- **Orthoses to treat hallux valgus in adults** One RCT found that, in adults, orthoses reduced pain compared with no treatment at 6 months but not at 1 year.
- **Antipronatory orthoses in children** One RCT in children found that antipronatory orthoses increased deterioration in metatarsophalangeal joint angles after 3 years compared with no treatment, although the difference was not statistically significant.

Surgery

- **Chevron osteotomy** One RCT found that chevron osteotomy improved outcomes compared with orthoses or no treatment after 1 year. A systematic review found conflicting evidence on the effects of chevron osteotomy compared with other metatarsal osteotomies.

- **Chevron osteotomy plus adductor tenotomy** A systematic review found no evidence that adductor tenotomy plus chevron osteotomy improved outcomes compared with chevron osteotomy alone.
- **Chevron osteotomy plus Akin osteotomy** One small RCT found no significant difference in outcomes between chevron osteotomy plus Akin osteotomy and Akin osteotomy plus distal soft tissue reconstruction at 1 year. However, this trial may have lacked power to detect a clinically significant difference.
- **Different methods of bone fixation** One small RCT found no significant difference between absorbable pin fixation and standard fixation in clinical or radiological outcomes; however, it may have lacked power to detect a clinically significant difference. One small RCT found that screw fixation plus early weight bearing reduced time to return to work and social activity compared with suture fixation and later weight bearing, but found no significant difference in radiological outcomes.
- **Keller's arthroplasty** One systematic review provided insufficient evidence on the effects of Keller's arthroplasty compared with other types of operation.

Postoperative care

- **Continuous passive motion** One systematic review provided insufficient evidence on the effects of continuous passive motion.
- **Early weight bearing** One systematic review provided insufficient evidence on the effects of early weight bearing.
- **Slipper casts** Two RCTs provided insufficient evidence on the effects of plaster slipper casts.

DEFINITION

Hallux valgus is a deformity of the great toe, whereby the hallux (great toe) moves towards the second toe, overlying it in severe cases. This movement of the hallux is described as abduction (movement away from the midline of the body) and it is usually accompanied by some rotation of the toe so that the nail is facing the midline of the body (valgus rotation). With the deformity, the metatarsal head becomes more prominent and the metatarsal is said to be in an adducted position as it moves towards the midline of the body.[1] Radiological criteria for hallux valgus vary, but a commonly accepted criterion is to measure the angle formed between the metatarsal and the abducted hallux. This is called the metatarsophalangeal joint angle or hallux abductus angle and it is considered abnormal when it is greater than 14.5°.[2] **Bunion** is the lay term used to describe a prominent and often inflamed metatarsal head and overlying bursa. Symptoms include pain, limitation in walking, and problems with wearing normal shoes.

INCIDENCE/ PREVALENCE

The prevalence of hallux valgus varies in different populations. In a recent study of 6000 UK school children aged 9–10 years, 2.5% had clinical evidence of hallux valgus, and 2% met both clinical and radiological criteria for hallux valgus. An earlier study found hallux valgus in 48% of adults.[2] Differences in prevalence may result from different methods of measurement, varying age groups, or different diagnostic criteria (e.g. metatarsal joint angle > 10° or > 15°).[3]

AETIOLOGY/ RISK FACTORS

Nearly all population studies have found that hallux valgus is more common in women. Footwear may contribute to the deformity, but studies comparing people who wear shoes with those who do not

have found contradictory results. Hypermobility of the first ray (see glossary, p 1415) and excessive foot pronation are associated with hallux valgus.[4]

PROGNOSIS We found no studies that looked at the progression of hallux valgus. While progression of deformity and symptoms is rapid in some people, others remain asymptomatic. One study found that hallux valgus is often unilateral initially, but usually progresses to bilateral deformity.[2]

AIMS OF INTERVENTION To reduce symptoms and deformity, with minimum adverse effects.

OUTCOMES Hallux abductus/metatarsophalangeal joint angle; intermetatarsal joint angle; range of motion of the first metatarsophalangeal joint (the total range of both dorsiflexion and plantarflexion); incidence of complications such as infection; reoperation; non-union; avascular necrosis; pain; general satisfaction and satisfaction with appearance; requirement for specialist or extra-width footwear; proportion of people with mobility problems; time to healing; development of transfer lesions (see glossary, p 1415); and adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal September 2003. An electronic search using a strategy developed by the Cochrane Musculoskeletal Injuries Group was undertaken to October 2003 and a hand search of podiatry journals to October 2003.

QUESTION What are the effects of conservative treatments?

OPTION ORTHOSES

One RCT in children found that antipronatory orthoses increased deterioration in metatarsophalangeal joint angles after 3 years compared with no treatment, although the difference was not statistically significant. One RCT found that orthoses reduced pain in adults with hallux valgus compared with no treatment at 6 months but not at 1 year.

Benefits: We found no systematic review. We found two RCTs.[2,5] **In children:** The first RCT compared antipronatory orthoses (see glossary, p 1414) versus no treatment in 122 children aged 9–10 years (13% of whom were boys) with metatarsophalangeal joint angles greater than 14.5° in one or both feet (see comment below).[2] On the basis of a clinical examination, 150 children were selected for x ray examination, and 122 of these children (13% of whom were boys) who were found to have metatarsophalangeal joint angles greater than 14.5° in one or both feet were subsequently included in the trial (see comment below). The RCT found that the metatarsophalangeal joint angles deteriorated both with orthoses and with no treatment, and found that the deterioration was greater in children treated with orthoses, although this difference was not significant after 3 years (analysis not by intention to treat; no direct statistical comparisons reported).[2] **In adults:** The second RCT (209 adults) compared three treatments: chevron osteotomy (see glossary, p 1414); orthoses, and no treatment (see benefits of chevron osteotomy, p 1409).[5] The RCT found that orthoses significantly

reduced pain intensity after 6 months compared with no treatment (pain intensity on visual analogue scale with range 0 [no pain] to 100 [unbearable pain]; pain score: 36 with orthoses *v* 45 with no treatment; difference adjusted for baseline characteristics −14, 95% CI −22 to −6), but found no significant difference in pain intensity after 12 months (mean pain score: 40 with orthoses *v* 40 with no treatment; difference adjusted for baseline characteristics −6, 95% CI −15 to +3). The RCT also found that orthoses significantly improved "global assessment" (not further defined in the paper) compared with no treatment but found no significant difference in satisfaction or functional assessment scores (AOFAS — see glossary, p 1415) after 12 months (proportion with improved global assessment: 46% with orthoses *v* 24% with no treatment; RR adjusted for baseline characteristics 0.38, 95% CI 0.18 to 0.78; satisfaction on visual analogue scale with range 0 [totally unsatisfied] to 100 [totally satisfied]: 70 with orthoses *v* 61 with no treatment; difference adjusted for baseline characteristics: +9, 95% CI −1 to +20; AOFAS score: 64 with orthosis *v* 66 with no treatment, difference adjusted for baseline characteristics 0, 95% CI −4 to +5). It also found no significant difference between orthoses and no treatment in the duration of the pain, ability to work, and cosmetic disturbance.[5]

Harms: The RCT in children did not report on harms.[2] The RCT in adults reported no complications with orthoses (see harms of chevron osteotomy, p 1409).

Comment: The use of antipronatory orthoses in children is questionable because earlier studies have found that hallux valgus in children is not related to pronation but arises from positional changes in the first ray.[6] The first RCT reported that 29/122 (25%) children (mainly from the control group) were lost to follow up.[2]

OPTION NIGHT SPLINTS

We found no RCTs about the effects of night splints compared with any other or no treatment.

Benefits: We found no RCTs that compared night splints versus any other or no treatment.

Harms: We found no RCTs.

Comment: None.

QUESTION What are the effects of surgery?

OPTION KELLER'S ARTHROPLASTY

One systematic review provided insufficient evidence on the effects of Keller's arthroplasty compared with other types of operation.

Benefits: We found one systematic review (search date 1998, 3 relevant RCTs; see comment below).[7] **Versus no treatment:** The review included no RCTs. **Versus distal osteotomy:** The review included one RCT (33 people) comparing distal metatarsal osteotomy (see

glossary, p 1414) versus Keller's arthroplasty (see glossary, p 1415).[8] The RCT found that osteotomy significantly improved both intermetatarsal angle and range of movement compared with Keller's arthroplasty but found no significant difference in proportion with unresolved pain or dissatisfaction after 3 years (intermetatarsal angle: 12.0° with Keller's arthroplasty *v* 7.0° with distal osteotomy; difference –5.0°, 95% CI –8.9° to –1.1°; reduction in range of movement: 14.0° with Keller's arthroplasty *v* 1.0° with distal osteotomy; difference: 13.0°, 95% CI 5.0° to 21.1°; proportion with unresolved pain: 4/14 [29%] with Keller's arthroplasty *v* 4/15 [27%] with distal osteotomy; OR 0.91, 95% CI 0.18 to 4.64; proportion dissatisfied: 4/14 [29%] with Keller's arthroplasty *v* 4/15 [27%] with distal osteotomy; OR 0.91, 95% CI 0.18 to 4.64). **Versus arthrodesis:** The second RCT included in the review (100 people) found that Keller's arthroplasty significantly reduced the proportion of people with reduced mobility compared with arthrodesis, but found no significant difference in the proportion with unresolved pain or dissatisfaction after 2 years (proportion with reduced mobility: 4/44 [9%] with Keller's arthroplasty *v* 11/37 [30%] with arthrodesis; OR 0.24, 95% CI 0.07 to 0.82; proportion with unresolved pain: 5/44 [11%] with Keller's osteotomy *v* 4/37 [11%] with osteotomy; OR 1.05, 95% CI 0.26 to 4.35; proportion dissatisfied: 11/44 [25%] with Keller's osteotomy *v* 10/37 [27%] with arthrodesis; OR 0.90, 95% CI 0.33 to 2.44).[9] **Plus joint distraction:** The third RCT (35 people) included in the review found that a Kirschner wire (see glossary, p 1415) to distract the joint during healing after Keller's arthroplasty significantly improved subjective assessment scores for symptoms after a minimum of 1 year compared with Keller's arthroplasty with no wire (assessment scale of 1 = constant pain to 4 = no symptoms; no actual scores provided; $P < 0.05$), but found no significant difference in the hallux abductus angle, pain, or movement after a minimum of 1 year (hallux valgus angle: 21° for both groups, no P value reported; no data reported for pain or movement).[10]

Harms: Reduced toe function has been described after Keller's procedure.[7] The systematic review reported high levels of patient dissatisfaction (up to 29%) in most trials.[7] **Versus arthrodesis:** The RCT did not present complete data for complications, but reported that cock-up deformity (see glossary, p 1414) was more common in the Keller's group (25/44 people) than the arthrodesis group (11/37), although this difference was not significant.[9] **Versus distal osteotomy:** The RCT found no significant difference in the incidence of postoperative superficial wound infections between groups (3/14 in the Keller's group *v* 1/15 in the osteotomy group; OR 3.85, 95% CI 0.35 to 50).[8] **Plus joint distraction:** In the RCT examining the effects of joint distraction after Keller's arthrodesis, one participant in each group had delayed wound healing.[10]

Comment: Both the RCT comparing Keller's arthroplasty versus arthrodesis and the RCT looking at the effects of joint distraction included people with hallux rigidus. Most of the people included in the review having

surgery were under 50 years of age and were followed up for no more than 3 years.[7] Longer term outcomes remain unclear. The RCTs reported results for numbers of feet, and did not always report standard deviations of the results. The systematic review analysed the results by numbers of people.[7]

OPTION CHEVRON OSTEOTOMY

One RCT found that chevron osteotomy improved outcomes compared with orthoses or no treatment after 1 year. A systematic review found conflicting evidence on the effects of chevron osteotomy compared with other metatarsal osteotomies. A systematic review found no evidence that adductor tenotomy plus chevron osteotomy improved outcomes compared with chevron osteotomy alone. One small RCT found no significant difference in outcomes between chevron osteotomy plus Akin osteotomy and Akin osteotomy plus distal soft tissue reconstruction at 1 year. However, this trial may have lacked power to detect a clinically significant difference.

Benefits:

Versus no treatment or versus orthoses: We found one systematic review (search date 1998, no relevant RCTs)[7] and one subsequent RCT.[5] The subsequent RCT (209 adults) compared three treatments: chevron osteotomy (see glossary, p 1414), orthoses, and no treatment (see benefits of orthoses, p 1406).[5] It found that chevron osteotomy significantly reduced pain intensity and significantly improved cosmetic appearance and functional status compared with no treatment at 1 year (mean pain intensity on a visual analogue scale from 0 [no pain] to 100 [unbearable pain]: 23 with chevron osteotomy *v* 40 with no treatment, difference adjusted for baseline characteristics –19, 95% CI –28 to –10; mean cosmetic appearance on a 7 point scale ranging from 0 [no cosmetic disturbance] to 6 [maximal cosmetic disturbance]: 1.9 with chevron osteotomy *v* 2.8 with no treatment, difference adjusted for baseline characteristics: –1.2, 95% CI –1.8 to –0.6; mean functional status [AOFAS — see glossary, p 1415]: 75 with chevron osteotomy *v* 66 with no treatment, difference adjusted for baseline characteristics 11, 95% CI 7 to 16). It found no significant difference in the ability to work after 1 year (ability to work on a visual analogue scale from 0 [total inability to work] to 100 [maximal working ability]: 89 with chevron osteotomy *v* 83 with no treatment, difference adjusted for baseline characteristics +4, 95% CI –3 to +11). The RCT also found that chevron osteotomy significantly reduced pain intensity and significantly improved cosmetic appearance and functional status compared with orthoses but found no significant difference in the ability to work after 1 year (pain intensity on a visual analogue score ranging from 0 [no pain] to 100 [unbearable pain]: 23 with chevron osteotomy *v* 40 with orthosis, difference adjusted for baseline characteristics –14, 95% CI –22 to –5; cosmetic appearance on a 7 point scale ranging from 0 [no cosmetic disturbance] to 6 [maximal cosmetic disturbance]: 1.9 with chevron osteotomy *v* 2.6 with orthosis, difference adjusted for baseline characteristics –1.4, 95% CI –2.1 to –0.8; functional status [AOFAS]: 75 with chevron osteotomy *v* 64 with orthosis, difference adjusted for baseline characteristics 11, 95% CI 7 to 15; ability to work on a visual analogue scale from 0 [total inability to work] to 100

[maximal working ability]: 89 with chevron osteotomy *v* 81 with orthosis, difference adjusted for baseline characteristics 6, 95% CI 0 to 13). **Versus other metatarsal osteotomies:** We found one systematic review (search date 1998, 3 relevant RCTs, 205 people).[7] The first RCT (66 people) included in the review found no significant difference between proximal chevron osteotomy and proximal crescentic osteotomy in the hallux abductus angle, intermetatarsal angle, transfer lesions (see glossary, p 1415), or functional assessment score (AOFAS) after 22 months.[11] It found that proximal chevron osteotomy significantly reduced healing time compared with proximal crescentic osteotomy ($P < 0.001$) and significantly reduced postoperative dorsiflexion at the healed site ($P = 0.005$). The second RCT (68 people) included in the review found that chevron osteotomy significantly improved the hallux abductus and intermetatarsal angle compared with proximal osteotomy. It found no significant difference in the proportion of participants experiencing pain, dissatisfaction with treatment, problems with footwear, or mobility between proximal osteotomy and chevron osteotomy after 2 years (OR for remaining in pain 0.55, 95% CI 0.13 to 2.42; AR for dissatisfaction with outcome 33% with both treatments; OR 0.99, 95% CI 0.36 to 2.75; OR for needing specialist footwear 0.38, 95% CI 0.04 to 3.83; OR for reduced mobility 0.38, 95% CI 0.04 to 3.83; all ORs for proximal osteotomy *v* chevron osteotomy).[12] Proximal osteotomy significantly improved hallux abductus angle and intermetatarsal angle compared with chevron osteotomy at 2 years (hallux abductus angle: 25.0° with chevron osteotomy *v* 20.0° with proximal osteotomy; difference 5.0°, 95% CI 0.5° to 9.5°; intermetatarsal angle: 13.0° with chevron osteotomy *v* 10.0° with proximal osteotomy; difference 3.0°, 95% CI 1.0° to 5.0°). The third RCT (51 people) included in the review found that Wilson osteotomy (see glossary, p 1415) significantly improved the hallux abductus angle compared with chevron osteotomy but found no significant difference in problems with footwear or mobility after 38 months (hallux abductus angle: 25.7° with chevron osteotomy *v* 13.3° with Wilson osteotomy; difference +12.4°, 95% CI +7.5° to +17.5°; footwear problems: 8/24 [33%] with chevron osteotomy *v* 3/26 [12%] with Wilson osteotomy; OR 3.85, 95% CI 0.87 to 16.67; limited walking: 5/24 [21%] with chevron osteotomy *v* 4/26 [15%] with Wilson osteotomy; OR 1.45, 95% CI 0.34 to 6.25).[13] **Plus adductor tenotomy:** We found one systematic review (search date 1998, 1 relevant RCT, 84 people).[7] The RCT included in the review found no significant difference in hallux abductus angle, range of motion, pain, patient satisfaction, people requiring special footwear, and mobility between chevron osteotomy plus adductor tenotomy and chevron osteotomy alone (final hallux abductus angle: 20.2° with chevron osteotomy plus adductor tenotomy *v* 23.5° with chevron osteotomy alone; mean difference –3.3°, 95% CI –8.63° to +2.03°; range of motion: 69° with chevron osteotomy plus adductor tenotomy *v* 67° with chevron osteotomy alone; mean difference +2°, 95% CI –2.7° to +6.73°; people remaining in pain: 8/38 [21%] with chevron osteotomy plus adductor tenotomy *v* 6/46 [13%] with chevron osteotomy alone; OR 1.78, 95% CI 0.56 to 5.67; people remaining dissatisfied: 10/38 [26%] with chevron

osteotomy plus adductor tenotomy *v* 7/46 [15%] with chevron osteotomy alone; OR 1.99, 95% CI 0.68 to 5.87; people requiring special footwear: 2/38 [5%] with chevron osteotomy plus adductor tenotomy *v* 7/46 [15%] with chevron osteotomy alone; OR 0.31, 95% CI 0.06 to 1.59; people with reduced mobility: 1/38 [3%] with chevron osteotomy plus adductor tenotomy *v* 1/46 [2%] with chevron osteotomy alone; OR 1.22, 95% CI 0.07 to 20.12).[14] **Plus Akin osteotomy:** We found one RCT (23 people; see comment below) comparing Akin osteotomy plus chevron osteotomy versus Akin osteotomy plus distal soft tissue reconstruction (DSTR) (see glossary, p 1414).[15] It found no significant difference in hallux abductus angle, intermetatarsal angle, or range of toe motion between the two treatment options after a minimum of 1 year (hallux abductus angle: 12.5° with chevron osteotomy plus Akin osteotomy *v* 17° with DSTR plus Akin osteotomy; mean difference +4.5°, 95% CI –5.77° to +14.72°; intermetatarsal angle: 7° with chevron osteotomy plus Akin osteotomy *v* 10° with DSTR plus Akin osteotomy; mean difference +3°, 95% CI –1.45° to +7.45°; range of toe motion: mean difference –3°, 95% CI –12.07° to +6.07°). However, this trial may have lacked power to detect a clinically important significant difference.

Harms:

Complications were reported by most of the RCTs. **Versus no treatment or versus orthoses:** The RCT comparing chevron osteotomy, orthoses, and no treatment reported complications in 4/71 (6%) people undergoing chevron osteotomy (complications consisted of one wound infection, one stress fracture, one episode of nerve damage, and one recurrence of deformity).[5] The RCT reported no complications associated with orthoses. **Versus other metatarsal osteotomies:** The RCT comparing proximal crescentic osteotomy versus proximal chevron osteotomy found one case of delayed wound healing in the chevron group and two cases in the proximal osteotomy group. Eight further people experienced complications, although the authors did not state which group they belonged to.[11] The RCT comparing proximal osteotomy and chevron osteotomy reported one wound infection and two stress fractures in people undergoing chevron osteotomy and 11 complications in people undergoing proximal osteotomy, consisting mostly of pain in other areas of the forefoot (metatarsalgia).[12] The RCT comparing Wilson osteotomy versus chevron osteotomy found no significant difference in the proportion with complications (11/26 [42%] with Wilson osteotomy *v* 9/24 [38%] with chevron osteotomy; RR 1.30, 95% CI 0.57 to 2.24).[13] Complications included swelling, over correction, slow healing, and recurrence of bunion. Transfer pain (see glossary, p 1415) and lesions were recurring problems in both groups. The RCT found that although Wilson osteotomy resulted in a significantly shortened metatarsal compared with chevron osteotomy ($P = 0.02$), with metatarsal dorsiflexion in 20% of people, this change in position did not correlate with development of new corns, callous, or pain. **Plus adductor tenotomy:** In the RCT that compared chevron osteotomy plus adductor tenotomy versus chevron osteotomy alone, about 25% of both groups remained dissatisfied during follow up.[14] This may be related to greater postoperative reduction in the circumference of the ball of the foot; the RCT

found that the ball circumference of dissatisfied people was significantly greater than that of satisfied people (P = 0.005). **Plus Akin osteotomy:** The RCT reported two complications with Akin osteotomy plus chevron osteotomy (one non-union and one where a transfer lesion developed, resulting in further surgery) and one complication with Akin osteotomy plus distal soft tissue reconstruction (nerve damage in the great toe).[15]

Comment: None of the RCTs included long term follow up. The RCT comparing chevron osteotomy plus Akin osteotomy with Akin osteotomy plus distal soft tissue reconstruction was poorly randomised and seems to comprise a subset of data from a larger RCT.[15]

OPTION DIFFERENT METHODS OF BONE FIXATION

One small RCT found no significant difference between standard fixation and absorbable pin fixation in clinical or radiological outcomes; however, it may have lacked power to detect a clinically significant difference. One small RCT found that screw fixation plus early weight bearing reduced time to return to work and social activity compared with suture fixation and later weight bearing, but found no significant difference in radiological outcomes.

Benefits: We found no systematic review. We found two RCTs comparing different methods of bone fixation after Mitchell's osteotomy (see glossary, p 1415).[16,17] The first RCT (28 people, 39 feet; see comment below) found no significant difference between a standard method of fixation and absorbable pin fixation in clinical or radiological outcomes after a mean follow up of 11 months (range 2–24 months; range of movement: 61.2° with standard fixation *v* 69.2° with absorbable pin fixation; mean difference +8.0°, 95% CI −7.3° to +23.6°; people remaining in pain on walking: 1/17 [5.9%] with standard fixation *v* 2/21 [9.5%] absorbable pin fixation; P = 0.58; people with marked walking limitation: 1/17 [5.9%] with standard fixation *v* 1/21 [4.8%] with absorbable pin fixation; P = 0.24; people dissatisfied with cosmetic appearance: 1/17 [5.9%] with standard fixation *v* 3/21 [14.3%] with absorbable pin fixation; P = 0.38; radiological outcomes: hallux abductus angle: 15.8° with standard fixation *v* 18.2° with absorbable pin fixation; mean difference +2.4°, 95% CI −4.81° to +9.61°; intermetatarsal angle: 9.1° with standard fixation *v* 9.4° with absorbable pin fixation; mean difference +0.3°, 95% CI −1.77° to +2.37°).[16] The second RCT (30 people) compared screw fixation followed by early weight bearing in a plaster shoe versus vicryl suture fixation followed by 6 weeks of non-weight bearing in a plaster boot.[17] It found that screw fixation followed by early weight bearing in a plaster shoe significantly reduced time taken to return to social activities and time taken to return to work, but found no significant difference in radiological outcomes after 6 months (social activities: mean 2.9 weeks with screw fixation *v* 5.7 weeks with suture fixation; P < 0.001; work: mean 4.9 weeks with screw fixation *v* 8.7 weeks with suture fixation; P < 0.001; radiological: hallux abductus angle: 10.8° with suture fixation *v* 12° with screw fixation; mean difference +1.2°, 95% CI −2.35° to +4.75°; intermetatarsal angle: 9.1° with suture fixation *v* 10.7° with screw fixation; mean difference +1.6°, 95% CI −0.56° to +3.76°).[17]

Harms: The first RCT (28 people, 39 feet) reported more complications with standard compared with pin fixation, although the difference was not significant (14/17 [82%] feet *v* 16/22 [73%] feet; RR 1.13, 95% CI 0.81 to 1.59).[16] Complications included recurrence of deformity (3/17 [18%] feet *v* 2/22 [9%] feet), problems primarily resulting in pain (5/17 [29%] feet *v* 6/22 [27%] feet), and continued swelling (3/17 [18%] feet *v* 0/22 [0%] feet). In the RCT (30 people) of screw fixation compared with suture fixation, 2/15 (13%) people had the screw removed because of pain.[17] The RCT reported that superficial infection occurred in three people overall (2 with screw fixation *v* 1 with suture fixation) and also found that fixation followed by early weight bearing in a plaster shoe significantly increased metatarsophalangeal joint stiffness after both 3 and 6 months.

Comment: Applicability of the results from the first RCT may be limited, as people were used as the unit of randomisation and feet as the unit of statistical analysis.[16] In addition, the first RCT was small and may have lacked power to detect clinically significant differences between treatments.

QUESTION What are the effects of postoperative care?

OPTION CONTINUOUS PASSIVE MOTION

One systematic review provided insufficient evidence on the effects of continuous passive motion.

Benefits: We found one systematic review (search date 1998, 1 relevant RCT, 39 people).[7] The RCT included in the review found no significant difference in the range of motion or time taken to return to normal footwear between continuous passive motion plus physiotherapy and physiotherapy alone (range of motion: 9.3° with continuous passive motion plus physiotherapy *v* 2.6° with physiotherapy alone; mean difference –6.7°, 95% CI –13.6° to +0.3°; time to return to normal footwear: no AR provided; $P < 0.01$).

Harms: No complications were reported by the RCT.[7]

Comment: None.

OPTION EARLY WEIGHT BEARING

One systematic review provided insufficient evidence on the effects of early weight bearing.

Benefits: We found one systematic review (search date 1998, 1 relevant RCT, 56 people).[7] The RCT compared early weight bearing (initial weight bearing in a cast from 2–4 weeks after the operation) with late weight bearing (initial weight bearing 4 weeks after the operation).[7] It found no significant difference in rates of non-union at the site of arthrodesis (1/29 [3%] with early weight bearing *v* 2/27 [7%] with late weight bearing; RR 0.46, 95% CI 0.05 to 4.85).

Harms: See benefits above.

Comment: The only outcome assessed by the RCT was non-union at the site of arthrodesis.[7]

OPTION SLIPPER CASTS

Two RCTs provided insufficient evidence on the effects of plaster slipper casts.

Benefits: We found no systematic review, but found two RCTs.[18,19] The first RCT (54 feet) compared a plaster slipper cast versus a crepe bandage after a Wilson osteotomy (see glossary, p 1415).[18] Cast and dressings were changed 12 days after surgery and then kept on for a further 4 weeks. The RCT found no significant difference between the plaster slipper and the crepe bandage in pain at 3 months, or time to return to normal activities (pain measured on a visual analogue scale, higher score = more painful, lower score = less painful, scale endpoints not stated; pain at 3 months: 1.5 with plaster slipper *v* 1.6 with crepe bandage; time to return to normal activities: 6.2 weeks with plaster slipper *v* 6.6 weeks with crepe bandage; P values not stated for either comparison). The second RCT (52 feet) compared a plaster slipper versus a crepe bandage after first metatarsophalanageal joint fusion.[19] Casts and dressings were changed 12 days after surgery and then kept on for a further 4 weeks. It found no significant difference between the plaster slipper and the crepe bandage in improvement in hallux valgus angle at 6 weeks postoperatively (mean change in hallux valgus angle: –13.4° with plaster slipper *v* –12.8° with crepe bandage, P value not reported).

Harms: The first RCT found that one failed union occurred with crepe bandaging and that two people receiving plaster slipper cast treatment developed superficial wound infections.[18] The second RCT found three failed corrections, four non-unions, and two wound infections in the plaster slipper group and one failed correction, one non-union, and two wound infections in the crepe bandage group.[19]

Comment: Both RCTs were small and may have lacked power to detect clinically significant differences between the groups.[18,19]

GLOSSARY

Akin osteotomy A procedure involving resection of the medial prominence of the first metatarsal head and a medial wedge osteotomy of the proximal phalanx of the great toe.

Antipronatory orthoses Insoles designed to reduce the amount of in-roll or flattening of the foot when walking.

AOFAS score American Orthopaedic Foot and Ankle Society functional assessment score, ranging from 0 to 100, higher scores indicating better functional ability.

Chevron osteotomy A v-shaped wedge of bone is removed from the distal end of the metatarsal shaft, allowing the metatarsal head to be realigned on the shaft.

Cock-up deformity Inability to place pulp of the great toe on the ground with the foot weight bearing.

Distal metatarsal osteotomy A cut is made in the neck of the metatarsal so that the head of the metatarsal can be realigned on the shaft.

Distal soft tissue reconstruction A procedure involving the release of various ligaments, the capsule, and tendons around the first metatarsophalangeal joint.

First ray The first metatarsal and medial cuneiform function as a single unit called the first ray.
Keller's arthroplasty A procedure involving removal of the medial side of the metatarsal head and straight resection of the base of the proximal phalanx.
Kirschner wire A thin but rigid wire that is used to fix bone fragments. It is passed through drilled channels in the bone (sometimes called a K-wire).
Mitchell's osteotomy A form of distal metatarsal osteotomy, whereby an incomplete osteotomy is performed perpendicular to the long axis of the bone. The distal portion is moved laterally and fixed in position. This results in shortening of the bone.
Proximal chevron osteotomy Removal of a V-shaped wedge of bone from the base of the metatarsal shaft, followed by displacement and fixation of the distal portion of bone.
Proximal crescentic osteotomy A curved cut is made across the base of the metatarsal shaft. The distal portion of bone is slid across the proximal end of bone and fixed into a corrected position.
Transfer lesions Areas of corns or callus that develop when the weight bearing forces are transferred from one area of the foot to another.
Transfer pain Refers to pain that occurs in another area of the foot after surgery. It usually occurs in the second/third metatarsal heads after the surgeon has altered the first metatarsal head.
Wilson osteotomy A double oblique cut is made in the distal portion of the metatarsal shaft and the metatarsal head is slid into a corrected position.

Substantive changes

Different methods of bone fixation No evidence added; re-categorised as unknown effectiveness after review of evidence and discussion with author.
Slipper casts One RCT added;[19] categorisation unchanged.

Carpal tunnel syndrome

Search date September 2002

Shawn Marshall

QUESTIONS

INTERVENTIONS

See glossary, p 1432

Key Messages

- **Diuretics** One small RCT found no significant difference with trichlormethiazide versus placebo in mean global symptom score after 2 or 4 weeks. One RCT found no significant difference with bendrofluazide versus placebo in the proportion of people with no improvement in symptoms after 4 weeks.
- **Endoscopic carpal tunnel release versus open carpal tunnel release** We found no RCTs comparing surgery versus placebo. One systematic review and subsequent RCTs found no clear evidence of a difference in symptoms with endoscopic carpal tunnel release versus open carpal tunnel release up to 12 months after the operation. RCTs found conflicting evidence on differences in the time taken to return to work between endoscopic carpal tunnel release versus open carpal tunnel release. Harms resulting from endoscopic carpal tunnel release and open carpal tunnel release vary between RCTs. One systematic review comparing the interventions suggests that endoscopic carpal tunnel release may cause more transient nerve problems whereas open carpal tunnel release may cause more wound problems.
- **Internal neurolysis in conjunction with open carpal tunnel release** Three RCTs found no significant difference with open carpal tunnel release alone versus open carpal tunnel release plus internal neurolysis in symptoms.

Carpal tunnel syndrome

- **Local corticosteroid injection (short term)** Two RCTs found local corticosteroid injection (methylprednisolone, hydrocortisone) versus placebo or no treatment significantly improved symptoms after 4–6 weeks. One small RCT found that local betamethasone injection versus betamethasone injection into the deltoid significantly improved symptoms after 1 month. One RCT found no significant difference with local methylprednisolone injection versus oral prednisolone in symptoms after 2 weeks, but found that local methylprednisolone injection versus oral prednisolone significantly improved symptoms after 8 and 12 weeks. One small RCT found that local methylprednisolone injection versus helium neon laser significantly improved symptoms after 20 days, but found no significant difference in symptoms between the two groups after 6 months. One small RCT found no significant difference with local methylprednisolone injection versus non-steroidal anti-inflammatory plus nocturnal neutral angle wrist splints in symptoms after 2 or 8 weeks.
- **Nerve and tendon gliding exercises** One small RCT found no significant difference with nerve and tendon gliding exercises plus neutral angle wrist splint versus neutral angle wrist splint alone in mean symptom severity score or mean functional status score assessed 8 weeks after the end of the treatment.
- **Non-steroidal anti-inflammatory drugs** One small RCT found no significant difference with tenoxicam versus placebo in mean global symptom score after 2 or 4 weeks. One RCT found no significant difference in symptom severity scores with ibuprofen plus nocturnal wrist splint versus chiropractic manipulation plus ultrasound plus nocturnal wrist splint after 9 weeks.
- **Oral corticosteroids (short term)** One small RCT found that oral prednisone versus placebo significantly improved the mean global symptom score after 2 weeks, but not after 4 or 8 weeks. One small RCT found that oral prednisolone versus placebo significantly improved the mean global symptom score after 2 and 4 weeks. One small RCT found that oral prednisolone versus placebo significantly improved the median global symptom score after 2 and 8 weeks. One RCT found no significant difference with local methylprednisolone injection versus oral prednisolone in symptoms after 2 weeks, but found that local methylprednisolone injection versus oral prednisolone significantly improved symptoms after 8 and 12 weeks.
- **Pyridoxine** One very small RCT found a similar improvement in symptoms with pyridoxine versus placebo or no treatment after 10 weeks. The RCT may have been too small to detect a clinically important difference between treatments. One small RCT found no significant difference with pyridoxine versus placebo in nocturnal pain, numbness, or tingling after 12 weeks.
- **Surgery versus placebo or non-surgical intervention** We found no RCTs comparing surgery versus placebo. One very small RCT found limited evidence that surgical section of the anterior carpal ligament versus splinting of the hand, wrist, and arm for 1 month increased the proportion of people with clinical improvement after 1 year.
- **Therapeutic ultrasound** One RCT found ultrasound versus placebo significantly increased the proportion of wrists with satisfactory improvement or complete remission of symptoms after 6 months. One RCT found no significant difference in mean symptom severity with high intensity or low intensity ultrasound versus placebo after 2 weeks. One RCT found no significant difference in symptom severity scores with ibuprofen plus nocturnal wrist splint versus chiropractic manipulation plus ultrasound plus nocturnal wrist splint after 9 weeks.

- **Wrist splints** One RCT found a significant improvement in symptoms after 2 and 4 weeks with a nocturnal hand brace versus no treatment. RCTs found no significant difference in symptoms with neutral angle versus 20° extension wrist splinting, or with full time versus night time only neutral angle wrist splinting.
- **Wrist splints after carpal tunnel release surgery** Two RCTs in people after carpal tunnel release surgery found no significant difference with wrist splinting versus no splinting in median grip strength or in the number of people who considered themselves "cured". Another RCT found that splinting versus no splinting significantly increased pain at 1 month and the number of days taken to return to work.
- **Local corticosteroid injection (long term); oral corticosteroids (long term)** We found no RCTs on the effects of these interventions.

DEFINITION

Carpal tunnel syndrome is a neuropathy caused by compression of the median nerve within the carpal tunnel.[1] Classical symptoms of carpal tunnel syndrome include numbness, tingling, burning, or pain in at least two of the three digits supplied by the median nerve (i.e. the thumb, index, and middle fingers).[2] The American Academy of Neurology has described diagnostic criteria (see glossary, p 1432) that rely on a combination of symptoms and physical examination findings.[3] Other diagnostic criteria include results from electrophysiological studies.[2]

INCIDENCE/ PREVALENCE

A general population survey in Rochester, Minnesota, found the age adjusted incidence of carpal tunnel syndrome to be 105 (95% CI 99 to 112) cases per 100 000 person years.[4,5] Age adjusted incidence rates were 52 (95% CI 45 to 59) cases for men and 149 (95% CI 138 to 159) cases for women per 100 000 person years. The study found incidence rates increased from 88 (95% CI 75 to 101) cases per 100 000 person years in 1961–1965 to 125 (95% CI 112 to 138) cases per 100 000 person years in 1976–1980. Incidence rates of carpal tunnel syndrome increased with age for men, whereas for women they peaked between the ages of 45–54 years. A general population survey in the Netherlands found prevalence to be 1% for men and 7% for women.[6] A more comprehensive study in southern Sweden found the general population prevalence for carpal tunnel syndrome was 3% (95% CI 2% to 3%).[7] As in other studies, the overall prevalence in women was higher than in men (male to female ratio 1 : 1.4); however, among older people, the prevalence in women was almost four times that in men (age group 65–74 years: men 1%, 95% CI 0% to 4%; women 5%, 95% CI 3% to 8%).

AETIOLOGY/ RISK FACTORS

Most cases of carpal tunnel syndrome have no easily identifiable cause (idiopathic).[4] Secondary causes of carpal tunnel syndrome include the following: space occupying lesions (tumours, hypertrophic synovial tissue, fracture callus, and osteophytes); metabolic and physiological (pregnancy, hypothyroidism, rheumatoid arthritis); infections; neuropathies (associated with diabetes mellitus or alcoholism); and familial disorders.[4] One case control study found that risk factors in the general population included repetitive activities requiring wrist extension or flexion, obesity, very rapid dieting, shorter height, hysterectomy without oopherectomy, and recent menopause.[8]

PROGNOSIS One observational study (carpal tunnel syndrome defined by symptoms and electrophysiological study results) found that 34% of people with idiopathic carpal tunnel syndrome without treatment had complete resolution of symptoms (remission) within 6 months of diagnosis.[9] Remission rates were higher for younger age groups, for women versus men, and for pregnant versus non-pregnant women. A more recent observational study of untreated idiopathic carpal tunnel syndrome also demonstrated that symptoms may spontaneously resolve in some people. The main positive prognostic indicators were short duration of symptoms and young age, whereas bilateral symptoms and a positive Phalen's test were indicators of a poorer prognosis.[10]

AIMS OF INTERVENTION To improve symptoms and reduce the physical signs of carpal tunnel syndrome; to prevent progression and loss of hand function secondary to carpal tunnel syndrome; to minimise loss of time from work.

OUTCOMES Clinical improvement of symptoms and reduction in physical signs; hand function; time to return to work.

METHODS *Clinical Evidence* search and appraisal September 2002.

QUESTION What are the effects of drug treatment?

OPTION ORAL CORTICOSTEROIDS

One small RCT found that oral prednisone versus placebo significantly improved the mean global symptom score after 2 weeks, but not after 4 or 8 weeks. One small RCT found that oral prednisolone versus placebo significantly improved the mean global symptom score after 2 and 4 weeks. One small RCT found that oral prednisolone versus placebo significantly improved the median global symptom score after 2 and 8 weeks. We found no RCTs that measured the effects of oral corticosteroids on symptoms long term. One RCT found no significant difference with local methylprednisolone injection versus oral prednisolone in symptoms after 2 weeks, but found that local methylprednisolone injection versus oral prednisolone significantly improved symptoms after 8 and 12 weeks.

Benefits: **Versus placebo:** We found one systematic review (search date 2000),[11] which included two RCTs[12,13] and found one subsequent RCT.[14] The systematic review did not pool data.[11] The first RCT (15 people) included in the review compared oral prednisone (20 mg daily for the first wk followed by 10 mg daily for the second wk) versus placebo.[12] The RCT found that prednisone significantly improved symptoms based on the mean Global Symptom Score (GSS) (see glossary, p 1432) compared with placebo at 2 weeks' follow up, but significance was not maintained at 4 or 8 weeks' follow up (results presented graphically; CI not provided). The second RCT (91 people) included in the review compared four treatments: oral prednisolone (20 mg daily for 2 wks followed by 10 mg daily for another 2 wks); an oral slow release non-steroidal anti-inflammatory drug (tenoxicam 20 mg daily); an oral diuretic (trichlormethiazide 2 mg daily); and placebo (see comment

below).[13] It found that prednisolone (26 people) versus placebo (23 people) significantly reduced the mean GSS after 2 weeks (difference in mean GSS –6.6, 95% CI –10.4 to –2.8) and after 4 weeks (–10.8, 95% CI –15.0 to –6.7). The subsequent RCT (36 people) compared oral prednisolone (25 mg daily for 10 days) versus placebo.[14] The RCT found that prednisolone versus placebo significantly reduced the median GSS after 2 weeks (difference in median GSS –6, 95% CI –11 to –1) and after 8 weeks (difference in median GSS –6, 95% CI –11 to 0). **Versus injected corticosteroids:** We found one systematic review[15] that included one RCT (60 people)[16] comparing a single local corticosteroid injection (methylprednisolone 15 mg) plus oral placebo versus oral corticosteroid (prednisolone 25 mg daily for 10 days) plus placebo injection. The review found no significant difference in the mean GSS with local methylprednisolone injection versus oral prednisolone after 2 weeks (WMD –4.2, 95% CI –8.7 to +0.3), but found a significant improvement with local methylprednisolone injection versus oral prednisolone after 8 weeks (WMD –7.2, 95% CI –11.5 to –2.9) and 12 weeks (WMD –7.0, 95% CI –11.6 to –2.4).[15]

Harms: In the first RCT comparing oral prednisone versus placebo, three people in each group reported adverse effects, although none of these people discontinued their treatment.[12] In the prednisone group, one person with diabetes reported mild hyperglycaemia, whereas other reported symptoms included nausea, abdominal discomfort, constipation, and altered taste sensation. Symptoms in the placebo group included nausea, abdominal discomfort, constipation, insomnia, headache, dysuria, and burning nostrils. In the second RCT comparing oral prednisolone versus placebo adverse effects reported included nausea and epigastric pain (nausea: 3/23 [13%] of people with prednisolone *v* 1/16 [6%] of people with placebo; epigastric pain: 2/23 [9%] *v* 2/16 [12%]).[13] The subsequent RCT did not report adverse events.[14] The RCT comparing local corticosteroid injection versus oral corticosteroid reported nine side effects in the oral prednisolone and placebo injection group: bloating (2 people), insomnia (2 people), polyphagia (3 people), and injection pain (2 people).[15] The RCT reported two people had injection pain in the local corticosteroid injection group. Common adverse reactions to oral corticosteroids include nausea, anxiety, acne, menstrual irregularities, insomnia, headaches, and mood swings. More serious adverse reactions include peptic ulcer, steroid psychosis, osteoporosis, and adrenal insufficiency.[17]

Comment: The RCT comparing oral prednisolone versus placebo reported that 18/91 (20%) people did not complete the trial, although analysis of data was not by intention to treat.[13]

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One small RCT found no significant difference with tenoxicam versus placebo in mean global symptom score after 2 or 4 weeks. One RCT found no significant difference in symptom severity scores with ibuprofen plus nocturnal wrist splint versus chiropractic manipulation plus ultrasound plus nocturnal wrist splint after 9 weeks.

Benefits: **Versus placebo:** We found one systematic review (search date 2000),[11] which included one RCT.[13] The RCT (91 people) included in the review compared four treatments: prednisolone; an oral slow release non-steroidal anti-inflammatory drug (NSAID) (tenoxicam 20 mg daily for 4 wks); trichlormethiazide; and placebo (see the benefits and comment under oral corticosteroids, p 1420).[13] It found that tenoxicam (18 people) versus placebo (16 people) did not significantly alter mean Global Symptom Score (see glossary, p 1432) after 2 weeks (difference in mean Global Symptom Score +3.1, 95% CI −1.4 to +7.6) or after 4 weeks (+3.2, 95% CI −1.7 to +8.1). **Versus other treatments:** We found one systematic review (search date 2000),[11] which included one RCT.[18] The RCT (91 people, age 21–45 years) included in the review compared an oral NSAID (ibuprofen 800 mg 3 times daily for 1 wk, then twice daily for 1 wk, and then as needed for 7 wks) plus nocturnal wrist splints versus chiropractic manipulation (3 sessions/wk for 2 wks, then 2 sessions/wk for 3 wks, then 1 session/wk for 4 wks) plus ultrasound treatments (1.0–1.5 W/cm^2 for 5 min) plus nocturnal wrist splints.[18] The RCT found no significant difference between treatments in symptom severity after 9 weeks (difference in mean symptom severity score for NSAID group *v* non-NSAID group −2.4, 95% CI −7.5 to +2.7; see comment below).[18]

Harms: The RCT comparing tenoxicam versus placebo reported nausea (3/18 [17%] of people with tenoxicam *v* 1/16 [6%] of people with placebo) and epigastric pain (3/18 [17%] *v* 2/16 [12%]).[13] The RCT comparing ibuprofen plus wrist splints versus chiropractic manipulation plus ultrasound plus wrist splints reported 10/46 (22%) people taking ibuprofen reported acute gastrointestinal intolerance, headache, and nausea.[18] Of these 10 people, 5/46 (11%) withdrew from the medication and 5/46 (11%) continued to take ibuprofen with an additional liquid antacid (see NSAIDs topic, p 1551). One person reported a sore neck after chiropractic manipulation.[18]

Comment: The RCT comparing ibuprofen plus wrist splints versus chiropractic manipulation plus ultrasound plus wrist splints used a numerical scoring system to grade symptom severity (0 = no symptoms; 16 = severe symptoms).[18]

OPTION DIURETICS

One small RCT found no significant difference with trichlormethiazide versus placebo in mean global symptom score after 2 or 4 weeks. One RCT found no significant difference with bendrofluazide versus placebo in the proportion of people with no improvement in symptoms after 4 weeks.

Benefits: We found one systematic review (search date 2000),[11] which included two RCTs.[13,19] The review did not pool data. The first RCT (91 people) included in the review compared four treatments: prednisolone; a non-steroidal anti-inflammatory drug; an oral diuretic (trichlormethiazide 2 mg daily for 4 wks); and placebo (see benefits and comment under oral corticosteroids, p 1420).[13] It found that trichlormethiazide (16 people) versus placebo (16 people) did not significantly alter mean Global Symptom Score (see

glossary, p 1432) after either 2 weeks (difference in mean Global Symptom Score +0.7, 95% CI −3.0 to +4.4) or after 4 weeks (+0.8, −3.2 to +4.8).[13] The second RCT (48 people, 81 hands) included in the review compared bendrofluazide 5 mg daily for 4 weeks versus placebo.[19] It found no significant difference with bendrofluazide versus placebo the proportion of people with "no improvement in symptoms at all" after 4 weeks (no improvement at all: 54% of people with bendrofluazide *v* 50% of people with placebo; difference +4%, 95% CI −18% to +25%; see comment below).[11]

Harms: The first RCT reported epigastric pain in 2/16 (12%) people with diuretic versus 2/16 (12%) people with placebo.[13] The second RCT reported one person "felt unwell in a nonspecific way" on bendrofluazide and was withdrawn from the study.[19]

Comment: The RCT comparing bendrofluazide versus placebo used a numerical score from 0 to 5 to assess the degree of improvement in symptoms reported by people (0 = no improvement at all; 5 = full recovery).[19]

OPTION PYRIDOXINE

One very small RCT found a similar improvement in symptoms with pyridoxine versus placebo or no treatment after 10 weeks. The RCT may have been too small to detect a clinically important difference between treatments. One small RCT found no significant difference with pyridoxine versus placebo in nocturnal pain, numbness, or tingling after 12 weeks.

Benefits: We found one systematic review (search date 2000),[11] which included two RCTs.[20,21] The review did not pool data.[11] The first RCT (15 people) included in the review compared oral pyridoxine (200 mg daily); placebo (dextrose pill); and no treatment.[21] The RCT found a similar improvement in symptoms with pyridoxine versus placebo or no treatment after 10 weeks (symptoms improved: 3/6 [50%] with pyridoxine *v* 4/5 [80%] with placebo *v* 3/4 [75%] with no treatment; no statistical analysis reported; see comment below).[21] The second RCT (35 people) included in the review compared oral pyridoxine (200 mg daily) versus placebo.[20] The RCT found no significant difference with pyridoxine versus placebo in nocturnal pain, numbness, or tingling after 12 weeks (reported as not significant; P values not provided).[20]

Harms: Neither RCT reported harms.[20,21] Common adverse reactions associated with pyridoxine include numbness, paraesthesia, and an unsteady gait.[17]

Comment: The first RCT did not specify which symptoms were assessed nor how changes were scored.[21] The RCT may have been too small to detect a clinically important difference between treatments.[21] The second RCT used an unvalidated 4-point questionnaire with discrete numerical scoring of symptom severity (0 = no symptoms; 4 = severe symptoms).[20]

OPTION LOCAL CORTICOSTEROID INJECTION

Two RCTs found local corticosteroid injection (methylprednisolone, hydrocortisone) versus placebo or no treatment significantly improved symptoms after 4–6 weeks. One small RCT found that local betamethasone injection versus betamethasone injection into the deltoid significantly improved symptoms after 1 month. One RCT found no significant difference with local methylprednisolone injection versus oral prednisolone in symptoms after 2 weeks, but found that local methylprednisolone injection versus oral prednisolone significantly improved symptoms after 8 and 12 weeks. One small RCT found that local methylprednisolone injection versus helium neon laser significantly improved symptoms after 20 days, but found no significant difference in symptoms between the two groups after 6 months. One small RCT found no significant difference with local methylprednisolone injection versus non-steroidal anti-inflammatory plus nocturnal neutral angle wrist splints in symptoms after 2 or 8 weeks. We found no RCTs that assessed long term outcomes.

Benefits: We found one systematic review (search date 2002, 5 RCTs, 220 people)[15] and one additional RCT.[22] **Versus placebo or no treatment:** The systematic review included one RCT, which compared local injection of methylprednisolone (40 mg) versus local placebo injection.[23] The review found that local methylprednisolone injection versus placebo injection significantly improved symptom severity after 1 month (clinical improvement: 23/30 [77%] with methylprednisolone injection *v* 6/30 [20%] with placebo injection; RR 3.8, 95% CI 1.82 to 8.05; see comment below).[15] The additional RCT compared three treatments: local injection of low dose hydrocortisone (25 mg); local injection of high dose hydrocortisone (100 mg); and no injection.[22] It found significant improvement after 6 weeks in the number of people with improved symptoms with both doses of hydrocortisone versus no injection (see comment below; 21/32 [66%] with low dose hydrocortisone *v* 1/20 [5%] with no injection; RR 13.1, 95% CI 1.9 to 90.1; NNT 2, 95% CI 2 to 3; 20/32 [63%] with high dose hydrocortisone *v* 1/20 [5%] with no injection; RR 12.5, 95% CI 1.8 to 86.0; NNT 2, 95% CI 2 to 4). The RCT found no significant difference after 6 weeks in the number of people with improvement with low dose versus high dose hydrocortisone (21/32 [66%] with low dose hydrocortisone *v* 20/32 [63%] with high dose hydrocortisone; RR 1.0, 95% CI 0.7 to 1.5). **Versus systemic steroids:** The systematic review included two RCTs.[16,24] The first RCT included in the review compared local injection of betamethasone (1.5 mg) plus placebo (saline) injection into the deltoid muscle versus local placebo injection plus betamethasone (1.5 mg) injection into the deltoid muscle.[24] The review found that local betamethasone injection versus systemic betamethasone injection significantly improved symptom severity after 1 month (clinical improvement: 9/18 [50%] with local injection *v* 3/19 [16%] with systemic injection; RR 3.17, 95% CI 1.02 to 9.87; see comment below).[15] The second RCT included in the review compared a single local corticosteroid injection plus oral placebo versus oral corticosteroid plus placebo injection.[16] See benefits of oral corticosteroids, p 1420. **Versus helium neon laser:** The systematic

review included one RCT, which compared local injection of methylprednisolone (20 mg) at baseline and 10 days later versus helium neon laser treatments given daily (3000 Hz for 20 min sessions, for an unstated number of days).[15] The review found that local injection of methylprednisolone versus helium neon laser significantly improved symptoms after 20 days (RR 0.27, 95% CI 0.09 to 0.83) but found no significant difference between the groups in symptoms after 6 months (RR 0.76, 95% CI 0.48 to 1.21).[15] **Versus oral non-steroidal anti-inflammatory plus neutral angle wrist splint:** The systematic review included one small RCT (23 people), which compared a local injection of methylprednisolone (40 mg), 4 cm proximal to the wrist crease, versus acemetacin (120 mg/day) plus neutral angle wrist splints worn at night.[15] The review found no significant difference with methylprednisolone injection versus non-steroidal anti-inflammatory plus nocturnal splints in symptoms measured by the symptom severity scale at 2 weeks (WMD 0.00, 95% CI −0.64 to +0.64) or 8 weeks (WMD 0.10, 95% CI −0.33 to +0.53).[15]

Harms: The systematic review did not report adverse events.[15] The RCT comparing local corticosteroid injection versus oral corticosteroid reported nine side effects in the oral prednisolone plus placebo injection group: bloating (2 people), insomnia (2 people), polyphagia (3 people), and injection pain (2 people).[16] The RCT reported two people had injection pain in the local corticosteroid injection group. Known serious adverse effects of local corticosteroid injection into the carpal tunnel include tendon rupture and injection into the median nerve.[25]

Comment: Two RCTs included in the systematic review only defined clinical outcomes loosely using a subjective ordinal ranking scale and neither RCT specified the magnitude of symptomatic improvement or the changes in specific symptoms.[23,24] The RCT comparing hydrocortisone injection versus placebo reported the number of people who scored their symptoms as "better" or "much better", but these terms were not quantified and changes in individual symptoms were not described.[22]

QUESTION What are the effects of non-drug treatment?

OPTION WRIST SPLINTS

One RCT found a significant improvement in symptoms after 2 and 4 weeks with a nocturnal hand brace versus no treatment. RCTs found no significant difference in symptoms with neutral angle versus 20° extension wrist splinting, or with full time versus night time only neutral angle wrist splinting.

Benefits: **Versus no treatment:** We found one RCT (83 people) that compared a nocturnal hand brace worn for 4 weeks versus no treatment.[26] It found a significant improvement with nocturnal hand brace versus no treatment in symptoms measured by the Boston Carpal Tunnel Symptom Questionnaire at 2 weeks (−1.03, 95% CI −1.98 to −0.08) and 4 weeks (−1.07, 95% CI −2.01 to −0.13). **Versus other treatments:** We found no RCTs. **Versus different**

splinting regimens: We found one systematic review (search date 1997, 1 RCT)[27] and one subsequent RCT.[28] The RCT in the review (59 people, 90 wrists) compared neutral angle wrist splinting versus wrist splinting in 20° extension (see comment below).[29] It found no significant difference after 2 weeks' follow up in the number of people who reported some degree of improvement in their symptoms (40/45 [89%] with neutral angle splinting *v* 38/45 [84%] with extension splinting; RR 1.1, 95% CI 0.9 to 1.2). The subsequent RCT (24 people) compared full time (day and night) wear of neutral angle wrist splints versus night time only wear. It found no significant difference after 6 weeks in mean symptom severity score (see comment below; difference in mean symptom severity score +0.1, 95% CI −0.3 to +0.5).[28]

Harms: In the RCT comparing nocturnal hand brace to no treatment, four people in the hand brace group experienced transient paraesthesias after the hand brace was removed.[26] Harms were not reported by the other RCTs.

Comment: The RCT in the systematic review graded improvement in symptoms as "none", "some", "a lot", or "complete"; however, individual symptoms and the method for grading changes in symptoms were not described.[29] The subsequent RCT used a validated numerical scale to assess changes in symptom severity.[28] The use of a night time splint was complete or nearly complete in 85% of people allocated to night time splinting only, but 23% of the people reported limited additional daytime use. Complete or nearly complete daytime wear was reported by only 27% of people allocated to full time wear. More men than women were included in the trial than would have been expected from the usual sex distribution of carpal tunnel syndrome.

OPTION NERVE AND TENDON GLIDING EXERCISES

One small RCT found no significant difference with nerve and tendon gliding exercises plus neutral angle wrist splint versus neutral angle wrist splint alone in mean symptom severity score or mean functional status score assessed 8 weeks after the end of the treatment.

Benefits: We found no systematic review but found one RCT.[30] The RCT (28 people, 36 wrists) compared nerve gliding and tendon gliding exercises (see glossary, p 1432) plus a custom made neutral angle wrist splint versus a wrist splint alone. The nerve and tendon gliding exercises were undertaken five times per day for 4 weeks, and people were instructed to wear the neutral angle wrist splints all night and during the day as much as possible for 4 weeks. The RCT found no significant difference with nerve and tendon gliding exercises plus neutral angle wrist splint versus neutral angle wrist splint alone in mean Symptom Severity score ($P = 0.2$) or mean Functional Status score ($P = 0.5$) at 8 weeks after the end of the treatment (see comment below).[30] The RCT found a significant improvement for pinch strength with exercise compared with wrist splint alone ($P = 0.026$) but found no significant difference in other physical examination parameters (grip strength, Phalen's sign, or Tinel's sign; see comment below).

Harms: The RCT did not report adverse events.[30]

Comment: The Symptom Severity Scale has 11 items concerning pain, nocturnal symptoms, numbness, tingling, and weakness; the Functional Status Scale measures eight items including difficulty in writing, buttoning clothes, opening jars, holding a book, gripping a telephone handle, household chores, carrying of grocery bags, bathing, and dressing.[30] Phalen's sign was performed by full flexion of the wrist for 60 seconds with the test recorded positive if paresthesia was experienced in at least one of three radial digits.[30] Tinel's sign was performed by percussing the median nerve at the wrist with the test recorded positive if paresthesia was experienced in at least one of three radial digits.[30]

OPTION THERAPEUTIC ULTRASOUND

One RCT found ultrasound versus placebo significantly increased the proportion of wrists with satisfactory improvement or complete remission of symptoms after 6 months. One RCT found no significant difference in mean symptom severity with high intensity or low intensity ultrasound versus placebo after 2 weeks. One RCT found no significant difference in symptom severity scores with ibuprofen plus nocturnal wrist splint versus chiropractic manipulation plus ultrasound plus nocturnal wrist splint after 9 weeks.

Benefits: **Versus placebo:** We found one systematic review (search date 2000),[11] which included two RCTs.[31,32] The review did not pool data.[11] The first RCT (45 people, 90 wrists) included in the review compared ultrasound (15 min, 5 times weekly for 2 wks followed by twice weekly for 5 wks at an intensity of 1.0 W/cm^2) versus placebo.[32] The dominant wrist was randomly allocated to ultrasound or placebo and the contralateral wrist was allocated to the other treatment. The RCT found at 6 months that significantly more wrists receiving ultrasound treatment had satisfactory improvement or complete remission of symptoms (22/30 [73%] wrists with ultrasound *v* 6/30 [20%] wrists with placebo; RR 3.7, 95% CI 1.7 to 7.7; NNT 2, 95% CI 2 to 4; see comment below).[32] The second RCT (18 women, 30 wrists) included in the review compared three groups: low intensity ultrasound (0.8 W/cm^2); high intensity ultrasound (1.5 W/cm^2); and placebo.[31] Each treatment was performed for 5 minutes, five times a week for 2 weeks. The RCT found no significant difference between low and high intensity ultrasound treatments or between either ultrasound treatment and placebo in mean symptom severity graded on a visual analogue scale at 2 weeks (mean difference with high intensity ultrasound *v* placebo −1.1, 95% CI −3.0 to +0.9; mean difference with low intensity ultrasound *v* placebo −0.4, 95% CI −2.5 to +1.6; mean difference with high intensity ultrasound *v* low intensity ultrasound −0.7, 95% CI −2.4 to +0.9).[31] **Plus chiropractic manipulation plus nocturnal wrist splint:** We found one systematic review,[11] which included one RCT[18] comparing ultrasound plus chiropractic manipulation plus nocturnal wrist splint versus ibuprofen plus wrist splint (see NSAIDs option, p 1422).

Harms: The RCT comparing ultrasound plus chiropractic manipulation plus wrist splint versus ibuprofen plus wrist splint found 10/46 (22%) people taking ibuprofen reported acute gastrointestinal intolerance, headache, and nausea.[18] Of these 10 people, 5/46 (11%) withdrew from the medication and 5/46 (11%) continued to take ibuprofen with an additional liquid antacid (see NSAIDs topic, p 1551). One person reported a sore neck after chiropractic manipulation.[18]

Comment: In the first RCT, 15/45 (33%) people did not complete the trial and analysis of data was not by intention to treat.[32] The RCT used "satisfactory improvement" and "complete remission" as outcome measures, although these terms were not clearly defined. The RCT comparing ultrasound plus chiropractic manipulation plus wrist splint versus ibuprofen plus wrist splint used a numerical scoring system to grade symptom severity (0 = no symptoms; 16 = severe symptoms).[18]

QUESTION What are the effects of surgical treatment?

OPTION SURGERY

We found no RCTs comparing surgery versus placebo. One very small RCT found limited evidence that surgical section of the anterior carpal ligament versus splinting of the hand, wrist, and arm for one month increased the proportion of people with clinical improvement after 1 year. One systematic review and subsequent RCTs found no clear evidence of a difference in symptoms with endoscopic carpal tunnel release versus open carpal tunnel release up to 12 months after the operation. RCTs found conflicting evidence on differences in the time taken to return to work between endoscopic carpal tunnel release versus open carpal tunnel release. Harms resulting from endoscopic carpal tunnel release and open carpal tunnel release vary between RCTs. One systematic review comparing the interventions suggests that endoscopic carpal tunnel release may cause more transient nerve problems whereas open carpal tunnel release may cause more wound problems.

Benefits: We found two systematic reviews (search date 2000, 14 RCTS, 1179 people;[33] search date 2001, 1 RCT, 22 women[34]) and one non-systematic review (search date 1997, 4 RCTs, 1394 people).[35] **Surgery versus placebo or non-surgical intervention:** We found no RCTs comparing surgery versus placebo. We found one systematic review, which included one very small RCT (22 women, symptoms ranging from 1 month to 20 years) comparing open surgical section of the anterior carpal ligament versus splinting of the hand, wrist, and arm for 1 month.[34] The review found surgical section of the anterior carpal ligament versus splinting of the hand, wrist, and arm significantly increased the proportion of people with clinical improvement after 1 year (clinical improvement: 10/11 [91%] with surgery v 2/11 [18%] with splinting; RR 5, 95% CI 1.4 to 17.8; see comment below).[34] **Endoscopic versus open carpal tunnel release:** We found one systematic review (search date 2000, 7 RCTS, 739 people; see comment below)[33] and two subsequent RCTs.[36,37] The systematic review included three "high quality" RCTs

and four "low quality" RCTs comparing endoscopic carpal tunnel release versus open carpal tunnel release.[33] The systematic review included three RCTs that assessed effects on symptoms after 3 months.[33] It found no significant difference in symptoms after 3 months with endoscopic versus open carpal tunnel release (reported as improvement in paraesthesia, numbness in 99% with endoscopic carpal tunnel release *v* 98% with open carpal tunnel release after 12 wks, difference +1%, 95% CI −3 to +5% in 1 RCT; reported as "no significant difference" in pain after 3 months in 1 RCT; reported as "no significant difference" in symptom severity score after 3 months in 1 RCT; P values not provided).[33] The systematic review included one RCT that evaluated effects on symptoms after 6 months and 12 months. It found no significant difference in pain with endoscopic versus open carpal tunnel release after 6 months and 12 months (reported as "no significant difference"; P value not provided).[33] The first subsequent small RCT (26 men) found that tingling sensations and severity of night time numbness were improved in the endoscopic versus the open carpal tunnel release group at 2 weeks, but were no longer significantly different by 4 weeks (P values not provided).[37] It found endoscopic versus open carpal tunnel release significantly improved the severity of night time hand or wrist pain after 4 weeks (P value not provided).[37] The second subsequent RCT (25 people with bilateral carpal tunnel syndrome) randomly assigned one wrist to undergo endoscopic release, at which time the contralateral wrist on the same person was assigned to undergo open release.[36] All operations in the RCT were carried out by the same surgeon. The RCT found no significant difference with endoscopic versus open carpal tunnel release in hand function, grip strength, or sensation assessed at 6, 12, 26, or 52 weeks after the operation (reported as not significant; results presented graphically; P value not provided).[36] The RCT found no significant difference with endoscopic versus open carpal tunnel release in people's satisfaction with either procedure assessed over the same period (reported as not significant; results presented graphically; P value not provided).[36] Four RCTs included in the systematic review found a significant decrease in the time taken to return to work and/or activities of daily living with endoscopic carpal tunnel release versus open carpal tunnel release (endoscopic carpal tunnel release *v* open carpal tunnel release: reported as median 14 days *v* 28 days, $P < 0.05$ in 1 RCT; mean 24 days *v* 42 days, $P < 0.05$ in 1 RCT; mean 14 days *v* 39 days, $P < 0.05$ in 1 RCT; mean 20 days *v* 30 days, $P < 0.05$ in 1 RCT), whereas three RCTs included in the review found no significant difference (endoscopic carpal tunnel release *v* open carpal tunnel release: reported as mean 17 days *v* 19 days, "no significant difference" in 1 RCT; reported as more than 4 wks absence from work 16% *v* 13%, difference 3%, 95% CI −7% to +4% in 1 RCT; reported as time to return to work 17 days *v* 17 days, "no significant difference" in 1 RCT; P value not provided).[33]

Harms:

Surgery versus placebo or non surgical intervention: None reported.[34] **Endoscopic versus open carpal tunnel release:** All seven RCTs included in the systematic review reported complications.[33] For endoscopic carpal tunnel release complications reported included partial transection of superficial palmar arch,

digital nerve contusion, ulnar nerve neurapraxia (see glossary, p 1433), wound haematoma, four conversion to the open procedure, transient neurapraxia, three transient numbness on radial side of ring finger, ulnar nerve paraesthesia, incomplete release, increased numbness in fingertips, subcutaneous heamatoma, loss of strength and mobility in wrist, and algodystrophy. For open carpal tunnel release, complications reported included painful hypertrophic scar, reflex sympathetic dystrophy, prolonged wound secretion, wound infection, scar tethering, five scar hypertrophy, two loss of strength, and swollen/stiff fingers. The systematic review stated "it seems that endoscopic carpal tunnel release gives more transient nerve problems (e.g. neurapraxia, numbness, paraesthesia) and open carpal tunnel release more wound problems (e.g. infection, hypertrophic scar, scar tenderness)".[33] The subsequent RCT reported persisting wound pain (1 wrist) with endoscopic release, and persisting symptoms and signs of carpal tunnel syndrome (1 wrist), superficial sensory nerve injury (1 wrist), and persisting wound pain (1 wrist) with open release.[36] Harms resulting from endoscopic and open carpal tunnel release vary between RCTs, although rates of complications for both procedures are generally low.[37–44]

Comment: **Surgery versus placebo or non surgical intervention:** The RCT was not blinded, and there was no information on baseline clinical and electrophysiological status of the two groups.[34] The method of randomisation was not described.[34] **Endoscopic versus open carpal tunnel release:** Meta-analysis in the systematic review was not undertaken as the data could not be pooled.[33] Endoscopic release techniques vary between RCTs, which may account for some of the variation in complication rates.[35]

OPTION INTERNAL NEUROLYSIS IN CONJUNCTION WITH OPEN CARPAL TUNNEL RELEASE

Three RCTs found no significant difference with open carpal tunnel release alone versus open carpal tunnel release plus internal neurolysis in symptoms.

Benefits: We found one systematic review (search date 2000, 3 RCTs, 148 people; see comment below),[33] which included three RCTs, comparing open carpal tunnel release alone versus open carpal tunnel release plus internal neurolysis (see glossary, p 1432).[45–47] The first RCT (59 people, 63 wrists) found no significant difference between treatments in the proportion of people reporting relief from all or the majority of their symptoms after 12 months (28/32 [88%] with open carpal tunnel release alone *v* 25/31 [81%] with open carpal tunnel release plus internal neurolysis; RR 1.1, 95% CI 0.9 to 1.3).[45] The second RCT (48 people, 48 wrists) found no significant difference between treatments in the proportion of people who reported complete relief of symptoms after 6 months (23/24 [96%] with open carpal tunnel release alone *v* 23/24 [96%] with open carpal tunnel release plus internal neurolysis; RR 1.0, 95% CI 0.9 to 1.1).[47] The third RCT (41 people, 47 wrists with severe carpal tunnel syndrome; see comment below) found no significant difference between treatments in the proportion of wrists with a good

(resolution of pain, improvement in sensory deficit, and no surgical complications) or excellent (resolution of pain, resolution of sensory deficit, and no surgical complications) clinical response (15/23 [65%] wrists with open carpal tunnel release alone *v* 16/24 [67%] wrists with open carpal tunnel release plus internal neurolysis; RR 1.0, 95% CI 0.6 to 1.5).[46]

Harms: The first and second RCTs did not report harms.[45,47] The third RCT (41 people, 47 wrists) found no significant difference between treatments in the proportion of wrists with persistent incisional pain, which was the most common complication reported in the trial (3/23 [13%] of wrists with open carpal tunnel release alone *v* 4/24 [17%] of wrists with open carpal tunnel release plus internal neurolysis; RR 0.8, 95% CI 0.2 to 3.1).[46] Other complications included 4% (1/24) wrists with hand swelling, 4% (1/24) wrists with adhesive capsulitis (see glossary, p 1432) in the open carpal tunnel release plus internal neurolysis group, and 4% (1/23) wrists with causalgia in the open carpal tunnel release alone group.

Comment: Meta-analysis in the systematic review was not undertaken as the data could not be pooled.[33] The third RCT defined severe carpal tunnel syndrome as including thenar atrophy, a fixed sensory deficit, or both, in addition to the more common symptoms and signs associated with the syndrome.[45]

QUESTION What are the effects of postoperative treatment?

OPTION WRIST SPLINTS AFTER CARPAL TUNNEL RELEASE SURGERY

Two RCTs in people after carpal tunnel release surgery found no significant difference with wrist splinting versus no splinting in median grip strength or in the number of people who considered themselves "cured". Another RCT found that splinting versus no splinting significantly increased pain at 1 month and the number of days taken to return to work.

Benefits: **Versus unrestricted range of motion:** We found no systematic review. We found three RCTs.[48–50] The first RCT (74 people, 82 wrists) compared rigid wrist splinting for 4 weeks after surgery versus no splinting plus advice to mobilise the affected wrist or wrists.[48] It found no significant difference between treatments in median grip strength (as a percentage of median preoperative grip strength: unsplinted 78%, 95% CI 70% to 86% *v* splinted 76%, 95% CI, 71% to 85%). The second RCT (47 people, 51 wrists) compared rigid wrist splinting for 2 weeks after surgery versus no splinting.[49] It found no significant difference in the number of people who considered themselves "cured" at follow up (see comment below; 12/26 [46%] with splinting *v* 8/17 [47%] with no splinting; RR 1.0, 95% CI 0.5 to 1.9). The third RCT (50 people, 50 wrists) compared rigid wrist splinting for 2 weeks after surgery versus no splinting.[50] It found that the average number of days taken to return to work was significantly lower in the unsplinted

group (17 days with no splinting *v* 27 days with splinting; P = 0.005; RR and CI not provided). **Versus bulky dressings:** We found one systematic review (search date 1997) comparing wrist splinting versus bulky dressings after carpal tunnel decompression.[27] It found no RCTs.

Harms: The first RCT found no significant difference between treatments in the number of people reporting scar pain after 6 months (6/37 [16%] with splinting *v* 6/44 [14%] with no splinting; RR 1.2, 95% CI 0.4 to 3.4).[48] The second RCT reported complications for one person in the unsplinted group who had persistent symptoms and required reoperation.[49] The third RCT reported that pillar pain (see glossary, p 1432) was increased at 1 months' follow up for the splinted group (P = 0.02), as was scar tenderness (P = 0.04), although subjective scores for pain were not significantly different between treatments at 3 or 6 months after surgery (data not available).[50]

Comment: In the second RCT, although the term "cured" was used as an outcome measure, its meaning was not defined in the context of the trial and the length of follow up was not specified.[48] The RCT found that 7/47 (15%) people were lost to follow up. Analysis of data was not by intention to treat. The RCTs were too small to exclude the possibility of a clinically important increase in the risk of some complications (e.g. transient ulnar nerve injury) with splinting compared with no splinting.

GLOSSARY

Adhesive capsulitis A condition in which the joint capsule becomes contracted and thickened causing restriction in the range of movement.

American Academy of Neurology diagnostic criteria[3] The likelihood of carpal tunnel syndrome increases with the number of standard symptoms and provocative factors. Symptoms include dull aching discomfort in the hand, forearm or upper arm; paraesthesia in the hand; weakness or clumsiness of the hand; dry skin, swelling, or colour changes in the hand; or occurrence of any of these symptoms in the distribution of the median nerve. Provocative factors include sleep, sustained arm or hand positions, or repetitive actions of the hand or wrist. Relieving factors include changes in hand posture and shaking the hand. Physical examination may be normal, or symptoms may be elicited by tapping or direct pressure over the median nerve at the wrist or with forced flexion or extension of the wrist. Physical signs include sensory loss in the median nerve distribution; weakness or atrophy in the thenar muscles; and dry skin on the thumb, index, or middle fingers. Electromyography and nerve conduction studies can confirm, but not exclude, the diagnosis of carpal tunnel syndrome.

Global Symptom Score The numerical sum of five common carpal tunnel syndrome symptoms (pain, numbness, paresthesia, weakness/clumsiness, and nocturnal wakening), which are each rated from 0 (no symptoms) to 10 (severe symptoms).[12,13]

Internal neurolysis Decompression within the nerve accomplished by performing an epineurotomy and then dividing the nerve into multiple fascicular groups.[46]

Nerve gliding exercises Exercise therapy directed at restoring and maximising excursion of the median nerve through the carpal tunnel.[51]

Pillar pain Pain at the radial or ulnar border of the carpal tunnel.

Tendon gliding exercises Exercise therapy directed at restoring and maximising excursion of the finger flexor tendons through the carpal tunnel.[51]

Ulnar neurapraxia Failure of nerve conduction of the ulnar nerve, usually reversible, due to metabolic or microstructural abnormalities without disruption of the axon.

QUESTIONS

INTERVENTIONS

Key Messages

- **Cognitive behavioural therapy** One systematic review found that cognitive behavioural therapy administered by highly skilled therapists in specialist centres improved quality of life and physical functioning compared with standard medical care or relaxation therapy. One additional multicentre RCT found that cognitive behavioural therapy administered by less experienced therapists may also be effective compared with guided support groups or no interventions.
- **Graded aerobic exercise** RCTs have found that a graded aerobic exercise programme improves measures of fatigue and physical functioning compared with flexibility and relaxation training or general advice. One RCT has found that an educational package to encourage graded exercise improved measures of physical functioning, fatigue, mood, and sleep at 1 year compared with written information alone.
- **Dietary supplements** One small RCT found no significant difference between a nutritional supplement (containing multivitamins, minerals, and coenzymes) and placebo in fatigue severity or functional impairment at 10 weeks.
- **Evening primrose oil** One small RCT found no significant difference between evening primrose oil and placebo in depression scores at 3 months.
- **Magnesium (intramuscular)** One small RCT found that intramuscular magnesium injections improved symptoms at 6 weeks compared with placebo. However, we were unable to draw reliable conclusions from this small study.
- **Antidepressants; corticosteroids; oral nicotinamide adenine dinucleotide** RCTs found insufficient evidence about the effects of these interventions in people with chronic fatigue syndrome.

Chronic fatigue syndrome

- **Immunotherapy** Small RCTs found limited evidence that immunoglobulin G modestly improved physical functioning and fatigue at 3–6 months compared with placebo, but it was associated with considerable adverse effects. Small RCTs found insufficient evidence on the effects of interferon alfa or aciclovir compared with placebo. One RCT found that staphylococcus toxoid improved symptoms at six months compared with placebo, although it is associated with local reaction and could cause anaphylaxis.
- **Prolonged rest** We found no RCTs on the effects of prolonged rest. Indirect observational evidence in healthy volunteers and in people recovering from a viral illness suggests that prolonged rest may perpetuate or worsen fatigue and symptoms.

DEFINITION Chronic fatigue syndrome (CFS) is characterised by severe, disabling fatigue and other symptoms, including musculoskeletal pain, sleep disturbance, impaired concentration, and headaches. Two widely used definitions of CFS, from the US Centers for Disease Control and Prevention[1] and from Oxford, UK,[2] were developed as operational criteria for research (see table 1, p 1449). There are important differences between these definitions. The UK criteria insist upon the presence of mental fatigue, whereas the US criteria include a requirement for several physical symptoms, reflecting the belief that CFS has an underlying immunological or infective pathology.

INCIDENCE/ PREVALENCE Community and primary care based studies have reported the prevalence of CFS to be 0–3%, depending on the criteria used.[3,4] Systematic population surveys have found similar prevalences of CFS in people of different socioeconomic status and in all ethnic groups.[4,5]

AETIOLOGY/ RISK FACTORS The cause of CFS is poorly understood. Women are at higher risk than men (RR 1.3–1.7 depending on diagnostic criteria used).[6]

PROGNOSIS Studies have focused on people attending specialist clinics. A systematic review of studies of prognosis (search date 1996) found that children with CFS had better outcomes than adults: 54–94% of children showed definite improvement (after up to 6 years' follow up), whereas 20–50% of adults showed some improvement in the medium term and only 6% returned to premorbid levels of functioning.[7] Despite the considerable burden of morbidity associated with CFS, we found no evidence of increased mortality. The systematic review found that outcome was influenced by the presence of psychiatric disorders (depression and anxiety) and beliefs about causation and treatment.[7]

AIMS OF INTERVENTION To reduce levels of fatigue and associated symptoms, to increase levels of activity, and to improve quality of life.

OUTCOMES Severity of symptoms and their effects on physical function and quality of life. These outcomes are measured in several different ways: the medical outcomes survey short form general health survey (SF-36),[8] a rating scale measuring limitation of physical functioning caused by ill health (score range 0–100, where 0 = limited in all activities and 100 = able to carry out vigorous activities); the Karnofsky scale,[9] a modified questionnaire originally developed for the rating of quality of life in people undergoing chemotherapy for malignancy; the Beck Depression Inventory,[10] a checklist for

quantifying depressive symptoms; the sickness impact profile,[11] a measure of the influence of symptoms on social and physical functioning; the Chalder fatigue scale,[12] a rating scale measuring subjective fatigue (score range 0–11, where scores ≥ 4 = excessive fatigue); the clinical global impression scale,[13] a validated measure of overall change compared with baseline at study onset, with seven possible scores from "very much worse" (score 7) to "very much better" (score 1); the checklist individual strength fatigue subscale (score range 8 (no fatigue at all) to 56 (maximally fatigued)[14]; and self reported severity of symptoms and levels of activity, the Nottingham health profile[15] contains questions in six categories: energy, pain perception, sleep patterns, sense of social isolation, emotional reactions, and physical mobility (weighted scores give maximum 100 for answer yes to all questions, and minimum 0 for someone with no complaints).

METHODS *Clinical Evidence* search and appraisal March 2003.

QUESTION What are the effects of treatments?

OPTION ANTIDEPRESSANTS

RCTs found insufficient evidence about the effects of antidepressants in people with chronic fatigue syndrome.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] **Fluoxetine:** The review identified two RCTs.[17,18] The first RCT (107 depressed and non-depressed people with chronic fatigue syndrome [CFS]) compared fluoxetine versus placebo for 8 weeks.[17] It found that fluoxetine significantly improved the Beck Depression Inventory compared with placebo (mean difference between fluoxetine and placebo in improvement in Beck Depression Inventory –0.19, 95% CI –0.35 to –0.02), but the difference may not be clinically important. It found no significant difference between fluoxetine and placebo in the sickness impact profile (mean difference between fluoxetine and placebo measured by fatigue subscale of Checklist Individual Strength –0.16, 95% CI –0.64 to +0.31).[19] The second RCT (136 people with CFS) compared four groups: fluoxetine plus graded exercise; drug placebo plus graded exercise; fluoxetine plus general advice to exercise; and drug placebo plus general advice to exercise. It found no significant difference in the level of fatigue, although modest improvements in measures of depression were seen at 12 weeks (Hospital Anxiety and Depression scale, mean change 1.1, 95% CI 0.03 to 2.2).[18,20] **Phenelzine:** The review identified one RCT.[16,21] The RCT (30 people with CFS) compared phenelzine versus placebo, using a modified Karnofsky scale and other outcome measures (including functional status questionnaire, profile of mood states, Centres for Epidemiological Study of Depression fatigue severity scale, and symptom severity checklist).[20] This study concluded that there was a pattern of improvement across several measures (significance tests for individual measures not carried out). **Moclobemide:** The review identified one RCT but did not report quantified results.[16,22] The RCT (90 people with CFS) compared moclobemide (450–600 mg daily) versus placebo.[22] It found

that moclobemide was associated with a non-significant increase in subjectively reported global improvement (moclobemide 24/47 [51%] *v* placebo 14/43 [33%]; OR 2.16, 95% CI 0.9 to 5.1), and a non-significant improvement in the clinician rated Karnofsky scale. **Sertraline versus clomipramine:** We found one RCT comparing sertraline versus clomipramine in people with CFS.[23] It found no significant difference between sertraline and clomipramine. There was no placebo group, which makes it difficult to draw useful conclusions.

Harms: **Fluoxetine:** One RCT assessed separately the symptoms (which could be attributed to either CFS or to known adverse effects of fluoxetine) before starting treatment, after 2 weeks, after 6 weeks, and at the end of treatment (week 8). It found that fluoxetine increased complaints of tremor and perspiration compared with placebo at 8 weeks (tremor: $P = 0.006$; perspiration: $P = 0.008$).[16] It found no significant difference between fluoxetine and placebo at 2 and 6 weeks. It found that fluoxetine increased withdrawal due to adverse effects (9/54 [17%] *v* 2/53 [4%]).[17] The second RCT also found increased withdrawal rates with fluoxetine (24/68 people [36%] with fluoxetine withdrew *v* 16/69 people [24%] with placebo).[18] **Phenelzine:** Three of 15 people (20%) who took phenelzine withdrew because of adverse effects compared with none who took placebo.[21] **Sertraline versus clomipramine:** The RCT provided no information on adverse effects.[23]

Comment: Clinical trials were performed in specialist clinics. **Fluoxetine:** The first RCT[17] used a shorter duration of treatment and studied people with a longer duration of illness compared with the second RCT.[18]

OPTION CORTICOSTEROIDS

Four RCTs found insufficient evidence about the effects of corticosteroids compared with placebo in people with chronic fatigue syndrome.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] **Fludrocortisone:** The systematic review[16] identified two RCTs.[24,25] The first large RCT (100 people with chronic fatigue syndrome [CFS] and neurally mediated hypotension) compared fludrocortisone (titrated to 0.1 mg daily) versus placebo for 9 weeks. It found no significant difference on a self rated global scale of "wellness" (recorded improvement of ≥ 15 points: fludrocortisone 14% *v* placebo 10%; $P = 0.76$; raw data not provided).[24] The second randomised crossover trial (20 people), which measured change in symptom severity (visual analogue scale of symptoms from 0–10 corresponding to "no problem" to "could not be worse") and functional status (using the SF-36) for 6 weeks. It found no significant difference between fludrocortisone and placebo.[25] **Hydrocortisone:** The review identified two RCTs.[16,26,27] The first RCT (65 people) compared hydrocortisone (25–35 mg daily) versus placebo for 12 weeks. It found that hydrocortisone significantly improved a self rated scale of "wellness" (recorded improvement of ≥ 5 points: hydrocortisone 53% *v* placebo 29%; $P = 0.04$). Other self rating scales did not show significant benefit (Beck Depression Inventory: hydrocortisone –2.1 *v* placebo –0.4,

P = 0.17; activity scale: hydrocortisone 0.3 *v* placebo 0.7, P = 0.32; sickness impact profile: hydrocortisone –2.5 *v* placebo –2.2; P = 0.85).[26] The second RCT (32 people, crossover design) compared a lower dose of hydrocortisone (5 or 10 mg daily) versus placebo for 1 month. It found that hydrocortisone improved fatigue in the short term compared with placebo (self report fatigue scale: hydrocortisone 28% *v* placebo 9%; results before crossover not provided).[27]

Harms: **Fludrocortisone:** In the first RCT, fludrocortisone increased withdrawal rates due to adverse events compared with placebo (12/50 [24%] *v* 4/50 [8%]; RR 3, 95% CI 1.04 to 8.67; NNT 6, 95% CI 3 to 8).[24] Four people withdrew from the trial because of worsening symptoms.[25] **Hydrocortisone:** One RCT (25–35 mg daily doses of hydrocortisone) found that 12 people (40%) experienced adrenal suppression (assessed by measuring cortisol levels).[26] Another RCT (5 or 10 mg daily doses of hydrocortisone) reported minor adverse effects in up to 10% of participants. Three people on hydrocortisone had exacerbation of acne and nervousness, and one person on placebo had an episode of fainting.[27]

Comment: The RCTs used different reasons for their choice of active treatment. The use of fludrocortisone, a mineralocorticoid, was based on the hypothesis that CFS is associated with neurally mediated hypotension.[28] The use of hydrocortisone, a glucocorticoid, in the other RCTs was based on evidence of underactivity of the hypothalamic–pituitary–adrenocortical axis in some people with CFS.[29] Any benefit from low dose glucocorticoids seems to be short lived, and higher doses are associated with adverse effects.

OPTION ORAL NICOTINAMIDE ADENINE DINUCLEOTIDE

One small RCT found insufficient evidence about the effects of oral nicotinamide adenine dinucleotide compared with placebo in people with chronic fatigue syndrome.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] It identified one poor quality randomised crossover trial (35 people), which compared nicotinamide adenine dinucleotide (10 mg daily) with placebo for 4 weeks.[30] Of the 35 people, two were excluded for non-compliance and seven were excluded for using psychotropic drugs. It found that nicotinamide adenine dinucleotide significantly improved scores on a self devised 50 item symptom rating scale compared with placebo (8/26 people [30%] attained a 10% improvement with nicotinamide adenine dinucleotide *v* 2/26 people [8%] with placebo; P < 0.05, calculated by authors).

Harms: Minor adverse effects (loss of appetite, dyspepsia and flatulence) were reported on active treatment but did not lead to cessation of treatment.[30]

Comment: The RCT had a number of problems with its methods, including the use of inappropriate statistical analyses, the inappropriate exclusion of people from the analysis, and lack of numerical data preventing independent analysis of the published results.[31]

OPTION EXERCISE

RCTs have found that a graded aerobic exercise programme improves measures of fatigue and physical functioning compared with flexibility training and relaxation training or general advice. One RCT found that an educational package to encourage graded exercise improved measures of physical functioning, fatigue, mood, and sleep at 1 year compared with written information alone.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] **Graded aerobic exercise:** The review identified two RCTs.[18,32] One RCT (66 people) compared graded aerobic exercise (active intervention) versus flexibility and relaxation training (control intervention) over 12 weeks.[32] All participants undertook individual weekly sessions supervised by an exercise physiologist. The aerobic exercise group built up their level of activity to 30 minutes of exercise a day (walking, cycling, swimming up to a maximum oxygen consumption of 60% of V_{O2}max). People in the flexibility and relaxation training group were taught stretching and relaxation techniques (maximum 30 minutes daily, 5 days/week) and were specifically told to avoid any extra physical activities. It found that Aerobic exercise increased reports of feeling "better" or "very much better" and improved physical fatigue and physical functioning compared with control (clinical global impression scale: 52% *v* 27%, P = 0.04; Chalder fatigue scale: –8.4 *v* –3.1, P = 0.004; SF-36 scale: 20.5 *v* 8.0, P = 0.01). The second RCT (136 people) compared four groups (graded aerobic exercise plus fluoxetine; graded aerobic exercise plus drug placebo; general advice plus fluoxetine; general advice plus drug placebo) over 24 weeks.[18] The graded exercise groups were given specific advice to undertake preferred aerobic exercise (such as walking, jogging, swimming, or cycling) for 20 minutes three times a week up to an energy expenditure of 75% of V_{O2}max. The general advice (exercise placebo) groups were not given any specific advice on frequency, intensity, or duration of aerobic activity they should be undertaking. It found that Graded exercise reduced fatigue at 26 weeks compared with general advice (Chalder fatigue scale < 4: 12/67 [18%] *v* 4/69 [6%]; RR 3.1, 95% CI 1.05 to 9.10; NNT 9, 95% CI 5 to 91). **Educational intervention:** The review[16] identified one RCT (148 people).[33] The RCT compared three types of educational interventions to encourage graded exercise with written information only (control group).[33] The participants in the three educational intervention groups received two treatment sessions, two telephone follow ups, and an educational package that provided an explanation of symptoms and encouraged home based exercise. One group received seven additional follow up telephone calls and another received seven additional face to face sessions over 4 months. People in the written information group received advice and an information booklet that encouraged graded activity but gave no explanation for the symptoms. The RCT found that the educational interventions improved physical functioning, fatigue, mood, sleep, and disability (self reported) compared with written information only. The RCT found no significant difference between the educational

interventions (mean for 3 educational intervention groups *v* written information, SF-36 subscale: ≥25 or an increase of ≥10, 1 year after randomisation, 69% *v* 6%, P < 0.001; Chalder fatigue scale: 3 *v* 10, P < 0.001; Hospital Anxiety and Depression scale: depression 4 *v* 10, P < 0.001; anxiety 7 *v* 10, P < 0.01).

Harms: None of the RCTs reported data on adverse effects, and we found no evidence that exercise is harmful in people with chronic fatigue syndrome. The second aerobic exercise RCT found no significant difference in withdrawal rates between exercise and no exercise (25/68 [37%] with exercise *v* 15/69 [22%] without exercise; RR 1.7, 95% CI 0.98 to 2.9).[18] The reasons for the withdrawals from the graded exercise groups were not stated.

Comment: Experience suggests that symptoms of chronic fatigue syndrome may be exacerbated by overly ambitious or overly hasty attempts at exercise.

OPTION PROLONGED REST

We found no RCTs on the effects of prolonged rest. Indirect observational evidence in healthy volunteers and in people recovering from a viral illness suggests that prolonged rest may perpetuate or worsen fatigue and symptoms.

Benefits: We found no systematic review or RCTs of prolonged rest in people with chronic fatigue syndrome.

Harms: We found no direct evidence of harmful effects of rest in people with chronic fatigue syndrome. We found observational evidence, which suggested that prolonged inactivity may perpetuate or worsen fatigue and is associated with symptoms in both healthy volunteers[34] and people recovering from viral illness.[35]

Comment: It is not clear that evidence from people recovering from viral illness can be extrapolated to people with chronic fatigue syndrome.

OPTION DIETARY SUPPLEMENTS

One small RCT found no significant difference between a nutritional supplement (containing multivitamins, minerals, and coenzymes) and placebo in fatigue severity or functional impairment at 10 weeks.

Benefits: We found one RCT (53 people who fulfilled US Centers for Disease Control and Prevention criteria for chronic fatigue syndrome with high fatigue severity and high disability scores; duration of illness ranged from 2 to 12 years) that compared a polynutrient supplement (containing several vitamins, minerals and coenzymes, taken twice daily) versus placebo for 10 weeks.[36] It found no significant difference between treatment in fatigue severity or functional impairment (change in Checklist Individual Strength fatigue subscale from baseline to 10 weeks: 51.4 to 48.6 with supplements *v* 51.3 to 48.2 with placebo; difference 2.16, 95% CI −4.30 to +4.39; Sickness Impact Scale < 750 at 10 weeks: 4% with supplements *v* 12% with placebo).

Harms: Three people (11%) on active treatment withdrew because of nausea.[36]

Comment: The RCT may have been too small to detect a clinically important difference.[36]

OPTION MAGNESIUM

One small RCT found that intramuscular magnesium injections improved symptoms at 6 weeks compared with placebo. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] The review identified one RCT (32 people with chronic fatigue syndrome, but not magnesium deficiency; see comment), which compared weekly intramuscular injections of magnesium sulphate 50% versus placebo (water for injection) for 6 weeks.[37] It found that magnesium improved overall benefit, energy, pain, and emotional reactions compared with placebo (overall benefit: 12/15 [80%] *v* 3/17 [18%]; RR 4.5, 95% CI 1.6 to 13.1; NNT 2, 95% CI 2 to 4; energy P = 0.002; pain: P = 0.001; and emotional reactions: P = 0.013).

Harms: The RCT reported no adverse effects.

Comment: In the RCT, plasma and whole blood magnesium were normal and only the red blood cell concentrations of magnesium were slightly lower than the normal range.[37] Three subsequent case control studies have not found a deficiency of magnesium in people with chronic fatigue syndrome.[38–40] In these three studies, magnesium was in the normal range and no different from controls without chronic fatigue syndrome. However, none of the studies state how the normal range was established, so it is difficult to say if they are equivalent.

OPTION EVENING PRIMROSE OIL

One small RCT found no significant difference between evening primrose oil and placebo in depression scores at 3 months.

Benefits: We found one systematic review (search date 2000), which did not report quantified results.[16] The review identified one RCT (50 people with chronic fatigue syndrome according to Oxford, UK, diagnostic criteria), which compared evening primrose oil (4 g daily) with placebo for 3 months.[41] It found no significant difference between treatments in depression scores (Beck Depression Inventory), physical symptoms, or participant assessment (at 3 months 46% were improved with placebo *v* 29% with evening primrose oil; P = 0.09; figures were not presented in a manner that allowed RR with CI to be calculated).

Harms: The RCT reported no adverse effects.

Comment: One RCT (63 people) compared evening primrose oil (4 g daily) versus placebo in people with a diagnosis of postviral fatigue syndrome.[42] This diagnosis was made on the basis of overwhelming fatigue, myalgia, and depression, which had been present for at

least 1 year, and all had been preceded by a febrile illness. At 3 months, 33/39 (85%) of the people on active treatment had improved compared with 4/24 (17%) on placebo — a significant benefit ($P < 0.0001$). The difference in outcome may be partly explained by participant selection: the study in people with chronic fatigue syndrome used currently accepted diagnostic criteria.[41] Also, whereas the RCT in people with postviral fatigue syndrome used liquid paraffin as a placebo,[42] the chronic fatigue syndrome RCT used sunflower oil, which is better tolerated and less likely to affect the placebo response adversely.[41]

OPTION IMMUNOTHERAPY

Small RCTs found limited evidence that immunoglobulin G modestly improved physical functioning and fatigue at 3–6 months compared with placebo, but it was associated with considerable adverse effects. Small RCTs found insufficient evidence on the effects of interferon alfa or aciclovir compared with placebo. One RCT found that staphylococcus toxoid improved symptoms at six months compared with placebo, although it is associated with local reaction and could cause anaphylaxis.

Benefits:

We found one systematic review (search date 2000), which did not report quantified results.[16] **Immunoglobulin G:** The review identified four relevant RCTs comparing immunoglobulin G versus placebo for 6 months.[43–46] The first RCT (30 people) compared monthly intravenous injections of immunoglobulin G (1 g/kg) versus placebo (albumin).[43] After 6 months, no large differences were found in measures of fatigue (self reported symptom severity) or in physical and social functioning (SF-36). It found that placebo significantly improved social function compared with immunoglobulin G (dichotomous figures not reported). The second RCT (49 people) compared monthly intravenous immunoglobulin G (2 g/kg) with intravenous placebo (a maltose solution) for 3 months.[44] It found that immunoglobulin G significantly increased the proportion of people who improved in terms of a physician rated assessment of symptoms and disability compared with placebo (10/23 [44%] *v* 3/26 [11%]; $P = 0.03$). The third RCT (99 adults) compared three doses of immunoglobulin G (0.5, 1, or 2 g/kg) versus placebo (albumin).[45] It found no significant difference in quality of life, scores on visual analogue scales, or changes in hours spent in non-sedentary activities. The fourth RCT (71 adolescents aged 11–18 years) compared immunoglobulin G (1 g/kg) with placebo (a solution of maltose plus albumin).[46] Three infusions were given 1 month apart. The RCT found that immunoglobulin G significantly improved mean functional outcome (assessed using the mean of clinician ratings from four areas of the participants' activities) compared with placebo (proportion of people who achieved improvement of ≥25% at 6 months: 26/36 [52%] with immunoglobin *v* 15/34 [31%] with placebo, RR 1.6, 95% CI 1.1 to 2.5). However, both groups showed significant improvements from baseline, which continued to the 6 month assessment after treatment. **Other treatments:** We found one systematic review (search date 2000)[16] and one subsequent RCT.[47] The review identified two RCTs (30 people) comparing interferon alfa with placebo.[48,49] The first RCT identified by the review only found treatment benefit on

subgroup analysis of people with isolated natural killer cell dysfunction.[48] The second randomised crossover trial identified by the review did not present results in a manner that allowed clear interpretation of treatment effect.[49] Other RCTs in the review found no significant difference between placebo and aciclovir,[50] dialysable leucocyte extract (in a factorial design with cognitive behavioural therapy),[51] or terfenadine.[52] The subsequent RCT (100 women who met both the ACS criteria for fibromyalgia and the US Centers for Disease Control and Prevention criteria for chronic fatigue syndrome and had functional impairment > 6 months) compared weekly subcutaneous injections of staphylococcus toxoid (dose increased weekly from 0.1 to 1.0 mL, followed by 1.0 mL doses every 4 weeks) versus placebo.[47] It found that staphylococcus toxoid significantly improved the clinical global impression of change scale at 26 weeks compared with placebo (minimally improved, much improved or very much improved: 32/49 [65%] with toxoid *v* 9/49 [18%] with placebo; $P < 0.001$).

Harms:

Immunoglobulin G: In the first RCT, adverse effects judged to be worse than pretreatment symptoms in either group included gastrointestinal complaints (18 people), headaches (23 people), arthralgia (6 people), and worsening fatigue. Of these symptoms, only headaches differed significantly between the groups (immunoglobulin G 14/15 [93%] *v* placebo 9/15 [60%]). Six participants (3 immunoglobulin G, 3 placebo) were considered to have major adverse effects. Adverse events by treatment group were only reported for headache.[43] **Other treatments:** In the RCT comparing interferon alfa 2/13 (15%) people taking active treatment developed neutropenia.[48] The RCT comparing staphylococcus toxoid with placebo found no significant difference in reported adverse effects, excluding local reactions (13/49[26%] with toxoid *v* 7/49 [14% with placebo, $P = 0.14$).[47] All those receiving the toxoid had a local reaction at the injection site.

Comment:

Immunoglobulin G: The first two RCTs differed in that the second used twice the dose of immunoglobulin G, did not require participants to fulfil the operational criteria (similar but not identical to US Centers for Disease Control and Prevention criteria) for chronic fatigue syndrome, and made no assessments of them during the study, instead waiting until 3 months after completion.[44] **Other treatments:** Terfenadine, particularly at high blood concentrations, is associated with rare hazardous cardiac arrhythmias.[53] The RCT that compared staphylococcus toxoid with placebo only included women who also had a diagnosis of fibromyalgia.[47]

OPTION COGNITIVE BEHAVIOURAL THERAPY

One systematic review found that cognitive behavioural therapy administered by highly skilled therapists in specialist centres improved quality of life and physical functioning compared with standard medical care or relaxation therapy. One additional multicentre RCT found that cognitive behavioural therapy administered by less experienced therapists may also be effective compared with guided support groups or no interventions.

Benefits: We found two systematic reviews (search dates 1998[54] and 2000[16]). The first review[54] identified three RCTs that met the reviewers' inclusion criteria (all participants fulfilled accepted diagnostic criteria for chronic fatigue syndrome [CFS] and the trials used adequate randomisation and controls).[51,55,56] The second review identified one additional RCT that met inclusion criteria, but the review did not report quantified results.[17,57] The first RCT (90 people with CFS according to Australian diagnostic criteria that are similar to US Centers for Disease Control and Prevention [CDC] criteria) identified by the reviews evaluated cognitive behavioural therapy (CBT) and immunological therapy (dialysable leucocyte extract) using a factorial design.[51] Cognitive behavioural therapy was given every 2 weeks for six sessions of 30–60 minutes each, and people were encouraged to exercise at home and feel less helpless. The comparison group received standard medical care. The trial found no significant difference in quality of life measures (Karnofsky scale and symptom report on a visual analogue scale) between CBT and standard medical care. The second RCT (60 people with CFS according to Oxford, UK, diagnostic criteria) identified by the reviews compared CBT with normal general practice care in people attending a secondary care centre.[56] It found that CBT significantly improved quality of life (Karnofsky scale) at 12 months compared with those receiving standard medical care (final score > 80: 22/30 [73%] with CBT *v* 8/30 [27%] with placebo; RR 2.75, 95% CI 1.54 to 5.32; NNT 3, 95% CI 2 to 5). The active treatment consisted of a cognitive behavioural assessment, followed by 16 weekly sessions of behavioural experiments, problem solving activity, and re-evaluation of thoughts and beliefs that inhibited a return to normal functioning. The third RCT (60 people with CFS according to CDC diagnostic criteria in people attending a secondary care centre) identified by the reviews compared CBT with relaxation therapy.[55] It found that CBT significantly improvement physical functioning compared with relaxation therapy (improvement based on predefined absolute or relative increases in the SF-36 score: 19/30 [63%] with CBT *v* 5/30 [17%] with relaxation; RR 3.7, 95% CI 2.37 to 6.31; NNT 3, 95% CI 1 to 7). Improvement continued over 6–12 months' follow up. Cognitive behavioural therapy was given in 13 weekly sessions. A 5 year follow up study of 53 (88%) of the original participants found that more people rated themselves as "much improved" or "very much improved" with CBT compared with relaxation therapy (17/25 [68%] with CBT *v* 10/28 [36%] with relaxation therapy; RR 1.9, 95% CI 1.1 to 3.4; NNT 4, 95% CI 2 to 19).[58] More people treated with CBT met the authors' criteria for complete recovery at 5 years, but the difference was not significant (17/31 [55%] with CBT *v* 7/22 [32%] with relaxation therapy; RR 1.7, 95% CI 0.9 to 3.4). The additional multicentre RCT identified by the second review (278 people with CFS according to CDC criteria) compared CBT, guided support groups, or no intervention.[57] The CBT consisted of 16 sessions over 8 months administered by 13 therapists with no previous experience of treating CFS. The guided support groups were similar to CBT in terms of treatment schedule, with the participants receiving non-directive support from a social worker. At 8 months' follow up, the RCT found that more people in the CBT group met the criteria for clinical improvement for

fatigue severity (checklist individual strength) and self reported improvement in fatigue compared with the guided support and no treatment groups (fatigue severity: CBT *v* support group, 27/83 [33%] *v* 10/80 [13%], RR 2.6, 95% CI 1.3 to 5.0; CBT *v* no intervention 27/83 [33%] *v* 8/62 [13%], RR 2.5, 95% CI 1.2 to 5.2; self reported improvement: CBT *v* support group 42/74 [57%] *v* 12/71 [17%], RR 3.4, 95% CI 1.9 to 5.8; CBT *v* no intervention 42/74 [57%] *v* 23/78 [30%], RR 1.9, 95% CI 1.3 to 2.9). The results were not corrected for multiple comparisons.

Harms: No harmful effects were reported.

Comment: The effectiveness of CBT for CFS outside of specialist settings has been questioned. The results of the multicentre RCT suggest that cognitive behavioural therapy may be effective when administered by less experienced therapists with adequate supervision. The trial had a high withdrawal rate (25% after 8 months), especially in the CBT and guided support groups. Although the presented confidence intervals are not adjusted for multiple comparisons, the results would remain significant after any reasonable adjustment. The authors commented that the results were similar after intention to treat analysis, but these results were not presented.[57] A randomised trial that comparing CBT and non-directive counselling found that both interventions were of benefit in the management of people who consulted their family doctor because of fatigue symptoms.[59] In this study, 28% of the sample conformed to CDC criteria for CFS.

TABLE 1 **Diagnostic criteria for chronic fatigue syndrome (see text, p 1436).**

CDC 1994[1]	**Oxford, UK[2]**
Clinically evaluated, medically unexplained fatigue of at least 6 months' duration that is:	Severe, disabling fatigue of at least 6 months' duration that:
– of new onset	– affects both physical and mental functioning
– not a result of ongoing exertion	– was present for more than 50% of the time
– not substantially alleviated by rest	
– a substantial reduction in previous levels of activity	
The occurrence of four or more of the following symptoms:	Other symptoms, particularly myalgia, sleep, and mood disturbance, may be present.
– subjective memory impairment	
– tender lymph nodes	
– muscle pain	
– joint pain	
– headache	
– unrefreshing sleep	
– postexertional malaise (> 24 hours)	
Exclusion criteria	
– Active, unresolved, or suspected disease likely to cause fatigue	– Active, unresolved, or suspect disease likely to cause fatigue
– Psychotic, melancholic, or bipolar depression (but not uncomplicated major depression)	– Psychotic, melancholic, or bipolar depression (but not uncomplicated major depression)
– Psychotic disorders	– Psychotic disorders
– Dementia	– Dementia
– Anorexia or bulimia nervosa	– Anorexia or bulimia nervosa
– Alcohol or other substance misuse	
– Severe obesity

QUESTIONS

INTERVENTIONS

See glossary, p 1465

Key Messages

- **Alendronate** Two systematic reviews in postmenopausal women have found that alendronate reduces vertebral and non-vertebral fractures compared with placebo.
- **Risedronate** One systematic review in postmenopausal women has found that risedronate reduces vertebral and non-vertebral fractures compared with placebo.
- **Calcitonin** One systematic review in postmenopausal women found that calcitonin reduced vertebral fractures compared with placebo, but found no significant difference between calcitonin and placebo in non-vertebral fractures.
- **Calcium plus vitamin D** One large RCT in women aged 69–106 years living in nursing homes found that calcium plus vitamin D3 reduced hip fractures and non-vertebral fractures over 18 months to 3 years compared with placebo. One smaller RCT in women and men aged 65 years or older found that calcium plus vitamin D3 reduced non-vertebral fractures compared with placebo, but found no significant difference in hip fractures. One smaller RCT in postmenopausal women found no significant difference between calcium plus vitamin D3 and placebo in hip fracture after 2 years. The two smaller RCTs may have lacked power to exclude a clinically important difference. One

systematic review in postmenopausal women reporting a combined analysis (for vitamin D alone and vitamin D plus calcium) found that standard or hydroxylated vitamin D with or without calcium reduced vertebral fractures compared with control, but found no significant difference between groups in non-vertebral fractures.

- **Etidronate** One systematic review in postmenopausal women found that etidronate reduced vertebral fractures over 2 years compared with control (placebo, calcium, or calcium plus vitamin D), but found no significant difference in non-vertebral fractures.
- **Hip protectors** One systematic review in elderly residents of nursing homes and one subsequent RCT found that hip protectors reduced hip fractures over 9–19 months compared with no hip protectors, whereas four other subsequent RCTs found no significant difference in hip fractures between groups. One other subsequent RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care. RCTs found no significant difference between hip protectors and no hip protectors in the occurrence of pelvic fractures.
- **Pamidronate** One RCT in men and postmenopausal women found that pamidronate reduced new vertebral fractures after 3 years compared with placebo. One small RCT in postmenopausal women found no significant difference between pamidronate and placebo in vertebral fracture rate, but it was too small to exclude a clinically important difference.
- **Environmental manipulation** We found no RCTs assessing environmental manipulation alone. One RCT in men and women aged over 70 years found no significant difference in new fractures over 4 years between health visitor care (aimed at assessing nutritional deficiencies, reducing smoking and alcohol intake, improving muscle tone and fitness, assessing medical conditions, use of medication, improving home environment such as lighting) and control. Another RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care.
- **Exercise** Three RCTs found no significant difference in falls resulting in fracture over 1 year between exercise (advice to walk briskly three times weekly or balance and strength exercises plus walking) and control. One small RCT in postmenopausal women found no significant difference between a 2 year back strengthening exercise programme and usual care in vertebral fractures over 10 years. Another RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care.
- **Calcium alone** One systematic review in postmenopausal women found no significant difference between calcium supplementation and placebo in vertebral or non-vertebral fractures.

Fracture prevention in postmenopausal women

- **Vitamin D alone** One large RCT in postmenopausal women and two large RCTs in postmenopausal women and men found no significant difference between vitamin D3 and placebo in hip fractures or non-vertebral fractures. One systematic review found limited evidence from two small RCTs in postmenopausal women that calcitriol reduced vertebral fractures over 3 years compared with placebo.
- **Hormone replacement therapy We found insufficient evidence of benefit, but reliable evidence of harm.** One systematic review in postmenopausal women found that hormone replacement therapy reduced vertebral fractures compared with control. However, another systematic review and one subsequent RCT in postmenopausal women found no significant difference in vertebral fractures. Two systematic reviews and two subsequent RCTs provided insufficient evidence on the effects of hormone replacement therapy on non-vertebral fractures. One large RCT of oestrogen plus progestin versus placebo for primary prevention of coronary heart disease in healthy postmenopausal women was stopped because hormonal treatment increased risks of invasive breast cancer, coronary events, stroke, and pulmonary embolism.

DEFINITION This topic covers interventions to prevent fractures in postmenopausal women. Fractures may be symptomatic or asymptomatic. A fracture is a break or disruption of bone or cartilage. Symptoms and signs may include immobility, pain, tenderness, numbness, bruising, joint deformity, joint swelling, limb deformity, and limb shortening.[1] Diagnosis is usually based on a typical clinical picture combined with results from an appropriate imaging technique. Usually in trials dealing with osteoporosis, menopause is considered to be present 12 months after the last menstruation.

INCIDENCE/ PREVALENCE The lifetime risk of fracture in white women is 20% for the spine, 15% for the wrist, and 18% for the hip.[2] The incidence of postmenopausal fracture increases with age.[3] One observational study found that age specific incidence rates for postmenopausal fracture of the hip increased exponentially beyond the age of 50 years.[4]

AETIOLOGY/ RISK FACTORS Fractures usually arise from trauma. General risk factors include those associated with an increased risks of falling (such as ataxia, drug and alcohol intake, loose carpets), age, osteoporosis, bony metastases, and other bone disorders. Postmenopausal women are at increased risk of fracture because of hormonal bone loss. Risk factors for fractures in postmenopausal women include increasing age, low body mass index, time since menopause, alcohol consumption, smoking, some endocrine diseases, such as hyperparathyroidism or thyroid disease, and steroid use, among others.

PROGNOSIS Fractures may result in pain, short or long term disability, haemorrhage, thromboembolic disease (see thromboembolism, p 284), shock, and death. Vertebral fractures are associated with pain, physical impairment, muscular atrophy, changes in body shape, loss of physical function, and lower quality of life.[5] About 20% of women die in the first year after a hip fracture, representing an increase in mortality of 12–20% compared with women of similar age and no hip fracture. Half of elderly women who had been independent become partly dependent after hip fracture. A third become totally dependent.

AIMS OF INTERVENTION To prevent fractures, with minimal adverse effects from treatment.

OUTCOMES Incidence of hip, wrist, non-vertebral and vertebral fractures (we have not reported intermediate outcomes such as bone mineral density data).

METHODS *Clinical Evidence* search and appraisal May 2003. We also hand searched journals of bone diseases and carried out manual searches using the bibliographies of review articles published after 1985. Some of the RCTs identified provide results generalised to fracture per person/year or overall fractures. These results provide an idea of the group effect of an intervention, but not of its effects on the incidence of fracture in an individual. Data on multiple fractures in one person clearly differ from data on multiple people experiencing a single fracture. Regulatory authorities and scientific groups have recommended that the results of studies evaluating new interventions are expressed in terms of the proportion of people experiencing new fractures.[6] This topic examines fracture prevention in postmenopausal women. However, we have included RCTs undertaken in people outside this group (men, premenopausal women) in some sections as results from these trials may be generalisable to postmenopausal women.

QUESTION What are the effects of treatments to prevent fractures in postmenopausal women?

OPTION BISPHOSPHONATES

Olivier Bruyere and Jean-Yves Reginster

Two systematic reviews in postmenopausal women have found that alendronate reduces vertebral and non-vertebral fractures compared with placebo. One systematic review in postmenopausal women found that etidronate reduced vertebral fractures over 2 years compared with control (placebo, calcium, or calcium plus vitamin D), but found no significant difference in non-vertebral fractures. One RCT in men and postmenopausal women found that pamidronate reduced new vertebral fractures after 3 years compared with placebo. One small RCT in postmenopausal women found no significant difference between pamidronate and placebo in vertebral fracture rate after 2 years, but it was too small to exclude a clinically important difference. One systematic review in postmenopausal women has found that risedronate reduces vertebral and non-vertebral fractures compared with placebo.

Benefits: **Alendronate:** We found two systematic reviews.[7,8] The first systematic review (search date 1999, 11 RCTs, 12 855 postmenopausal women) included RCTs that randomised postmenopausal women to alendronate or placebo and had a follow up of at least 1 year.[7] It found that alendronate (5 mg or more) significantly reduced vertebral fractures compared with placebo (8 RCTs, 9360 women; RR 0.52, 95% CI 0.43 to 0.65). It also found that alendronate (10 mg or more) significantly reduced non-vertebral fractures compared with placebo (6 RCTs, 3723 women; RR 0.51, 95% CI 0.38 to 0.69). The review did not state how fractures were diagnosed. The second systematic review (search date 1998, 7 RCTs, 10 287

postmenopausal women aged 39–85 years) found that, compared with placebo, alendronate significantly reduced vertebral fractures (fractures confirmed radiologically; 4 RCTs; RR 0.54, 95% CI 0.45 to 0.66) and non-vertebral fractures (6 RCTs; RR 0.81, 95% CI 0.72 to 0.92).[8] It found that fewer people had hip fractures over 1–4 years, but the difference was not significant (3 RCTs; RR 0.64, 95% CI 0.40 to 1.01; results presented graphically). **Etidronate:** We found one systematic review (search date 1998, 13 RCTs, 1010 postmenopausal women) comparing etidronate versus placebo, calcium, or calcium plus vitamin D.[9] It found that etidronate significantly reduced vertebral fractures over 2 years compared with control (9 RCTs: 32/538 [6%] *v* 54/538 [10%]; RR 0.60, 95% CI 0.41 to 0.88), but found no significant difference in non-vertebral fractures (7 RCTs: 48/433 [11%] *v* 49/434 [11%]; RR 0.98, 95% CI 0.68 to 1.42). The review did not describe clearly how fractures were diagnosed. **Pamidronate:** We found no systematic review but found two RCTs comparing pamidronate (150 mg/day) versus placebo.[10,11] The first RCT (23 men and 78 postmenopausal women) found that pamidronate significantly reduced new radiologically confirmed vertebral fractures after 3 years compared with placebo (5/46 [11%] with pamidronate *v* 15/45 [33%] with placebo; RR 0.33, 95% CI 0.14 to 0.77).[10] The second RCT (48 postmenopausal women) found no significant difference after 2 years between pamidronate and placebo in vertebral fractures (fractures confirmed radiologically; 13/100 person years with pamidronate *v* 24/100 person years with control; P = 0.07; see methods, p 1453).[11] However, it was too small to exclude a clinically important difference. **Risedronate:** We found one systematic review (search date 2000, 8 RCTs, 14 832 postmenopausal women), which included placebo controlled trials of risedronate in postmenopausal women (defined as > 6 months postmenopausal) with a follow up of at least 1 year.[12] The review found that risedronate (2.5 mg or more) significantly reduced vertebral fractures compared with placebo (5 RCTs, 2604 women; RR 0.64, 95% CI 0.54 to 0.77). It also found that risedronate (2.5 mg or more) significantly reduced non-vertebral fractures compared with placebo (7 RCTs, 12 958 women; RR 0.73, 95% CI 0.61 to 0.87). The review did not state how fractures were diagnosed.

Harms: **Alendronate:** Observational evidence suggests that oral alendronate is associated with oesophageal erosions and ulcerative oesophagitis. However, one RCT[13] identified by the second review[8] (in which people took alendronate with 180–240 mL water on rising in the morning and remained upright for at least 30 minutes after swallowing the tablet and until they had eaten something) found no significant difference in oesophagitis with alendronate compared with placebo. **Risedronate:** One observational study found limited evidence suggesting that the gastrointestinal safety of risedronate seems to be in the same range as alendronate.[14]

Comment: **Risedronate:** The systematic review noted that the major methodological weakness of included RCTs was loss to follow up, which was over 20% in most RCTs and over 35% in the largest RCT.[12]

However, it noted the magnitude of the treatment effect was unrelated to loss to follow up.[12] **Pamidronate:** Although one of the RCTs included both men and women at risk of hip fracture,[10] it is likely that the results are generalisable to postmenopausal women.

OPTION CALCIUM AND VITAMIN D ALONE OR IN COMBINATION

Olivier Bruyere and Jean-Yves Reginster

One systematic review in postmenopausal women found no significant difference between calcium supplementation and placebo in vertebral or non-vertebral fractures. One large RCT in postmenopausal women and two large RCTs in postmenopausal women and men found no significant difference between vitamin D3 and placebo in hip fractures or non-vertebral fractures. One systematic review found limited evidence from two small RCTs in postmenopausal women that calcitriol reduced vertebral fractures over 3 years compared with placebo. One systematic review in postmenopausal women reporting a combined analysis (for vitamin D alone and Vitamin D plus calcium) found that standard or hydroxylated vitamin D with or without calcium reduced vertebral fractures compared with control, but found no significant difference between groups in non-vertebral fractures. One large RCT in women aged 69–106 years living in nursing homes found that calcium plus vitamin D3 reduced hip fractures and non-vertebral fractures over 18 months to 3 years compared with placebo. One smaller RCT in women and men aged 65 years or older found that calcium plus vitamin D3 reduced non-vertebral fractures compared with placebo, but found no significant difference in hip fractures. One smaller RCT in postmenopausal women found no significant difference between calcium plus vitamin D3 and placebo in hip fracture after 2 years. The two smaller RCTs may have lacked power to exclude a clinically important difference.

Benefits:

Calcium versus placebo: We found one systematic review (search date 1998, 15 RCTs, 1806 postmenopausal women), which included trials of calcium supplementation in women older than 45 years with an absence of menses for a minimum of 6 months.[15] It found no significant difference between calcium and placebo in vertebral fractures (5 RCTs, 576 women; RR 0.77, 95% CI 0.54 to 1.09). It also found no significant difference between calcium and placebo in non-vertebral fractures (2 RCTs, 222 women; RR 0.86, 95% CI 0.43 to 1.72). It noted that the two RCTs reporting non-vertebral fractures had very few events, and the pooled confidence intervals were therefore wide (absolute numbers not reported). **Vitamin D3 versus placebo:** We found one systematic review (search date 2000, 1 RCT)[16] and two subsequent RCTs.[17,18] The RCT identified by the review (2578 people; 1916 women, 662 men, age 70 years or older, living at home; see comment below) found no significant difference between vitamin D3 and placebo in hip fracture (confirmed by clinical assessment and X ray films; 58/1284 [4.5%] *v* 48/1280 [3.7%]; RR 1.20, 95% CI 0.83 to 1.75), or any non-vertebral fracture over 3 years (135/1284 [11%] *v* 122/1280 [10%]; RR 1.10 95% CI 0.87 to 1.39).[16] The first subsequent RCT (1144 people resident in nursing homes; mean age 85 years; 75% were women) found no significant difference between vitamin D3 (10 μg/day) and placebo in hip fracture or any

non-vertebral fracture (fractures confirmed by hospital discharge letter or X ray film) after 2 years' treatment (hip fracture: 50/569 [8.8%] with vitamin D *v* 47/575 [8.2%] with placebo; RR 1.09, 95% CI 0.73 to 1.63; non-vertebral fracture: 69/569 [12.1%] with vitamin D *v* 76/575 [13.2%] with placebo; RR 0.92, 95% CI 0.66 to 1.27).[17] The second subsequent RCT (2686 people; 2037 men and 649 women; age 65–85 years) reported separate results for men and women in the trial.[18] In women, it found no significant difference between vitamin D3 and placebo in first fractures at any site after 5 years (42/326 [13%] with vitamin D3 v 58/323 [18%] with placebo; RR 0.68, 95% CI 0.46 to 1.01). In women, it also found no significant difference between vitamin D3 and placebo in first hip fractures after 5 years (10/326 [3%] with vitamin D3 *v* 10/323 [3%] with placebo; RR 0.98, 95% CI 0.41 to 2.36) or vertebral fractures (4/326 [1%] with vitamin D3 v 6/323 [2%] with placebo; RR 0.65, 95% CI 0.18 to 2.3). **Vitamin D analogue (calcitriol) versus placebo:** The systematic review[16] also identified two small RCTs (68 women aged ≥54 years) comparing calcitriol (1,25 dihydroxy vitamin D) versus placebo. It found that calcitriol significantly reduced new vertebral fractures over 3 years compared with placebo (fractures confirmed radiologically; 8/34 [23%] with calcitriol *v* 17/34 [50%] with placebo; RR 0.49, 95% CI 0.25 to 0.95). **Calcium plus vitamin D3 versus placebo:** We found one systematic review (search date 2000, 2 RCTs, 3715 people)[16] and one subsequent RCT.[19] One of the RCTs identified by the review (3270 mobile elderly women, aged 69–106 years, living in nursing homes) found that, compared with placebo, calcium plus vitamin D3 significantly reduced hip fractures (80/1387 [6%] with calcium plus vitamin D3 *v* 110/1403 [8%] with placebo; RR 0.74, 95% CI 0.60 to 0.91) and all non-vertebral fractures (160/1387 [11%] with calcium plus vitamin D3 *v* 215/1403 [15%] with placebo; RR 0.75, 95% CI 0.62 to 0.91) over 18 months. This difference remained significant after 3 years of treatment (hip fracture: 137/1176 [12%] with calcium plus vitamin D3 *v* 178/1127 [16%] with placebo; RR 0.74, 95% CI 0.60 to 0.91; all non-vertebral fracture: 255/1176 [22%] with calcium plus vitamin D3 *v* 308/1127 [27%] with placebo; RR 0.72, 95% CI 0.60 to 0.84). The review did not state how fractures were diagnosed.[16] The other RCT identified by the review (246 women, 199 men, aged 65 years or older, living at home; see comment below) found no significant difference between calcium plus vitamin D3 and placebo in hip fractures over 3 years (0/187 [0%] *v* 1/202 [0.5%]; RR 0.36, 95% CI 0.01 to 8.78), but was underpowered to exclude a clinically important difference. It found that calcium plus vitamin D reduced overall non-vertebral fractures compared with placebo (11/187 [6%] with calcium plus vitamin D *v* 26/202 [13%] with placebo; RR 0.46, 95% CI 0.23 to 0.90). Fractures were diagnosed by self report, interview, and validation from case records.[16] The subsequent RCT (583 women in institutional care, mean age 85 years, range 64–99 years) found no significant difference between calcium plus vitamin D3 and placebo in hip fracture at 2 years (27/393 [6.9%] with calcium plus vitamin D *v* 21/190 [11.1%] with placebo; RR for placebo *v* calcium plus vitamin D 1.69, 95% CI 0.96 to 3.00).[19] **Standard or hydroxylated vitamin D alone or with**

calcium versus control (placebo or calcium): We found one systematic review (search date 1999, 25 RCTs, 8124 postmenopausal women; see comment below), which included RCTs of standard or hydroxylated vitamin D with or without calcium supplementation in women older than 45 years with an absence of menses for a minimum of 6 months and a follow up of at least 1 year.[20] It analysed combined results for RCTs that used vitamin D alone or vitamin D plus calcium. It found that standard or hydroxylated vitamin D with or without calcium significantly reduced vertebral fractures compared with control (8 RCTs, 1130 women; RR 0.63, 95% CI 0.45 to 0.88). It found no significant difference between standard or hydroxylated vitamin D with or without calcium and control in the occurrence of non-vertebral fractures (6 RCTs, 6187 women; RR 0.77, 95% CI 0.57 to 1.04).

Harms: **Vitamin D3 or vitamin D analogue (calcitriol) versus placebo or calcium:** The systematic review found that vitamin D or vitamin D analogues compared with placebo or calcium increased hypercalcaemia (5 RCTs, 1009 people; 22/498 [4.4%] with vitamin D or vitamin D analogues *v* 18/511 [3.5%] with placebo or calcium; RR 1.71, 95% CI 1.01 to 2.89).[16]

Comment: Although some RCTs included both men and women at risk of hip fracture, it is likely that the results are generalisable to postmenopausal women.[16,17] The review that compared vitamin D alone or plus calcium versus control noted that inferences from the results of its analysis were limited by the variability of study designs, weaknesses in the primary study methods (including lack of blinding in many studies), the paucity of data, and the inconsistency of results of included RCTs.[20]

OPTION CALCITONIN

Olivier Bruyere and Jean-Yves Reginster

One systematic review in postmenopausal women found that calcitonin reduced vertebral fractures compared with placebo, but found no significant difference between calcitonin and placebo in non-vertebral fractures.

Benefits: We found two systematic reviews.[21,22] The first systematic review (search date 2000, 30 RCTs, 3993 postmenopausal women) included trials of at least 1 year duration, which compared calcitonin versus placebo or calcium and/or vitamin D in postmenopausal women.[21] It found that calcitonin significantly reduced vertebral fractures compared with placebo (4 RCTs, 1404 women; RR 0.46, 95% CI 0.25 to 0.87; see comment below). It found no significant difference between calcitonin and placebo in non-vertebral fractures (3 RCTs, 1481 women; RR 0.52, 95% CI 0.22 to 1.23). The second systematic review (search date 1996, 14 RCTs, 7 RCTs in perimenopausal women with crush fractures or osteoporosis, 7 RCTs in men and women with osteoporosis or taking corticosteroids, 1309 people, exact proportions of women and men not specified; see comment below) compared calcitonin (salcatonin) versus placebo, no treatment, calcium, or calcium plus vitamin D (see comment below).[22] It included three RCTs identified by the first systematic review. It found that fewer people developed vertebral or

non-vertebral fractures with calcitonin compared with no calcitonin, but the difference was not significant (vertebral fractures: 166/1190 [14%] people with calcitonin *v* 96/554 [17%] with no calcitonin; RR 0.80, 95% CI 0.64 to 1.01; non-vertebral fractures: RR 0.48, 95% CI 0.20 to 1.15; no further data provided). The review did not state how fractures were diagnosed.

Harms: The first systematic review found the relative risk for headache from one included RCT was 0.57 (95% CI 0.34 to 0.93) and that for climacteric symptoms from another included RCT was 0.20 (95% CI 0.05 to 0.77).[21] It noted that, in general, included trials were poor in their reporting of adverse events. The second systematic review gave no information on harms.[22]

Comment: The first systematic review suggested caution in interpreting the magnitude of the effect of calcitonin in the pooled estimates.[21] The pooled estimate for vertebral fractures was based on three small RCTs and a fourth larger RCT with a large variability in results between them. Losses to follow up were 18.7%, 21%, 45%, and 59.3% in the four RCTs.[21] Similar issues were raised in the pooled estimate for non-vertebral fractures.[21] The second systematic review commented that its conclusions are limited because many of the RCTs identified did not report the occurrence of fractures, were not double blinded, and only two of the RCTs identified were of over 2 years' duration.[22]

OPTION ENVIRONMENTAL MANIPULATION

John Edwards

We found no RCTs assessing environmental manipulation alone. One RCT in men and women aged over 70 years found no significant difference in new fractures over 4 years between health visitor care (aimed at assessing nutritional deficiencies, reducing smoking and alcohol intake, improving muscle tone and fitness, assessing medical conditions, use of medication, improving home environment such as lighting) and control. Another RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care.

Benefits: We found no systematic review and no RCTs assessing environmental manipulation (see glossary, p 1465) alone. We found one RCT (674 men and women, age > 70 years) comparing health visitor care (aimed at assessing nutritional deficiencies, reducing smoking and alcohol intake, improving muscle tone and fitness, assessing medical conditions and use of medication, and improving home environment, such as lighting) versus control (not specified).[23] It found no significant difference between health visitor care and control in new fractures over 4 years (16/350 [4.5%] with health visitor care *v* 14/324 [4.3%] with control; RR 1.06, 95% CI 0.52 to 2.13). The RCT did not state how fractures were diagnosed. We found one further RCT assessing a multifactorial intervention (including an environmental manipulation component — see benefits of hip protectors, p 1460).[24]

Harms: The RCT examining health visitor care gave no information on harms.[23]

Comment: Although the RCT examining health visitor care included both men and women at risk of hip fracture, it is likely that the results are generalisable to postmenopausal women.[23]

OPTION EXERCISE

John Edwards

Three RCTs found no significant difference in falls resulting in fracture over 1 year between exercise (advice to walk briskly three times weekly or balance and strength exercises plus walking) and control. One small RCT in postmenopausal women found no significant difference between a 2 year back strengthening exercise programme and usual care in vertebral fractures over 10 years. Another RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care.

Benefits: We found one systematic review (search date 2001, 3 RCTs comparing exercise versus control in preventing falls resulting in fracture)[25] and one subsequent RCT.[26] The review did not perform a meta-analysis because of the heterogeneity of methods and interventions among trials.[25] The first RCT identified by the review (165 postmenopausal women living in the community who had fractured an upper limb in the previous 2 years) compared advice to walk briskly for up to 40 minutes three times weekly versus advice to carry out upper limb exercises. It found no significant difference between groups in falls resulting in fracture after 1 year (2/81 [2%] with brisk walking *v* 3/84 [4%] with upper limb exercises; RR 0.69, 95% CI 0.12 to 4.03). The second RCT identified by the review (77 women and 22 men, aged > 65 years, living in the community; see comment below) compared a home based exercise programme (balance and strength exercises plus walking) versus no exercise programme for 14 weeks. It found no significant difference between groups in falls resulting in fracture over 44 weeks (1/45 [2%] with exercise *v* 0/48 [0%] with no exercise; RR 3.20, 95% CI 0.13 to 76.48). The third RCT (162 women, 78 men, aged > 75 years; see comment below) found no significant difference in falls resulting in fracture over 1 year with a home exercise programme (balance and strength exercises plus walking) compared with usual care (2/121 [2%] with home exercise *v* 7/119 [6%] with usual care; RR 0.28, 95% CI 0.06 to 1.33). The review did not state how fractures were diagnosed in the RCTs.[25] The subsequent RCT (65 postmenopausal women) compared a programme of back muscle strengthening exercises versus usual care for 2 years.[26] It found no significant difference in vertebral fractures at 10 years between strengthening exercises and usual care (fractures confirmed radiologically; 3/27 [11.1%] with exercise *v* 7/23 [30.4%] with usual care; P = 0.85). We found one further RCT assessing a multifactorial intervention (including an exercise component — see benefits of hip protectors, p 1460).[24]

Harms: One of the RCTs found that brisk walking significantly increased the number of falls compared with control (15.0/100 person years, 95% CI 1.4/100 person years to 29.0/100 person years — see methods, p 1453).[25] This result should be interpreted with caution as reporting of falls is subject to recall bias.

Comment: Most of the RCTs identified by the review examined falls rather than fractures as the main outcome of interest.[25]

OPTION HIP PROTECTORS

John Edwards

One systematic review in elderly residents of nursing homes and one subsequent RCT found that hip protectors reduced hip fractures over 9–19 months compared with no hip protectors, whereas four other subsequent RCTs found no significant difference in hip fractures between groups. One other subsequent RCT in men and women aged over 65 years in institutional care found that a multifactorial intervention (including staff education, environmental manipulation, exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) reduced hip fractures over 34 weeks compared with usual care. RCTs found no significant difference between hip protectors and no hip protectors in the occurrence of pelvic fractures.

Benefits: **Hip fractures:** We found one systematic review[27] and six subsequent RCTs.[24,28–32] The systematic review (search date 2000) identified six RCTs (3412 people, predominantly women; see comment below) assessing the effects of hip protectors versus no hip protectors on hip fractures.[27] It could not perform a meta-analysis of all of the RCTs because some of the RCTs used cluster randomisation and others randomised individuals. In the RCTs that randomised individuals, the review found that hip protectors significantly reduced hip fractures over 9–19 months compared with no hip protectors (3 RCTs, 202 people, 90–100% women in 2 RCTs, proportion of women and men not stated in 1 RCT; 4/111 [4%] *v* 15/91 [16%]; RR 0.22, 95% CI 0.09 to 0.57). The review did not state how fractures were diagnosed.[27] The first subsequent RCT (164 women, mean age 83 years) found that hip protectors significantly reduced hip fractures over about 1 year compared with control (1/88 [1%] *v* 8/76 [10%]; RR 0.11, 95% CI 0.01 to 0.84).[28] The RCT did not state how fractures were diagnosed. The second subsequent RCT (64 women and 8 men in a nursing home, age 71–96 years) found no significant difference between hip protectors and no hip protectors in hip fractures over 1 year (1/36 [3%] *v* 7/36 [19%]; RR 0.14, 95% CI 0.02 to 1.10), but it was too small to exclude a clinically important difference (see comment below).[29] The RCT did not state how hip fractures were diagnosed. The third subsequent RCT (174 women aged ≥ 75 years) found no significant difference in hip fractures between hip protectors and no hip protectors at 18 months (8/86 [9.3%] with hip protectors *v* 7/88 [8.0%] without; RR 1.17, 95% CI 0.44 to 3.08).[30] It may have lacked power to exclude a clinically important difference. The RCT did not state how hip fractures were diagnosed. The fourth subsequent RCT was a cluster randomised trial (439 men and women resident in institutional care, aged ≥ 65 years, 72% women).[24] It

compared a multifactorial intervention (including staff education, environmental manipulation [see glossary, p 1465], exercise, walking aids, drug regimen reviews, and hip protectors for those considered at higher risk) versus usual care for 34 weeks. It found that the multifactorial intervention significantly reduced hip fractures over 34 weeks compared with usual care (3/188 [1.6%] with active intervention *v* 12/196 [6.1%] with usual care; RR 0.26, 95% CI 0.07 to 0.91). The RCT did not state how hip fractures were diagnosed. It was not clear which components of the intervention were responsible for reported effects. The fifth subsequent RCT was a cluster randomised trial (49 nursing homes, 942 residents aged 70 years or older, of which 813 were women, at "high risk" of falling; see comment below), which compared education (structured education of staff about hip protectors who then taught residents) plus the provision of free hip protectors versus usual care (brief information about hip protectors to the study co-ordinator and two hip protectors provided for demonstration purposes).[31] It found no significant difference between groups in the proportion of people with hip fractures after 15 months (21/459 [5%] people with intervention *v* 39/483 [8%] with usual care; RR 0.57, CI not reported; absolute risk difference −3.5%, 95% CI −7.3% to +0.3%). The sixth subsequent RCT (561 people of which 501 were women, age 70 years or over, living in sheltered housing or residential or nursing homes, at "high risk" of falls) found no significant difference in the occurrence of first hip fractures between provision of hip protector plus education (on bone health and risk factors for falls) and education alone (hip fracture: 18/276 [6%] with hip protector plus education *v* 19/285 [7%] with education alone; RR 0.98, 95% CI 0.52 to 1.82; see comment below).[32] **Pelvic fractures:** The systematic review identified three RCTs.[27] It could not perform a meta-analysis because of different trial methods. All three RCTs included men and women (see comment below). The first RCT (1801 people aged > 75 years, about 80% women) identified by the review found no significant difference in pelvic fractures over a mean 11–15 months between hip protectors and no hip protectors (2/653 [0.3%] with hip protectors *v* 12/1148 [1%] with no hip protectors; RR 0.29, 95% CI 0.07 to 1.31). The second RCT identified by the review (665 people aged > 69 years living in a nursing home, 70% women) found no significant difference in pelvic fractures over 11 months (0/247 [0%] with hip protectors *v* 2/418 [0.5%] with no hip protectors; RR 0.34, 95% CI 0.02 to 7.01). The third RCT identified by the review (64 men and 8 women, aged 71–96 years living in a nursing home) found no significant difference between hip protectors and no hip protectors in pelvic fractures over 12 months, but it may have been too small to exclude a clinically important difference (0/36 [0%] with hip protectors *v* 2/36 [5%] with no hip protectors; RR 0.20, 95% CI 0.01 to 4.03). The review did not state how fractures were diagnosed in the RCTs.[27] One subsequent RCT (174 women aged ≥ 75 years) found no significant difference in pelvic fractures at 18 months between hip protectors and no hip protectors (2/86 [2.3%] with hip protectors *v* 2/88 [2.3%] with no hip protectors; RR 1.02, 95% CI 0.15 to 7.10; not stated whether fractures were radiologically confirmed).[30] However, the RCT may have lacked power to exclude a clinically

important difference. Another subsequent RCT (561 people of whom 501 were women, age 70 years or over, living in sheltered housing or residential or nursing homes, at "high risk" of falls) found no significant difference in pelvic fractures between provision of hip protector plus education (on bone health and risk factors for falls) and education alone (pelvic fractures: 2/276 [0.7%] with hip protector plus education *v* 3/285 [1%] with education alone; RR 0.69, 95% CI 0.12 to 4.09; see comment below).[32] It did not state whether pelvic fractures were radiologically confirmed.

Harms:

Non-hip or non-pelvic fractures and injuries: One of the RCTs identified by the review (665 people) found no significant difference between hip protectors and no hip protectors in non-hip fractures over 11 months (15/247 [6.1%] with hip protectors *v* 25/418 [6.0%] with no hip protectors; RR 1.02, 95% CI 0.55 to 1.89).[27] Another small RCT identified by the review found no significant difference in non-hip fractures between hip protectors and no hip protectors (2/35 [5.7%] with hip protectors *v* 0/24 [0%] with no hip protectors; RR 3.47, 95% CI 0.17 to 69.27). A third RCT identified by the review (1801 people) also found no significant difference in the proportion of people with lower limb or other non-hip fractures over a mean of 11–15 months between hip protectors and no hip protectors (23/653 [3.5%] with hip protectors *v* 59/1148 [5.1%] with no hip protectors; RR 0.69, 95% CI 0.43 to 1.10). The first subsequent RCT found no significant difference in non-hip fractures over a mean 377 days between hip protectors and no hip protectors (2/88 [2.3%] with hip protectors *v* 0/76 [0%] with no hip protectors).[28] Another RCT found no significant difference in non-hip and non-pelvic fractures after 18 months (4/86 [4.7%] with hip protectors *v* 2/88 [4.5%] with no hip protectors; RR 1.02, 95% CI 0.26 to 3.96), but it may have been too small to exclude a clinically important difference.[30] One cluster randomised RCT found no significant difference between hip protectors plus education and usual care in non-hip fractures (35/459 [8%] with intervention *v* 32/483 [7%] with usual care; absolute risk difference +1%, 95% CI −4% to +6%; see comment below).[31] One RCT found no significant difference in non-hip non-pelvic fractures between hip protector plus education and education alone (14/276 [5%] with intervention *v* 11/285 [4%] with education alone; RR 1.31, 95% CI 0.61 to 2.84; see comment below).[32] **Falls:** One of the RCTs identified by the review found that hip protectors increased the proportion of people who fell on the hip compared with no hip protectors, but the difference was not significant (8/101 [7.9%] *v* 1/40 [2.5%]; RR 3.17, 95% CI 0.41 to 24.5).[27] The first subsequent RCT found no significant difference in the proportion of people sustaining one or more falls over about 1 year (40/88 [45%] *v* 28/76 [37%]; RR 1.23, 95% CI 0.85 to 1.79).[28] The other five RCTs identified by the review[27] and the second subsequent RCT[29] found a similar incidence of falls with hip protectors compared with no hip protectors, but gave no information on the proportion of people who fell. These results should be interpreted with caution as reporting of falls is subject to recall bias. **Mortality:** One RCT identified by the review found no significant difference in mortality over 12 months between hip protectors and no hip protectors (6/36 [17%] with hip protectors *v* 8/36 [22%] with no hip protectors; RR 0.75, 95% CI 0.29 to

1.94).[27] The first subsequent RCT also found no significant difference in mortality between hip protectors and no hip protectors but it may have been too small to exclude a clinically important difference (6/88 [7%] with hip protectors *v* 8/76 [10%] with no hip protectors; RR 0.65, 95% CI 0.23 to 1.78).[28] **Hospital admission:** One of the RCTs identified by the review found no significant difference between hip protectors and no hip protectors in the proportion of people permanently hospitalised over 12 months (10/36 [28%] with hip protectors *v* 9/36 [25%] with no hip protectors; RR 1.11, 95% CI 0.51 to 2.41).[27] The first subsequent RCT found no significant difference in the proportion of people who were hospitalised for reasons other than fracture over a mean of 377 days, but it may have been too small to exclude a clinically important difference (10/88 [11%] with hip protectors *v* 9/76 [12%] with no hip protectors; RR 0.96, 95% CI 0.41 to 2.24).[28]

Comment: Much of the evidence is taken from RCTs that included both men and women at risk of hip fracture. However, it is likely that the results are generalisable to postmenopausal women.[24,27] The results of the second subsequent RCT should be interpreted with caution as 60% of people who entered the trial were lost to follow up.[29] The RCT had protocol violations as three people were allocated to the hip protector group after randomisation when people initially randomised to hip protectors refused to wear them.[29] The fifth subsequent RCT may have been underpowered and included the possibility of selection bias.[31] The sixth subsequent RCT had methodological problems in that it was found *post hoc* to be underpowered and so the study period was extended from 52 weeks to a mean of 69.6 weeks to increase the total burden of fractures and hence the power of the study.[32]

OPTION HORMONE REPLACEMENT THERAPY

We found insufficient evidence of benefit, but reliable evidence of harm. One systematic review in postmenopausal women found that hormone replacement therapy reduced vertebral fractures compared with control. However, another systematic review and one subsequent RCT in postmenopausal women found no significant difference in vertebral fractures. Two systematic reviews and two subsequent RCTs provided insufficient evidence on the effects of hormone replacement therapy on non-vertebral fractures. One large RCT of oestrogen plus progestin versus placebo for primary prevention of coronary heart disease in healthy postmenopausal women was stopped because hormonal treatment increased risks of invasive breast cancer, coronary events, stroke, and pulmonary embolism.

Benefits: **Vertebral fractures:** We found two systematic reviews[33,34] and one subsequent RCT.[35] The first systematic review (search date 2001, 13 RCTs, mean age 48–73 years) included RCTs of postmenopausal women who were healthy, or who also had coronary artery disease, a vertebral fracture, or established osteoporosis.[33] It included RCTs that compared hormone replacement therapy (HRT) with placebo, calcium with or without vitamin D, or no treatment, with a follow up of at least 1 year. It found that HRT significantly reduced the incidence of vertebral fractures compared with control

(13 RCTs; 42/3507 [1.2%] with HRT *v* 63/3216 [2%] with control; RR 0.67, 95% CI 0.45 to 0.98). The second systematic review (search date 1999) included RCTs that evaluated HRT in postmenopausal women.[34] The HRT could be given in conjunction with a calcium and vitamin D supplement provided the comparison group received the same supplement, and the follow up was at least 1 year. It excluded three RCTs included in the first systematic review[33] on methodological grounds.[34] It found no significant difference between HRT and control in the incidence of vertebral fractures (5 RCTs, 3385 women; RR 0.66, 95% CI 0.41 to 1.07). The subsequent RCT (16 608 postmenopausal women, age 50–79 years) found that HRT (oestrogen plus progestin) significantly reduced vertebral fractures compared with placebo (HR 0.66, 95% CI 0.44 to 0.98).[35] However, after adjustment for multiple statistical testing as outlined in the monitoring plan, the difference between groups was no longer statistically significant (HR 0.66, 95% CI 0.32 to 1.34). **Non-vertebral fractures:** We found two systematic reviews[34,36] and two subsequent RCTs[35,37] comparing HRT versus placebo, no treatment, calcium, or calcium plus vitamin D. The first review (search date 2000, 22 RCTs, 8774 women) found that HRT compared with placebo, no treatment, calcium, or calcium plus vitamin D significantly reduced the proportion of women with non-vertebral fractures after 1–10 years' follow up (258/4929 [5%] *v* 307/3845 [8%]; RR 0.73, 95% CI 0.56 to 0.94).[36] This reduction remained significant in women taking HRT who had a mean age younger than 60 years (14 RCTs: RR 0.67, 95% CI 0.46 to 0.98; no further data provided). When RCTs in women with a mean age of 60 years or older were analysed, the review found no significant difference in non-vertebral fractures between HRT and placebo (8 RCTs: RR 0.88, 95% CI 0.71 to 1.08; no further data provided).[36] The second review (search date 1999) found no significant difference between HRT and control in non-vertebral fractures (6 RCTs, 5383 postmenopausal women; RR 0.87, 95% CI 0.71 to 1.08).[34] One large subsequent RCT (2763 postmenopausal women aged < 80 years) found no significant difference between HRT and placebo in hip fractures (fractures confirmed radiologically; 14/1380 [1.0%] with HRT *v* 13/1383 [0.9%] with placebo; RR 1.1, 95% CI 0.5 to 2.3) or wrist fracture (29/1380 [2.1] with HRT *v* 29/1383 [2.0] with placebo; RR 1.0, 95% CI 0.6 to 1.7), but it may have been too small to exclude a clinically important difference because the outcomes of interest were rare.[37] The second subsequent RCT (16 608 healthy postmenopausal women aged 50–79 years) compared oestrogen plus progestin versus placebo.[35] It found that HRT significantly reduced hip fractures after a mean 5.2 years' follow up compared with placebo (fractures confirmed radiologically; 44/8506 [0.52%] with HRT *v* 62/8102 [0.77%] with placebo; RR of hip fracture 0.66, 95% CI 0.45 to 0.98). However, after adjustment for multiple significance testing as specified in the monitoring plan, the difference was no longer significant (RR 0.66, 95% CI 0.33 to 1.33).

Harms: In one of the RCTs identified by the review assessing non-vertebral fractures, 96/464 women (21%) withdrew from the trial, and more women withdrew from the HRT groups than from the non-HRT groups (72/232 [31%] women *v* 24/232 [10%]; RR 3.0, 95%

CI 2.0 to 4.6).[38] The most common reasons cited for withdrawal were menstrual disorders and headache. The second subsequent RCT comparing oestrogen plus progestin versus placebo as a primary prevention strategy for coronary heart disease in healthy postmenopausal women was stopped after 5.2 years' follow up because of increased risk of invasive breast cancer, coronary events, stroke, and pulmonary embolism among women receiving HRT compared with placebo (invasive breast cancer: 166/8506 [2.0%] with HRT *v* 124/8102 [1.5%] with placebo; RR 1.3, 95% CI 1.0 to 1.6; coronary events: 164/8506 [1.9%] with HRT *v* 122/8102 [1.5%] with placebo; RR 1.3, 95% CI 1.0 to 1.6; stroke: 127/8506 [1.5%] with HRT *v* 85/8102 [1.1%] with placebo; RR 1.4, 95% CI 1.1 to 1.9; pulmonary embolism: 70/8506 [0.8%] with HRT *v* 31/8102 [0.4%] with placebo; RR 2.1, 95% CI 1.4 to 3.3).[35] See also HRT under secondary prevention of ischaemic cardiac events, p 197.

Comment: In the second RCT identified by the review assessing non-vertebral fractures,[36] the use of multiple treatment groups without the correct statistical analyses limits the validity of the study results.[38] In the subsequent large RCT (2763 postmenopausal women aged < 80 years), prevention of fractures was a secondary outcome, the primary outcome was the secondary prevention of coronary heart disease.[37] In addition to the RCTs described, we found many observational studies with conflicting results.[2,39–45] One non-systematic review of 11 observational studies found a reduced risk of hip fracture in women taking oestrogen compared with non-users.[2] A prospective cohort study (9704 women, age ≥ 65 years) found a significant reduction in radiologically confirmed hip fractures with oral oestrogen only in women who started HRT within 5 years of menopause and who used it continuously thereafter.[42] Other observational studies found similar fracture rates with HRT compared with no HRT.[46] We found no observational studies that detected an increased risk of fracture with HRT. Several observational studies found that only 8–20% of women continued HRT for at least 3 years.[47,48]

GLOSSARY

Environmental manipulation This involves the restructuring of a person's environment to remove hazards and reduce the risk of falling or of a fall resulting in fracture.

QUESTIONS

INTERVENTIONS

Key Messages

Treatment of acute gout

- **Corticosteroids** We found no RCTs on the effects of intra-articular, parenteral, or oral corticosteroids in people with gout.
- **Non-steroidal anti-inflammatory drugs** One RCT provided limited evidence that tenoxicam reduced short term pain and tenderness in people with gout compared with placebo. However, this study was too small to provide reliable conclusions. We found no RCTs comparing other non-steroidal anti-inflammatory drugs with placebo in people with gout. Five RCTs found no significant difference in efficacy between different non-steroidal anti-inflammatory drugs in people with acute gout; however, these RCTs may have lacked power to detect clinically relevant differences. One equivalence study found that etoricoxib and indometacin had equivalent effects on pain, but that indometacin was associated with more adverse effects.
- **Oral colchicine** One small RCT provided limited evidence that colchicine improved pain in people with gout. However, we were unable to draw reliable conclusions from this small RCT. The high incidence of adverse effects in people taking colchicine precludes its use as routine treatment.

Prevention of recurrent gout

- **Advice to lose weight, reduce alcohol intake, or reduce dietary intake of purines; allopurinol; benzbromarone; colchicine; probenecid; sulphinpyrazone** We found no RCTs on the effects of these treatments to prevent recurrent gout.

DEFINITION Gout is a syndrome caused by deposition of urate crystals.[1] It typically presents as an acute monoarthritis of rapid onset. The first metatarsophalangeal joint is the most commonly affected joint (podagra). Gout also affects other joints: joints in the foot, ankle, knee, wrist, finger, and elbow are the most frequently affected. Crystal deposits (tophi) may develop around hands, feet, elbows, and ears. Diagnosis is usually made clinically. The American College of Rheumatology criteria for diagnosing gout are as follows: (1) characteristic urate crystals in joint fluid; (2) a tophus proved to contain urate crystals; or (3) the presence of six or more defined clinical laboratory and x ray phenomena (see table 1, p 1476).[2] We have included studies of people meeting the ACR criteria, studies in which the diagnosis was made clinically, and studies that used other criteria.

INCIDENCE/ PREVALENCE Gout is more common in older people and men.[3] In people aged 65–74 years in the UK, the prevalence is about 50/1000 in men and about 9/1000 in women.[4] The annual incidence of gout in people aged over 50 years in the USA is 1.6/1000 for men and 0.3/1000 for women.[5] Gout may be more common in some non-white ethnic groups.[3] Cohort studies of former medical students found the annual incidence of gout to be 3.1/1000 in black men and 1.8/1000 in white men.[6] After correcting for the higher prevalence of hypertension among black men, which is a risk factor for gout, the relative risk of gout in black men compared with white men was 1.3 (95% CI 0.77 to 2.19).

AETIOLOGY/ RISK FACTORS Urate crystals form when serum urate concentration exceeds 0.42 mmol/L.[7] Serum urate concentration is the principal risk factor for a first attack of gout,[8] although 40% of people have normal serum urate concentration during an attack of gout.[7,9–11] A cohort study of 2046 men followed for about 15 years found that the annual incidence is about 0.4% in men with a urate concentration of 0.42–0.47 mmol/L, rising to 4.3% when serum urate concentration is 0.45–0.59 mmol/L.[12] A 5 year longitudinal study of 223 asymptomatic men with hyperuricaemia estimated 5 year cumulative incidence of gout to be 10.8% for those with baseline serum urate of 0.42–0.47 mmol/L, 27.7% for baseline urate 0.48–0.53 mmol/L, and 61.1% for baseline urate levels of 0.54 mmol/L or more.[8] The study found that a 0.6 mmol/L difference in baseline serum urate increased the odds of an attack of gout by a factor of 1.8 (OR adjusted for other risk factors for gout: 1.84, 95% CI 1.24 to 2.72). It also found that alcohol and diuretics were risk factors for gout (adjusted OR for any alcohol intake *v* no alcohol intake: 3.45, 95% CI 1.58 to 7.56; adjusted OR for diuretics *v* no diuretics: OR 6.55, 95% CI 2.98 to 14.35). Other suggested risk factors for gout include obesity, insulin resistance, dyslipidaemia, hypertension, and cardiovascular disorders.[13,14]

PROGNOSIS We found few reliable data about prognosis or complications of gout. One study found that 3/11 (27%) people with untreated gout of the first metatarsophalangeal joint experienced spontaneous resolution after 7 days.[15] A case series of 614 people with gout who had not had treatment to reduce urate levels, and could recall the interval between first and second attacks, reported recurrence rates

of 62% after 1 year, 78% after 2 years, and 84% after 3 years.[16] An analysis of two prospective cohort studies of 371 black and 1181 white male former medical students followed up for about 30 years found no significant difference in risk of coronary heart disease in men who had developed gout compared with men who had not (RR 0.85, 95% CI 0.40 to 1.81).[17]

AIMS OF INTERVENTION **For treating gout:** to reduce the severity and duration of pain and loss of function, with minimal adverse effects of treatment. **For preventing recurrence:** to reduce the frequency and severity of recurrent attacks, and minimise the adverse effects of interventions.

OUTCOMES **For treating gout:** severity of symptoms (pain scores, proportion of people with improved symptoms), adverse effects of treatment. **For preventing recurrence (over 6 months):** number of recurrent episodes a year, severity of recurrent episodes a year, adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal August 2003 and hand searches of selected references. Only papers with 6 months or longer of follow up were included for prevention of recurrent gout. We excluded studies that were non-randomised, had 10 or fewer people in each treatment arm, had more than 20% loss to follow up, were crossover trials that did not present results before crossover, were not fully published (e.g. abstracts of conference proceedings, which could not be appraised for quality), or which reported only non-clinical outcomes such as serum urate levels.

QUESTION What are the effects of treatments for acute gout?

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One RCT provided limited evidence that tenoxicam reduced short term pain and tenderness in people with gout compared with placebo. However, this study was too small to provide reliable conclusions. We found no RCTs comparing other non-steroidal anti-inflammatory drugs with placebo in people with gout. Five RCTs found no significant difference in efficacy between different non-steroidal anti-inflammatory drugs in people with acute gout; however, these RCTs may have lacked power to detect clinically relevant differences. One equivalence study found that etoricoxib and indometacin had equivalent effects on pain, but that indometacin was associated with more adverse effects.

Benefits: We found no systematic review. **Versus placebo:** We found one RCT (30 people aged 21–70 years with gout of the knee, ankle, wrist, big toe, or elbow), which compared tenoxicam (40 mg once daily) with placebo.[18] Tenoxicam significantly increased the proportion of people showing at least a 50% reduction in pain and tenderness compared with placebo after 1 day (pain and tenderness assessed on a four point scale: "disappeared", "improved by ≥ 50%", "unchanged or improved by < 50%", or "increased"; AR for "pain improved by ≥ 50%": 10/15 [67%] with tenoxicam *v* 4/15 [26%] with placebo; $P < 0.05$; AR for "tenderness improved by ≥ 50%": 6/15 [40%] with tenoxicam *v* 1/15 [7%] with placebo; $P < 0.05$; AR for "pain on mobilisation improved ≥ 50%": 4/15

[27%] with tenoxicam *v* 1/15 [7%] with placebo; P < 0.05). However, it found no significant difference between tenoxicam and placebo in physician rated efficacy after 4 days (physician rated efficacy "good or excellent": 7/15 [47%] with tenoxicam *v* 4/15 [26%] with placebo; P value not reported).[18] **Versus each other:** We found six RCTs.[19–24] All found no significant difference in effectiveness between different types of non-steroidal anti-inflammatory drugs. However, they may have lacked power to show differences or establish equivalence. The first RCT (150 men with gout for < 24 hours, mean age 49 years) was an equivalence study, which compared indometacin ([indomethacin] 50 mg three times daily) with etoricoxib (120 mg once daily).[19] It found indometacin and etoricoxib had equivalent effects on pain after 2–5 days (pain measured on a Likert scale: 0 = no pain to 4 = extreme pain; difference +0.11, 95% CI −0.14 to +0.35; equivalence prespecified as ±0.5). The second RCT (93 people with gout) compared indometacin (200 mg for 1 day in divided doses followed by a reducing regimen for 28 days) with azapropazone (600 mg 3 times daily for 4 days followed by 600 mg twice daily for 28 days).[20] It found no significant difference in the proportion of people who reported that the treatment "suited them" after 4 days (35/47 [74%] with indometacin *v* 40/46 [87%] with azapropazone; P value quoted as "not significant"). The third RCT (61 people with gout aged 18–75 years) compared etodolac (300 mg twice daily) with naproxen (500 mg twice daily).[21] It found no significant difference in pain between etodolac and naproxen after 2, 4, or 7 days (assessed on a scale 0–5, higher scores indicating worse pain; mean pain score at 2 days: 2.6 with etodolac *v* 2.8 with naproxen; P value quoted as "not significant"; mean pain score at 4 days: 1.8 with etodolac *v* 2.0 with naproxen; P value quoted as "not significant"; mean pain score at 7 days: 1.4 with etodolac *v* 1.4 with naproxen; P value quoted as "not significant"). The fourth RCT (60 people with gout aged 18–75 years) compared etodolac (300 mg twice daily) with naproxen (500 mg twice daily).[22] It found no significant difference in pain between etodolac and naproxen after 1, 2, 4, and 7 days (assessed on a five point rating scale: 1 = no pain to 5 = very severe pain; results presented graphically, no AR or P values reported). The fifth RCT (59 people with gout for < 48 hours, aged 35–88 years) compared indometacin (up to 225 mg for 1 day in divided doses followed by 50 mg 3 times daily) versus ketoprofen (450 mg in divided doses for 1 day followed by 100 mg 3 times daily).[23] It found no significant difference in pain score between indometacin and ketoprofen after 2, 5, or 8 days (assessed on a four point scale: 0 = no pain to 3 =severe pain; mean pain score at 2 days: 0.9 with indometacin *v* 1.1 with ketoprofen; P value quoted as "not significant"; mean pain score at 5 days: 0.8 with indometacin *v* 1.3 with ketoprofen; P value quoted as "not significant"; mean pain score at 8 days: 0.3 with indometacin *v* 0.4 with ketoprofen; P value quoted as "not significant"). The sixth RCT (29 people with gout) compared indometacin (50 mg 4 times daily for 4 days followed by 25 mg 4 times daily for 5 days) with flurbiprofen (100 mg 4 times daily for 1 day followed by 50 mg 4 times daily for 5 days).[24] It found no significant difference

between indometacin and flurbiprofen in the proportion of people with improved pain at rest after 2 days (proportion with improved pain at rest: 11/12 [92%] with indometacin *v* 11/12 [92%] with flurbiprofen; P value not reported). **Versus other treatments:** We found no RCTs.

Harms: The harms of non-steroidal anti-inflammatory drugs are considered in detail elsewhere in *Clinical Evidence* (see non-steroidal anti-inflammatory drugs, p 1551) and include gastrointestinal ulceration and haemorrhage. The first RCT found that indometacin produced significantly more adverse events than etoricoxib (proportion with adverse events: 17/75 [23%] with etoricoxib *v* 35/75 [47%] with indometacin; P = 0.003).[19] No differences in important adverse event rates were found when indometacin was compared with ketoprofen,[23] azapropazone,[20] or flurbiprofen.[24] Neither study comparing etodolac versus naproxen reported any important adverse events.[21,22]

Comment: **Versus placebo:** The RCT comparing tenoxicam versus placebo conducted multiple significance tests and no adjustment was reported for this.[18] **Versus each other:** Phenylbutazone and indometacin were established as treatments for gout based on uncontrolled studies. Only the comparison between etoricoxib and indometacin was powered to show equivalence in efficacy between the two compounds tested.[18] Etoricoxib, a selective inhibitor of cyclo-oxygenase-2, may be a useful alternative to conventional non-steroidal anti-inflammatory drugs for people at high risk of gastrointestinal adverse effects. We found five RCTs that compared phenylbutazone with other non-steroidal anti-inflammatory drugs. These have not been considered further because phenylbutazone for gout has been restricted in many countries because it can cause aplastic anaemia and other serious adverse effects.[25]

OPTION CORTICOSTEROIDS

We found no systematic review or RCTs on the effects of parenteral, oral, or intra-articular corticosteroids in people with gout.

Benefits: We found no systematic review or RCTs.

Harms: We found insufficient evidence in people with gout. Potential harms of oral corticosteroids are covered elsewhere in *Clinical Evidence* (see asthma, p 1966).

Comment: None.

OPTION ORAL COLCHICINE

One small RCT provided limited evidence that colchicine improved pain in people with gout. However, we were unable to draw reliable conclusions from this RCT. The high incidence of adverse effects associated with colchicine precludes its use as routine treatment for acute gout.

Benefits: We found no systematic review. **Versus placebo:** We found one small RCT (43 hospital inpatients with gout confirmed by synovial fluid examination, aged 55–91 years; 40/43 were men), which compared colchicine (1 mg followed by 0.5 mg every 2 hours as

tolerated or until complete response) versus placebo.[26] It found that colchicine reduced pain compared with placebo after 48 hours (pain assessed on a 10 cm visual analogue scale; proportion with ≥ 50% improvement in pain: 73% with colchicine *v* 36% with placebo; $P < 0.05$).

Harms: The RCT found that all participants taking colchicine experienced diarrhoea, vomiting, or both, within about 24 hours; 5/21 [24%] participants taking placebo developed nausea.[26] The 50% improvement in pain occurred before diarrhoea and vomiting in 9/22 (40%), after the onset of diarrhoea and vomiting in 12/22 (55%), and at the same time in one.

Comment: Colchicine has been used since antiquity to treat gout. A large number of observational studies support its use. Although it may be efficacious, narrow benefit to toxicity ratio limits its use in people with gout.[27]

QUESTION What are the effects of treatments to prevent gout in people with prior acute episodes?

OPTION COLCHICINE

We found no RCTs on the effects of colchicine in preventing attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ADVICE TO LOSE WEIGHT

We found no RCTs on the effects of advice to lose weight to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ADVICE TO REDUCE ALCOHOL INTAKE

We found no RCTs on the effects of advice to reduce alcohol intake to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ADVICE TO REDUCE DIETARY INTAKE OF PURINES

We found no RCTs on the effects of advice to reduce dietary intake of purines to prevent attacks of gout in people with prior episodes.

Gout

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ALLOPURINOL

We found no RCTs on the effects of allopurinol to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: We found one quasi-randomised trial (37 men with a history of gout, aged 27–78 years), which compared probenecid 1–2 g daily versus allopurinol 300–600 mg daily.[28] Both groups took prophylactic colchicine during the first few months of treatment. Treatment allocation was by the last digit of the hospital number. The trial found no significant difference between probenecid and allopurinol for recurrence after a mean follow up of 18.6 months (recurrence free: 8/17 [47%] with probenecid *v* 9/20 [45%]; no P value stated). However, results may have been biased by non-random treatment allocation and because five people allocated to probenecid received sulphinpyrazone instead.

OPTION PROBENECID

We found no RCTs on the effects of probenecid to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs (see comment below).

Harms: We found no RCTs.

Comment: We found one quasi-randomised trial (37 men with a history of gout, aged 27–78 years), which compared probenecid 1–2 g daily versus allopurinol 300–600 mg daily.[28] See comment under allopurinol for details, p 1474.

OPTION SULPHINPYRAZONE

We found no RCTs on the effects of sulphinpyrazone to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematics review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION BENZBROMARONE

We found no RCTs on the effects of benzbromarone to prevent attacks of gout in people with prior episodes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

TABLE 1 **American College of Rheumatology criteria for acute gout (people must fulfill six or more criteria; see text, p 1469).[2]**

1	More than one attack of acute arthritis
2	Maximum inflammation developed within 1 day
3	Monoarthritis attack
4	Redness observed over joints
5	First metatarsophalangeal joint painful or swollen
6	Unilateral first metatarsophalangeal joint attack
7	Unilateral tarsal joint attack
8	Tophus (proved or suspected)
9	Hyperuricaemia
10	Asymmetric swelling within a joint on x ray film
11	Subcortical cysts without erosions on x ray film
12	Monosodium urate monohydrate microcrystals in joint fluid during an attack
13	Joint culture negative for organism during attack

QUESTIONS

INTERVENTIONS

Likely to be beneficial

Unknown effectiveness

Unlikely to be beneficial

Covered elsewhere in *Clinical Evidence*

Non-specific acute low back pain, p 1500 and chronic low back pain, p 1516.

See glossary, p 1489

Key Messages

- **Microdiscectomy (as effective as standard discectomy)** We found no RCTs comparing microdiscectomy versus conservative treatment. Three RCTs found no significant difference in clinical outcomes between microdiscectomy and standard discectomy. One RCT found no significant difference in satisfaction or pain between video-assisted arthroscopic microdiscectomy and standard discectomy at about 30 months, although postoperative recovery was slower with standard discectomy. We found insufficient evidence on the effects of automated percutaneous discectomy compared with microdiscectomy.
- **Spinal manipulation** One RCT in people with sciatica caused by disc herniation found that spinal manipulation increased self perceived improvement after 2 weeks compared with a placebo of infrequent infrared heat. One RCT comparing spinal manipulation, manual traction, exercise, and corsets found no significant difference among groups in self perceived improvement after 1 month. One RCT found that spinal manipulation increased the proportion of people with improved symptoms compared with traction. Concerns exist regarding possible further herniation from spinal manipulation in people who are surgical candidates.

Herniated lumbar disc

- **Standard discectomy (short term benefit)** One RCT found that standard discectomy increased self reported improvement at 1 year, but not at 4 and 10 years, compared with conservative treatment (physiotherapy). Three RCTs found no significant difference in clinical outcomes between standard discectomy and microdiscectomy. Adverse effects were similar with both procedures.
- **Acupuncture** One systematic review found insufficient evidence on the effects of acupuncture in people with herniated lumber discs.
- **Advice to stay active** One systematic review of conservative treatments for sciatica caused by lumbar disc herniation found no RCTs on advice to stay active.
- **Automated percutaneous discectomy** We found no RCTs comparing automated percutaneous discectomy versus either conservative treatment or standard discectomy. We found insufficient evidence on the clinical effects of automated percutaneous discectomy compared with microdiscectomy.
- **Exercise therapy** One systematic review of one RCT found no significant difference in global improvement between isometric exercise and manual traction in people with sciatica caused by disc herniation.
- **Heat or ice** One systematic review identified no RCTs of heat or ice for sciatica caused by lumbar disc herniation.
- **Massage** One systematic review identified no RCTs of massage in people with symptomatic lumbar disc herniation.
- **Bed rest** One systematic review of conservative treatment found no RCTs on bed rest in people with symptomatic herniated discs. One subsequent RCT in people with sciatica found no significant difference between bed rest and watchful waiting for 2 weeks in people's perceived improvement, mean pain scores, mean disability scores, or mean satisfaction scores after 12 weeks.
- **Epidural corticosteroid injections** One systematic review found limited evidence that epidural steroid injections increased global improvement compared with placebo. However, one subsequent RCT found no significant difference between epidural steroid injections plus conservative treatment and conservative treatment alone in pain, mobility, or people returning to work at 6 months. Another subsequent RCT found no significant difference between epidural steroid injection and control injection in pain, disability, or self rated improvement after 35 days.
- **Non-steroidal anti-inflammatory drugs** One systematic review found no significant difference in overall improvement between non-steroidal anti-inflammatory drugs and placebo in people with sciatica caused by disc herniation.
- **Analgesics; antidepressants; laser discectomy; muscle relaxants** We found no systematic review or RCTs on these interventions for treatment of people with symptomatic herniated lumbar discs.

DEFINITION Herniated lumbar disc is a displacement of disc material (nucleus pulposus or annulus fibrosis) beyond the intervertebral disc space.[1] The diagnosis can be confirmed by radiological examination; however, magnetic resonance imaging findings of herniated disc are not always accompanied by clinical symptoms.[2,3] This review covers treatment of people who have clinical symptoms relating to confirmed or suspected disc herniation. It does not include treatment of people with spinal cord compression or people with cauda equina

syndrome (see glossary, p 1489), which often requires emergency intervention. The management of non-specific acute low back pain, p 1500 and chronic low back pain, p 1516 are covered elsewhere in *Clinical Evidence*.

INCIDENCE/ PREVALENCE The prevalence of symptomatic herniated lumbar disc is about 1–3% in Finland and Italy, depending on age and sex.[4] The highest prevalence is among people aged 30–50 years,[5] with a male to female ratio of 2 : 1.[6] In people aged between 25 and 55 years, about 95% of herniated discs occur at the lower lumbar spine (L4–L5 level); in people over 55 years of age, disc herniation is more common above this level.[7,8]

AETIOLOGY/ RISK FACTORS Radiographical evidence of disc herniation does not reliably predict low back pain in the future or correlate with symptoms; 19–27% of people without symptoms have disc herniation on imaging.[2,9] Risk factors for disc herniation include smoking (OR 1.7, 95% CI 1.0 to 2.5), weight bearing sports (e.g. weight lifting, hammer throw etc), and certain work activities such as repeated lifting. Driving motor vehicles is also associated with increased risk (OR 1.7, 95% CI 0.2 to 2.7, depending on the vehicle model).[6,10,11] This may be because the resonant frequency of the spine is similar to that of certain vehicles.

PROGNOSIS The natural history of disc herniation is difficult to determine because most people take some form of treatment for their back pain, and a formal diagnosis is not always made.[6] Clinical improvement is usual in most people, and only about 10% of people still have sufficient pain after 6 weeks to consider surgery. Sequential magnetic resonance images have shown that the herniated portion of the disc tends to regress over time, with partial to complete resolution after 6 months in two thirds of people.[12]

AIMS OF INTERVENTION To relieve pain; increase mobility and function; and improve quality of life.

OUTCOMES **Primary outcomes:** pain, function, or mobility; individuals' perceived overall improvement; quality of life; and adverse effects of treatment. **Secondary outcomes:** return to work; use of analgesia; and duration of hospitalisation.

METHODS *Clinical Evidence* search and appraisal August 2003. The authors searched Amed and the Physiotherapy Evidence Database (PEDro) in January 2003.

QUESTION What are the effects of drug treatments?

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One systematic review found no significant difference in overall improvement between non-steroidal anti-inflammatory drugs and placebo in people with sciatica caused by disc herniation.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 3 RCTs, 321 people) of medical treatments for sciatica caused by disc herniation.[13] The RCTs compared non-steroidal anti-inflammatory drugs (NSAIDs) (piroxicam 40 mg daily for 2 days

or 20 mg daily for 12 days; indometacin [indomethacin] 75–100 mg 3 times daily; phenylbutazone 1200 mg daily for 3 days or 600 mg daily for 2 days) versus placebo. The review found no significant difference between NSAIDs and placebo in global improvement after 5–30 days (pooled AR for improvement in pain: 80/172 [46.5%] *v* 57/149 [38.3%]; OR for global improvement 0.99, 95% CI 0.6 to 1.7; see comment below).

Harms: The systematic review did not report the adverse effects of NSAIDs. NSAIDs may cause gastrointestinal complications (see NSAIDs topic, p 1551).

Comment: The absolute numbers in the RCTs relate to the outcomes of improvement in pain (3 RCTs) and return to work (1 RCT).[13] However, the meta-analysis used the outcome measure of global improvement. The relationship between these measures is unclear.

OPTION ANALGESICS

We found no systematic review or RCTs of analgesics to treat people with symptomatic herniated lumbar discs.

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION ANTIDEPRESSANTS

We found no systematic review or RCTs of antidepressants to treat people with symptomatic herniated lumbar discs.

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION MUSCLE RELAXANTS

We found no systematic review or RCTs of muscle relaxants to treat people with symptomatic herniated lumbar discs.

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION EPIDURAL CORTICOSTEROID INJECTIONS

One systematic review found limited evidence that epidural steroid injections increased global improvement compared with placebo. However, one subsequent RCT found no significant difference between epidural steroid injections plus conservative treatment and conservative

treatment alone in pain, mobility, or people returning to work at 6 months. Another subsequent RCT found no significant difference between epidural steroid injection and control injection in pain, disability, or self rated improvement after 35 days.

Benefits: We found one systematic review (search date 1998, 4 RCTs of epidural steroids, 265 people)[13] of medical treatments for sciatica caused by disc herniation and two subsequent RCTs.[14,15] The review compared four different doses of epidural steroid injections (8 mL methylprednisolone 80 mg; 2 mL methylprednisolone 80 mg; 10 mL methylprednisolone 80 mg; and 2 mL methylprednisolone acetate 80 mg) versus placebo (saline or lidocaine [lignocaine] 2 mL) after follow up periods of 2, 21, and 30 days.[13] The review found limited evidence that epidural steroids increased the proportion of people with self perceived global improvement (which was not defined) compared with placebo. The result was of borderline significance (73/160 [45.6%] with steroid *v* 56/172 [32.5%] with placebo; OR 2.2, 95% CI 1.0 to 4.7). The first subsequent RCT (36 people with disc herniation confirmed by magnetic resonance imaging) compared epidural steroids (3 injections of methylprednisolone 100 mg in 10 mL bupivacaine 0.25% during the first 14 days of hospitalisation) plus conservative non-operative treatment versus conservative treatment alone.[14] Conservative treatment involved initial bed rest and analgesia followed by graded rehabilitation (hydrotherapy, electroanalgesia, postural exercise classes) followed by physiotherapy. It found no significant difference between groups in mean pain scores at 6 weeks and 6 months measured on a visual analogue scale (at 6 months: 32.9 [range 0–85] with steroids *v* 39.2 [range 0–100] with conservative treatment). It found no significant difference in mean mobility scores (Hannover Functional Ability Questionnaire: 61.8 [range 25–88] with steroids *v* 57.2 [range 13–100]), in the number of people who had back surgery (2/17 [12%] with steroids *v* 4/19 [21%]; RR 0.56, 95% CI 0.09 to 2.17), or in people returning to work within 6 months (15/17 [88%] with steroids *v* 14/19 [74%]; RR 1.19, 95% CI 0.75 to 1.33).[14] The second subsequent double blind RCT (85 people with sciatica caused by herniated disc) compared epidural steroid injections (2 mL prednisolone acetate at 2 day intervals for a total of 3 injections) versus control (2 mL isotonic saline).[15] It found no significant difference between groups in self rated success of treatment after 35 days (people rating improvement as "recovery" or "marked improvement": 21/43 [49%] with steroid *v* 20/42 [48%] with control; P = 0.91). The RCT also found no significant difference between steroid injection and control injection in pain scores after 35 days (mean change from baseline measured by unspecified visual analogue scale: –30.3 mm with steroid *v* –25.2 mm with control; treatment effect –5.1, 95% CI –18.7 to +8.4) or disability/function (Roland-Morris Index score, mean change from baseline: –5.3 with steroid *v* –3.2 with control; treatment effect –2.1, 95% CI –5.0 to +0.8).[15]

Harms: No serious adverse effects were reported in the RCTs included in the systematic review, although 26 people complained of transient headache or transient increase in sciatic pain.[13] The first subsequent RCT did not report adverse effects of epidural injections.[14]

The second subsequent RCT reported that clinically significant adverse effects occurred in 2/43 (5%) people in the steroid group and 3/42 (7%) people in the control group (P = 0.676).[15] It reported that headache occurred in two people in each group, and thoracic pain occurred in one person with control.

Comment: None.

QUESTION What are the effects of non-drug treatments?

OPTION BED REST

One systematic review of conservative treatment found no RCTs on bed rest in people with symptomatic herniated discs. One subsequent RCT in people with sciatica found no significant difference between bed rest and watchful waiting for 2 weeks in people's perceived improvement, mean pain scores, mean disability scores, or mean satisfaction scores after 12 weeks.

Benefits: We found one systematic review[13] and one subsequent RCT.[16] The systematic review (search date 1998) of conservative treatments for sciatica caused by disc herniation identified no RCTs of bed rest for treatment of people with symptomatic herniated discs.[13] The subsequent RCT (183 people with sciatica, intensity sufficient to justify 2 weeks of bed rest as treatment) compared bed rest at home (instructed to stay in the supine or lateral recumbent position with 1 pillow under the head) versus a control of watchful waiting (advised to be up and about whenever possible) for 2 weeks.[16] Most people had nerve root compression on magnetic resonance imaging (109 people out of 161 people who had magnetic resonance imaging performed). It found no significant difference between bed rest and control in people's perceived improvement (87% with bed rest *v* 87% with control; OR 1.0, 95% CI 0.4 to 2.9; based on regression analysis; see comment below), mean pain scores (McGill Pain Questionnaire: 8 with bed rest *v* 7 with control; difference –0.6, 95% CI –3.3 to +2.1; based on regression analysis), mean disability scores (revised Roland Disability Scale: 15.2 with bed rest *v* 15.7 with control; difference –0.5, 95% CI –2.6 to +1.6; based on regression analysis), or mean satisfaction scores (7 with bed rest *v* 8 with control; difference –0.1, 95% CI –0.6 to +0.3; based on regression analysis) after 12 weeks.

Harms: The subsequent RCT did not report on harms of bed rest.[16]

Comment: The regression analysis in the RCT adjusted odds ratios and differences between treatments for several variables including baseline differences in age, sex, presence or absence of paresis, disease duration, and people's history with respect to sciatica, among others.[16] We found one further systematic review (search date 1996) of bed rest and advice to stay active in people with acute low back pain that found three RCTs that included people with sciatica or radiating pain.[17] However, no further details are given in the review on the proportion of people in these RCTs with herniated discs. The review concluded that there was little evidence on bed rest specifically for herniated lumbar discs, although the RCTs they did find questioned the efficacy of bed rest for sciatica.[17]

OPTION ADVICE TO STAY ACTIVE

One systematic review of conservative treatments for sciatica caused by lumbar disc herniation found no RCTs of advice to stay active.

Benefits: We found one systematic review (search date 1998) of conservative treatments for sciatica caused by disc herniation, which found no RCTs of advice to stay active.[13] We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION MASSAGE

One systematic review identified no RCTs of massage in people with symptomatic lumbar disc herniation.

Benefits: We found one systematic review (search date 1998) of conservative treatments for sciatica caused by disc herniation, which found no RCTs of massage.[13] We found no subsequent RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION HEAT OR ICE

One systematic review identified no RCTs of heat or ice for sciatica caused by lumbar disc herniation.

Benefits: We found one systematic review (search date 1998) of conservative treatments for sciatica caused by disc herniation, which identified no RCTs on the use of heat or ice for herniated lumbar discs.[13] We found no subsequent RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION SPINAL MANIPULATION

One RCT in people with sciatica caused by disc herniation found that spinal manipulation increased self perceived improvement after 2 weeks compared with a placebo of infrequent infrared heat. One RCT comparing spinal manipulation, manual traction, exercise, and corsets found no significant difference among groups in self perceived improvement after 1 month. One RCT found that spinal manipulation increased the proportion of people with improved symptoms compared with traction. Concerns exist regarding possible further herniation from spinal manipulation in people who are surgical candidates.

Benefits: We found two systematic reviews[13,18] and one subsequent RCT.[19] The first systematic review (search date 1998), which did not perform meta-analysis, identified two RCTs of spinal manipulation for sciatica caused by disc herniation.[13] The second systematic review (search date not reported) identified no RCTs.[18] The first RCT

(207 people) included in the first review compared spinal manipulation (every day if necessary) versus placebo (infrared heat 3 times weekly).[13] It found that spinal manipulation increased overall self perceived improvement at 2 weeks compared with placebo (98/123 [80%] *v* 56/84 [67%]; RR 1.19, 95% CI 1.01 to 1.32; NNT 8, 95% CI 5 to 109).[13] The second included RCT (322 people) compared four interventions: spinal manipulation, manual traction, exercise, and corsets, in a factorial design.[13] It found no significant difference among treatments in overall self perceived improvement after 28 days (quantified results not reported). The subsequent RCT (112 people with symptomatic herniated lumbar disc) compared pulling and turning manipulation versus traction.[19] It found that significantly more people were "improved" (absence of lumbar pain, improvement in lumbar functional movement) or "cured" (absence of lumbar pain, straight leg raising of > 70°, ability to return to work) with spinal manipulation compared with traction (54/62 [87%] with manipulation *v* 33/50 [66%] with traction; RR 1.32, 95% CI 1.06 to 1.65; NNT 5, 95% CI 4 to 16; timescale not reported).

Harms: The first systematic review did not report adverse effects.[13] The second systematic review identified one review of 135 case reports of serious complications after spinal manipulation published between 1950 and 1980.[18] However, the frequency of these effects was not certain. The case review attributed these complications to cervical manipulation, misdiagnosis, presence of coagulation dyscrasias, presence of herniated nucleus pulposus, or improper techniques. The subsequent RCT found that two out of 60 people receiving traction had syncope; no adverse effects were reported in people receiving manipulation.[19] We found a third systematic review (search date 2001, 5 prospective observational studies).[20] The largest study included in the review (4712 treatments in 1058 people undergoing both cervical and lumbar spinal manipulations) found that the most common reaction was local discomfort (53%), followed by headache (12%), tiredness (11%), radiating discomfort (10%), dizziness (5%), nausea (4%), hot skin (2%), and other complaints (2%). The incidence of serious adverse effects is reported as rare, and is estimated from published case series and reports to occur in one in 1–2 million treatments. The most common of these serious effects were cerebrovascular accidents (the total number of people having manipulations was not reported and the rate of this adverse effect cannot be estimated). However, it is difficult to assess whether such events are directly related to treatment.

Comment: In the third review, which examined risks, the percentages include both cervical and lumbar spinal manipulations, which may overestimate the effect of lumbar spinal manipulations.[20] The authors of the review advise caution in interpreting these results, as they are speculative and based on assumptions about the numbers of manipulations performed and unreported cases. More reliable data are needed on the incidence of specific risks. It is unclear whether the populations studied in the RCTs cited included people who were surgical candidates for disc herniation. Concerns exist regarding possible further herniation from spinal manipulation in people who are surgical candidates.

OPTION EXERCISE THERAPY New

One systematic review of one RCT found no significant difference in global improvement between isometric exercise and manual traction in people with sciatica caused by disc herniation.

Benefits: We found one systematic review (search date 1998) of conservative treatments for sciatica caused by disc herniation.[13] The review included one RCT (50 people) that compared isometric exercise versus manual traction (both for 5–7 days; see comment below). The review found no significant difference between groups in a global measure of improvement (reported as no significant difference, absolute numbers and P value not reported; see comment below). We found no subsequent RCTs.

Harms: The review did not report on harms of exercise.[13]

Comment: The review did not report further details of treatment regimens. The global measure of improvement was not further defined.[13]

OPTION ACUPUNCTURE New

One systematic review found insufficient evidence on the effects of acupuncture in people with herniated lumber discs.

Benefits: We found one systematic review (search date 1998) in people with back and neck pain, which identified one small RCT of acupuncture in people with sciatica.[21] The RCT (30 people with acute sciatica; see comment below) compared acupuncture at electronically detected non-traditional points versus sham acupuncture. The review reported that the RCT found that acupuncture significantly improved three outcomes compared with sham acupuncture and reported that the RCT concluded that there was an overall benefit of acupuncture.[21] However, the review disagreed with the RCTs overall conclusion of benefit stating that it only found a significant difference between groups in three out of 12 outcome measures, and that there was no significant difference between acupuncture and sham acupuncture in pain intensity at rest, the most clinically relevant outcome, after 5 days (absolute numbers not given, P value not reported).[21] The review found one RCT in people with neck and lumbar pain (see comment below).

Harms: No adverse effects from the two RCTs were reported in the systematic review.[21]

Comment: In the RCT of people with acute sciatica, the acute sciatica may not have been caused by disc herniation.[21] The review also included one small crossover RCT (42 people, radicular and pseudo radicular cervical and lumbar pain due to stenosis and/or herniated disc) that compared laser acupuncture at traditional points versus sham laser acupuncture. The review found no significant difference between groups in reduction of pain intensity after 24 hours, although pain was significantly improved in the laser acupuncture group at 15 minutes, 1 hour, and 6 hours compared with control. The sample sizes in both RCTs included in the review were small and provide little evidence of the effectiveness of acupuncture specifically in people with herniated lumbar disc.

QUESTION What are the effects of surgery?

OPTION STANDARD DISCECTOMY

One RCT found that standard discectomy increased self reported improvement at 1 year, but not at 4 and 10 years, compared with conservative treatment (physiotherapy). Three RCTs found no significant difference in clinical outcomes between standard discectomy and microdiscectomy. Adverse effects were similar with both procedures.

Benefits:

Versus conservative treatment: We found two systematic reviews (search dates 1999[22] and not reported[23]) which included the same RCT (126 people with symptomatic L5/S1 disc herniation)[24] comparing standard discectomy (see glossary, p 1489) versus conservative treatment (6 weeks of physiotherapy). Each person assessed and graded their improvement in terms of pain and function into four categories: "good" (completely satisfied), "fair", "poor", and "bad" (completely incapacitated for work because of pain). The RCT found that discectomy significantly increased the proportion of people reporting their improvement as "good" after 1 year compared with conservative treatment (intention to treat analysis: 39/60 [65%] with surgery *v* 24/66 [36.4%] with conservative treatment; RR 1.79, 95% CI 1.30 to 2.18; NNT 3, 95% CI 2 to 9). However, at 4 and 10 years, there was no significant difference in the same outcome (at 4 years, AR for "good" improvement: 40/60 [66.7%] with surgery *v* 34/66 [51.5%] with conservative treatment; RR 1.29, 95% CI 0.96 to 1.56; at 10 years: 35/60 [58.3%] *v* 37/66 [56.1%]; RR 1.04, 95% CI 0.73 to 1.32). **Versus microdiscectomy:** One systematic review (search date 1999)[22] identified three RCTs (219 people) comparing standard discectomy versus microdiscectomy (see glossary, p 1489). It did not perform meta-analysis because outcomes were not comparable. The first RCT in the review (60 people with lumbar disc herniation) found no significant difference between standard discectomy and microdiscectomy in the proportion of people who rated their operative outcome as "good", "almost recovered", or "totally recovered" at 1 year (intention to treat analysis: 26/30 [87%] with standard discectomy *v* 24/30 [80%] with microdiscectomy; RR 1.08, 95% CI 0.78 to 1.20).[25] It found no difference between treatments in the change in preoperative and postoperative pain scores (visual analogue scale; P value not reported) or in the duration of time taken to return to work (both 10 weeks). The second RCT in the review (79 people with lumbar disc herniation) found no significant difference between microdiscectomy and standard discectomy in pain in the legs or back (visual analogue scale, not specified) or in analgesia use at any point during the 6 week follow up (absolute numbers not reported).[26] The third RCT (80 people) found that clinical outcomes and duration of sick leave were similar at 15 months, but the review did not provide further details.[22]

Harms:

Versus conservative treatment: The RCT included in both systematic reviews did not report on complications of standard discectomy.[24] **Versus microdiscectomy:** One systematic review reported that there was no significant difference between standard

discectomy and microdiscectomy in perioperative bleeding, duration of stay, or scar tissue (numbers not reported).[22] The first RCT included in the review reported one person in each group with a nerve root tear and, of the people having microdiscectomy, one had a dural leak and one had suspected discitis.[25] The second RCT included in the review did not report on the complications of either procedure.[26] Complication rates were reported inconsistently in studies, making it difficult to combine results to produce overall rates. Rates of complications for all types of discectomy have been compiled (see table 1, p 1492).[23]

Comment: The RCT of standard discectomy versus conservative treatment had considerable crossover between the two treatment groups.[24] Of 66 people randomised to receive conservative treatment, 17 received surgery; of 60 people randomised to receive surgery, one refused the operation.[24] The results presented above are based on an intention to treat analysis. One systematic review of published reports (search date not reported) found 99 cases of vascular complications following lumbar disc surgery since 1965.[27] Reported risk factors for vascular complications included: previous disc or abdominal surgery leaving adhesions; chronic disc pathology from disruption or degeneration of anterior annulus fibrosus and anterior longitudinal ligament or peridiscal fibrosis; improper positioning of the patient; retroperitoneal vessels and operated disc in close proximity; and vertebral anomalies, such as hypertrophic spurs compressing vessels during operation. The systematic review did not state out of how many operations the 99 complications arose from, therefore we can not estimate the incidence of adverse vascular events from discectomy.[27]

OPTION MICRODISCECTOMY

We found no RCTs comparing microdiscectomy versus conservative treatment. Three RCTs found no significant difference in clinical outcomes between microdiscectomy and standard discectomy. One RCT found no significant difference in self reported satisfaction or pain score between video-assisted arthroscopic microdiscectomy and standard discectomy after about 30 months, although postoperative recovery was slower with standard discectomy. We found insufficient evidence on the effects of automated percutaneous discectomy compared with microdiscectomy.

Benefits: We found no systematic review. **Versus conservative treatment:** We found no RCTs. **Versus standard discectomy:** See glossary, p 1489. See benefits of standard discectomy, p 1486. **Video-assisted arthroscopic microdiscectomy versus standard discectomy:** We found one RCT (60 people with proven lumbar disc herniation and associated radiculopathy after failed conservative treatment).[28] It found no significant difference between video-assisted arthroscopic discectomy and standard discectomy in the proportion of people who were "very satisfied" on a 4 point satisfaction scale after about 31 months (22/30 [73%] with microdiscectomy [see glossary, p 1489] *v* 20/30 [67%] with standard discectomy; RR 1.10, 95% CI 0.71 to 1.34). There was also no significant difference in mean pain score (visual analogue scale

from 0 [no pain] to 10 [severe and incapacitating pain]: 1.2 with microdiscectomy *v* 1.9 with standard discectomy). However, the mean duration of postoperative recovery was almost twice as long with open surgery as with microdiscectomy (49 days *v* 27 days; P value not reported). **Versus automated percutaneous discectomy:** See glossary, p 1489. See benefits of automated percutaneous discectomy, p 1488.

Harms: **Video-assisted arthroscopic microdiscectomy versus open discectomy:** The RCT reported that one person undergoing open discectomy had leakage of spinal fluid from the dural sac 2 weeks after the operation.[28] No other postoperative complications or neurovascular injuries were observed in either the standard discectomy or the microdiscectomy groups. Complication rates were reported inconsistently in studies, making it difficult to combine results to produce overall rates. Rates of complications for all types of discectomy have been compiled (see table 1, p 1492).[23]

Comment: None.

OPTION AUTOMATED PERCUTANEOUS DISCECTOMY

We found no RCTs comparing automated percutaneous discectomy with either conservative treatment or standard discectomy. We found insufficient evidence on the clinical effects of automated percutaneous discectomy compared with microdiscectomy.

Benefits: **Versus conservative treatment:** We found no systematic review or RCTs. **Versus standard discectomy:** One systematic review (search date not reported) identified no RCTs comparing automated percutaneous discectomy (APD) versus standard discectomy (see glossary, p 1489).[23] **Versus microdiscectomy:** One systematic review (search date 1999) identified two RCTs that were not directly comparable because there were differences in the equipment used.[22] One RCT (71 people with radiographical confirmation of disc herniation) was stopped prematurely, after an interim analysis at 6 months found that APD was associated with significantly lower success rate than microdiscectomy (see glossary, p 1489) (overall outcome was classified as "success" or "failure" by the clinician and a masked observer [details not reported]: 9/31 [29%] with APD *v* 32/40 [80%] with microdisectomy; $P < 0.001$).[29] However, the other RCT (40 people with radiographical confirmation of disc herniation) reported similar improvements in the composite clinical score with APD versus microdiscectomy (scale 0–10, including back and leg pain, and sensory and motor deficit) at 2 years (preoperative scores: 4.55 with APD *v* 4.2 with microdiscectomy; scores at 2 years: 8.23 with APD *v* 7.67 with microdiscectomy).[30] More people in the APD group rated their surgical outcomes as "excellent" or "good" than did those in the microdiscectomy group 2 years after surgery (14/20 [70%] with APD *v* 11/20 [55%] with microdiscectomy; $P = 0.33$).

Harms: The systematic review found that re-operations for recurrent or persistent disc herniations at the same level as the initial operations were reported more frequently with APD compared with either

microdiscectomy or standard discectomy (APD 83%, 95% CI 76% to 88% *v* microdiscectomy 64%, 95% CI 48% to 78% *v* standard discectomy 49%, 95% CI 38% to 60%).[23] The first RCT did not report adverse effects.[29] The second RCT reported that no complications had occurred with APD, but did not comment on whether there had been any complications in the microdiscectomy group.[30] The mean duration of recovery after surgery was longer in people who had microdiscectomy compared with those who had APD (mean weeks of postoperative recovery [range]: 22.9 weeks [4 weeks to 1 year] with microdiscectomy group *v* 7.7 weeks [1–26 weeks] with APD). Complication rates were reported inconsistently in studies, making it difficult to combine results to produce overall rates. Rates of complications for all types of discectomy have been compiled (see table 1, p 1492).[23]

Comment: None.

OPTION LASER DISCECTOMY

Systematic reviews found no RCTs on the effects of laser discectomy in people with disc herniations.

Benefits: Three systematic reviews (search dates 1999,[22] not reported,[23] and 2000[31]) found no RCTs on the effectiveness of laser discectomy (see glossary, p 1489).

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Automated percutaneous discectomy Techniques using minimal skin incisions (generally several, all < 3–5 mm) to allow small instruments to be inserted, using radiography to visualise these instruments, and using extensions for the surgeon to reach the operative site without having to dissect tissues.

Cauda equina A collection of spinal roots descending from the lower part of the spinal cord, which occupy the vertebral canal below the spinal cord.

Cauda equina syndrome Compression of the cauda equina causing symptoms, including changes in perineal sensation (saddle anaesthesia), and loss of sphincter control.

Laser discectomy The surgeon places a laser through a delivery device that has been directed under radiographic control to the disc, and removes the disc material using the laser. It uses many of the same techniques used in automated percutaneous discectomy.

Microdiscectomy Removal of protruding disc material, using an operating microscope to guide surgery.

Standard discectomy Surgical removal, in part or whole, of an intervertebral disc, generally with loop magnification (i.e. eyepieces).

Substantive changes

Epidural corticosteroid injections One RCT added;[15] recategorised as Unlikely to be beneficial.

Bed rest One RCT added;[16] recategorised as Unlikely to be beneficial.

Leg cramps

Search date June 2003

Gavin Young

QUESTIONS

INTERVENTIONS

Key Messages

Idiopathic leg cramps

- **Quinine** One systematic review has found that quinine reduces the frequency of nocturnal leg cramp attacks compared with placebo over 4 weeks. We found no evidence about the optimal dose of quinine or length of treatment.
- **Quinine plus theophylline** One small RCT found limited evidence that quinine plus theophylline reduced the number of nights affected by leg cramps compared with quinine alone over 2 weeks.
- **Analgesics; antiepileptic drugs; compression hosiery** We found no RCTs on the effects of these interventions on idiopathic leg cramps.
- **Vitamin E** One small RCT found no significant difference between vitamin E and placebo in the number of nights disturbed by leg cramps.

Leg cramps in pregnancy

- **Magnesium salts** One systematic review identified one small RCT in pregnant women, which found that magnesium tablets (primarily magnesium lactate, magnesium citrate) reduced leg cramps compared with placebo after 3 weeks.
- **Calcium salts** One systematic review identified two RCTs that compared calcium versus vitamin C or no treatment, which found different results.

Leg cramps

- **Multivitamins and mineral supplements** One systematic review identified one small RCT in pregnant women, which found no significant difference between a multivitamin plus mineral tablet and placebo in leg cramps in the ninth month of pregnancy.
- **Sodium chloride** One systematic review found insufficient evidence about the effects of sodium chloride on leg cramps in pregnancy.

DEFINITION Leg cramps are involuntary, localised, and usually painful skeletal muscle contractions, which commonly affect calf muscles. Leg cramps typically occur at night and usually last only seconds to minutes. Leg cramps may be idiopathic (see glossary, p 1498) or related to a definable process or condition such as pregnancy, renal dialysis, or venous insufficiency.

INCIDENCE/ PREVALENCE Leg cramps are common and their incidence increases with age. About half of the people attending a general medicine clinic have had leg cramps within 1 month of their visit, and over two thirds of people over 50 years of age have experienced leg cramps.[1]

AETIOLOGY/ RISK FACTORS Very little is known about the causes of leg cramps. Risk factors include pregnancy, exercise, salt depletion, renal dialysis, electrolyte imbalances, peripheral vascular disease (both venous and arterial), peripheral nerve injury, polyneuropathies, motor neuron disease, muscle diseases, and certain drugs. Other causes of calf pain include trauma, deep venous thrombosis (see thromboembolism, p 284), and ruptured Baker's cyst (see glossary, p 1498).

PROGNOSIS Leg cramps may cause severe pain and sleep disturbance, both of which are distressing.

AIMS OF INTERVENTION To reduce the frequency and severity of attacks of cramp, with minimal adverse effects of treatment.

OUTCOMES Frequency, duration, and severity of attacks; number of disturbed nights.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION **What are the effects of treatments for idiopathic leg cramps?**

OPTION **COMPRESSION HOSIERY**

We found no RCTs on the effects of compression hosiery in people with idiopathic leg cramps.

Benefits: We found no systematic review or RCTs.

Harms: We found no evidence on harms related to compression hosiery in people with idiopathic leg cramps (see glossary, p 1498) (see compression under prevention and treatment of venous leg ulcers, p 2576).

Comment: None.

OPTION QUININE

One systematic review has found that quinine reduces the frequency of nocturnal leg cramps compared with placebo over 4 weeks. We found no evidence about the optimal dose of quinine or length of treatment.

Benefits: We found one systematic review (search date 1997, 8 RCTs, 659 people).[2] Meta-analysis of individual patient data found that quinine significantly reduced the frequency of nocturnal leg cramps compared with placebo over a 4 week period (ARR 3.6 cramps/month with quinine *v* placebo, 95% CI 2.15 to 5.05; RR 0.21, 95% CI 0.12 to 0.30).

Harms: Adverse effects of quinine include headache, digestive disorders, tinnitus, fever, blurred vision, dizziness, and pruritus.[2] In the systematic review, tinnitus was significantly more common with quinine than placebo (AR for tinnitus 20/659 [3.0%] with quinine *v* 7/659 [1.1%] with placebo; RR 2.86, 95% CI 1.22 to 6.71; NNH 50, 95% CI 27 to 230). Elevated quinine levels may cause cinchonism (see glossary, p 1498) — a syndrome that includes nausea, vomiting, tinnitus, and deafness.[3]

Comment: The systematic review excluded two RCTs because of a lack of individual participant data. Both of these RCTs found that quinine reduced leg cramps compared with placebo. We found no evidence about the optimal dose of quinine or length of treatment.

OPTION QUININE PLUS THEOPHYLLINE

One small RCT found limited evidence that quinine plus theophylline reduced nocturnal leg cramps compared with quinine alone over 2 weeks.

Benefits: We found no systematic review. We found one single blind RCT (164 people), which compared quinine plus theophylline versus quinine alone for 2 weeks.[4] Baseline frequencies of leg cramp were measured for 1 week before randomisation, when all people received placebo. Among 126 people who completed at least 4 days' treatment in the 2 week period, quinine plus theophylline was rated as "good" or "very good" significantly more often than quinine alone or placebo (34/39 [87%] with quinine plus theophylline *v* 28/45 [62%] with quinine *v* 17/42 [40%] with placebo; $P < 0.001$ for quinine plus theophylline *v* either comparison; see comment below). After 2 weeks of treatment, theophylline plus quinine significantly reduced the mean number of nights affected by cramp compared with quinine alone (from 4.7 nights to 1.1 nights with theophylline plus quinine *v* from 4.8 nights to 2.2 nights with quinine alone; $P = 0.009$).

Harms: Six people reported adverse effects while taking placebo in the week before randomisation (nausea and vomiting in 2 people, nausea, heartburn, depression, bitter aftertaste). Three people reported adverse effects with quinine (nausea and vomiting, bloating and tenesmus, and nausea alone), resulting in two people withdrawing from the study. Four people had adverse effects with quinine plus theophylline (fall in blood pressure and dizziness, nausea in 2 cases, palpitations and tinnitus) and all four withdrew from the study.

Leg cramps

Comment: The results of the RCT should be treated with caution, as it did not specify criteria to categorise outcomes as "good" or "very good" and pooled the results only for people who received treatment for at least 4 out of 14 days (126 people out of 164 enrolled) without using an intention to treat analysis.

OPTION VITAMIN E

One small RCT found no significant difference between vitamin E and placebo in the frequency of nocturnal leg cramps.

Benefits: We found no systematic review. We found one crossover RCT (27 men), which compared vitamin E versus placebo.[5] It found no significant difference between treatments in the median number of nights with leg cramps (14 nights with vitamin E *v* 15 nights with placebo; $P > 0.05$).

Harms: Adverse effects were reported as similar in the vitamin E and placebo groups, but no details were provided.[5]

Comment: None.

OPTION ANALGESICS

We found no RCTs on the effects of analgesics on idiopathic leg cramps.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ANTIEPILEPTIC DRUGS

We found no RCTs on the effects of antiepileptic drugs on idiopathic leg cramps.

Benefits: We found no systematic review or RCTs.

Harms: Harms associated with the use of antiepileptic drugs are well described (see epilepsy, p 1655).

Comment: None.

QUESTION What are the effects of treatments for leg cramps in pregnancy?

OPTION MAGNESIUM SALTS

One systematic review identified one small RCT in pregnant women, which found that magnesium tablets (magnesium lactate, magnesium citrate) reduced leg cramps compared with placebo after 3 weeks.

Benefits: We found one systematic review (search date 2001,[6] 1 RCT,[7] 73 pregnant women 22–36 weeks' gestation), which compared chewable magnesium tablets (magnesium lactate, magnesium citrate) versus chewable placebo tablets (sorbitol, fructose–dextrose) given for 3 weeks. The review found that magnesium significantly reduced

the proportion of people reporting leg cramps compared with placebo after 3 weeks' treatment (AR for persistence 23/34 [68%] with magnesium *v* 33/35 [94%] with placebo; OR 0.18, 95% CI 0.05 to 0.60; see comment below).[6] The RCT found that magnesium decreased the proportion of women who rated themselves "unchanged" or "worse" compared with placebo ("unchanged": 7/34 [21%] with magnesium *v* 16/35 [46%] with placebo; "worse": 0/34 [0%] with magnesium *v* 5/35 [14%] with placebo).[7]

Harms: Adverse effects (mainly slight nausea) were described as infrequent in both groups.[6] One woman in the placebo group discontinued treatment because of severe nausea.[6]

Comment: The RCT did not describe the method of randomisation, and symptoms were assessed after 3 weeks of treatment with no further follow up.[6]

OPTION MULTIVITAMINS AND MINERAL SUPPLEMENTS

One systematic review identified one small RCT in pregnant women, which found no significant difference between multivitamin plus mineral tablet and placebo in leg cramps in the ninth month of pregnancy.

Benefits: We found one systematic review (search date 2001,[6] 1 RCT,[8] 62 pregnant women), which compared a multivitamin plus mineral tablet (containing 12 different ingredients; see comment below) versus placebo. Supplements were given from 3 months' gestation. The review found no significant difference between multivitamin plus mineral and placebo in the proportion of women reporting leg cramps in the ninth month of pregnancy (AR for persistence 2/11 [18%] with multivitamin plus mineral *v* 10/18 [56%] with placebo; OR 0.23, 95% CI 0.05 to 1.01).[6]

Harms: The RCT found that 4% of women had adverse effects (nausea, vomiting, diarrhoea), but did not make clear how many of these women were taking an active treatment.[8]

Comment: This small RCT was primarily undertaken to examine the effects of a multivitamin plus mineral supplement on zinc and copper levels during pregnancy.[8] In total, 29/62 (48%) of women were assessed for cramp at 9 months' gestation.[6] The high dropout rate is not explained. The supplement contained: zinc gluconate, copper gluconate, iron gluconate, magnesium lactate, chromium chloride, ascorbic acid, thiamine nitrate, riboflavin (riboflavine), pyridoxal chlorhydrate, folic acid, cyanocobalamin, and α-tocopheral acetate.[6]

OPTION SODIUM CHLORIDE

One systematic review found insufficient evidence about the effects of sodium chloride in pregnant women with leg cramps.

Benefits: We found one systematic review (search date 2001, no RCTs),[6] which identified one controlled clinical trial[9] published in 1947 (see comment below).

Harms: We found no RCTs.

Comment: The controlled clinical trial was of poor quality. Initially, sodium chloride and calcium lactate were given to alternate participants.[9] It was then decided, based on the difference between the results of the two treatments, to also use two further control groups (saccharin and no treatment).[9] The dose of sodium chloride changed during the course of the study.[6]

OPTION CALCIUM SALTS

One systematic review identified two RCTs that compared calcium versus vitamin C or no treatment. The RCTs found different results.

Benefits: We found one systematic review (search date 2001),[6] which included two RCTs[10,11] and one controlled clinical trial (see comment below). The first RCT (42 pregnant women) found that calcium (calcium gluconate, lactate, and carbonate) significantly improved leg cramps compared with no treatment (AR for lack of improvement in cramps 2/21 [10%] with calcium *v* 18/21 [86%] with no treatment; OR 0.05, 95% CI 0.02 to 0.17).[6] The second RCT (60 pregnant women) found no significant difference in leg cramps with calcium (calcium gluconate, lactate, and carbonate) compared with vitamin C (AR for lack of improvement in cramps 11/30 [37%] with calcium *v* 8/30 [27%] with vitamin C; OR 1.58, 95% CI 0.54 to 4.63; see comment below).[6]

Harms: The RCTs did not report harms.[6]

Comment: There was a marked difference in the response of the control group in the two included RCTs. In the first RCT, 18/21 (86%) women with no treatment had no improvement in cramps.[10] In the second RCT, 8/30 (27%) women with vitamin C had no improvement.[11] The controlled clinical trial identified by the review was of poor quality (see comment under sodium chloride, p 1498).

GLOSSARY

Baker's cyst A cyst or out-pouching that occurs in the lining of the knee joint. Rupture of the cyst may be associated with calf pain.

Cinchonism Adverse effects caused by quinine and other derivatives of cinchona bark. It usually presents with nausea, vomiting, headache, tinnitus, deafness, vertigo, and visual disturbances.

Idiopathic leg cramps Leg cramps of unknown cause. The term is used in this review to distinguish the most common type of leg cramps from leg cramps in people who are receiving dialysis, have venous insufficiency, or are pregnant.

Low back pain and sciatica (acute)

Search date February 2003

Maurits van Tulder and Bart Koes

QUESTIONS

INTERVENTIONS

See glossary, p 1512

Key Messages

- **Advice to stay active** Two systematic reviews and one subsequent RCT found that advice to stay active increased the rate of recovery, reduced pain, reduced disability, and reduced time spent off work compared with advice to rest in bed or bed rest.
- **Non-steroidal anti-inflammatory drugs** One systematic review and one additional RCT have found that non-steroidal anti-inflammatory drugs increased overall improvement after 1 week and reduced the need for additional analgesics compared with placebo. One systematic review and additional RCTs have found no significant difference among non-steroidal anti-inflammatory drugs or between non-steroidal anti-inflammatory drugs and other treatments (paracetamol, opioids, muscle relaxants, and non-drug treatments) in pain relief.
- **Behavioural therapy** One RCT found that cognitive behavioural therapy reduced acute low back pain and disability compared with traditional care or electromyographic biofeedback.

- **Multidisciplinary treatment programmes (for subacute low back pain)** We found no RCTs in people with acute low back pain. One systematic review in people with subacute low back pain found limited evidence that multidisciplinary treatment, including a workplace visit, reduced sick leave compared with usual care.
- **Muscle relaxants** Systematic reviews have found that muscle relaxants improve symptoms (including pain and muscle tension) and increase mobility compared with placebo, but found no significant difference in outcomes among muscle relaxants. Adverse effects in people using muscle relaxants were common and included dependency, drowsiness, and dizziness.
- **Acupuncture** We found no RCTs of acupuncture specifically in people with acute low back pain.
- **Analgesics (paracetamol, opioids)** We found no placebo controlled RCTs. Systematic reviews have found no consistent difference between analgesics and non-steroidal anti-inflammatory drugs in reducing pain.
- **Back schools** One systematic review found limited evidence that back schools increased rates of recovery and reduced sick leave compared with placebo in the short term. The review found no significant difference in outcomes between back school and physiotherapy, and found that back school increased pain and sick leave compared with McKenzie exercises.
- **Epidural steroid injections** One RCT found that epidural steroids increased the proportion of people who were pain free compared with subcutaneous lidocaine (lignocaine) injections after 3 months. A second RCT found no significant difference in the proportion of people cured or improved between epidural steroids and epidural saline, epidural bupivacaine, or dry needling.
- **Lumbar supports** We found no RCTs on the effects of lumbar supports.
- **Massage** One systematic review found insufficient evidence from one RCT about the effects of massage compared with spinal manipulation or electrical stimulation.
- **Spinal manipulation** Systematic reviews found conflicting evidence on the effects of spinal manipulation.
- **Traction** RCTs found conflicting evidence on the effects of traction.
- **Back exercises** Systematic reviews and additional RCTs have found either no significant difference between back exercises and conservative or inactive treatments in pain or disability, or have found that back exercises increase pain or disability.
- **Bed rest** Systematic reviews have found that bed rest could be worse than no treatment, advice to stay active, back exercises, physiotherapy, spinal manipulation, or non-steroidal anti-inflammatory drugs. One systematic review has found that adverse effects of bed rest include joint stiffness, muscle wasting, loss of bone mineral density, pressure sores, and venous thromboembolism.
- **Colchicine; electromyographic biofeedback; temperature treatments (short wave diathermy, ultrasound, ice, heat); transcutaneous electrical nerve stimulation** We found insufficient evidence on the effects of these interventions.

DEFINITION Low back pain is pain, muscle tension, or stiffness localised below the costal margin and above the inferior gluteal folds, with or without leg pain (sciatica — see glossary, p 1513),[1] and is defined as acute when it persists for less than 12 weeks.[2] Non-specific low

back pain is low back pain not attributed to a recognisable pathology (such as infection, tumour, osteoporosis, rheumatoid arthritis, fracture, or inflammation).[1] This review excludes low back pain or sciatica with symptoms or signs at presentation that suggest a specific underlying condition.

INCIDENCE/ PREVALENCE

Over 70% of people in developed countries will experience low back pain at some time in their lives.[3] Each year, 15–45% of adults suffer low back pain, and 1/20 (5%) people present to hospital with a new episode. Low back pain is most common between the ages of 35–55 years.[3]

AETIOLOGY/ RISK FACTORS

Symptoms, pathology, and radiological appearances are poorly correlated. Pain is non-specific in about 85% of people. About 4% of people with low back pain in primary care have compression fractures and about 1% have a tumour. The prevalence of prolapsed intervertebral disc is about 1–3%.[3] Ankylosing spondylitis and spinal infections are less common.[4] Risk factors for the development of back pain include heavy physical work, frequent bending, twisting, lifting, and prolonged static postures. Psychosocial risk factors include anxiety, depression, and mental stress at work.[3,5]

PROGNOSIS

Acute low back pain is usually self limiting (90% of people recover within 6 weeks), although 2–7% develop chronic pain. One study found recurrent pain accounted for 75–85% of absenteeism from work.[6]

AIMS OF INTERVENTION

To relieve pain; to improve function; to develop coping strategies for pain, with minimal adverse effects from treatment; and to prevent the development of chronic back pain (see definition of low back pain [chronic], p 1516).[2,7]

OUTCOMES

Pain intensity (visual analogue or numerical rating scale); overall improvement (self reported or observed); back pain specific functional status (such as Roland Morris questionnaire, Oswestry questionnaire); impact on employment (days of sick leave, number of people returned to work); medication use; intervention specific outcomes (such as coping and pain behaviour for behavioural treatment, strength and flexibility for exercise, depression for antidepressants, and muscle spasm for muscle relaxants and electromyographic biofeedback [see glossary, p 1512]).

METHODS

Clinical Evidence search and appraisal February 2003. In addition, the authors searched Medline (1966 to December 1998), Embase (1980 to September 1998), and Psychlit (1984 to December 1998), using the search strategy recommended by the Cochrane Back Review Group.[8] Most earlier RCTs of treatments for low back pain were small (< 50 people/intervention group; range 9–169 people/intervention group), short term (mostly < 6 months' follow up), and of low overall quality. Problems included lack of power, no description of randomisation procedure, incomplete analysis with failure to account for people who withdrew from trials, and lack of blinding.[9] The quality of many recent RCTs is higher.

QUESTION What are the effects of oral drug treatments?

OPTION ANALGESICS (PARACETAMOL, OPIOIDS)

Systematic reviews have found no consistent difference between analgesics and non-steroidal anti-inflammatory drugs for pain, but have found that electroacupuncture or ultrasound improves pain relief compared with analgesics.

Benefits: We found two systematic reviews (search dates not stated[2] and 1995;[9] no placebo controlled RCTs; 6 comparative RCTs; no statistical pooling of data provided). **Versus non-steroidal anti-inflammatory drugs:** The reviews identified two RCTs (110 people), which found no significant difference between meptazinol (an opioid) and paracetamol or diflunisal (a non-steroidal anti-inflammatory drug [NSAID]) in pain relief.[2,9] A third RCT (219 people) identified by the reviews found that paracetamol increased pain relief compared with mefenamic acid (a NSAID).[2,9] **Versus non-drug treatments:** The reviews identified one RCT (40 people), which found that electroacupuncture (see glossary, p 1512) increased pain relief compared with paracetamol after 6 weeks, and one RCT (73 people), which found that ultrasound treatment significantly increased the proportion of people who were pain free after 4 weeks compared with analgesics.[2,9]

Harms: See paracetamol (acetaminophen) poisoning, p 1826. RCTs have found adverse effects (constipation and drowsiness) with analgesics in about 50% of people. One systematic review (search date 1995) found that combinations of paracetamol plus weak opioids increased the risk of adverse effects compared with paracetamol alone (single dose studies OR 1.1, 95% CI 0.8 to 1.5; multiple dose studies OR 2.5, 95% CI 1.5 to 4.2).[10]

Comment: None.

OPTION COLCHICINE

One RCT found insufficient evidence on the effects of colchicine.

Benefits: We found one systematic review (search date not stated, 1 RCT, 27 people), which found no significant difference between oral colchicine and placebo in outcomes, although the RCT identified by the review was too small to rule out a clinically important difference.[2]

Harms: The review reported gastrointestinal irritation and skin problems in about 33% of people taking colchicine.[2] Other adverse effects included chemical cellulitis and agranulocytosis.[11]

Comment: The review identified two further RCTs, which did not distinguish between acute and chronic low back pain.[2]

OPTION MUSCLE RELAXANTS

Systematic reviews have found that muscle relaxants improve symptoms (including pain and muscle tension) and increase mobility compared with placebo, but found no significant difference among muscle relaxants in outcomes. The reviews found that adverse effects in people using muscle relaxants are common and include dependency, drowsiness, and dizziness.

Benefits: We found three systematic reviews (search date not stated;[2] search date 1995,[9] 14 RCTs, 1160 people, no statistical pooling of data provided; search date 1999,[12] 11 RCTs). **Versus placebo:** The first two reviews identified nine RCTs (762 people), which compared a range of muscle relaxants (tizanidine, cyclobenzaprine, dantrolene, carisoprodol, baclofen, orphenadrine, or diazepam) versus placebo.[2,9] Seven of these RCTs found that muscle relaxants reduced pain and muscle tension and increased mobility compared with placebo. The remaining two RCTs found no significant difference in outcomes. The third review identified 11 RCTs comparing cyclobenzaprine versus placebo (2297 people with acute back or neck pain and muscle spasm).[12] The review did not pool results. Of eight included RCTs (1359 people) that reported a global measure of symptom improvement, six found that cyclobenzaprine significantly improved a global symptom measure compared with placebo (follow up 8–21 days). However, the clinical importance of these results is unclear. **Versus each other:** The first two reviews identified three RCTs (236 people), which found no significant difference among muscle relaxants (cyclobenzaprine, carisoprodol, and diazepam) in pain intensity, although two of the RCTs found that cyclobenzaprine or carisoprodol significantly increased overall improvement compared with diazepam.[2,9]

Harms: The reviews found that adverse effects included drowsiness or dizziness in up to 70% of people and a risk of dependency even after 1 week. More people experienced one or more adverse events with muscle relaxants compared with placebo (68% of people with baclofen *v* 30% of people with placebo).[2,9] One RCT identified by the reviews found that chlormezanone significantly increased adverse effects compared with methocarbamol (dyspepsia and drowsiness; 14/52 [27%] with chlormezanone *v* 6/55 [11%] with methocarbamol; RR 2.50, 95% CI 1.02 to 5.93; NNH 6, 95% CI 3 to 90).[2,9] One systematic review found that adverse reactions were significantly more common with cyclobenzaprine compared with placebo (53% with cyclobenzaprine *v* 28% with placebo; $P < 0.002$).[12] The most common adverse effects with cyclobenzaprine were drowsiness (20%), dry mouth (8%), and dizziness (7%).

Comment: None.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One systematic review and one additional RCT have found that non-steroidal anti-inflammatory drugs increased overall improvement after 1 week and reduced the proportion of people requiring additional analgesics compared with placebo. One systematic review and additional

RCTs have found no significant difference among non-steroidal anti-inflammatory drugs or between non-steroidal anti-inflammatory drugs and other treatments (paracetamol, opioids, muscle relaxants, and non-drug treatments) in pain relief.

Benefits: We found one systematic review (search date 1998, 45 RCTs, statistical pooling only for non-steroidal anti-inflammatory drugs [NSAIDs] *v* placebo)[13] and three additional RCTs.[14–16] **NSAIDs versus placebo:** The review identified nine RCTs, which found that NSAIDs increased the proportion of people experiencing global improvement compared with placebo after 1 week (pooled OR 2.0, 95% CI 1.4 to 3.0), and reduced the proportion of people requiring additional analgesics (pooled OR 0.64, 95% CI 0.45 to 0.91).[13] The review identified four RCTs (313 people), which found no significant difference between NSAIDs and placebo in relief of sciatica (see glossary, p 1513). The additional RCT (532 people) found that oral meloxicam (7.5 or 15.0 mg) increased pain relief compared with placebo after 3 and 7 days.[17] **Versus each other:** The review identified 18 RCTs (1982 people), which found no significant difference among NSAIDs in outcomes.[13] One additional RCT (104 people) found that nimesulide versus ibuprofen improved functional status, but found no significant difference in pain relief after 10 days.[14] A second additional RCT (489 people) found no significant difference between meloxicam and diclofenac in pain relief.[17] **Versus paracetamol:** The review identified two RCTs (93 people), which found no significant difference between mefenamic acid and paracetamol in recovery rates, and one RCT (60 people), which found that mefenamic acid increased pain relief compared with paracetamol.[13] The review identified one RCT (60 people), which found that mefenamic acid improved pain relief compared with dextropropoxyphene plus paracetamol. **Versus muscle relaxants plus opioid analgesics:** The review identified five RCTs (399 people), which found no significant difference between NSAIDs and muscle relaxants plus opioids in pain relief or overall improvement.[13] **Versus non-drug treatments:** The review identified three RCTs (461 people).[13] The first RCT (110 people) found that NSAIDs improved range of movement compared with bed rest, although the second RCT (241 people) found no significant difference between treatments in range of movement. Two RCTs (354 people) comparing NSAIDs versus physiotherapy or spinal manipulation found no significant difference in pain relief or improvement in mobility. **Versus NSAIDs plus adjuvant treatment:** The review identified three RCTs (232 people), which found no significant difference between NSAIDs alone and NSAIDs plus muscle relaxants in outcomes.[13] One RCT identified by the review,[13] and one additional RCT[18] found no significant difference between NSAIDs and versus NSAIDs plus vitamin B combinations in pain relief, although one of the RCTs found that NSAIDs alone reduced the proportion of people returning to work after 1 week compared with NSAIDs plus vitamin B combinations (78% of people with combination treatment *v* 35% with NSAIDs alone).

Harms: NSAIDs may cause gastrointestinal complications (see non-steroidal anti-inflammatory drugs, p 1551). One systematic review of harms of NSAIDs found that ibuprofen and diclofenac had the

lowest gastrointestinal complication rate mainly because of the low doses used in practice (pooled OR for adverse effects versus placebo 1.30, 95% CI 0.91 to 1.80).[19] RCTs have found no significant difference with nimesulide versus ibuprofen, or with meloxicam versus diclofenac in adverse effects.

Comment: None.

QUESTION What are the effects of local injections?

OPTION EPIDURAL STEROID INJECTIONS

One systematic review has identified one RCT, which found that epidural steroids increased the proportion of people who were pain free after 3 months compared with subcutaneous lidocaine (lignocaine) injections. The review identified a second RCT, which found no significant difference between epidural steroids and epidural saline, epidural bupivacaine, or dry needling in the proportion of people cured or improved.

Benefits: We found one systematic review (search date 1998, 2 RCTs).[20] The first included RCT (57 people with acute low back pain and sciatica — see glossary, p 1513) found no significant difference between epidural steroids and subcutaneous lidocaine injections in pain relief after 1 month, but found that epidural steroids increased the proportion of people who were pain free after 3 months. The second RCT (63 people) compared four treatments: epidural steroids, epidural saline, epidural bupivacaine, and dry needling. It found no difference between any of the treatments in the proportion of people improved or cured.

Harms: Adverse effects were infrequent and included headache, fever, subdural penetration, and, more rarely, epidural abscess and respiratory depression.[20]

Comment: None.

QUESTION What are the effects of non-drug treatments?

OPTION ADVICE TO STAY ACTIVE

Two systematic reviews and subsequent RCTs found that advice to stay active (with or without other treatments) reduced disability, pain, and time spent off work compared with bed rest (with or without other treatments).

Benefits: We found one systematic review that compared advice to stay active alone versus advice to rest in bed or bed rest (search date 1998, 4 RCTs, 491 people with acute back pain or sciatica [see glossary, p 1513], no statistical pooling of data).[21] A second systematic review compared advice to stay active with or without other treatments versus those other treatments alone (search date not stated, 6 RCTs, 1957 people).[22] The first review identified two high quality RCTs.[21] The first RCT (186 people with acute low back pain) found that advice to stay active versus advice to rest in bed for 2 days significantly improved functional status and reduced sick

leave after 3 weeks (weighted mean improvement in Oswestry questionnaire score for advice to remain active *v* bed rest 4.4, 95% CI 0.6 to 8.2; weighted mean reduction for days of sick leave for advice to remain active *v* bed rest 4.5 days, 95% CI 1.4 days to 7.6 days). However, the trial found no significant difference in pain intensity between groups after 3 weeks. The second RCT (183 people with sciatica) found no significant difference between advice to stay active and advice to rest in bed for 14 days in pain intensity, recovery, or duration of sick leave after 3 weeks (results not quantified in review). The second review similarly found that advice to stay active significantly reduced sick leave and reduced chronic disability compared with traditional medical treatment (analgesics as required, advice to rest, and "let pain be your guide") (see benefits of bed rest, p 1508).[22] We found two subsequent RCTs. The first subsequent RCT (457 people) found that advice to stay active significantly increased rates of recovery, reduced pain, and reduced disability compared with no advice.[23] The second subsequent RCT (278 people) found no significant differences in pain intensity and functional disability between normal activity and bed rest after 1 month (intensity of pain measured on visual analogue scale [0 = no pain and 100 = extreme unbearable pain]: 10.2 mm with normal activity *v* 13.7 mm with bed rest; difference +3.5 mm; 97.5% CI –2.6 mm to +0.5 mm; functional disability measured on the Eifel index, a French version of the Roland–Morris questionnaire [range 0–24]; at 1 month: 2.47 with normal activity *v* 3.3 with bed rest; difference –0.82; 99% CI –2.55 to +0.50). However, the second subsequent RCT found normal activity significantly reduced sick leave compared with bed rest up to day 5 (52% with advice to stay active *v* 86% with bed rest; $P < 0.0001$).[23]

Harms: The reviews and subsequent RCT did not report harms.[21,22,24]

Comment: Limitations in methods preclude meaningful quantification of effect sizes. Advice to stay active was provided either as a single treatment or in combination with other interventions such as back schools, a graded activity programme, or behavioural counselling. The two lower quality RCTs included in the first review were reported to have moderate to high risk of bias.[21] The first did not measure pain at follow up. The second found that 48 hours of strict bed rest significantly improved pain compared with advice to stay active (time to outcome and further details not reported in review).

OPTION BACK SCHOOLS

One systematic review found limited evidence that back schools increased rates of recovery and reduced sick leave compared with placebo in the short term. The review found no significant difference between back school and physiotherapy in outcomes and found that back school exercises increased pain and sick leave compared with McKenzie exercises.

Benefits: We found one systematic review (search date 1997, 3 RCTs, no statistical pooling of data provided).[25] The first included RCT (145 people), which found that back schools (short wave diathermy at lowest intensity) increased rates of recovery and reduced sick leave

compared with placebo in the short term. The second included RCT (142 people) found no significant difference between back schools and physiotherapy in short term and long term outcomes. The third included RCT (100 people) found that ongoing McKenzie exercises (see glossary, p 1513) reduced pain and sick leave compared with one 45 minute session of back school for up to 5 years.

Harms: The review did not report harms.[25]

Comment: None.

OPTION BED REST

Systematic reviews have found no evidence that bed rest is better, but have found evidence that it could be worse than no treatment, advice to stay active, back exercises, physiotherapy, spinal manipulation, or non-steroidal anti-inflammatory drugs. One systematic review has found that adverse effects of bed rest include joint stiffness, muscle wasting, loss of bone mineral density, pressure sores, and venous thromboembolism.

Benefits: We found six systematic reviews (search date not stated, 4 RCTs;[2] search date 1995, 4 RCTs;[7] search date 1995, 6 RCTs;[9] search date 1999, 9 RCTs;[26] search date not stated, 10 RCTs;[22] search date not stated, 5 RCTs;[27] no statistical pooling provided). **Versus no treatment:** The reviews identified five RCTs (663 people), which compared bed rest versus no treatment and found either no significant difference between treatments or that no treatment improved outcomes compared with bed rest.[2,7,9,22,26,27] **Versus different lengths of bed rest:** The reviews identified two RCTs (254 people), which found no significant difference in outcomes with 7 days versus 2–4 days of bed rest.[2,7,9,22,26,27] **Versus other interventions:** The reviews identified five RCTs (921 people), which compared bed rest versus other interventions (advice to stay active, back exercises, physiotherapy, spinal manipulation, or non-steroidal anti-inflammatory drugs).[2,7,9,22,26,27] They found either no significant difference in outcomes (pain, recovery rate, time to return to daily activities, and sick leave) or an improvement in outcomes with the comparative interventions. The most recent systematic review found no significant difference between bed rest and advice to stay active in pain intensity after 3 weeks.[26]

Harms: One systematic review found that adverse effects of bed rest included joint stiffness, muscle wasting, loss of bone mineral density, pressure sores, and venous thromboembolism (see thrombo-embolism, p 284).[22]

Comment: None.

OPTION BEHAVIOURAL THERAPY

One RCT found that cognitive behavioural therapy reduced acute low back pain and disability compared with traditional care or electromyographic biofeedback.

Benefits: We found four systematic reviews (search dates not stated,[2] 1995,[7,9] and 1994;[28] no statistical pooling of data provided) and one subsequent RCT.[29] The reviews identified one RCT (107 people), which found that cognitive behavioural therapy (see glossary, p 1512) versus traditional care (analgesics plus back exercises until pain had subsided) reduced pain and perceived disability after 9–12 months. The additional RCT (50 people with acute low back pain and sciatica) found that risk factor based cognitive behavioural therapy versus electromyographic biofeedback (see glossary, p 1512) increased pain relief.[29]

Harms: The reviews and subsequent RCT did not report on harms.[2,7,9,28,29]

Comment: None.

OPTION ELECTROMYOGRAPHIC BIOFEEDBACK

We found insufficient evidence on electromyographic biofeedback.

Benefits: We found one RCT (50 people with acute low back pain and sciatica — see glossary, p 1513), which found that risk factor based cognitive behavioural therapy versus electromyographic biofeedback (see glossary, p 1512) improved pain relief.[29]

Harms: The RCT did not report on harms.[29]

Comment: None.

OPTION EXERCISE/BACK EXERCISES

Systematic reviews and additional RCTs have found either no significant difference between back exercises and conservative or inactive treatments in pain or disability, or have found that back exercises increase pain or disability.

Benefits: We found five systematic reviews (search dates not stated,[2] 1995,[7,9,30] and 1999;[31] no statistical pooling of data provided) and two additional RCTs.[17,32] The most recent review identified eight RCTs (1149 people), which compared specific back exercises (flexion, extension, aerobic, or strengthening programmes such as McKenzie exercises [see glossary, p 1513]) versus other conservative treatments (usual care by general practitioner, continuation of ordinary activities, bed rest, manipulation, non-steroidal anti-inflammatory drugs, mini back school, or short wave diathermy).[31] Seven of these RCTs found either no difference between treatments or that back exercises increased pain intensity and disability. The eighth RCT found that back exercises versus a mini back school improved pain and return to work. The review identified four RCTs (888 people) comparing back exercises versus inactive treatments (bed rest, educational booklet, and placebo ultrasound).[31] It found no significant difference between back exercises and inactive treatment in pain relief, global improvement, or functional status. The first additional RCT (66 people) found that endurance training back exercises increased improvement in functioning and pain relief after 3 weeks compared with no treatment, but found no significant

difference in functioning or pain after 6 weeks.[17] The second additional RCT (41 people) found no significant difference between advice, minimal bed rest, or analgesics versus the same treatment plus specific, localised exercise of the multifidus muscle in pain and disability.[32]

Harms: The reviews and additional RCTs did not report harms.[2,7,9,17,30–32]

Comment: None.

OPTION LUMBAR SUPPORTS

We found no RCTs on the effects of lumbar supports.

Benefits: We found no systematic review or RCTs specifically in people with acute low back pain.

Harms: Harms associated with prolonged lumbar support use include decreased strength of the trunk musculature, a false sense of security, heat, skin irritation, and general discomfort.[2]

Comment: None.

OPTION MULTIDISCIPLINARY TREATMENT PROGRAMMES (FOR SUBACUTE LOW BACK PAIN)

We found no RCTs in people with acute back pain. However, one systematic review in people with subacute low back pain found limited evidence that multidisciplinary treatment including a workplace visit reduced sick leave compared with usual care.

Benefits: We found no RCTs specifically in people with acute back pain. We found one systematic review (search date 1998, 2 RCTs, 233 people with subacute low back pain), which found that multidisciplinary treatment (see glossary, p 1513), including a workplace visit, reduces sick leave compared with usual care.[33]

Harms: The review did not report harms.[33]

Comment: None.

OPTION TEMPERATURE TREATMENTS (SHORT WAVE DIATHERMY, ULTRASOUND, ICE, AND HEAT)

Two systematic reviews identified no RCTs on the effects of temperature treatments.

Benefits: We found two systematic reviews (search date not stated[2] and 1992[34]), which found no RCTs.

Harms: The reviews did not report harms.[2,34]

Comment: None.

OPTION MASSAGE

One systematic review found insufficient evidence from one RCT about the effects of massage compared with spinal manipulation or electrical stimulation.

Benefits: We found one systematic review (search date 2001, 1 RCT).[35] It identified one RCT (90 people), which compared massage (see glossary, p 1512) versus spinal manipulation or electrical stimulation and found no significant difference in pain relief, functional status, or mobility.[35]

Harms: The review gave no information on harms.[35]

Comment: None.

OPTION SPINAL MANIPULATION

Systematic reviews found conflicting evidence on the effects of spinal manipulation.

Benefits: We found six systematic reviews (search dates not stated,[2,36] 1995;[7,9,37] and 1997;[38] 18 RCTs; no statistical pooling of data provided). **Versus placebo:** The reviews identified five RCTs (383 people) comparing spinal manipulation versus placebo.[2,7,9,36–38] Two RCTs found that manipulation increased pain relief after 3 weeks, two RCTs found no significant difference in pain relief, and one RCT found that manipulation increased rates of recovery. **Versus other treatments:** The reviews identified 12 RCTs (899 people) comparing spinal manipulation versus other treatments (short wave diathermy, massage [see glossary, p 1512], exercises, back school, or drug treatment). Four of the reviews found that the results of these RCTs were conflicting.[2,7,9,37] The fifth review (7 RCTs, 731 people) found that spinal manipulation significantly increased recovery after 2–3 weeks (NNT 5, 95% CI 4 to 14).[36] The sixth review found limited evidence that spinal manipulation improved outcomes.[38]

Harms: In the RCTs that used a trained therapist to select people and perform spinal manipulation, the risk of serious complications was low (estimated risk: vertebrobasilar strokes 1/20 000–1/1 000 000 people; cauda equina syndrome < 1/1 000 000 people).[39]

Comment: Current guidelines do not advise spinal manipulation in people with severe or progressive neurological deficit.[2,11]

OPTION TRACTION

RCTs found conflicting evidence on the effects of traction.

Benefits: We found three systematic reviews (search dates 1995[7,9] and 1992[40]). The reviews identified two RCTs (225 people), which compared traction versus bed rest plus corset or infrared treatment. One RCT found that traction significantly increased overall improvement compared with both other treatments after 1 and 3 weeks, but the second RCT found no significant difference in overall improvement after 2 weeks.

Harms: The reviews did not report on harms.[7,9,40] Potential adverse effects include debilitation, loss of muscle tone, bone demineralisation, and thrombophlebitis.[2]

Low back pain and sciatica (acute)

Comment: Of 16 RCTs identified, 12 RCTs (921 people) did not distinguish between acute and chronic low back pain, or included people with back pain of specific cause.[7,9,40–42]

OPTION TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

We found no RCTs about effects of transcutaneous electrical nerve stimulation in people with acute back pain.

Benefits: We found no systematic reviews or RCTs specifically in people with acute low back pain.

Harms: We found no RCTs in people with acute low back pain.

Comment: None.

OPTION ACUPUNCTURE

We found no RCTs of acupuncture specifically in people with acute low back pain.

Benefits: We found two systematic reviews (search dates 1996; see comment below), which found no RCTs of acupuncture (see glossary, p 1512) in people with acute low back pain.[43,44]

Harms: One systematic review (search date 1996) found that serious, rare, adverse effects included infections (HIV, hepatitis, bacterial endocarditis) and visceral trauma (pneumothorax, cardiac tamponade).[45]

Comment: Three RCTs identified by the systematic reviews combined acute and chronic low back pain and two RCTs did not specify the duration of symptoms. One RCT included people with back and neck pain.[43,44]

GLOSSARY

Acupuncture Needle puncture of the skin at traditional "meridian" acupuncture points. Modern acupuncturists also use non-meridian points and trigger points (tender sites occurring in the most painful areas). The needles may be stimulated manually or electrically. Placebo acupuncture is needling of traditionally unimportant sites or non-stimulation of the needles once placed.

Cognitive behavioural therapy This aims to identify and modify people's understanding of their pain and disability using cognitive restructuring techniques (such as imagery and attention diversion) or by modifying maladaptive thoughts, feelings, and beliefs.

Electroacupuncture Non-penetrative electrical stimulation of classical acupuncture points with low amplitude, pulsed electrical current.

Electromyographic biofeedback A person receives external feedback of their own electromyogram (using visual or auditory scales), and uses this to learn how to control the electromyogram and hence the tension within their own muscles. Electromyogram biofeedback for low back pain aims to relax the paraspinal muscles.

Massage Massage is manipulation of soft tissues (i.e. muscle and fascia) using the hands or a mechanical device, to promote circulation and relaxation of muscle spasm or tension. Different types of soft tissue massage include Shiatsu, Swedish, friction, trigger point, or neuromuscular massage.

McKenzie exercises Extension exercises that use self generated stresses and forces to centralise pain from the legs and buttocks to the lower back. This method emphasises self care.

Multidisciplinary treatment Intensive physical and psychosocial training by a team (e.g. a physician, physiotherapist, psychologist, social worker, and occupational therapist). Training is usually given in groups and does not involve passive physiotherapy.

Sciatica Pain that radiates from the back into the buttock or leg and may also be used to describe pain anywhere along the course of the sciatic nerve.

QUESTIONS

INTERVENTIONS

See glossary, p 1530

Key Messages

- **Exercise** Systematic reviews and additional RCTs have found that exercise improves pain and functional status compared with usual care. RCTs found conflicting evidence on the effects of different types of exercise, or exercise compared with inactive treatments.
- **Intensive multidisciplinary treatment programmes** One systematic review has found that intensive multidisciplinary biopsychosocial rehabilitation with functional restoration reduces pain and improves function compared with inpatient or outpatient non-multidisciplinary treatments or usual care. The review found no significant difference between less intensive multidisciplinary treatments and non-multidisciplinary treatment or usual care in pain or function.
- **Analgesics** One RCT found that tramadol decreased pain and functional status compared with placebo. A second RCT found that paracetamol increased the proportion of people who rated the treatment as good or excellent compared with diflunisal.

- **Back schools in occupational settings versus no treatment** One systematic review has found that, in occupational settings, back schools improve pain and reduce disability compared with no treatment. Systematic reviews and one subsequent RCT found conflicting evidence on the effects of back schools compared with other treatments.
- **Behavioural therapy** Systematic reviews have found that behavioural therapy reduces pain and improves functional status and behavioural outcomes compared with no treatment, placebo, or waiting list control. Systematic reviews found no significant difference in functional status, pain, or behavioural outcomes between different types of behavioural therapy, and found conflicting results with behavioural therapy compared with other treatments.
- **Massage versus other treatments** One systematic review found that massage combined with exercises and education is more effective than inert treatment. The review found conflicting evidence about the effects of massage compared with other treatments.
- **Non-steroidal anti-inflammatory drugs** One RCT found that naproxen increased pain relief compared with placebo. One systematic review and additional RCTs found no significant difference with non-steroidal anti-inflammatory drugs compared with each other for symptom outcomes. Two RCTs found conflicting evidence on the effects of non-steroidal anti-inflammatory drugs compared with other analgesics.
- **Trigger point and ligamentous injections** One systematic review found limited evidence that steroid plus local anaesthetic injection of trigger points increased pain relief compared with local anaesthetic injection alone, and that phenol increased pain relief compared with saline injection of the lumbar interspinal ligament.
- **Acupuncture** We found conflicting evidence from two systematic reviews and two subsequent RCTs about the effects of acupuncture compared with placebo or no treatment. One systematic review and one subsequent RCT have found that acupuncture reduces pain intensity and increases overall improvement compared with transcutaneous electrical nerve stimulation.
- **Antidepressants** One systematic review and additional RCTs have found that antidepressants significantly increase pain relief compared with placebo. However, they found no consistent difference in functioning or depression. Additional RCTs found conflicting results on pain relief with antidepressants compared with each other or analgesics.
- **Electromyographic biofeedback** One systematic review found no difference in pain relief or functional status between electromyographic biofeedback and placebo or waiting list control, but found conflicting results on the effects of electromyographic biofeedback compared with other treatments.
- **Epidural steroid injections** One systematic review found no significant difference between epidural steroid injections and placebo in pain relief after 6 weeks or 6 months.
- **Lumbar supports** We found insufficient evidence on the effects of lumbar supports.
- **Muscle relaxants** We found insufficient evidence about the benefits of muscle relaxants. One RCT found that adverse effects in people using muscle relaxants are common and include dependency, drowsiness, and dizziness.
- **Physical conditioning programmes** One systematic review has found that physical conditioning programmes with a cognitive behavioural approach plus physical training for workers with back pain reduced sick days but not the risk of being off work at 12 months compared with general practitioner care.

Low back pain and sciatica (chronic)

- **Spinal manipulation** We found five systematic reviews, which identified 13 RCTs. One of the reviews found that spinal manipulation improved outcomes compared with placebo; one concluded that improvements in pain and disability scores were too small to be clinically worthwhile, and the other three were conflicting.
- **Transcutaneous electrical nerve stimulation** One systematic review found no significant difference in pain relief between transcutaneous electrical nerve stimulation and sham stimulation.
- **Facet joint injections** One systematic review found no significant difference in pain relief between facet joint injections and placebo or facet joint nerve blocks.
- **Traction** One systematic review and two additional RCTs found no significant difference between traction and placebo or between traction plus massage and interferential treatment in pain relief or functional status.

DEFINITION

Low back pain is pain, muscle tension, or stiffness localised below the costal margin and above the inferior gluteal folds, with or without leg pain (sciatica — see glossary, p 1531),[1] and is defined as chronic when it persists for 12 weeks or more (see definition of low back pain and sciatica [acute], p 1500).[2] Non-specific low back pain is low back pain not attributed to a recognisable pathology (such as infection, tumour, osteoporosis, rheumatoid arthritis, fracture, or inflammation).[1] This review excludes low back pain or sciatica with symptoms or signs at presentation that suggest a specific underlying condition.

INCIDENCE/ PREVALENCE

Over 70% of people in developed countries will experience low back pain at some time in their lives.[3] Each year, 15–45% of adults suffer low back pain, and 1/20 people present to hospital with a new episode. About 2–7% of patients with acute low back pain will go on to become chronic. Low back pain is most common between the ages of 35–55 years.[3]

AETIOLOGY/ RISK FACTORS

Symptoms, pathology, and radiological appearances are poorly correlated. Pain is non-specific in about 85% of people. About 4% of people with low back pain in primary care have compression fractures and about 1% have a tumour. The prevalence of prolapsed intervertebral disc is about 1–3%.[3] Ankylosing spondylitis and spinal infections are less common.[4] Risk factors for the development of back pain include heavy physical work, frequent bending, twisting, lifting, and prolonged static postures. Psychosocial risk factors include anxiety, depression, and mental stress at work.[3,5] Having a previous history of low back pain and a longer duration of the present episode are significant risk factors for chronicity. A recently published systematic review of prospective cohort studies found that some psychological factors (distress, depressive mood, and somatisation) are associated with an increased risk of chronic low back pain.[6] Individual and workplace factors have also been reported to be associated with the transition to chronic low back pain.[7]

PROGNOSIS

Generally, the clinical course of an episode of low back pain seems to be favourable, and most pain will resolve within 2 weeks. Back pain among primary care patients typically has a recurrent course characterised by variation and change, rather than an acute, self

limiting course.[8] Most back pain patients will have experienced a previous episode, and acute attacks often occur as exacerbations of chronic low back pain. In general, recurrences will occur more frequently and be more severe if patients had frequent or long lasting low back pain complaints in the past. The course of sick leave due to low back pain is similarly favourable. One study reported that 67% of patients with sick leave due to low back pain will have returned to work within a week, and 90% within 2 months. However, the longer the period of sick leave the less likely the return to work becomes. Less than half of the low back pain patients who have been off work for 6 months will return to work. After 2 years of work absenteeism, the chance to return to work is virtually zero.[9]

AIMS OF INTERVENTION To relieve pain; to improve function; to develop coping strategies for pain, with minimal adverse effects from treatment.[2,10]

OUTCOMES Pain intensity (visual analogue or numerical rating scale); overall improvement (self reported or observed); back pain specific functional status (such as Roland Morris questionnaire, Oswestry questionnaire); impact on employment (days of sick leave, number of people returned to work); medication use; intervention specific outcomes (such as coping and pain behaviour for behavioural treatment, strength, and flexibility for exercise, depression [in people with depression and low back pain] for antidepressants, and muscle spasm for muscle relaxants and electromyographic biofeedback — see glossary, p 1530).

METHODS *Clinical Evidence* search and appraisal February 2003. The authors also searched Medline (1966 to December 1998), Embase (1980 to September 1998), and Psychlit (1984 to December 1998), using the search strategy recommended by the Cochrane Back Review Group.[11] Most of the earlier RCTs of treatments for low back pain were small (< 50 people/intervention group; range 9–169), short term (mostly < 6 months' follow up), and of low overall quality. Problems included lack of power, no description of randomisation procedure, incomplete analysis with failure to account for people who withdrew from trials, and lack of blinding.[12] The quality of the methods used by many recent RCTs is higher.

QUESTION What are the effects of oral drug treatments?

OPTION ANALGESICS (PARACETAMOL, OPIOIDS)

One RCT found that tramadol decreased pain and increased functional status compared with placebo. One RCT found no significant difference between paracetomol and diflusinal in the proportion of people who rated the treatment as good or excellent. Two RCTs found no significant difference in pain relief between non-steroidal anti-inflammatory drugs and an opioid analgesic.

Benefits: **Analgesics versus placebo:** One RCT (254 people) found that tramadol (an opioid) decreased pain and improved functional status compared with placebo.[13] **Analgesics versus non-steroidal anti-inflammatory drugs:** See non-steroidal anti-inflammatory drugs, p 1551.

Low back pain and sciatica (chronic)

Harms: RCTs found adverse effects (constipation and drowsiness) with analgesics in about 50% of people. One systematic review (search date 1995) comparing combinations of paracetamol plus weak opioids versus paracetamol alone found that combination treatment increased the risk of adverse effects (single dose studies OR 1.1, 95% CI 0.8 to 1.5; multiple dose studies OR 2.5, 95% CI 1.5 to 4.2).[14]

Comment: None.

OPTION ANTIDEPRESSANTS

One systematic review and additional RCTs have found that antidepressants versus placebo significantly increase pain relief, but found no consistent difference in functioning or depression. One RCT found that maproteline increased pain relief compared with paroxetine.

Benefits: We found one systematic review (search date 2000)[15] and six additional RCTs (2 RCTs in people with low back pain and depression; 2 RCTs in people with low back pain without depression; 2 RCTs did not report whether people were depressed).[16–21] **Versus placebo:** The review found that antidepressants significantly increased pain relief compared with placebo (SMD 0.41, 95% CI 0.22 to 0.61), but found no significant difference in functioning (SMD +0.24, 95% CI –0.21 to +0.69).[15] The six additional RCTs compared an antidepressant (imipramine, amitriptyline, trazodone, nortriptyline, doxepin, maprotiline, paroxetine, or clomipramine) with placebo and reported on depression. Most found no difference in depression, although two RCTs[17,19] found that an antidepressant significantly reduced depression compared with placebo. **Versus each other:** One RCT (67 people) found that maprotiline significantly increased pain relief compared with paroxetine (mean decrease on 0–20 scale: 5.41 with maprotiline *v* 2.34 with paroxetine).[20]

Harms: Adverse effects of antidepressants included dry mouth, drowsiness, constipation, urinary retention, orthostatic hypotension, and mania.[2] One RCT found that the prevalence of dry mouth, insomnia, sedation, and orthostatic symptoms was 60–80% with tricyclic antidepressants.[16] However, rates were only slightly lower in the placebo group and none of the differences were significant.

Comment: None.

OPTION MUSCLE RELAXANTS

One systematic review found insufficient evidence from one RCT about the effects of muscle relaxants. The included RCT found that adverse effects are common and include dependency, drowsiness, and dizziness.

Benefits: We found one systematic review (search date 1995, 1 RCT).[12] The RCT (50 people) identified by the review found that tetrazepam increased overall improvement and reduced pain after 10 days compared with placebo (64% with tetrazepam *v* 29% with placebo of people).[12]

Harms: The review found that adverse effects of muscle relaxants included drowsiness or dizziness in up to 70% of people and a risk of dependency even after 1 week.[12]

Comment: None.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One small RCT found that naproxen increased pain relief compared with placebo. One systematic review and additional RCTs found no significant differences in symptoms between different non-steroidal anti-inflammatory drugs. One RCT identified by the review found no significant difference between diflunisal and paracetamol in the proportion of people who rated the treatment as good or excellent. Two RCTs found no significant difference in pain relief between non-steroidal anti-inflammatory drugs and an opioid analgesic.

Benefits: We found one systematic review (search date 1998)[22] and two additional RCTs.[23,24] **Versus placebo:** One RCT (37 people) identified by the review found that naproxen increased pain relief compared with placebo.[22] **Versus each other:** Four RCTs (453 people) identified by the review found no significant difference between different non-steroidal anti-inflammatory drugs for symptoms.[22] The first additional RCT (196 people) found no significant difference between nimesulide and diclofenac in pain or functioning.[23] **Versus analgesics:** One RCT (29 people) identified by the review found no significant difference between diflunisal and paracetamol in the proportion of people rating their treatment as good or excellent at 4 weeks (10/16 [62%] *v* 4/12 [33%]; RR 1.87, 95% CI 0.77 to 4.55; calculated by *Clinical Evidence*).[22] However, the study may have lacked power to exclude a clinically significant difference. A second RCT (155 people) identified by the review found no difference between a parenteral non-steroidal anti-inflammatory drug and a parenteral opioid in pain relief.[22] One additional RCT (155 people) found no significant difference between ketorolac and meperidine in outcomes.[24]

Harms: Non-steroidal anti-inflammatory drugs may cause gastrointestinal complications (see non-steroidal anti-inflammatory drugs, p 1551). RCTs in people with acute and chronic back pain have found that ibuprofen and diclofenac have the lowest gastrointestinal complication rate mainly because of the low doses used in practice (pooled OR for adverse effects *v* placebo 1.30, 95% CI 0.91 to 1.80).[2,25,26] The first additional RCT found that nimesulide has a similarly low rate of gastrointestinal adverse effects as diclofenac.[23]

Comment: None.

QUESTION What are the effects of local injections?

OPTION EPIDURAL STEROID INJECTIONS

One systematic review found no significant difference between epidural steroid injections and placebo in pain relief after 6 weeks or 6 months.

Low back pain and sciatica (chronic)

Benefits: **Versus placebo:** We found one systematic review (search date 1996, 4 RCTs, 302 people) comparing epidural steroid injections versus placebo.[27] It found no significant difference in pain relief after 6 weeks (pooled RR 0.93, 95% CI 0.79 to 1.09) or 6 months (pooled RR 0.92, 95% CI 0.76 to 1.11).[27]

Harms: The review found that adverse events were infrequent.[27] These included headache, fever, subdural penetration, and, more rarely, epidural abscess and respiratory depression.

Comment: RCTs identified by the review were generally small (range 22–73 people), and included people with a variety of conditions (chronic low back pain with and without sciatica [see glossary, p 1531], sciatica alone, lumbar radicular pain syndrome, and post-laminectomy pain syndrome).

OPTION FACET JOINT INJECTIONS

One systematic review found no significant difference in pain relief between facet joint injections and placebo or facet joint nerve blocks.

Benefits: We found one systematic review (search date 1996, 3 RCTs, no statistical pooling of data).[27] Two RCTs (206 people) identified by the review found no significant difference in pain relief, disability, and flexibility between intra-articular corticosteroid and placebo (intra-articular saline) injections after 1, 3, or 6 months.[27] The third RCT (86 people) identified by the review found no significant difference in pain relief between facet joint injections and facet joint nerve blocks after 2 weeks, 1 month, or 3 months.[27]

Harms: The review found that adverse effects included pain at injection site, infection, haemorrhage, neurological damage, and chemical meningitis.[27]

Comment: Two RCTs from the review[27] did not distinguish between acute and chronic pain and have not been included in this review.

OPTION TRIGGER POINT AND LIGAMENTOUS INJECTIONS

One systematic review found limited evidence that steroid plus local anaesthetic injection of trigger points increased pain relief compared with local anaesthetic injection alone and that phenol increased pain relief compared with saline injection of the lumbar interspinal ligament.

Benefits: We found one systematic review (search date not stated, 2 RCTs, 138 people).[2] The first RCT (57 people) identified by the review found that trigger point injection using steroid (methylprednisolone or triamcinolone) plus lidocaine increased the number of people with complete relief of pain compared with lidocaine alone after 3 months (60–80% with steroid plus lidocaine *v* 20% with lidocaine alone).[2] The other RCT (81 people) identified by the review found that dextrose–glycerine–phenol increased pain relief compared with saline injection into the lumbar interspinal ligament after 1, 3, and 6 months.[2]

Harms: The review found that potential harms included nerve or other tissue damage, infection, and haemorrhage.[2]

Comment: None.

QUESTION What are the effects of non-drug treatments?

OPTION BACK SCHOOLS

One systematic review has found that, in occupational settings, back schools improve pain and reduce disability compared with no treatment. Systematic reviews and one subsequent RCT found conflicting evidence on the effects of back schools compared with other treatments.

Benefits: We found two systematic reviews (search date 1997, 14 RCTs, no statistical pooling of data;[28] search date 2000, 18 RCTs[29]) and one subsequent RCT.[30] Five RCTs (880 people) identified by the first review found that intensive back school programmes (see glossary, p 1530) in an occupational setting improved pain and reduced disability compared with no treatment. They found no difference in outcomes compared with other treatments (physiotherapy, callisthenics group training, or usual care).[28] Six RCTs (529 people) identified by the first review and the subsequent RCT compared back schools versus no treatment, waiting list control, or short wave diathermy. Four of these RCTs found that back schools improved outcomes in the short term;[28] two of these RCTs found no difference in the short term, and the remaining two RCTs found no difference in the long term.[28,30] Five RCTs (861 people) identified by the first review found that back schools increased pain relief and reduced disability compared with manipulation, non-steroidal anti-inflammatory drugs, or physiotherapy exercises after 6 months, but found no significant difference after 1 year.[28] The second systematic review found that back schools significantly increased pain relief after 3 months compared with no treatment or any other treatment, but found no difference in outcomes in the long term (see comment below).[29]

Harms: The reviews and subsequent RCT did not report on harms.[28–30]

Comment: The second review, which combined randomised and non-randomised studies, compared back schools, no treatment, and other active treatments in the same meta-analysis, and did not take the methods of the studies into account.[29]

OPTION BEHAVIOURAL THERAPY

Systematic reviews have found that behavioural therapy reduces pain and improves functional status and behavioural outcomes compared with no treatment, placebo, or waiting list control. Systematic reviews found no significant difference in functional status, pain, or behavioural outcomes between different types of behavioural therapy, and found conflicting results with behavioural therapy compared with other treatments.

Benefits: We found five systematic reviews (search dates not stated,[2] 1995,[10,12] 1994,[31] and 1999;[32] 20 RCTs, no statistical pooling of data). **Versus placebo, no treatment, or waiting list control:** Eleven RCTs (1223 people) identified by the reviews found that behavioural therapy compared with no treatment, placebo, or

waiting list control, reduced pain intensity and improved functional status and behavioural outcomes.[2,10,12,31,32] **Different types of behavioural therapy versus each other:** The reviews identified nine RCTs (308 people), which found no significant difference between different types of behavioural therapy (cognitive behavioural therapy, operant behavioural treatments, and respondent behavioural treatment — see glossary, p 1530) in functional status, pain, or behavioural outcomes (including anxiety, depression, pain behaviour, and coping).[2,10,12,31,32] **Versus other treatments:** Two RCTs (202 people) identified by the reviews found that behavioural therapy increased the proportion of people who had returned to work after 12 weeks compared with traditional care (rest, analgesics, or physiotherapy) or back exercises, but found no difference in pain or depression after 6 months or 12 months.[2,10,12,31,32] Six RCTs (343 people) identified by the reviews comparing behavioural therapy plus other treatments (physiotherapy and back education, multidisciplinary treatment [see glossary, p 1531] programmes, inpatient pain management programmes, and back exercises) found that behavioural therapy plus the other treatments improved functional status in the short term compared with other treatments alone, but found no difference in pain or behavioural outcomes.[2,10,12,31,32]

Harms: The reviews did not report on harms.[2,10,12,31,32]

Comment: None.

OPTION ELECTROMYOGRAPHIC BIOFEEDBACK

One systematic review found no difference in pain relief or functional status between electromyographic biofeedback and placebo or waiting list control, but found conflicting results on the effects of electromyographic biofeedback compared with other treatments.

Benefits: We found one systematic review (search date 1995, 5 RCTs, 168 people, no statistical pooling of data).[12] **Versus placebo or waiting list control:** Three RCTs (102 people) identified by the review found no difference with electromyographic biofeedback (see glossary, p 1530) compared with placebo or waiting list control in pain relief or functional status.[12] **Versus other treatments:** Two RCTs (30 people) identified by the review found conflicting results with electromyographic biofeedback compared with progressive relaxation training in outcomes.[12] One RCT (30 people) identified by the review found no difference between rehabilitation programmes plus biofeedback versus biofeedback alone in pain or range of movement.[12]

Harms: The review did not report on harms.[12]

Comment: None.

OPTION EXERCISE

Systematic reviews and additional RCTs have found that exercise improves pain and functional status compared with usual care. RCTs found conflicting evidence on the effects of different types of exercise, or exercise compared with inactive treatments.

Benefits: We found five systematic reviews (search date not stated,[2] 1995,[10,12,33] and 1999;[34] 23 RCTs, 2240 people; no statistical pooling of data) and 14 additional RCTs.[35–48] **Versus inactive treatment:** Six RCTs (587 people) identified by one review compared exercise versus inactive treatments (hot packs plus rest, semi-hot packs plus sham traction, waiting list control, transcutaneous electrical nerve stimulation [TENS], sham TENS, detuned ultrasound, or short wave diathermy).[34] Three of these RCTs found that exercise increased overall improvement, whereas the remaining three RCTs found no significant difference in overall improvement. One additional small RCT (59 people) found that active rehabilitation consisting of 24 exercise sessions during 12 weeks improved pain intensity and functional disability compared with inactive treatments.[40] **Versus other treatments:** Nine RCTs (1020 people) identified by the reviews compared exercise with other treatments.[2,10,12,33,34] Three of these RCTs found no significant difference between exercise and conventional physiotherapy in pain, functional status, overall improvement, or return to work. One RCT found that exercise (as part of a combined physiotherapy programme) improved pain, functional status, and return to work compared with usual care by the general practitioner.[49] Three RCTs found that exercise improved both pain and functional status compared with back school education (see glossary, p 1530) plus early morning lumbar flexion control. One additional RCT (132 people) found that a full time, intensive 3 week multidisciplinary programme improved ability to work (but not return to work) and disability after 4 and 24 months, and improved pain relief after 4 months compared with exercise or exercise plus psychological pain management.[35,36] A second additional RCT (109 people) found no significant difference between exercise and massage (see glossary, p 1530) in pain and disability 4 weeks after the end of treatment.[37] **Versus each other:** One additional RCT (148 people) found no significant difference between active physiotherapy and muscle reconditioning with training devices and low impact aerobics in pain intensity after 6 months and 1 year, but found that muscle reconditioning and aerobic exercises reduced disability after 6 and 12 months compared with active physiotherapy.[42–45] A second additional RCT found that a combined exercise and motivation programme reduced pain and improved disability after 4 and 12 months compared with exercises alone.[39] **Extension exercises (including McKenzie exercises):** See glossary, p 1530. Three RCTs (153 people) identified by one review compared extension versus flexion back exercises.[34] Two of these RCTs found no significant difference in pain intensity, and the third RCT found that extension exercises reduced global improvement compared with flexion exercises. A subsequent RCT (60 patients) found no significant difference between extension exercises and whole body vibration exercises in pain intensity (VAS scale 0–10) and disability (Pain disability Index 0–70, where 0 = no limitation and 70 = most severe limitation) during 12 weeks of treatment and after 6 months (pain intensity: data not shown; change in pain disability index: from 20.3 at baseline to 10.5 after treatment with extension *v* 20.7 at baseline to 11.6 after treatment with vibration).[50] **Strengthening exercises:** Nine RCTs (899 people) identified by the reviews found

no significant difference between strengthening exercises and other types of exercise in outcomes, and found conflicting evidence on strengthening exercises compared with inactive treatment.[2,10,12,33,34] **Stabilisation exercises:** One additional RCT (44 people with spondylolysis and spondylolisthesis) found that a 10 week specific stabilising exercise programme reduced pain intensity and functional disability after 30 months compared with usual care.[48] **Postural exercises (Mensendieck/Cesar):** One additional RCT (77 people who had just finished treatment for their last episode of back pain) found that a Mensendieck exercise (see glossary, p 1530) group treatment for 13 weeks reduced recurrences of back pain compared with usual care, but found no significant differences in sick leave, pain, or functioning after 1 and 3 years.[46,47] A second additional RCT (222 people) found that Cesar therapy (see glossary, p 1530) increased overall improvement after 3 and 6 months compared with usual care by the general practitioner, but found no significant difference after 1 year.[38] **Group exercises:** One additional RCT (109 people) found no significant differences between individual and group exercises in pain and disability 4 weeks after the end of treatment.[37]

Harms: The reviews and RCTs did not report on harms.

Comment: One additional study compared an intensive training programme versus home exercises versus control in people with both acute and chronic low back pain. Randomisation was only successful for home exercise versus control.[41]

OPTION LUMBAR SUPPORTS

We found insufficient evidence on the effects of lumbar supports.

Benefits: We found one systematic review (search date 1999, 1 RCT).[51] The RCT (19 people) identified by the review found that a lumbar corset plus a synthetic support improved symptom severity and functional disability compared with lumbar corset without synthetic support.[51]

Harms: The review did not report on harms.[51] Harms associated with prolonged lumbar support use include decreased strength of the trunk musculature, a false sense of security, heat, skin irritation, and general discomfort.

Comment: Five RCTs (1200 people) identified by the review did not differentiate between acute and chronic pain.[51]

OPTION MULTIDISCIPLINARY TREATMENT PROGRAMMES

One systematic review has found that intensive multidisciplinary biopsychosocial rehabilitation with functional restoration reduces pain and improves function compared with inpatient or outpatient non-multidisciplinary treatments or usual care. The review found no significant difference between less intensive multidisciplinary treatments and non-multidisciplinary treatment or usual care in pain or function.

Benefits: We found one systematic review (search date 1998, 10 RCTs, 1964 people),[52] which compared multidisciplinary treatment (see glossary, p 1531) versus a control treatment. The review found that

intensive multidisciplinary biopsychosocial rehabilitation with functional restoration reduced pain and improved function compared with inpatient or outpatient non-multidisciplinary treatments or usual care.[52] The review found no significant difference between less intensive outpatient multidisciplinary treatments and non-multidisciplinary outpatient treatment or usual care in pain or function.[52]

Harms: The review did not report on harms.[52]

Comment: We found one RCT (195 people) that compared three treatments: extensive multidisciplinary treatment; light multidisciplinary treatment, and usual care. There was no overall analysis according to treatment allocation. However, subgroup analysis found that men returned to work more quickly with light multidisciplinary treatment than with usual care. It found no significant differences between extensive multidisciplinary treatment and usual care in men and no significant differences between any two interventions in women.[53]

OPTION PHYSICAL CONDITIONING PROGRAMMES

One systematic review has found that physical conditioning programs with a cognitive behavioural approach plus physical training for workers with back pain reduced sick days but not risk of being off work at 12 months compared with general practitioner care.

Benefits: We found one systematic review of physical conditioning programmes compared with other treatments in adults with work disability related to back pain (search date 2000, 16 relevant RCTs).[54] The programmes were heterogeneous, all involving a cognitive behavioural approach plus a range of types of physical training (including aerobics, muscle strength and endurance training, and co-ordination training) given by a physiotherapist or a multidisciplinary team. The interventions varied in length from one session only to 1 hour per week for 18 months, most lasting between 3 and 6 weeks. The review found that physical conditioning programmes reduced the number of sick days compared with general practitioner advice or care after 12 months (2 RCTs, average reduction in sick days 45, 95% CI 3 to 88). There was no significant difference between physical conditioning programmes and general practitioner advice or care in the proportion of people off work at 12 months (physicial conditioning *v* general practitioner care: OR 0.8, 95% CI 0.58 to 1.09).[54]

Harms: The review did not report on harms.[54]

Comment: None.

OPTION MASSAGE

One systematic review found that massage combined with exercises and education is more effective than inert treatment. The review found conflicting evidence about the effects of massage compared with other treatments.

Low back pain and sciatica (chronic)

Benefits: We found one systematic review (search date 2001; 9 RCTs, 891 people; no statistical pooling of data; see comment below).[55] The review included one RCT, which found that massage combined with exercises and education is more effective than inert treatment (sham laser). The other eight RCTs included in the review compared massage with other treatments and found conflicting results.

Harms: The review did not report on harms.[55]

Comment: Problems with control group selection in the included RCTs limit the usefulness of their results.[55]

OPTION SPINAL MANIPULATION

We found five systematic reviews, which identified 13 RCTs. One of the reviews found that spinal manipulation improved outcomes compared with placebo; another review concluded that improvements in pain intensity and disability scores were not clinically worthwhile; and three reviews found that the results of the RCTs were conflicting.

Benefits: We found five systematic reviews (search dates 1995,[10,12,56] 2001,[57] and not stated[58]). Four RCTs (514 people) identified by the reviews compared manipulation versus placebo, and nine RCTs (597 people) identified by the reviews compared manipulation versus conservative treatments (usual care, short wave diathermy, massage, exercises, back schools (see glossary, p 1530), and drug treatment). Three of the reviews found that the results of included RCTs were conflicting.[10,56,58] The fourth review (5 RCTs, 543 people) found that spinal manipulation improved outcomes compared with placebo.[12] The fifth review found that spinal manipulation did not produce clinically worthwhile decreases in pain intensity scores compared with sham treatment or non-steroidal anti-inflammatory drugs, and no clinically worthwhile reductions in disability compared with non-steroidal anti-inflammatory drugs.[57]

Harms: In the RCTs identified by the reviews that used a trained therapist to select people and perform spinal manipulation, the risk of serious complications was low (estimated risk: vertebrobasilar strokes 1/20 000 to 1/1 000 000 people; cauda equina syndrome < 1/1 000 000 people).[10,12,56,58]

Comment: Current guidelines do not advise spinal manipulation in people with severe or progressive neurological deficit.[2,58]

OPTION TRACTION

One systematic review and two additional RCTs found no significant difference between traction and placebo or between traction plus massage and interferential treatment in pain relief or functional status.

Benefits: We found one systematic review (search date 1995, 1 RCT)[10] and two additional RCTs.[59,60] Two RCTs (176 people) found no significant difference between traction and placebo in global improvement, pain relief, or functional status after 5–9 weeks.[10,61] The second additional RCT (152 people) found no significant difference between lumbar traction plus massage and interferential treatment (see glossary, p 1530) in pain relief or improvement of disability 3 weeks and 4 months after the end of treatment.[59]

Harms: The review and additional RCTs did not report on harms.[10,59,60] Potential adverse effects include debilitation, loss of muscle tone, bone demineralisation, and thrombophlebitis.[2]

Comment: None.

OPTION TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

One systematic review found no significant difference in pain relief between transcutaneous electrical nerve stimulation and sham stimulation.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 421 people).[61] It found no significant difference between transcutaneous electrical nerve stimulation and sham stimulation in pain measured using a visual analogue scale (3 RCTs, 171 people; pooled standardised mean difference –0.21, 95% CI –0.51 to +0.1).[61]

Harms: The review did not report on harms.[61]

Comment: None.

OPTION ACUPUNCTURE

We found conflicting evidence from two systematic reviews and two subsequent RCTs about the effects of acupuncture compared with placebo or no treatment. One systematic review and one subsequent RCT have found that acupuncture reduces pain intensity and increases overall improvement compared with transcutaneous electrical nerve stimulation

Benefits: We found two systematic reviews (search dates 1996, 12 RCTs; see comment below)[62,63] and three subsequent RCTs.[64–66] The reviews identified seven RCTs (380 people) comparing acupuncture (see glossary, p 1530) versus no treatment, placebo acupuncture, waiting list control, or transcutaneous electrical nerve stimulation.[62,63] One review found no significant difference between acupuncture and placebo acupuncture or no treatment in clinical outcomes.[63] The second review found that acupuncture increased overall improvement compared with control interventions (OR 2.3, 95% CI 1.3 to 4.1), but found no significant difference between acupuncture and placebo acupuncture in outcomes (OR 1.4, 95% CI 0.8 to 2.3).[62] The first subsequent RCT (60 people) found that acupuncture significantly reduced pain intensity and the number of analgesic tablets consumed a week compared with transcutaneous electrical nerve stimulation.[64] The second RCT (50 people) compared three treatments: manual acupuncture, electroacupuncture, and mock transcutaneous electrical nerve stimulation (placebo).[65] It found that manual and electroacupuncture significantly increased overall clinical improvement after 1 month compared with placebo (judged subjectively by investigator blinded to treatment allocation; 16/34 [47%] with acupuncture *v* 2/16 [13%] with placebo, $P < 0.05$; CI not reported). The third RCT (131 people) compared three treatments: acupuncture, sham acupuncture, and no treatment.[66] It found that acupuncture significantly reduced pain intensity and disability after 3 months, and disability after 9 months compared with control intervention. It found no significant

difference between acupuncture and sham acupuncture for pain intensity and disability 9 months after the end of treatment (improvement in 10 cm visual analogue pain score 1.7 for acupuncture *v* 1.8 for sham acupuncture; improvement in 70 point pain disability index 9.0 for acupuncture *v* 8.5 for sham acupuncture).

Harms: One systematic review found that serious and rare adverse effects included infections (HIV, hepatitis, bacterial endocarditis) and visceral trauma (pneumothorax, cardiac tamponade).[63]

Comment: Three RCTs identified by the systematic reviews combined acute and chronic low back pain and two RCTs did not specify the duration of symptoms.[62,63] One RCT identified by the reviews included people with back and neck pain.[62,63]

GLOSSARY

Acupuncture Acupuncture is needle puncture of the skin at traditional "meridian" acupuncture points. Modern acupuncturists also use non-meridian points and trigger points (tender sites occurring in the most painful areas). The needles may be stimulated manually or electrically. Placebo acupuncture is needling of traditionally unimportant sites or non-stimulation of the needles once placed.

Back school Back school techniques vary widely, but essentially consist of repeated sessions of instruction about anatomy and function of the back and isometric exercises to strengthen the back.

Cesar therapy Cesar therapy is based on the hypothesis that there is an association between postural and movement deficiencies and back pain. The treatment aims to initiate a learning process aimed at correction of postural and movement deficiencies.

Cognitive behavioural therapy Cognitive behavioural therapy aims to identify and modify peoples understanding of their pain and disability using cognitive restructuring techniques (such as imagery and attention diversion) or by modifying maladaptive thoughts, feelings, and beliefs.

Electromyographic biofeedback With electromyographic biofeedback, a person receives external feedback of their own electromyogram (using visual or auditory scales), and uses this to learn how to control the electromyogram and hence the tension within their own muscles. Electromyogram biofeedback for low back pain aims to relax the paraspinal muscles.

Interferential therapy Interferential therapy is a low frequency current treatment that uses two medium frequency currents which "interfere" with each other to produce a beat frequency that the body recognises as a low frequency energy source. It is used as treatment for disorders in which inflammation is supposed to be a problem, such as back pain, osteoarthritis, rheumatoid arthritis, muscular pain/strain, and sports injuries.

Massage Massage is manipulation of soft tissues (i.e. muscle and fascia) using the hands or a mechanical device, to promote circulation and relaxation of muscle spasm or tension. Different types of soft tissue massage include Shiatsu, Swedish, friction, trigger point, or neuromuscular massage.

McKenzie exercises McKenzie exercises use self generated stresses and forces to centralise pain from the legs and buttocks to the lower back. This method emphasises self care.

Mensendieck therapy The Mensendieck approach combines postural exercises and education, emphasising "learning by doing". It is based on the assumption that human beings, through insight and guidance, can take responsibility for their own health and thus avoid the consequences of functional disability. Mensendieck therapy has been used for decades in the Netherlands and Scandinavia.

Multidisciplinary treatment Multidisciplinary treatment is intensive physical and psychosocial training by a team (e.g. a physician, physiotherapist, psychologist, social worker, and occupational therapist). Training is usually given in groups and does not involve passive physiotherapy.

Operant behavioural treatments Operant behavioural treatments include positive reinforcement of healthy behaviours and consequent withdrawal of attention from pain behaviours, time contingent instead of pain contingent pain management, and spouse involvement, while undergoing a programme aimed at increasing exercise tolerance towards a preset goal.

Respondent behavioural treatment Respondent behavioural treatment aims to modify physiological responses directly (e.g. reducing muscle tension by explaining the relation between tension and pain, and using relaxation techniques).

Sciatica Pain that radiates from the back into the buttock or leg and is most commonly caused by prolapse of an intervertebral disk; the term may also be used to describe pain anywhere along the course of the sciatic nerve.

QUESTIONS

INTERVENTIONS

See glossary, p 1548

Key Messages

Uncomplicated neck pain

- **Manual treatments (mobilisation and manipulation)** Systematic reviews and RCTs found limited evidence that manipulation or mobilisation improved symptoms compared with other or no treatment in people with neck pain.

- **Physical treatments (active physiotherapy, exercise, pulsed electromagnetic field treatment)** Systematic reviews and RCTs have found that active physiotherapy reduces pain compared with passive treatment, and that exercise programmes reduce pain compared with management that does not include exercise programmes. One RCT provided limited evidence that pulsed electromagnetic field treatment reduced pain compared with sham treatment.
- **Drug treatments (analgesics, non-steroidal anti-inflammatory drugs, antidepressants, or muscle relaxants)** We found insufficient evidence on the effects of analgesics, non-steroidal anti-inflammatory drugs, antidepressants, or muscle relaxants for neck pain, although they are widely used. Several drugs used to treat neck pain are associated with well documented adverse effects.
- **Multidisciplinary (multimodal) treatment** RCTs provided insufficient evidence to compare effects of multimodal treatment with other treatments in people with uncomplicated neck pain.
- **Physical treatments (heat or cold, traction, biofeedback, spray and stretch, acupuncture, laser)** Systematic reviews provided insufficient evidence about the effects of these physical treatments.
- **Soft collars and special pillows** We found no RCTs of sufficient quality on the effects of soft collars or special pillows.
- **Patient education** Three RCTs found no significant difference between patient education (advice or group instruction) with or without analgesics compared with no treatment, stress management, placebo, or usual care.

Acute whiplash

- **Early mobilisation** Systematic reviews and subsequent RCTs provided limited evidence that early mobilisation reduced pain compared with immobilisation or rest plus a collar.
- **Early return to normal activity** Systematic reviews and subsequent RCTs provided limited evidence that advice to "act as usual" plus anti-inflammatory drugs improved mild symptoms compared with immobilisation plus 14 days' sick leave.
- **Electrotherapy** One small RCT provided limited evidence that electromagnetic field treatment reduced pain after 4 weeks but not after 3 months compared with sham treatment.
- **Multimodal treatment** One RCT found that multimodal treatment reduced pain at the end of treatment and after 6 months compared with physical treatment.
- **Drug treatments** We found no RCTs of drug treatments in acute whiplash injury.
- **Home exercise programmes** One RCT found no significant difference between different home exercise programmes in pain or disability.

Chronic whiplash

- **Percutaneous radiofrequency neurotomy** One RCT provided limited evidence that percutaneous radiofrequency neurotomy reduced pain compared with sham treatment after 27 weeks.
- **Multimodal treatment (physiotherapy plus cognitive behavioural treatment)** One RCT found no difference between multimodal treatment (physiotherapy plus cognitive behavioural treatment) in disability, pain, or range of movement at the end of treatment or at 3 months.

Neck pain

- **Physiotherapy** One RCT found no significant difference between physiotherapy alone and multimodal treatment in disability, pain, or range of movement at the end of treatment or at 3 months.

Neck pain with radiculopathy

- **Drug treatments (epidural steroid injections, analgesics, non-steroidal anti-inflammatory drugs, or muscle relaxants)** We found no RCTs on the effects of epidural steroid injections, analgesics, non-steroidal anti-inflammatory drugs, or muscle relaxants.
- **Surgery versus conservative treatment** One RCT found no significant difference between surgery and conservative treatment in symptoms after 1 year.

DEFINITION

In this topic we have differentiated uncomplicated neck pain from whiplash, although many studies, particularly in people with chronic pain (duration more than 3 months), do not specify which types of people are included. Most studies of acute pain (duration less than 3 months) are confined to whiplash. We have included under radiculopathy those studies involving people with predominantly radicular symptoms arising in the cervical spine. Neck pain often occurs in combination with limited movement and poorly defined neurological symptoms affecting the upper limbs. The pain can be severe and intractable, and can occur with radiculopathy or myelopathy.

INCIDENCE/ PREVALENCE

About two thirds of people will experience neck pain at some time in their lives.[1,2] Prevalence is highest in middle age. In the UK about 15% of hospital based physiotherapy and in Canada 30% of chiropractic referrals are for neck pain.[3,4] In the Netherlands neck pain contributes up to 2% of general practitioner consultations.[5]

AETIOLOGY/ RISK FACTORS

Most uncomplicated neck pain is associated with poor posture, anxiety and depression, neck strain, occupational injuries, or sporting injuries. With chronic pain, mechanical and degenerative factors (often referred to as cervical spondylosis) are more likely. Some neck pain results from soft tissue trauma, most typically seen in whiplash injuries. Rarely, disc prolapse and inflammatory, infective, or malignant conditions affect the cervical spine and present with neck pain with or without neurological features.

PROGNOSIS

Neck pain usually resolves within days or weeks but can recur or become chronic. In some industries, neck related disorders account for as much time off work as low back pain (see low back pain and sciatica [acute], p 1500).[6] The percentage of people in whom neck pain becomes chronic depends on the cause but is thought to be about 10%,[1] similar to low back pain. Neck pain causes severe disability in 5% of affected people.[2] **Whiplash:** Whiplash injuries are more likely to cause disability than neck pain due to other causes; up to 40% of sufferers reported symptoms even after 15 years' follow up.[7] Factors associated with a poorer outcome after whiplash are not well defined.[8] The incidence of chronic disability after whiplash varies among countries, although reasons for this variation are unclear.[9]

AIMS OF INTERVENTION To recover from acute episode within 4 weeks; to maintain activities of daily living and reduce absenteeism from work; to prevent development of long term symptoms; to improve symptoms.

OUTCOMES Pain; range of movement; function; adverse effects of treatment; return to work; level of disability (Neck Disability Index [see glossary, p 1548]).[10]

METHODS *Clinical Evidence* search and appraisal September 2003. We also searched the following databases: Chirolars (now called Mantis) for English language articles from 1966 to November 1999; Bioethicsline (1973–1997); Cumulative Index to Nursing and Allied Health (Cinahl) (1982–1997); and Current Contents (1994–1997). Criteria for assessment of RCTs were based on a 100 point scale, including study population, interventions, effects, and data presentation and analysis.[11]

QUESTION **What are the effects of treatments for people with uncomplicated neck pain without severe neurological deficit?**

OPTION PHYSICAL TREATMENTS

Systematic reviews and RCTs have found that active physiotherapy reduces pain compared with passive treatment, and that exercise programmes reduce pain compared with management that does not include exercise programmes. One RCT provided limited evidence that pulsed electromagnetic field treatment reduced pain compared with sham treatment. Systematic reviews provided insufficient evidence about the effects of other physical treatments (heat or cold, traction, biofeedback, spray and stretch, acupuncture, and laser).

Benefits: **All physical modalities:** We found three systematic reviews covering all physical modalities.[12–14] The first systematic review (search date 1993, 13 RCTs, 760 people with neck pain but without neurological deficit) found no significant benefit from any of the following physical treatments: heat or cold, traction, electrotherapy (pulsing electromagnetic field or transcutaneous electrical nerve stimulation), biofeedback, spray and stretch, acupuncture, or laser.[14] The second systematic review (search date 1995, 17 RCTs, 1202 people) found possible benefit from active physiotherapy and pulsed electromagnetic field treatment, but not for traction, acupuncture, or other physical treatments.[12] The third systematic review (search date 2000, 7 CCTs/RCTs, 507 people with chronic neck pain) found some evidence of benefit for proprioceptive and strengthening exercise based on two low quality studies,[15,16] but no evidence that thermotherapy, massage, biofeedback, traction, ultrasound, transcutaneous electrical nerve stimulation, or combined rehabilitation interventions improved symptoms.[13] **Exercise:** We found one systematic review (4 RCTs, search date 2001)[17] and three subsequent RCTs (4 published papers).[18–21] The first RCT (47 people) included in the review found that active physiotherapy, including exercise (for 60 minutes each visit; mean 13 visits) significantly reduced pain immediately after treatment compared with passive treatment (heat, massage, and light stretching for

20 minutes each visit; mean 10 visits; $P < 0.05$).[22] The second RCT included in the review (2 published papers, 103 women with work related neck pain) compared three exercise regimens (strength training, endurance training, and coordination exercises) versus stress management over 10 weeks.[23,24] It found that exercise significantly reduced pain compared with stress management after 10–12 weeks ($P < 0.05$), but found no significant difference between any of the exercise programmes versus each other. It found no significant differences in neck pain between the different exercise regimens and stress management or versus each other after 3 years' follow up (AR for neck pain: 47% with strength training *v* 50% with endurance training *v* 58% with coordination exercises *v* 39% with stress management; no individual P values reported for each treatment *v* stress management). The third and fourth RCTs included in the review compared intensive training, mobilisation physiotherapy, and manipulation (see glossary, p 1548). (see benefits of manual treatments: mobilisation and manipulation, p 1540).[25,26] The first subsequent RCT (77 people) found no significant difference in pain intensity between general exercise, McKenzie treatment (see glossary, p 1548), and low power ultrasound (control) after 4 weeks of treatment and at 12 months (pain intensity after treatment measured on a 100 mm visual analogue scale [0 mm = no pain; 100 mm = unbearable pain]: 27 mm with general exercise *v* 19 mm with McKenzie treatment *v* 21 mm with control treatment; significance not stated; pain intensity at 12 months: 30 mm with general exercise *v* 26 mm with McKenzie treatment *v* 25 mm with control treatment; P value not reported).[18] However, it found that McKenzie treatment significantly reduced pain intensity compared with control treatment at 6 months (21 mm with McKenzie treatment *v* 27 mm with control treatment; $P < 0.05$). The second subsequent RCT (180 female office workers with chronic neck pain) compared a programme of specific "endurance" (dynamic) or "strength" (isometric) exercises carried out three times a week for 1 year versus no specific exercise programme. All participants were encouraged to undertake simple aerobic and stretching exercises.[19] It found that endurance and strength exercises improved neck pain compared with control after 12 months of treatment (pain assessed on a 100 mm visual analogue scale; median improvement in pain score: 40 with strength exercise *v* 35 with endurance exercise *v* 16 with control; $P < 0.001$ for exercise groups *v* control). Strength and endurance exercises improved disability significantly more than control (median improvement in NDI: 9 with strength exercise *v* 8 with endurance exercise *v* 3 with control; $P < 0.001$).[19] The third subsequent RCT (2 published papers, 183 patients with neck pain for at least 2 weeks) compared mobilisation, active exercise, or usual general practitioner care (see benefits of manual treatments: mobilisation, p 1540).[20,21] **Traction:** We found one systematic review (search date 1992, 3 RCTs, 639 people) comparing traction versus a range of alternative treatments, including heat, mobilisation, exercise, no treatment, collar, and analgesics.[27] The review found no consistent difference in pain between traction and any of the other treatments. **Pulsed electromagnetic field treatment**: We found one systematic review (search date 1995, 1 RCT).[12] The RCT

included in the review (in 81 people with neck pain and radiographic evidence of cervical osteoarthritis and 86 people with osteoarthritis of the knee; with symptoms for at least 1 year; see comment below) compared true versus sham pulsed electromagnetic field treatment.[28] Subgroup analysis in people with chronic neck pain found that pulsed electromagnetic field treatment significantly reduced pain ($P < 0.04$) and pain on passive motion ($P = 0.03$), but found no significant difference between treatments in difficulty with activities of daily living, tenderness, self assessment of improvement, or physicians' global assessment after 18 episodes of treatment. The RCT also found that active versus sham pulsed electromagnetic field treatment significantly increased the number of people who had improved in at least three of six variables (pain, pain on passive motion, activities of daily living, tenderness, self assessed improvement, physicians' global assessment; 57/82 [70%] with active treatment *v* 37/82 [45%] with sham treatment; RR 1.54, 95% CI 1.21 to 1.80; NNT 4, 95% CI 3 to 11). This benefit was sustained up to 1 month (see comment below). **Acupuncture:** Two systematic reviews (search dates 1998, 13 RCTs) compared needle or laser acupuncture versus several different control procedures (sham treatments, diazepam, and physiotherapy) and found no consistent differences between treatments.[29,30] One subsequent RCT (177 people with chronic neck pain mainly because of fibromyalgia or whiplash) compared three groups: acupuncture, massage, and sham laser acupuncture.[31] It found no significant difference between acupuncture and sham laser acupuncture after 1 week (difference in pain score on a 100 point visual analogue scale: acupuncture *v* sham laser acupuncture +6.9 points, 95% CI –5.0 points to +18.9 points; $P = 0.33$), but found that acupuncture significantly reduced motion related pain after 1 week compared with massage (acupuncture reduced pain by 16.3 points more than massage on a 100 point visual analogue scale, 95% CI 4.4 points to 28.3 points; $P = 0.005$). The RCT found no significant difference between treatments after 3 months.

Harms: We found no good data on harms. The incidence of serious adverse events seems to be low for all physical treatments considered.

Comment: Although randomisation was properly conducted, baseline characteristics of treated and placebo groups were, by chance, different in the RCT comparing true versus sham pulsed electromagnetic field treatment.[28] People allocated to active treatment had higher pain scores, more tenderness, and more difficulty with the activities of daily living than the placebo group. The analysis in the RCT was based on changes from the baseline value, and it is not known how much of the observed effect was caused by bias introduced by the baseline differences. One systematic review of physical medicine modalities for mechanical neck disorders has been withdrawn from the Cochrane Library because it is now considered out of date, but the data are included in another systematic review, which is described above.[14]

OPTION MANUAL TREATMENTS: MOBILISATION AND MANIPULATION

Systematic reviews and RCTs found limited evidence that manipulation or mobilisation improved symptoms compared with other or no treatment in people with neck pain.

Benefits: We found four systematic reviews (search dates 1990,[11] 1993,[14] 1995,[32] 1995[12]), and four subsequent RCTs (in 5 published articles),[20,21,25,26,33] which assessed mobilisation and manipulation (see glossary, p 1548). Four reviews found that mobilisation or manipulation improved symptoms compared with a variety of control procedures.[11,12,14,32] **Mobilisation or manipulation:** One RCT (included in two reviews;[14,32] 256 people with chronic neck and back pain, 64 having chronic neck pain alone) compared four treatments: manual treatment (mobilisation, manipulation, or both); physical treatment (heat, electrotherapy, ultrasound, shortwave diathermy); usual medical care (analgesics, advice, home exercise, and bed rest); and placebo (detuned shortwave diathermy or ultrasound).[34] It found that manual treatment significantly improved outcomes after 12 months compared with all of the other treatments (statistical analysis specifically for people with neck pain was not provided). However, it was not possible to compare directly the effects of the two manual treatments, and more people received manipulation. **Mobilisation:** One RCT (included in 4 systematic reviews;[11,12,14,32] 30 people with acute pain who were all given a collar and allowed to take analgesics) found no significant difference in pain with mobilisation (10 people) compared with transcutaneous electrical nerve stimulation (10 people) or compared with control (10 people).[35] However, the trial may have lacked power to detect a clinically significant difference. A second RCT (included in two reviews;[14,32] 63 people) found that mobilisation plus analgesia significantly reduced pain compared with less active physiotherapy plus analgesia after 1 month (83% of the mobilisation group improved *v* 60% of the physiotherapy group; $P < 0.05$) but not thereafter.[36] A subsequent RCT (183 patients with neck pain for longer than 2 weeks) compared three 6 week courses of treatment: mobilisation, active exercise, or usual general practitioner care (analgesics, education, and counselling) and found that mobilisation slightly but significantly improved treatment "success" compared with active exercise or usual care at 7 weeks (participant rating on a 6 point scale from "much worse" to "completely recovered"; "success" defined as "much improved" or "completely recovered"; AR for "success": 68.3% with mobilisation *v* 50.8% with active exercise [ARI 17.5%, 95% CI 0.1% to 34.8%] *v* 35.9% with general practitioner care [ARI 32.4%, 95% CI 15.8% to 49%]). It found no significant difference between the "success" rate at 7 weeks with active exercise compared with general practitioner care (ARI +14.9%, 95% CI −2.4% to +32.3%).[20] Long term follow up found that mobilisation significantly increased "success" rate compared with other treatments at 26 weeks, but not at 1 year (no figures provided for "success" at 26 weeks; AR for "success" at 1 year: 71.7% with mobilisation *v* 62.7% with active exercise [ARI +9%, 95% CI −7.9% to +25.8%] *v* 56.3 with general practitioner care [ARI +15.4%, 95% CI −1.3% to +32.1%]).[21] **Manipulation:**

One of the reviews performed a meta-analysis (3 RCTs, 155 people with chronic pain)[34,37,38] of manipulation compared with other treatments (diazepam, anti-inflammatory drugs, usual medical care).[32] It found no significant difference in improved outcomes between manipulation and other treatments (+12.6 mm on a 100 mm visual analogue scale, 95% CI −0.15 mm to +25.5 mm). **Mobilisation versus manipulation:** One RCT included in two systematic reviews[14,32] (100 people with mainly chronic neck pain) compared a single mobilisation treatment versus a single manipulation treatment.[39] It found no significant difference between treatments in immediate improvement in pain (69% with mobilisation *v* 85% with manipulation; RR of improvement in pain with manipulation compared with mobilisation 1.23; P = 0.16 after adjusting for pretreatment differences between groups). The RCT found that people in the manipulation group had improved range of movement, but the result was not significant (5.1° with manipulation *v* 3.9° with mobilisation; P = 0.5 [*t* test]). The first subsequent RCT (119 people with chronic neck pain) compared three treatments: mobilisation physiotherapy, manipulation, and intensive training.[26] It found no significant difference in pain between groups by the end of treatment (P = 0.44) or after 12 months, although pain score improved from baseline in both groups (median pain score on a 30 point scale improved from 12 to 6 with intensive training or mobilisation *v* from 13 to 6 with manipulation). Another subsequent RCT (336 patients with chronic neck pain) found no significant difference in average pain, severe pain (average and severe pain measured on a 0–10 point index: 0 = no pain; 10 = unbearable pain), and neck disability scores (neck disability index measured on a 0–50 point index: 0 = no disability; 50 = most severe disability) between a variable number of chiropractic mobilisations and a variable number of manipulations after 6 months (severe pain difference from manipulation *v* mobilisation: −0.02 points; 95% CI −0.69 points to +0.65 points; average pain from manipulation *v* mobilisation: +0.010 points; 95% CI −0.52 points to +0.54 points; difference in neck disability scores: +0.46 points; 95 CI −0.89 points to +1.82 points).[33] **Manipulation plus exercise:** The second subsequent RCT (191 people with chronic neck pain who received a home exercise programme and were able to use proprietary medication), which compared three treatments: strengthening exercises plus manipulation (combined treatment), strengthening exercises alone, and manipulation alone.[25] The duration of each treatment episode was the same. It found that strengthening exercises plus manipulation significantly improved participant satisfaction compared with both other treatments alone (P = 0.03), and significantly improved objective strength and range of movement compared with manipulation alone after 11 weeks (P < 0.05). The RCT also found that both the combined treatment and the strengthening exercises alone significantly improved pain (P = 0.02) and patient satisfaction (P = 0.002) compared with manipulation alone after 1 year, although it found no significant differences between treatments in health status, neck disability, or medication use. The 2 year follow up to this study (data available for 145/178 [76%] of original participants) found that manipulation alone significantly increased participant rated pain compared with

manipulation plus exercise and exercise alone (P = 0.05 for manipulation *v* manipulation plus exercise; P = 0.02 for manipulation *v* exercise alone).[40] It found no significant differences in neck disability and general health status among the three groups.

Harms: **Mobilisation:** We found occasional reports of increased pain, but no serious adverse effects or deaths. **Manipulation:** The estimated risk from case reports of cerebrovascular accident is 1–3/million manipulations,[41] and estimated risk of all serious adverse effects (such as death or disc herniation) is 5–10/10 million manipulations.[32]

Comment: In one RCT, only 336 of 960 eligible people agreed to participate.[33] This may reduce the external validity of the study. We found one systematic review examining mobilisation and manipulation for mechanical neck disorders. It included people with many types of neck pain, including uncomplicated pain, whiplash, and neck pain with radiculopathy, and reported that the trials were clinically heterogeneous. However, it did not provide a subgroup analysis in people with uncomplicated neck pain.[42] Across all of the people in the review, it reported that results were inconclusive.

OPTION MULTIDISCIPLINARY (MULTIMODAL) TREATMENT

RCTs provided insufficient evidence to compare the effects of multimodal treatments with other treatments in people with uncomplicated neck pain.

Benefits: We found one systematic review (search date 2002, 1 RCT, 70 people)[43] and two additional RCTs in people with chronic neck pain.[44,45] The RCT included in the systematic review found no significant difference in time off work or physical function between multimodal cognitive behavioural therapy (administered directly by a psychologist) and exercise plus behavioural modification (with a psychologist acting as an advisor to other therapists) after 6 months.[43] The first subsequent RCT (76 people) compared three treatments: multimodal treatment (which emphasised exercise, relaxation, and behavioural support), supervised home exercises, and a recommendation to exercise.[44] It found that both supervised multimodal training and supervised exercise significantly reduced pain compared with a recommendation to exercise at 3 months (improvement in pain score from baseline on 10 cm visual analogue scale, 29 mm with multimodal treatment *v* 28 mm with supervised exercise *v* 12 mm with exercise recommendation; multimodal treatment or supervised exercise *v* exercise recommendation, P < 0.001), but it found no significant difference between treatments in pain after 12 months (individual data were not provided in the paper). The second subsequent RCT (243 people with chronic spinal pain) compared three treatments: multimodal cognitive behavioural therapy (6 sessions), an educational pamphlet, and a more extensive information programme.[45] It found no significant difference among treatments in pain but found that multimodal cognitive behavioural therapy significantly reduced time off work compared with an educational pamphlet (AR for sick leave of > 30 days in 6 months, 1% with multimodal cognitive behavioural therapy *v* 10% with educational pamphlets; RR 10; P < 0.05).[45]

Harms: None reported.

Comment: None.

OPTION PATIENT EDUCATION

Three RCTs found no significant difference between patient education (advice or group instruction) with or without analgesics, compared with no treatment, stress management, placebo, or usual care.

Benefits: We found three RCTs.[46–48] The first RCT (282 nursing aides with neck, shoulder, or back pain) compared three groups: an individualised education and exercise programme, stress management, and no intervention. It found no significant difference in pain between the groups immediately after treatment, or at 12 and 18 months (people with improved pain at 12 months: 8/41 with individualised education *v* 19/57 with stress management *v* 18/57 with no intervention; P value not reported).[46] The second RCT (79 hospital secretaries with chronic neck pain) compared three treatments: group instruction (traditional neck), neck school plus individual advice, and usual care.[47] It found no significant differences in neck movement or sick leave between groups (no data reported). The third RCT (93 people) found no significant difference between individualised education plus analgesic drugs/anti-inflammatory drugs and placebo (no data available).[48]

Harms: None reported.

Comment: None.

OPTION SOFT COLLARS AND SPECIAL PILLOWS

We found no RCTs of significant quality on the effects of soft collars or special pillows.

Benefits: **Soft collars:** We found no systematic reviews or RCTs. **Special pillows:** We found no reliable RCTs (see comment below).

Harms: None reported.

Comment: We found one crossover RCT (41 people with chronic neck pain), which found that a water based pillow significantly reduced morning pain and improved quality of sleep compared with both a roll type pillow and a standard pillow ($P < 0.01$).[49] However, results in each group may have been confounded by pre-crossover treatment.

OPTION DRUG TREATMENTS (ANALGESICS, NON-STEROIDAL ANTI-INFLAMMATORY DRUGS, ANTIDEPRESSANTS, OR MUSCLE RELAXANTS)

We found insufficient evidence on the effects of analgesics, non-steroidal anti-inflammatory drugs, antidepressants, or muscle relaxants for neck pain, although they are widely used. Several drugs used to treat neck pain are associated with well documented adverse effects.

Benefits: We found one systematic review (search date 1993[14]) and one subsequent RCT.[50] **Simple analgesics (paracetamol, opioids) and oral non-steroidal anti-inflammatory drugs:** The review

found no RCTs. **Antidepressants:** The review found no RCTs in people with uncomplicated neck pain (see comment below). **Muscle relaxants and benzodiazepines:** We found no systematic review or RCTs solely in people with neck pain. We found one systematic review (2 RCTs, 159 people with chronic neck or back pain with acute spasm), which compared three treatments: cyclobenzaprine, diazepam, and placebo.[14] Both RCTs identified by the review found that cyclobenzaprine significantly improved symptoms compared with diazepam and placebo after 2 weeks ($P < 0.05$ in each study), but measured and follow up pain data could not be extracted.[51,52] Applicability of results may be limited in people with uncomplicated neck pain because people with other musculoskeletal disorders were included in the studies. The subsequent RCT (157 people with chronic neck pain) found that eperisone significantly improved pain control compared with placebo after 6 weeks ($P < 0.05$).[50]

Harms: **Simple analgesics (paracetamol and opioids):** We found no reports of harm from simple analgesics. **Oral non-steroidal anti-inflammatory drugs:** See harms of non-steroidal anti-inflammatory drugs, p 1551. One systematic review found no direct comparisons of harms of manipulation and non-steroidal anti-inflammatory drugs.[41] Calculations based on indirect comparisons found that the risk of a harm with non-steroidal anti-inflammatory drugs was considerably greater than for manipulation. **Antidepressants:** The reviews found no RCTs (see harms of antidepressants under generalised anxiety disorder, p 1302). **Muscle relaxants and benzodiazepines:** The RCTs found minor adverse effects, including weakness, dizziness, drowsiness, and gastrointestinal problems occurring in 4% of people treated with muscle relaxants.[14,50] (See harms of benzodiazepines under generalised anxiety disorder, p 1302).

Comment: Applicability of results in people with uncomplicated neck pain may be limited, because many of the RCTs included people with other musculoskeletal disorders, including back pain and acute whiplash.

QUESTION What are the effects of treatments for acute whiplash injury?

OPTION TREATMENTS FOR ACUTE WHIPLASH INJURY

Systematic reviews and subsequent RCTs provided limited evidence that early mobilisation reduced pain compared with immobilisation or rest plus a collar, that multimodal treatment reduced pain compared with physical treatment, and that electromagnetic field treatment reduced pain in the short term compared with sham treatment. The studies found that advice to "act as usual" plus anti-inflammatory drugs improved symptoms compared with immobilisation plus 14 days' sick leave. One RCT found no significant difference between different home exercise programmes in pain or disability. We found no RCTs of drug treatments in acute whiplash injury.

Benefits: **Early mobilisation versus immobilisation or less active treatment:** We found one systematic review,[8] and two subsequent RCTs.[53,54] The review (search date 1993, 2 RCTs, 165 people)[8]

compared five treatments: early mobilisation physiotherapy, immobilisation, analgesics, rest, and education. It found that early mobilisation significantly increased pain relief and improved range of movement after 4 and 8 weeks ($P < 0.01$). The first subsequent RCT (97 people) found that active mobilisation significantly improved symptoms compared with rest plus a neck collar ($P < 0.001$), but only if mobilisation was started immediately after injury.[54] If mobilisation was delayed by more than 96 hours, there was no significant difference between treatments after 6 months. The second subsequent RCT (97 people) found early benefits in pain relief and movement with early mobilisation compared with immobilisation, but no significant difference in recovery after 12 weeks.[53] **Early return to normal activity versus immobilisation plus rest:** We found one systematic review (search date 2000, 1 RCT).[55] The RCT included in the review (201 people presenting to an emergency department with acute whiplash) compared advice to "act as usual" plus anti-inflammatory drugs versus immobilisation plus 14 days' sick leave.[56] It found that advice to "act as usual" plus anti-inflammatory drugs improved symptoms (including pain during daily activities, neck stiffness, memory, concentration, and headache) after 6 months, but found no significant difference between treatments in objective variables such as neck range and length of sick leave. The RCT also found no significant difference in severe symptoms after 6 months (AR for severe symptoms: 11% with advice to "act as usual" *v* 15% with immobilisation; RR 0.75, 95% CI 0.08 to 1.42). **Home exercise programmes:** We found one systematic review (search date 2001, 1 RCT, 59 people).[17] The RCT included in the review compared two home mobilisation regimens: a regular exercise regimen versus the same exercise regimen plus instructions to perform an isometric exercise at least 3 times a day.[57] It found no significant difference between treatments in disability or pain after 3 or 6 months. **Electrotherapy:** We found one systematic review (search date 2000, 1 RCT).[55] The RCT (40 people with acute whiplash who all received analgesia and a neck collar) included in the review compared active pulsing electromagnetic field treatment versus sham pulsing electromagnetic field treatment.[58] It found that active pulsing electromagnetic field treatment significantly reduced pain compared with sham treatment after 4 weeks ($P < 0.05$), but not after 3 months. **Multimodal treatment:** We found one systematic review (search date 2000, 1 RCT, 60 people).[55] The RCT included in the review compared multimodal treatment (postural training, psychological support, eye fixation exercises, and manual treatment) with physical treatment (electrical, sonic, ultrasound, and transcutaneous electrical nerve stimulation).[59] It found that multimodal treatment significantly reduced pain by the end of treatment ($P < 0.05$) and after 1 and 6 months ($P < 0.001$). The RCT also found that multimodal treatment reduced the time taken to return to work. **Drug treatments:** One systematic review (search date 2000) found no RCTs.[55]

Harms: The reviews and RCTs did not consistently report adverse effects, although one trial has found that early mobilisation physiotherapy is not always well tolerated.[60]

Comment: Only the 40% of people most severely affected by whiplash were included in the RCT comparing home exercise programmes, which may have led to a poorer outcome than that seen in practice.[57] The management of acute whiplash injury remains controversial and needs further investigation. We found one systematic review (search date 1998) examining mobilisation and manipulation for mechanical neck disorders.[42] It included people with many types of neck pain, including uncomplicated pain, whiplash, and neck pain with radiculopathy, and reported that trials were clinically heterogeneous. However, it did not provide a subgroup analysis in people with whiplash. Across all of the people in the review, it reported that results were inconclusive.

QUESTION What are the effects of treatments for chronic whiplash injury?

OPTION TREATMENTS FOR CHRONIC WHIPLASH INJURY

One RCT provided limited evidence that percutaneous radiofrequency neurotomy reduced pain compared with sham treatment after 27 weeks. One RCT found no significant difference between physiotherapy alone and multimodal treatment in disability, pain, or range of movement at the end of treatment or at 3 months.

Benefits: **Percutaneous radiofrequency neurotomy:** We found one systematic review of percutaneous radiofrequency neurotomy for neck pain (search date 2002; 1 RCT; 24 people).[61] The RCT found that neurotomy significantly increased the proportion of people who were free from pain compared with sham treatment after 27 weeks (58% with active treatment *v* 8% with sham treatment; ARR 50%, 95% CI 3% to 85%; NNT 2, 95% CI 1 to 29), and that neurotomy significantly increased the median time taken for more than half of the pain to return (263 days with radiofrequency neurotomy *v* 8 days with sham treatment; $P = 0.04$).[62] **Physiotherapy:** We found one RCT (33 people with chronic whiplash), which compared physiotherapy alone versus multimodal treatment (physiotherapy combined with cognitive behavioural therapy; see comment below).[63] It found no significant differences between treatments in disability, pain, or range of movement at the end of treatment or at 3 months. However, significantly more people treated with multimodal treatment were satisfied with pain control at the end of treatment and their ability to perform activities at 3 months ($P < 0.05$). **Multimodal therapy:** See physiotherapy for chronic whiplash above.

Harms: The RCTs did not report on adverse effects.[62,63]

Comment: Few RCTs have considered treatment for chronic whiplash and many people with whiplash are included in general RCTs of chronic mechanical neck pain. Limitations of the RCT comparing physiotherapy versus multimodal treatment include its small size, and the difference in time spent with the therapist in the two groups.[63]

QUESTION **What are the effects of treatments for neck pain with radiculopathy?**

OPTION SURGERY VERSUS CONSERVATIVE TREATMENT

One RCT found no significant difference between surgery and conservative treatment in symptoms after 1 year.

Benefits: We found one systematic review (search date 2000, 1 RCT).[64] The RCT included in the review (81 people with severe radicular symptoms for at least 3 months; outcome assessors not blinded; see comment below) compared surgery versus conservative treatment (physiotherapy or immobilisation in a neck collar).[65] It found no significant difference between treatments in symptoms after 1 year (mean visual analogue scale change on 100 mm scale: +30 mm with surgery *v* +39 mm with physiotherapy; mean difference −9 mm, 95% CI −23.4 mm to +5.4 mm).

Harms: The RCT did not report adverse effects.[65]

Comment: In the RCT, the number of people with prolapsed intervertebral disc was not stated.[65] The RCT reported that people who did not improve between 3 and 12 months were given additional treatments: one person in the physiotherapy group and five in the collar group underwent surgery; eight people in the surgery group underwent a second operation; and 12 people in the surgery group and 11 in the collar group received physiotherapy. The RCT also reported that 41% of people had a high anxiety score and 31% of people had a high depression score, which correlated with pain intensity after but not before treatment. At 1 year, 20% of people were depressed, which suggests that treatment should aim to improve both physical and psychological symptoms.[66] Conservative treatment needs further assessment, particularly in people considered to be poor risk candidates for surgery.

OPTION DRUG TREATMENTS (EPIDURAL STEROID INJECTIONS, ANALGESICS, NON-STEROIDAL ANTI-INFLAMMATORY DRUGS, OR MUSCLE RELAXANTS)

We found no RCTs examining the effects of epidural steroid injections, analgesics, non-steroidal anti-inflammatory drugs, or muscle relaxants.

Benefits: **Periradicular, cervical epidural steroid injections, or both:** We found no systematic review or RCTs. **Simple analgesics (paracetamol and opioids) and oral non-steroidal anti-inflammatory drugs:** We found no systematic review or RCTs. **Antidepressants:** We found no systematic review or RCTs. **Muscle relaxants and benzodiazepines:** We found no systematic review or RCTs.

Harms: **Periradicular, cervical epidural steroid injections, or both:** Case reports have documented occasional complications, such as infection or bleeding after cervical epidural injection. The incidence of adverse events after different cervical injection techniques is unknown.

Neck pain

Comment: None.

GLOSSARY

Manipulation The use of short or long lever high velocity thrusts directed at one or more of the cervical spine joints that does not involve anaesthesia or instrumentation.

McKenzie treatment Consists of comprehensive mechanical evaluation to assess the effect of repetitive movements, static positioning, or both, on the patient's symptoms. This mechanical diagnosis is meant to enable the physiotherapist to develop a mechanical treatment strategy aimed not only at resolving the patient's current symptoms, but also at long-term prevention of recurrence.

Mobilisation Any manual treatment to improve joint function that does not involve high velocity movement, anaesthesia, or instrumentation.

Neck disability index (NDI) is a 10 item self report measure. Items pertain to pain intensity, personal care, lifting, reading, headaches, concentration, work, driving, sleeping, and recreation. Each item is rated on a 6 point scale (0–5), so the NDI scores vary from 0–50. The results are recalculated and expressed on a scale ranging from 0% (no disability) to 100% (maximum disability).

Substantive changes

Physical treatments for uncomplicated neck pain One systematic review and two RCTs (in published 3 papers) added;[17,19–21] categorisation unchanged.

Mobilisation/manipulation for uncomplicated neck pain One RCT (2 papers) added, which found that mobilisation improved treatment success compared with other treatments.[20,21] Categorisation changed from Unknown effectiveness to Likely to be beneficial.

Home exercise programmes for acute whiplash One systematic review added;[17] categorisation unchanged.

Percutaneous radiofrequency neurotomy for chronic whiplash One systematic review added;[61] categorisation unchanged.

Key Messages

Differences between non-steroidal anti-inflammatory drugs (NSAIDs)

- **Topical NSAIDs in acute and chronic pain conditions** One systematic review in people with acute and chronic pain conditions has found that topical NSAIDs reduce pain compared with placebo.
- **Choice between different NSAIDs** Systematic reviews found no important differences in efficacy between different NSAIDs. Cyclo-oxygenase-2 (COX 2) inhibitors reduce gastroscopically diagnosed ulcers compared with other NSAIDs, but the clinical importance of this effect is not clear, and COX 2 inhibitors may increase the risk of myocardial infarction.
- **Topical versus systemic NSAIDs or alternative analgesics** One systematic review found no high quality RCTs of topical NSAIDs compared with oral forms of the same NSAID, or with paracetamol.
- **NSAIDs in increased doses** Systematic reviews have found that benefits of NSAIDs increase towards a maximum value at high doses. Recommended doses are close to creating the maximum benefit. In contrast, three systematic reviews found no ceiling for adverse effects, which increased in an approximately linear fashion with dose.

Non-steroidal anti-inflammatory drugs

Preventing gastrointestinal adverse effects

- **H_2 blockers in people who cannot avoid NSAIDs** One systematic review in people who had taken NSAIDs for 3 months has found that H_2 blockers reduce endoscopically diagnosed gastric and duodenal ulcers compared with placebo. We found limited evidence from one weak RCT that misoprostol reduced the number of people with NSAID induced gastric ulcers compared with 300 mg daily ranitidine.
- **Omeprazole in people who cannot avoid NSAIDs** One systematic review in people who had taken NSAIDs for at least 3 months has found that omeprazole reduces endoscopically diagnosed gastric and duodenal ulcers compared with placebo.
- **Misoprostol in people who cannot avoid NSAIDs** One systematic review in people who had taken NSAIDs for at least 3 months has found that misoprostol reduces gastric or duodenal ulcers compared with placebo. However, RCTs have found that misoprostol increases clinical gastrointestinal adverse events, such as diarrhoea and abdominal pain compared with placebo. One RCT found no significant difference in the number of people taking NSAIDs and with proven gastric ulceration or erosion in successful response to treatment with misoprostol compared with omeprazole.

DEFINITION Non-steroidal anti-inflammatory drugs (NSAIDs) have anti-inflammatory, analgesic, and antipyretic effects, and inhibit platelet aggregation. The drugs have no documented effect on the course of musculoskeletal diseases, such as osteoarthritis, p 1560.

INCIDENCE/ PREVALENCE NSAIDs are widely used. Almost 10% of people in the Netherlands used a non-aspirin NSAID in 1987, and the overall use was 11 defined daily doses (see glossary, p 1558) per 1000 population per day.[1] In Australia in 1994, overall use was 35 defined daily doses per 1000 population per day, with 36% of the people receiving NSAIDs for osteoarthritis, 42% for sprain and strain or low back pain, and 4% for rheumatoid arthritis; 35% were aged over 60 years.[2]

AIMS OF INTERVENTION To reduce symptoms in rheumatic disorders; to avoid severe gastrointestinal adverse effects.

OUTCOMES **Primary outcomes:** pain intensity; personal preference for one drug over another; global efficacy; clinically significant gastrointestinal complications. **Secondary outcomes:** number of tender joints; perforation; gastrointestinal haemorrhage; dyspepsia; and ulcer detected by routine endoscopy.

METHODS *Clinical Evidence* search and appraisal May 2003. More than 100 systematic reviews and thousands of RCTs have compared various NSAIDs. Many RCTs are unpublished or published in sources that are not indexed in publicly available databases. The quality of the RCTs is variable and bias is common, both in the design and analysis of the RCTs, to such an extent that one systematic review identified false significant findings favouring new drugs over control drugs in 6% of RCTs.[3] We included only large RCTs that provided clinically important information not already covered in the systematic reviews. We have favoured systematic reviews that have not been sponsored or authored by industry, as bias in such reviews has been

repeatedly demonstrated, but may be difficult to detect.[4] For example, it is easy seemingly to follow the rules for systematic reviews and yet adopt inclusion and exclusion criteria that omit inconvenient studies.

QUESTION **Are there any important differences between available non-steroidal anti-inflammatory drugs (NSAIDs)?**

OPTION **DIFFERENCES BETWEEN AVAILABLE NSAIDS**

Systematic reviews found no important differences in efficacy between different NSAIDs. Cyclo-oxygenase-2 (COX 2) inhibitors reduce gastroscopically diagnosed ulcers compared with other NSAIDs, but the clinical importance of this effect is not clear, and COX 2 inhibitors may increase the risk of myocardial infarction.

Benefits:

Indometacin (indomethacin) versus newer NSAIDs: We found one systematic review (search date 1985, 37 crossover RCTs, 1416 people with rheumatoid arthritis), which compared indometacin (indomethacin) with 10 newer NSAIDs for a median of 2 weeks with each drug.[5] Four of the RCTs included a placebo period and one RCT compared four drugs. It found that 5% more people (95% CI 0% to 10%) preferred the newer NSAID to indometacin. **COX 2 inhibitors versus older NSAIDs:** We found two systematic reviews.[6,7] Both found that COX 2 inhibitors were no more effective for clinical outcomes than older NSAIDs. See table A on web extra. **Other comparisons of NSAIDs:** We found five other systematic reviews comparing different NSAIDs.[8–12] The first of these systematic reviews (search date 1988, 88 RCTs each comparing 2 NSAIDs, 6440 people with rheumatoid arthritis) found no significant differences in the number of tender joints improved between 17 different NSAIDs.[8] The second and third reviews (search dates 1994[9] and 1996[10]) found no clear differences between various NSAIDs used to treat osteoarthritis of the hip (39 RCTs)[9] or the knee (16 RCTs; see NSAIDs under osteoarthritis, p 1560).[10] The fourth and fifth systematic reviews were of people with acute musculoskeletal syndromes and identified generally poor quality RCTs.[11,12] The fourth review (search date 1998, 17 RCTs for shoulder pain) was inconclusive.[12] The fifth systematic review (search date 1993, 84 RCTs, 32 025 people with soft tissue injuries of the ankle was unable to pool data. **Dose response relation:** We found three systematic reviews.[13,14,8] The first review (search date 1985; 19 RCTs in which participants were randomised to more than 1 dose of 9 different NSAIDs) found a dose response relation that saturated at high doses.[13] This and the second systematic review (search date 1992, 1545 people)[14] found that the recommended dosages were close to providing a ceiling effect.[13,14] The third of these reviews (115 RCTs) found no significant differences between various doses of drugs;[8] 10/21 RCTs of ibuprofen had used a daily dosage of 1200 mg or less.[8]

Harms:

COX 2 inhibitors versus non selective NSAIDs We found two systematic reviews in people with rheumatoid arthritis, one prespecified meta-analysis in people with osteoarthritis, and one

systematic review assessing the risk of cardiovascular events associated with selective COX 2 inhibitors.[6,7,15,16] Overall, they found that COX 2 inhibitors reduced endoscopically detected upper gastrointestinal ulcers compared with other NSAIDs, although effects on clinical gastrointestinal adverse effects were less marked, and there was some evidence that COX 2 inhibitors may increase cardiovascular risk compared with other NSAIDs. See table A on web extra. **Dose response relation:** Three systematic reviews (search dates 1992[14,17] and 1994[18]) found no ceiling effect for adverse effects; the incidence of adverse effects increased in an approximately linear fashion with dose.

Comment: Important differences in adverse effects seem to exist between different NSAIDs. In contrast, the beneficial effects of NSAIDs seem similar. People's preferences for particular drugs have not been replicated and could, therefore, be because of chance or natural fluctuations in disease activity.[19,20] The evidence suggests that if the NSAID is unsatisfactory, switching to another NSAID will not solve the problem.[19,20] Likewise, doubling the dose of an NSAID leads to only a small increase in effect, which may not be clinically relevant. In acute musculoskeletal problems, it is doubtful whether NSAIDs have any clinically relevant anti-inflammatory effect; we found no large double blind RCT comparing an NSAID with paracetamol. Paracetamol has been studied in osteoarthritis, where it had much the same effect as naproxen (see simple analgesics v NSAIDs under osteoarthritis, p 1560). One RCT identified by the review of celecoxib (the CLASS study), which compared the gastrointestinal toxicity of celecoxib versus ibuprofen and diclofenac, has been criticised because the publication differs from the trial protocol in objectives, primary outcomes, statistical analysis, and trial duration.[6]

QUESTION **What are the effects of co-treatments to reduce the risk of gastrointestinal adverse effects of non-steroidal anti-inflammatory drugs (NSAIDs)?**

OPTION **CO-TREATMENTS TO REDUCE THE RISK OF GASTROINTESTINAL ADVERSE EFFECTS OF NSAIDS**

One systematic review in people who had taken NSAIDs for 3 months has found that H_2 blockers reduce endoscopically diagnosed gastric and duodenal ulcers compared with placebo. One systematic review in people who had taken NSAIDs for at least 3 months has found that misoprostol reduces gastric or duodenal ulcers compared with placebo. We found limited evidence from one weak RCT that misoprostol reduced the number of people with NSAID induced gastric ulcers compared with 300 mg of ranitidine daily. However, RCTs have found that misoprostol increases clinical gastrointestinal adverse events, such as diarrhoea and abdominal pain, compared with placebo. One RCT found no significant difference in the number of people taking NSAIDs and with proven gastric ulceration or erosion in successful reponse to treatment with omeprazole compared with misoprostol. One systematic review in people who had taken NSAIDs for at least 3 months has found that omeprazole reduces endoscopically diagnosed gastric and duodenal ulcers compared with placebo.

Benefits: We found one systematic review.[21] **Misoprostol versus placebo:** The systematic review (search date 2002) included people who had received NSAIDs for at least 3 months.[21] Eleven RCTs (3641 people) assessed endoscopically diagnosed ulcers and found that misoprostol (all doses from 400 to 800 μg per day combined) significantly reduced endoscopically confirmed ulcers compared with placebo after at least 3 months (gastric ulcer: RR 0.26, 95% CI 0.17 to 0.39; duodenal ulcer: RR 0.47, 95% CI 0.33 to 0.69). Indirect comparisons of different RCTs suggested a dose response relationship for gastric ulcers in the dose range 400 to 800 μg (misoprostol 400 μg: RR 0.42, 95% CI 0.28 to 0.67; misprostol 800 μg: RR 0.17, 95% CI 0.11 to 0.24; difference between 400 and 800 μg; P = 0.006). Only one RCT (8843 people with rheumatoid arthritis, mean age 68 years, all treated with NSAIDs) presented clinically relevant outcomes.[22] It found that misoprostol 800 μg significantly reduced gastrointestinal events (perforation, gastric outlet obstruction, or bleeding detected by clinical symptoms or investigation) compared with placebo at 6 months (25/4404 [0.6%] with misoprostol *v* 42/4439 [1.0%] with placebo; ARR 0.4%; NNT 265, 95% CI 133 to 6965).[22] The NNT would drop as higher risk patients are considered. **H_2 blockers versus placebo:** The systematic review identified five RCTs (1005 people who had received NSAIDs for at least 3 months) comparing H_2 blockers with placebo.[21] It found that standard doses of H_2 blockers significantly reduced endoscopic ulcers at 3 months or longer (48/494 [10%] with H_2 blockers *v* 75/487 [15%] with placebo; RR 0.63, 95% CI 0.45 to 0.88) **Omeprazole versus placebo:** The systematic review identified three RCTs (774 people who had received NSAIDs for at least 3 months).[21] It found that omeprazole reduced the development of ulcers detected by endoscopy compared with placebo (ARR 13%, 95% CI 8% to 18% for gastric ulcer; ARR 9%, 95% CI 5% to 12% for duodenal ulcer). **Misoprostol versus proton pump inhibitor:** The systematic review identified two RCTs comparing misoprostol with proton pump inhibitors.[21] The first RCT in the review (935 people treated with NSAIDs who had ulcers or more than 10 erosions at endoscopy) compared misoprostol (200 μg four time daily) with omeprazole (20 mg or 40 mg daily) once daily.[23] Treatment success was defined as fewer than five erosions at each site, no ulcers, and not more than mild dyspepsia.[23] It found no significant difference in treatment success between misoprostol and omeprazole at 8 weeks (71% with misoprostol *v* 76% with omeprazole 20 mg *v* 75% with omeprazole 40 mg). The second RCT in the review (537 people, long term NSAID users with endoscopically confirmed gastric ulcer) compared four treatments: misoprostol (200 μg four times daily); two different doses of lansoprazole (15 mg and 30 mg) once daily, and placebo. It found that misoprostol significantly increased the length of time to recurrence compared with the other treatments (time to gastric ulcer: misoprostol *v* placebo, P < 0.001; misoprostol *v* lansoprazole 15 mg, P = 0.01; misoprostol *v* lansoprazole 30 mg, P = 0.04; AR of being free of gastric ulcer at 12 weeks: 93% with misoprostol *v* 51% with placebo *v* 80% with lansoprazole 15 mg *v* 82% with lansoprazole 30 mg).[24] **Omeprazole versus H_2 blockers:** In a

similarly designed RCT (541 people), treatment was successful in 80% given omeprazole (20 mg), 79% given omeprazole (40 mg), and 63% given ranitidine (300 mg daily).[25] The estimated proportions in remission after 6 months were 72% with omeprazole (20 mg) and 59% with ranitidine (300 mg) (ARR for omeprazole *v* ranitidine 13%, 95% CI 4% to 22%; NNT 8). **Misoprostol versus H_2 blockers:** The systematic review identified one RCT comparing misoprostol (800 μg) with ranitidine (300 mg daily).[21] In the RCT (538 people with NSAID related upper gastrointestinal pain without endoscopic evidence of ulcers), one third of the people were excluded from analysis because of problems with adherence and missing endoscopic examinations.[26] It found that misoprostol significantly reduced the number of people with gastric ulcers at least 3 mm in diameter at 8 weeks compared with ranitidine (1% with misoprostol *v* 6% with ranitidine; ARR for misoprostol *v* ranitidine 5%, 95% CI 2% to 9%; NNT 20). It found no significant difference in the number of people with duodenal ulcers (1% with both drugs).[26]

Harms:

Misoprostol versus placebo: In one of the large RCTs, significantly more people receiving misoprostol than placebo withdrew from the study because of adverse events, primarily diarrhoea and abdominal pain (1210/4404 [27%] *v* 896/4439 [20%]; ARI 7%; RR 1.36, 95% CI 1.26 to 1.47; NNH 14, 95% CI 12 to 19).[22] There was no significant difference in the number of deaths (17/4404 [0.4%] deaths in the misoprostol group *v* 21/4439 [0.5%] in the placebo group; ARR 0.1%; RR 0.82, 95% CI 0.43 to 1.55). One person on placebo died as a direct result of gastrointestinal toxicity. **Omeprazole versus H_2 blockers:** Few adverse events were reported in the RCT comparing omeprazole with ranitidine. Treatment discontinuations (all causes) occurred in 10% of people taking omeprazole (20 mg), 10% taking omeprazole (40 mg), and 14% taking ranitidine; significance not reported).[25] **Misoprostol versus H_2 blockers:** In the largest RCT comparing misoprostol versus ranitidine, adverse events (mostly gastrointestinal) occurred in 77% of people taking misoprostol and 66% taking ranitidine, with withdrawal rates of 13% on misoprostol and 7% on ranitidine (ARR for withdrawal ranitidine *v* misoprostol 6%, 95% CI 1% to 11%; NNT 17).[26]

Comment:

The clinical relevance of results for gastrointestinal ulceration is doubtful. The only RCT that used clinically relevant outcomes found little difference between active drug and placebo, except for people at high risk.[22] The rate of ulcers was more than 10 times higher in the studies where the investigators looked for them with regular endoscopy than in earlier RCTs of NSAIDs.[27] These ulcers were sometimes defined as endoscopic lesions with a size of only 3 mm, sometimes as any lesion of an unequivocal depth, and sometimes no definition was provided at all.

QUESTION **What are the effects of topical non-steroidal anti-inflammatory drugs (NSAIDs)?**

OPTION TOPICAL NSAIDS

One systematic review has found that topical NSAIDs are more effective in acute pain conditions and chronic pain conditions compared with placebo. We found no high quality RCTs of topical versus oral formulations of the same drug, and found no direct comparisons of topical NSAIDs with paracetamol.

Benefits: **Topical NSAIDs:** We found one systematic review (search date 1996, 86 RCTs, 10 160 people) and one additional RCT.[28,29] **Versus placebo:** The review, partly sponsored by two manufacturers, performed separate subgroup analyses in people with acute and chronic conditions. The review identified 37 RCTs in about 2000 people with acute pain conditions (soft tissue trauma, strains and sprains). Most of these RCTs were small. Meta-analysis of all seven RCTs with more than 80 people per group found that topical NSAIDs were more effective than placebo (RR for "good outcome" defined by patient global judgement; pain on movement; spontaneous pain; and physician global judgement was 1.6, 95% CI 1.3 to 1.9; NNT 5, 95% CI 4 to 6). In people with chronic pain conditions (osteoarthritis, tendinitis; 12 RCTs in about 1000 people), meta-analysis found that topical NSAIDs were more effective than placebo (RR for "good outcome" defined by patient global judgement; pain on movement; spontaneous pain; and physician global judgement was 2.0, 95% CI 1.5 to 2.7; NNT 4, 95% CI 3 to 4). The additional RCT (116 people with osteoarthritis of the hip or knee) compared copper salicylate gel with placebo applied to the forearm.[29] It found no significant difference in the proportion of people reporting good effect (term not defined but measured on a four-point ranking scale, with very good, good, fair, and poor: 22% with copper salicylate gel *v* 21% with placebo). **Oral NSAIDs:** Five RCTs in the systematic review compared topical with oral NSAIDs, but they all had inadequate design and power.[28] We found no high quality RCT comparing the same NSAID given orally and topically. **Versus paracetamol:** We found no RCTs.

Harms: In the systematic review, local adverse effects occurred in 3% of people in both groups and systemic adverse events in 1%.[28] In the additional RCT, more people receiving copper salicylate gel reported adverse reactions, most commonly skin reactions (any adverse event 48/58 [83%] with copper salicylate gel *v* 29/56 [52%] with placebo; RR 1.6, 95% CI 1.2 to 2.1; NNH 4, 95% CI 3 to 7), and more people withdrew from the RCT because of these reactions (10/58 [17%] *v* 1/58 [2%]; ARR 13%; RR 10, 95% CI 1 to 76; NNH 6, 95% CI 3 to 20).[29]

Comment: Sample size bias hampers the interpretation of the available RCTs. We found no high quality RCTs comparing topical versus systemic administration of the same NSAID, and no RCTs comparing a topical NSAID with paracetamol.

GLOSSARY

Defined daily dose The assumed average daily dose for the main indication of a specified drug. The defined daily dose per 1000 population per day is an estimate of the proportion of that population receiving treatment with that drug.
Double doses Twice the defined daily dose.

Substantive changes

Comparing NSAIDs Two systematic reviews added;[6,7] conclusion unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 1583

Key Messages

- **Hip replacement** One systematic review of RCTs and observational studies has found that hip replacement is effective for at least 10 years.
- **Knee replacement** Systematic reviews of observational studies have found that knee replacement is effective in relieving pain and improving function. One RCT found limited evidence that unicompartmental knee replacement is more effective than tricompartmental replacement at 5 years' follow up. One systematic review of observational studies found better outcomes with unicompartmental knee operations compared with bicompartmental operations.

- **Oral non-steroidal anti-inflammatory drugs (NSAIDs) (short term pain relief)** Systematic reviews have found that NSAIDs reduce short term pain in osteoarthritis compared with placebo. NSAIDs are associated with an increased risk of gastrointestinal haemorrhage. RCTs provided insufficient evidence to compare the effects of oral versus topical NSAIDs. RCTs found no good evidence that simple analgesics, such as paracetamol (acetaminophen), are significantly different from NSAIDs in pain relief. Concerns exist relating to trial quality and commercial bias.
- **Simple oral analgesics (short term pain relief)** Systematic reviews in people with osteoarthritis of the hip or knee found limited evidence that simple analgesics, such as paracetamol, reduced pain compared with placebo. RCTs found no good evidence that simple analgesics, such as paracetamol (acetaminophen), are significantly different from NSAIDs in pain relief.
- **Topical agents (short term pain relief)** One systematic review and RCTs have found that topical agents containing NSAIDs reduce pain compared with placebo. One systematic review found that systemic adverse events were no more common than with placebo. RCTs provided insufficient evidence to compare the effects of oral versus topical NSAIDs. We found no RCTs comparing topical agents versus other local treatments such as heat or cold packs. RCTs found limited evidence that capsaicin improved pain compared with placebo.
- **Exercise (pain relief and improved function)** Systematic reviews and subsequent RCTs have found that exercise and physical therapy reduce pain and disability in people with hip or knee osteoarthritis, although many of the RCTs were limited by poor methods and reporting.
- **Intra-articular glucocorticoid injections of the knee (short term pain relief)** One systematic review and one subsequent RCT found limited evidence that intra-articular glucocorticoids reduced pain for 1–4 weeks compared with placebo.
- **Intra-articular hyaluronan injections of the knee** One systematic review and RCTs found limited evidence that hyaluronan reduced pain for 1–6 months compared with placebo.
- **Osteotomy** We found no RCTs comparing osteotomy versus conservative treatment. Two RCTs found similar functional outcomes with osteotomy compared with knee replacement. Two RCTs provided insufficient evidence on the effects of different types of osteotomy.
- **Physical aids** RCTs in people with knee osteoarthritis found limited evidence that joint bracing or taping may improve disease specific quality of life and symptoms compared with control treatment. RCTs provided insufficient evidence to compare the effects of different insoles.
- **Chondroitin** One systematic review and RCTs provided insufficient evidence on the effects of chondroitin in people with osteoarthritis.
- **Education** RCTs provided insufficient evidence to assess the effects of education and behavioural change in people with hip or knee osteoarthritis.
- **Glucosamine** Systematic reviews and subsequent RCTs found limited evidence that glucosamine improved symptoms compared with placebo, but publication bias and poor trial quality makes the results difficult to interpret.
- **Glucosamine plus chondroitin** We found no RCTs of glucosamine plus chondroitin alone. RCTs found limited evidence that glucosamine plus chondroitin plus manganese ascorbate improved disease severity scores compared with placebo.

Osteoarthritis

- **Hip replacement (who is most likely to benefit)** We found no RCTs. One systematic review of observational studies has suggested younger age (< 45 years), older age (> 75 years), and weight over 70 kg may be associated with worse outcomes in terms of pain relief and function after hip replacement. One cohort study found that younger people were at greater risk of revision, whereas another study found lower rates of implant survival in obese people.
- **Intra-articular injections of the knee other than glucocorticoid or hyaluronan** We found insufficient evidence on the effects of other intra-articular treatments, such as radioactive isotopes, glycosaminoglycan polysulphuric acid, orgotein, and morphine.
- **Knee replacement (who is most likely to benefit)** We found no RCTs. We found insufficient evidence from observational studies on the effects of obesity on knee replacement outcomes. We found limited evidence from observational studies that knee replacement is effective in elderly people.
- **Oral NSAIDs in older people and people at risk of renal disease or peptic ulceration** Studies have found that NSAIDs increased the risk of renal or gastrointestinal damage in older people with osteoarthritis, particularly those with intercurrent disease.
- **Simple oral analgesics in people with existing liver damage** Observational evidence suggests that lower doses of paracetamol may cause liver damage in people with liver disease.

DEFINITION Osteoarthritis is a heterogeneous condition for which the prevalence, risk factors, clinical manifestations, and prognosis vary according to the joints affected. It most commonly affects hands, knees, hips, and spinal apophyseal joints. It is usually defined by pathological or radiological criteria rather than clinical features, and is characterised by focal areas of damage to the cartilage surfaces of synovial joints, associated with remodelling of the underlying bone and mild synovitis. When severe, there is characteristic joint space narrowing and osteophyte formation, with visible subchondral bone changes on radiography.

INCIDENCE/ PREVALENCE Osteoarthritis is a common and important cause of pain and disability in older adults.[1,2] Radiographic features are practically universal in at least some joints in people aged over 60 years, but significant clinical disease probably affects 10–20% of people. Knee disease is about twice as prevalent as hip disease in people aged over 60 years (about 10% *v* 5%).[3,4]

AETIOLOGY/ RISK FACTORS The main initiating factors are abnormalities in joint shape or injury. Genetic factors are probably implicated.

PROGNOSIS The natural history of osteoarthritis is poorly understood. Only a minority of people with clinical disease of the hip or knee joint progress to requiring surgery.

AIMS OF INTERVENTION To reduce pain, stiffness, and disability; to limit the risk of progressive joint damage; to improve quality of life, with minimal adverse effects.

OUTCOMES Frequency and severity of joint pain (particularly activity related pain and night pain); stiffness; functional impairment and disability; quality of life; perioperative complications (infection, bleeding, venous thromboembolism, and death); prosthesis survival and the need for revision surgery; a global knee rating scale that includes

measures of pain, function, and range of movement; a modified Knee Society score;[5] the Western Ontario and McMaster osteoarthritis (WOMAC) scale;[6–8] the Lequesne Index;[9] the Arthritis Self-Efficacy (ASE); the Multidimensional Health Assessment Questionnaire (MDHAQ); the Brief Pain Inventory (BPI) questionnaire; the British Orthopedic Association (BOA) score.

METHODS *Clinical Evidence* search and appraisal November 2002. Additional hand searches by the authors of their own files. Observational (non-RCT) data have been included in some sections where appropriate control studies are lacking or may be considered unethical.

QUESTION What are the effects of treatments?

OPTION EXERCISE AND PHYSICAL THERAPY

Systematic reviews and subsequent RCTs have found that exercise and physical therapy reduce pain and disability in people with hip or knee osteoarthritis, although many of the RCTs were limited by weak methods and poor reporting.

Benefits: We found four systematic reviews,[10–13] one subsequent non-systematic review,[14] and 10 subsequent RCTs[15–24] of exercise in people with osteoarthritis of the knee or hip. A variety of therapies were included in the reviews, including aerobic exercise, strengthening exercise, stretching exercise, functional training, and range of motion exercise, among others. In the first systematic review (search date 1997, 11 RCTs, osteoarthritis of knee or hip), most of the included trials compared exercise therapy versus placebo or no treatment.[10] It concluded that exercise regimens were beneficial but that more evidence was needed (see table 1, p 1588). The second systematic review (search date 1993) of non-medicinal and non-invasive treatments for hip and knee osteoarthritis included trials that compared exercise therapy versus stretching and strengthening, diathermy, or routine care.[11] It concluded that, of seven modalities reviewed, exercise had the strongest evidence of benefit. The third systematic review (search date 1994) of exercises for osteoarthritis of the knee found only three admissible RCTs.[12] The review concluded that, despite a favourable impression, the evidence currently available was inadequate. The fourth systematic review (search date 2000) of selected rehabilitation interventions for knee pain concluded that therapeutic exercise (compared in RCTs with untreated control or usual care) or transcutaneous electrical nerve stimulation (compared in RCTs with placebo) were both beneficial for knee osteoarthritis.[13] The non-systematic review identified 13 RCTs comparing exercise to a variety of other interventions, including education, usual care, subtherapeutic ultrasound, sham electrical stimulation, and control (not specified).[14] The review found that there was small to moderate beneficial effects for pain and function from use of strengthening exercise, aerobic exercise interventions, or both. The first subsequent RCT (24 obese people with osteoarthritis, body mass index $\geq 28\ kg/m^2$) compared an exercise plus weight loss diet versus an exercise programme alone.[15] It found no significant differences in 6 month pain or function scores (no figures reported). The second subsequent RCT

(179 people with osteoarthritis, average age 74 years) found that a progressive home based exercise programme plus non-steroidal anti-inflammatory medication was significantly better than non-steroidal anti-inflammatory medication alone for pain (Western Ontario and McMaster osteoarthritis [WOMAC — see glossary, p 1583] pain subscale; P = 0.003), physical activity (WOMAC physical activity subscale; P = 0.006), pain at rest (visual analogue scale [VAS]; P = 0.02), and pain when walking (VAS; P = 0.002).[16] The third subsequent RCT (105 people) compared an education plus exercise package versus no intervention over 6 months.[17] It found that pain and quality of life were significantly improved at 6 weeks with the programme compared with no intervention, but the difference was not significant at 6 months (Impact of Rheumatic Disease on General Health and Lifestyle pain scale, in which a lower score is an improvement: change at 6 weeks, –0.4 with treatment *v* +1.2 with control, P = 0.045; at 6 months +0.2 with treatment *v* +0.6 with control, P = NS). The fourth subsequent RCT (126 people) compared personal exercise treatment; small group exercise treatment; and no treatment.[18] Pre-specified analysis combined the results from the two exercise groups and found a significant effect on pain after 8 weeks of treatment compared with no treatment (exercise *v* no treatment, P < 0.01; change in WOMAC pain scale: 10.6, 95% CI 6.3 to 15.0 with exercise *v* –1.5, 95% CI –5.5 to +2.4 with no treatment) and functional improvement (WOMAC function scale: 7.7, 95% CI 4.2 to 11.2 with exercise *v* –0.1, 95% CI –3.9 to +3.7 with no treatment). It found no significant difference between individual and group exercise treatment.[18] The fifth subsequent RCT (201 people) compared physiotherapist provided exercise versus standard care (patient education and drug treatment from their general medical practitioner if required).[19] Study inclusion criteria were American College of Rheumatology defined osteoarthritis of the hip or knee. Exclusion criteria included exercise treatment within the previous 6 months, problems on fewer than 10 out of 30 days, age under 40 or over 85 years, and indication for hip or knee replacement. It found that exercise significantly improved pain at 12 and 24 weeks compared with standard care (measured on a VAS in which 0 mm = no pain, 100 mm = very severe pain: difference at 12 weeks –17.0, 95% CI –23.6 to –10.4; difference at 24 weeks –11.5, 95% CI –19.7 to –3.3) but not at 36 weeks (difference at 36 weeks –6.6, 95% CI –14.7 to +1.6). Observed disability was determined by studying videos of performance of a series of standardised tests. A total disability score was calculated from five measures: 5 metres walking time, stand to sit time, stand to recline time, and levels of caution and rigidity during the performance of the tasks. It found no significant differences between groups (–0.19, 95% CI –0.38 to –0.01 at 12 weeks; –0.09, 95% CI –0.30 to +0.12 at 24 weeks; –0.10, 95% CI –0.31 to +0.11 at 36 weeks). The RCT suggested decreasing benefit over time may have been because of falling compliance.[19] The sixth subsequent RCT (250 people aged 60 years or above) compared aerobic exercise, resistance exercise, and education (including discussions and social gatherings).[20] Inclusion criteria included pain in knees on most days, difficulty with one of a range of daily activities (e.g. walking, climbing stairs,

shopping, cleaning, self-care activities), and radiographic evidence of knee osteoarthritis. It found that, compared with the education group, the exercise groups had significantly lower risks of loss of activities of daily living for both exercise groups compared with education (RR 0.57, 95% CI 0.38 to 0.85), for the resistance exercise group compared with education (RR 0.60, 95% CI 0.38 to 0.97), and for the aerobic exercise group compared with education (RR 0.53, 95% CI 0.33 to 0.85). The seventh subsequent RCT (69 people) compared physiotherapist led exercise versus no exercise.[21] The results presented were for a subgroup of people who reported osteoarthritis symptoms who were part of a larger RCT (299 people) examining the impact of exercise on sedentary older people. It found no significant difference at 12 months using the WOMAC scale. The eighth subsequent RCT (316 people with knee osteoarthritis, aged 60 years or over) compared four groups over 18 months: exercise alone; dietary weight loss alone; exercise plus dietary weight loss; and a healthy lifestyle control group (which included group presentations and talks on topics concerning osteoarthritis, obesity, and exercise).[22] Inclusion criteria included a body mass index of 28 kg/m^2 or more, knee pain on most days, a sedentary activity pattern, and difficulty in one of a range of daily activities (e.g. walking, climbing stairs, bending, kneeling, house cleaning, self care activities) and radiographic evidence of tibiofemoral osteoarthritis. The RCT found no significant difference among groups in a composite mental health score of the SF-36 after 18 months. It found that exercise plus dietary weight loss significantly improved a composite physical health score of the SF-36 compared with the healthy lifestyle control ($P < 0.01$; absolute numbers not reported), and exercise plus dietary weight loss or exercise alone significantly improved peoples' satisfaction with physical function compared with the healthy lifestyle control (either treatment *v* healthy lifestyle, $P < 0.01$; absolute numbers not reported). The RCT found that exercise alone, dietary weight loss alone, or exercise plus dietary weight loss all significantly improved peoples' satisfaction with their own appearance compared with the healthy lifestyle control (any treatment *v* healthy lifestyle, $P < 0.01$; absolute numbers not reported).[22] The ninth subsequent RCT (102 people with knee osteoarthritis) compared three groups: isometric resistance training; dynamic resistance training; and control (no intervention).[23] In both training groups, strength exercises for the legs were completed three times a week for 16 weeks. Inclusion criteria included a score of five or more on the WOMAC pain subscale and physician validated knee pain. Exclusion criteria included knee pain other than osteoarthritis and contraindications to exercise. The RCT found no significant difference in the WOMAC stiffness subscale within or among groups. The RCT found that the WOMAC functional limitations scale declined significantly from baseline in the dynamic resistance group ($P < 0.05$), but not in the isometric resistance or control groups. It found that the dynamic and isometric resistance groups reported similar significant declines from baseline in the time to perform functional tasks (time to get down to the floor, to get up off the floor, to go up 27 stairs, to go down 27 stairs) and the WOMAC pain subscale ($P < 0.05$), whereas the control group did not differ significantly over the

duration of the study.[23] The 10th subsequent RCT (23 people aged 41–75 years with knee osteoarthritis) compared three groups: concentric isokinetic resistance training; combined concentric–eccentric isokinetic resistance training; and control (no training).[24] Inclusion criteria included bilateral osteoarthritis grade 2 or 3 as judged by Kellgren and Lawrence criteria. Exclusion criteria included health problems that might pose a risk during training. The RCT found that both training groups significantly increased functional capacity after 8 weeks compared with control (either training group *v* control, $P < 0.01$) and significantly decreased pain (either training group *v* control, $P < 0.01$). Functional capacity measurement included walking, standing, rising from a chair, stair climbing, and descending stairs.[24]

Harms: The reviews and RCTs did not report on adverse events.[10–20,22–24]

Comment: Many of the RCTs are limited by methodological and reporting issues. However, the most recent systematic review concluded that there was good evidence of benefit from therapeutic exercise or transcutaneous electrical nerve stimulation in knee osteoarthritis.

OPTION EDUCATION AND BEHAVIOURAL CHANGE

RCTs provided insufficient evidence to assess the effects of education and behavioural change in people with hip or knee osteoarthritis.

Benefits: We found one systematic review[25] and four subsequent RCTs.[26–29] The systematic review (search date 1993) included 10 controlled trials (see comment below) of education over 2–48 weeks.[25] Effect sizes associated with education were not significant for pain (WMD +0.16, 95% CI –0.69 to +1.02) or disability (WMD 0, 95% CI –0.61 to +0.61). The first subsequent RCT (211 people with osteoarthritis of the knee) compared self care education versus attention only education (see glossary, p 1583) over 1 year.[26] The self care education group improved more for both pain and disability. At both 4 and 12 months, there was a significant difference for function and pain with self care education compared with attention only education. The second subsequent RCT (252 people) assessed methods to improve adherence to treatment plans.[27] The RCT compared a targeted education programme versus an information pack, both delivered through a computer over 8 weeks. The targeted education programme explained the nature of the medication, side effects and benefits one might expect, the importance of the person in making decisions about the appropriateness of the medication, and other practical advice. The RCT found no significant difference in quality of life, pain, or disability between groups. The targeted education programme significantly improved stiffness compared with controls (effect size –0.63, 95% CI –0.81 to –0.45 *v* –0.39, 95% CI –0.53 to –0.25).[27] The third subsequent RCT (113 people) compared an isokinetic exercise regimen versus generic information lectures given by health professionals over 12 weeks.[28] It found no significant difference in leg strength, pain, or function between the groups. The fourth subsequent RCT (544 people with all types of arthritis) compared an education programme versus a waiting list control.[29] The intervention consisted of six weekly

meetings, each lasting about 2 hours. The meetings involved providing information on arthritis, self management, exercise, cognitive symptom management, dealing with depression, nutrition, communication with family and health professionals, and contracting. Inclusion criteria were age greater than 18 years, and arthritis confirmed by a general medical practitioner. It found significant differences in favour of the intervention group at 4 months for pain (Arthritis Self-Efficacy Scale [see glossary, p 1582]: 2.65, 99% CI 0.85 to 4.44), fatigue (visual analogue scale [VAS] score: 0.48, 99% CI −1 to 0.04, P = 0.020), anxiety (Hamilton Depression Rating Scale [HAD]: −0.59, 99% CI −1.2 to +0.03, P = 0.014), and depression (HAD scale: −0.86, 99% CI −1.46 to −0.26), but found no significant difference between groups in the Health Assessment Questionnaire (P = 0.351) or VAS pain (P = 0.707).[29]

Harms: The review and subsequent RCTs did not report on adverse events.[25–29]

Comment: We found few well designed RCTs, and the participants in many RCTs were not representative of those in the general population. Studies of individual education in the systematic review also included biofeedback, exercises, and social support.[25] The systematic review did not state whether the controlled trials were RCTs.[25] One trial, which found a large improvement for pain and disability, was excluded from the analysis because its results were so different from the others.[25] It also included exercise in the intervention. The remaining nine trials had no significant heterogeneity of results.

OPTION PHYSICAL AIDS

RCTs in people with knee osteoarthritis found limited evidence that joint bracing or taping may improve disease specific quality of life and symptoms compared with control treatment. RCTs provided insufficient evidence to compare the effects of different insoles.

Benefits: We found no systematic reviews. We found five RCTs on physical aids.[30–34] **Joint bracing or taping:** The first RCT (119 people) compared two forms of valgus knee bracing (neoprene sleeve and unloader brace) versus control. It found that, compared with control, both the knee brace groups significantly improved disease specific quality of life (P = 0.001) and function (P < 0.001). It found no significant difference between Western Ontario and McMaster osteoarthritis (WOMAC) (see glossary, p 1583) scores for the two braces (P = 0.062).[30] The second small RCT (14 people) found that taping of the knee was associated with a reduction in pain compared with control (difference in mean pain score between neutral *v* medical taping 15.5, 95% CI 2.4 to 28.6; figures as presented in original paper, units not clear; differences in pain score between neutral and lateral taping −8, 95% CI −22.5 to +6.5; figures as presented in original paper, units not clear).[31] **Insoles:** The third RCT (90 women, age > 45 years, and with American College of Rheumatology (ACR) diagnosed osteoarthritis, but not congenital foot problems, fused joints, foot deformity, or limitations of range of motion) compared a strapped insole versus an inserted insole.[32] Both groups were also given indometacin (indomethacin)

(30 mg) twice daily. The RCT did not test the significance of differences between groups. It found that the Lequesne Index (see glossary, p 1583) significantly improved in both groups from baseline (strapped insole group, from mean 11.1 to 8.2, P = 0.006 *v* inserted insole group, from 10.1 to 8.8, P = 0.009), but pain significantly decreased only for the strapped insole group (visual analogue scale [VAS] mean 43.4 to 21.3, P = 0.041 *v* 42.3 to 46.5, P value not reported). The fourth RCT (156 people) compared laterally elevated insoles versus neutral insoles.[33] Study inclusion criteria included ACR defined osteoarthritis, age 18 years or more, pain on daily basis for at least 1 month, pain of greater than 3 on 10 cm VAS after physical activity, evidence of medial femorotibial osteoarthritis on radiograph, functional class of less than IV on Steinbrocker score, and greater or similar reduction in lateral than medial joint space. Exclusion criteria included secondary knee or hip osteoarthritis, hallux deformity of foot, advanced arthropathy of the hindfoot, any disease treated with insoles in previous 6 months, tibial osteotomy in previous 5 years, joint lavage in previous 3 months, intra-articular corticosteroid injection in previous month, and a change in osteoarthritis drug treatment within the previous week. The RCT included people with a range of osteoarthritis severity. No subgroup analysis was specified. At 6 months, the RCT found that the results of the WOMAC subscales showed no significant difference between groups for pain (percentage improved 19.5% with laterally wedged insoles *v* 21.6% with neutrally wedged insoles; P = 0.84), for stiffness (percentage improved 19.5% *v* 25.7%; P = 0.44), and for function (12.2% *v* 13.5%; P = 0.82). Reported compliance with the treatments was 88% for elevated insoles and 74.3% for the neutral insoles at 6 months.[33] The fifth RCT (71 women) compared insoles with subtalar strapping to insoles with talonavicular strapping over 8 weeks.[34] Both groups were also given acemetacin. Inclusion criteria included medial knee pain that met ACR criteria for a diagnosis of knee osteoathritis. Exclusion criteria included joint space narrowing, patellofemoral osteophytosis seen on lateral view, or lateral tibiofemoral compartment osteophytosis seen on anteroposterior view. The RCT did not test the significance of differences between groups. It found that in the subtalar strapping group, the femorotibial angle with insole use (179.0° ± 4.8°) was reduced by an average of –3.2° ± 2.7° with respect to without insole use. In the talonavicular strapping group, the femorotibial angle (180.2° ± 5.2°) differed by –0.4° ± 1.1° when compared with prior to insole use.[34]

Harms: The third RCT reported that adverse events were more common in the strapped insole group (13%) than in the inserted insole group (2%, significance not reported).[32] In the strapped insole group, three people complained of popliteal pain, two complained of back pain, and one reported foot sole pain. One person complained of foot sole pain in the inserted insole group. In no cases was the adverse effect so serious that the participant stopped wearing the insole.

Comment: None.

OPTION SIMPLE ORAL ANALGESICS

Systematic reviews in people with osteoarthritis of the hip or knee found limited evidence that simple analgesics, such as paracetamol, reduced pain compared with placebo. Observational evidence suggests that lower doses of paracetamol (acetaminophen) may cause liver damage in people with liver disease. RCTs found no good evidence that simple analgesics, such as paracetamol, are significantly different from non-steroidal anti-inflammatory drugs in pain relief.

Benefits: We found two systematic reviews, one evaluating simple analgesics in osteoarthritis of the hip (search date 1994, 3 RCTs)[35] and one evaluating simple analgesics in osteoarthritis of the knee (search date 1994).[36] The reviews found limited evidence that simple analgesics were effective in controlling pain associated with osteoarthritis compared with placebo. The only placebo controlled RCT included in the knee review (25 people with osteoarthritis of the knee)[36] found that, compared with placebo, paracetamol was superior for short term pain relief (improvement in pain at rest: 73% of knees with paracetamol *v* 5% of knees with control; P = 0.0001) and global responses (improved global response: 18/22 [82%] with paracetamol *v* 1/22 [5%] with control; RR 18.0, 95% CI 6.9 to 22.0; NNT 1, 95% CI 1 to 4).[37] **Versus oral non-steroidal anti-inflammatory drugs (NSAIDs):** We found two systematic reviews (search date 1994,[35] 1 RCT; and search date 1994,[36] 5 RCTs[38–42]), one additional study,[43] and one subsequent RCT.[44] The systematic reviews found no evidence for the superiority of NSAIDs over simple analgesics. One RCT (178 people with knee osteoarthritis) in the review compared naproxen versus paracetamol over 2 years.[38] The RCT found no significant difference in effects. Another RCT (184 people with osteoarthritis) in the review compared two doses of ibuprofen versus paracetamol.[39] It found no significant differences between the three groups. One subsequent study of 20 crossover trials of one person each ("n of 1" trials) compared paracetamol versus diclofenac.[43] It concluded that, although some people's pain was adequately controlled by paracetamol alone, others responded better to a NSAID. The subsequent crossover RCT (227 people) compared paracetamol (acetaminophen) versus diclofenac plus misoprostol over a 6 week period.[44] Inclusion criteria were age over 40 years, Kellgren and Lawrence grade 2–4 osteoarthritis, and visual analogue scale (VAS) score pain of greater than or equal to 30 mm. Exclusion criteria were severe comorbidities and hypersensitivity to test drugs. It found, compared with paracetamol, significantly better results with diclofenac plus misoprostol on the primary outcome of the Western Ontario and McMaster osteoarthritis score (see glossary, p 1583) for the target joint (difference −7.75; P < 0.001), and the Multidimensional Health Assessment Questionnaire pain score (difference −14.6; P < 0.001). Pre-specified subgroup analysis found the difference on the primary outcome measures increased with disease severity.

Harms: Liver damage results from overdose of paracetamol, or at lower doses in people with existing liver damage.[45] See paracetamol poisoning, p 1826. **Versus oral NSAIDs:** See harms of NSAIDs,

p 1570. The subsequent RCT of paracetamol versus diclofenac plus misoprostol found that paracetamol was associated with fewer adverse effects (P = 0.046) and gastrointestinal events (P = 0.006). The subgroup analysis did not examine the number of adverse effects.[44]

Comment: None.

OPTION ORAL NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

Systematic reviews have found that non-steroidal anti-inflammatory drugs (NSAIDs) reduce short term pain in osteoarthritis compared with placebo (see NSAIDs, p 1551). NSAIDs are associated with an increased risk of gastrointestinal haemorrhage. RCTs provided insufficient evidence to compare the effects of oral versus topical NSAIDs. RCTs found no good evidence that simple analgesics, such as paracetamol (acetaminophen), are significantly different from NSAIDs in pain relief. Studies have found that NSAIDs increased the risk of renal or gastrointestinal damage in older people with osteoarthritis, particularly those with intercurrent disease. Concerns exist relating to trial quality and commercial bias.

Benefits: We found three systematic reviews of analgesic and anti-inflammatory treatment in osteoarthritis of the hip (search date 1994, 14 RCTs)[35] and knee (search date 1996, 16 RCTs;[46] search date 1994, 45 RCTs[36]). The reviews found that NSAIDs were effective at reducing short term pain compared with placebo. We identified hundreds of RCTs comparing NSAIDs versus other NSAIDs or placebo for treatment of osteoarthritis. Most of these trials found benefit from using NSAIDs to treat osteoarthritis. **Versus topical NSAIDs:** See benefits of topical agents, p 0. **Versus simple oral analgesics:** See benefits of simple oral analgesics, p 1569.

Harms: One RCT (812 people with osteoarthritis of the knee) found that indometacin (indomethacin) may accelerate joint damage in osteoarthritis.[47] A high withdrawal rate made the results difficult to interpret. Studies have found a risk with NSAIDs of gastrointestinal or renal damage in older people with osteoarthritis, particularly those with intercurrent disease.[48,49] Case control studies of several thousand people suggest that the odds ratio of gastrointestinal haemorrhage when taking any NSAID is about 4–5, the risk increasing with certain drugs and with increased doses.[49,50] A meta-analysis (search date 1994) ranked the risk from different drugs and found it to be dose dependent (see table 2, p 1588).[51] We found insufficient evidence about the gastrointestinal effects of cyclo-oxygenase-2 inhibitors versus traditional NSAIDs to calculate the comparative risk for more recently introduced NSAIDs (see differences between NSAIDs under NSAIDs, p 1551). **Versus simple oral analgesics:** See harms of simple oral analgesics, p 1569.

Comment: Despite the many studies of NSAID use in osteoarthritis, the evidence we found on efficacy remains poor and difficult to generalise. Most RCTs suffer from weak methods, including short duration; exclusion of older people, those with intercurrent disease, or those at risk of gastrointestinal and other drug complications; variable outcome measures; comparison of one drug versus

another rather than versus placebo; and funding bias.[52,53] In the absence of clear evidence of the superiority of one type of treatment or product, other considerations such as safety (particularly the risk of gastrointestinal bleeding with NSAIDs) and cost should determine the choice of drug (see NSAIDs, p 1551).

OPTION GLUCOSAMINE

Systematic reviews and subsequent RCTs found limited evidence that glucosamine improved symptoms compared with placebo, but publication bias and poor trial quality makes the results difficult to interpret.

Benefits: We found two systematic reviews[54,55] and five subsequent RCTs.[56–60] The first review (search date 1999, 6 RCTs of glucosamine, 911 people) found a significant effect of glucosamine on symptoms, but it reported that publication bias and trial quality made the results difficult to interpret.[54] The second review (search date 1999, 16 RCTs, 2029 people) of glucosamine versus placebo found that glucosamine significantly reduced pain compared with placebo (7 RCTs; summary random effects SMD of glucosamine *v* placebo 1.40, 95% CI 0.65 to 2.14).[55] It found four RCTs comparing glucosamine versus a non-steroidal anti-inflammatory drug (NSAID). Three of the RCTs reported on pain, and these all found greater pain reduction with glucosamine than with an NSAID (see comment below).[55] The first subsequent RCT (98 people) compared glucosamine (500 mg 3 times daily) versus placebo over a 60 day period.[56] It found no significant difference in resting pain ($P = 0.66$) or walking pain ($P = 0.69$). The second subsequent RCT (212 people) compared glucosamine (1500 mg sulphate once daily) versus placebo over 3 years.[57] It found glucosamine significantly improved symptoms (Western Ontario and McMaster osteoarthritis [WOMAC — see glossary, p 1583] scale mean difference in symptoms at 3 years 21.6%, 95% CI 3.5% to 39.6%). The third subsequent RCT (202 people) compared glucosamine sulphate versus placebo over 3 years.[59] Inclusion criteria included diagnosis of knee osteoarthritis of the medial femorotibial compartment based on American College of Rheumatology criteria, and Lequesne index (see glossary, p 1583) score of at least 4 points. Exclusion criteria included clinically significant articular and rheumatic diseases other than osteoarthritis, evidence of rapid progression, Lequesne index score over 12 points, or systemic or intra-articular corticosteroid therapy within 3 months. The RCT found that glucosamine significantly reduced mean joint space narrowing measured by radiography after 3 years compared with placebo (difference in means: 0.23 mm, 95% CI 0.09 mm to 0.37 mm), and glucosamine significantly improved pain and function after 3 years compared with placebo (difference in means; Lequesne index: 0.91, 95% CI 0.34 to 1.5; WOMAC total scale: 3.1, 95% CI 0.77 to 5.5; WOMAC pain subscale: 0.7, 95% CI 0.06 to 1.3; WOMAC function subscale: 2.1, 95% CI 0.28 to 3.9; WOMAC stiffness subscale: 0.42, 95% CI 0.09 to 0.75).[59] The fourth subsequent RCT (80 people aged 42–94 years) compared glucosamine sulphate versus placebo over 6 months.[60] Inclusion criteria included radiologically defined, symptomatic osteoarthritis of at least one knee and discomfort for most days in the previous 3 months. People

were excluded if they had prosthetic material in both knees, had previously taken glucosamine, or had recently received injections or an arthroscopic washout of the index knee. The RCT found no significant difference between glucosamine and placebo in symptoms (global pain, pain on movement, pain at rest, McGill affective, McGill sensory, WOMAC pain, function, and stiffness subscales). It found that glucosamine significantly increased knee flexion compared with placebo (mean difference: 13°, 95% CI 23.1° to 2.0°), but noted that the difference was small and could have been due to measurement error.[60] The fifth subsequent RCT (45 people) compared glucosamine sulphate versus ibuprofen for osteoarthritis of the temporomandibular joint.[58] Inclusion criteria included pain intensity greater than three on visual analogue scale, degenerative joint disease not as a result of trauma, infection or general joint/muscle disease, no history of intra-articular joint injections, no previous use of glucosamine or chondroitin sulphate and, if using an occlusal splint, it must have been for at least 3 months. It found significant differences in favour of glucosamine at 90 days for functional pain, on the Brief Pain Inventory (see glossary, p 1583), and paracetamol (acetaminophen) use between 90 and 120 days (for all results $P < 0.05$).

Harms: The second systematic review reported that the safety profile of glucosamine in the 16 RCTs was excellent.[55] Out of the nearly 1000 people randomised to glucosamine treatment in the RCTs, 14 were withdrawn because of toxicity (comparative figures not reported), but it found insufficient evidence on long term tolerance.

Comment: We were unable to replicate the review's calculation of an effect size for glucosamine compared with an NSAID.[55] The first review reported that there was likely to be some benefit from glucosamine, but the evidence did not allow us to estimate confidently the size of the effect.[55]

OPTION CHONDROITIN SULPHATE

One systematic review and RCTs provided insufficient evidence on the effects of chondroitin in people with osteoarthritis.

Benefits: We found one systematic review (search date 1999),[54] one subsequent RCT,[61] and one additional RCT.[62] The review reported that trial quality and publication bias probably had a major effect on results, making them difficult to interpret.[54] The subsequent RCT (130 people) found no significant difference between chondroitin sulphate (1 g/day) compared with placebo over 6 months on the Lequesne Index (see glossary, p 1583) ($P = 0.12$).[61] The additional RCT (146 men) compared chondroitin sulphate (400 mg 3 times daily) versus diclofenac sodium (50 mg 3 times daily) over 6 months.[62] At the end of the first month, diclofenac was significantly better than chondroitin measured on the Lequesne Index ($P < 0.001$) but, by day 60, the chondroitin group was significantly better than the diclofenac group ($P < 0.01$), and people in the diclofenac group were taking placebo by this period, whereas the chondroitin group were still on active treatment (see comment below).

Harms: The review did not report harms.[54]

Comment: During the first month, people in the non-steroidal anti-inflammatory drug group were treated with diclofenac and placebo, but from months 2 to 3 they were given placebo only. People in the chondroitin group were given chondroitin and placebo for the first month and then from months 2 to 3 they received chondroitin only.[62]

OPTION GLUCOSAMINE PLUS CHONDROITIN

We found no RCTs of glucosamine plus chondroitin alone. RCTs found limited evidence that glucosamine plus chondroitin plus manganese ascorbate improved disease severity scores compared with placebo.

Benefits: We found no RCTs of glucosamine plus chondroitin alone versus placebo. We found two RCTs[63,64] of glucosamine plus chondroitin plus manganese ascorbate (see comment below).

Harms: The second RCT found no significant difference in adverse effects between glucosamine plus chondroitin plus manganese versus placebo (17% with intervention *v* 19% with placebo).[64]

Comment: The first RCT (34 people) compared a combination of glucosamine plus chondroitin plus manganese ascorbate versus placebo. It found significant improvement in disease score (–16.3%; $P = 0.05$), self assessment (–0.89; $P < 0.05$), and visual analogue scale pain score (–26.6%; $P < 0.05$).[63] The second RCT (93 people) compared a combination of glucosamine plus chondroitin plus manganese versus placebo over 6 months.[64] It found no overall significant difference in the number of people achieving a 25% improvement on the Western Ontario and McMaster osteoarthritis (WOMAC) or Lequesne Indexes (see glossary, p 1583). Pre-specified subgroup analysis of mild and moderate cases found a significant difference in the response rates for WOMAC scores (58% *v* 28%; $P = 0.04$) but not in the Lequesne Index. Subgroup analysis of severe cases found no significant difference in response rates for either the WOMAC or Lequesne Index.

OPTION TOPICAL AGENTS

One systematic review and RCTs have found that topical agents containing non-steroidal anti-inflammatory drugs (NSAIDs) reduce pain compared with placebo. One systematic review found that systemic adverse events were no more common with topical NSAIDs than with placebo. RCTs provided insufficient evidence to compare the effects of oral versus topical NSAIDs. We found no RCTs comparing topical agents versus other local treatments such as heat or cold packs. RCTs found limited evidence that capsaicin improved pain compared with placebo.

Benefits: **Topical NSAIDs versus placebo:** See NSAIDs, p 1551. We found one systematic review (search date 1996, 86 trials),[65] three subsequent RCTs, and one additional RCT comparing topically applied agents containing NSAIDs versus placebo.[66–69] The systematic review found that these agents reduced pain compared with placebo (RR for relief of chronic musculoskeletal pain because of

osteoarthritis and tendinitis 2.0, 95% CI 1.5 to 2.7).[65] The additional RCT (70 people with mild knee osteoarthritis) showed a significant improvement (measured by Western Ontario and McMaster osteoarthritis [WOMAC — see glossary, p 1583]) in the treatment group receiving diclofenac gel compared with the control group receiving vehicle gel (P = 0.05).[67] One subsequent RCT (119 people with osteoarthritis) found better pain relief with a topical NSAID (diclofenac–hyaluronan gel) compared with placebo gel, but the difference was not significant (P = 0.057).[66] The second subsequent RCT (237 people) compared eltenac gel (3 g three times daily) at 0.1%, 0.3%, and 1.0% concentrations or placebo gel over a 6 week period.[68] It found no significant difference between any of the treatment groups compared with placebo for pain (differences on a global pain scale eltenac 0.1% *v* placebo –6.1, 90% CI –20.5 to +8.2; eltenac 1.0% *v* placebo –10.8, 90% CI –25.3 to +3.6). The third subsequent RCT (100 people) compared 5% ibuprofen cream versus placebo cream over 7 days.[69] Inclusion criteria included age 45–70 years, primary knee osteoarthritis according to American College of Rheumatology criteria, and a total score of 5–13 on the Lequesne index (see glossary, p 1583). Exclusion criteria included secondary osteoarthritis, obesity, or chronic painful disease of the hip or ankle joint. Response was defined by reduced pain on movement measured by a difference of ≥ 20 mm from baseline on a 100 mm visual analogue scale (VAS). The RCT found that ibuprofen cream significantly increased response compared with placebo (response: 32/50 [64%] with ibuprofen *v* 15/50 [30%] with placebo; P = 0.000615). It found that ibuprofen cream significantly improved pain and disability compared with placebo (VAS pain on motion: –12.2 mm, 95% CI –17.9 mm to –6.6 mm; VAS pain at rest: –12.2 mm, 95% CI –17.3 mm to –7.1 mm; VAS pain on pressure: –7.5 mm, 95% CI –13.5 mm to –1.5 mm; Lequesne index: –1.6, 95% CI –13.5 to –1.5).[69] **Topical NSAIDs versus oral NSAIDs:** We found no RCT comparing the same NSAID given orally and topically. One good quality RCT (included in the review) in 235 people with mild osteoarthritis of the knee compared topical piroxicam gel versus oral ibuprofen (1200 mg/day) and found no significant difference in pain relief between the two groups (good or excellent relief in 60% *v* 64%; P = 0.56).[70] A second RCT (321 people with osteoarthritis of the fingers) compared diclofenac emulgel plus placebo versus placebo gel plus ibuprofen.[71] It found no significant difference in pain but fewer people withdrew on the gel (5 on active gel *v* 16 with active tablet). **Capsaicin:** One non-systematic meta-analysis of three RCTs of topically applied capsaicin found that capsaicin cream reduced pain compared with placebo (OR 4.4, 95% CI 2.8 to 6.9; dichotomous outcome not defined).[72] One subsequent RCT (70 people with osteoarthritis) compared 0.025% capsaicin cream versus non-medicated cream.[73] Active treatment resulted in significantly greater pain reduction than placebo (no quantified estimates of benefit available). A second subsequent RCT (200 people) compared topical capsaicin; glyceryl trinitrate; topical capsaicin plus glyceryl trinitrate; and placebo gel.[74] It found that pain scores were significantly reduced from baseline with topical capsaicin, glyceryl trinitrate, and topical capsaicin plus glyceryl trinitrate, but not for placebo gel;

direct statistical comparisons of the different treatments was not performed. **Versus other local treatments:** We found no systematic review or RCTs comparing agents containing NSAIDs or capsaicin with simple rubefacients (see glossary, p 1583) or local applications such as hot packs.

Harms: The main adverse effect of topical treatment is local skin irritation; systemic adverse effects were no more common than with placebo.[65] We found no reports of gastric or renal problems.

Comment: The evidence is poor, with most studies being short term, including a mixture of patient groups, and comparing different agents with no placebo control. The RCT comparing topical versus oral NSAIDs did not use the same drug so it is difficult to disentangle the effects of this and the different routes of administration.[68]

OPTION INTRA-ARTICULAR INJECTION OF THE KNEE

One systematic review and one subsequent RCT found limited evidence that intra-articular glucocorticoids reduced pain for 1–4 weeks compared with placebo. One systematic review, and RCTs found limited evidence that intra-articular hyaluronan reduced pain for 1–6 months compared with placebo. We found insufficient evidence on the effects of other intra-articular treatments.

Benefits: **Glucocorticoids:** We found one systematic review (search date not stated, 10 RCTs)[75] and one subsequent RCT.[76] The systematic review found that intra-articular injection of glucocorticoids into the knee (1 trial used 4 injections, the rest used single injections) provided a little additional pain relief compared with placebo (not defined).[75] Pain reduction lasted from 1 week to 1 month. The subsequent RCT (89 people randomised to 4 groups) evaluated a single injection with 24 weeks' follow up.[76] It found a short term benefit (1–4 weeks) of the steroid injection compared with placebo (saline) for both pain and for a functional index. **Hyaluronan:** We found one systematic review (search date not stated),[75] two subsequent non-systematic reviews,[77,78] and four additional RCTs.[79–82] The systematic review identified 10 RCTs of hyaluronan in the knee joint.[75] Treatment consisted of several injections of high molecular weight hyaluronan complexes over several weeks. The review found slightly greater benefit with the injections than with placebo at 1–6 months after treatment. The non-systematic reviews identified four additional RCTs not in the systematic review.[77,78] The first RCT (495 people) compared hyaluronan versus placebo injections (once weekly for 5 weeks) or oral naproxen with follow up to 26 weeks.[83] It found a significant difference in walking pain in favour of hyaluronan compared with placebo (8.8 mm on a 100 mm visual analogue scale [VAS] score; $P = 0.005$). It also found a significant difference in the number of people pain free or with only slight pain with hyaluronate compared with placebo (38.9% *v* 33.1%; $P = 0.04$). About a third (162/495 [33%]) of people, however, did not complete the RCT, and results were not by intention to treat. The second RCT (90 people) found a significant difference between hyaluronan compared with 6-methylprednisolone (1 injection weekly for 5 weeks) over a

60 day period for pain reduction (P = 0.003).[84] The third RCT (52 people) found no significant difference between hyaluronan and placebo injection (1 injection weekly for 5 weeks) over 26 weeks.[85] The fourth RCT (110 people) compared hyaluronate versus placebo injections (4 injections over a 3 week period) with 52 weeks' follow up.[85] At 3 weeks, it found a significant difference in pain after exercise (P = 0.026) and function (P = 0.027), although no difference in pain at rest (P = 0.16). At 1 year, there was only a significant difference in functional improvement (P = 0.046). The first additional RCT (36 people) compared five administrations of hyaluronic acid versus saline solution.[79] It found no significant difference in pain at day 35, but by day 90 there was significant differences in favour of hyaluronic acid for spontaneous pain (P < 0.05), pain on pressure (P < 0.05), and pain on movement (P < 0.05). However, the RCT entered the same four people into the trial twice, making the results difficult to interpret. The second additional RCT (100 people) found, compared with placebo, a significant benefit on the Lequense Index with hyaluronan at 5 weeks (P = 0.03) and 4 months (P = 0.04).[80] The third additional RCT (120 people) compared four treatments: hyaluronate injection (2 mL at 10 mg/mL) plus placebo tablets; placebo injection (2 mL of saline) plus non-steroidal anti-inflammatory drugs (NSAIDs); hyaluronate injection plus NSAIDs; and placebo injection plus placebo tablets.[81] People were graded 1–3 on Altman radiographic scale (0 mild to 3 severe). Exclusion criteria were exhibiting non-osteoarthritis arthritis, NSAID intolerance, peptic ulcer disease, avian allergy, consumption of herbal osteoarthritis products (glucosamine), and intra-articular injections of hyaluronan or corticosteroid in previous 6 months. The population characteristics were mean age 65.5 years, mean osteoarthritis grade 2.2, and mean chronic disease score 1. The results showed that on the VAS Western Ontario and McMaster osteoarthritis (WOMAC) pain scale (see glossary, p 1583) and disability scale, all the active group treatments showed significant reductions compared with baseline at week 4 (P < 0.05). However, all groups, including the placebo group, showed significant reductions compared with baseline on the VAS WOMAC stiffness scale at week 4 (P < 0.05). The statistical significance of differences between treatments was not tested.[81] The fourth additional RCT (43 people aged 55–78 years with bilateral knee osteoarthritis) compared hyaluronic acid injection versus no treatment.[82] One knee was randomly allocated to treatment, the other knee acted as control. Inclusion entry criteria included radiographic changes equivalent to Kellgren stage II–III bilaterally, and Lequesne scores (see glossary, p 1583) to vary by no more than ±2 points in the total value in both knees. Exclusion criteria included neurological deficits in the lower extremities, other diseases (e.g. joint infections, crystalline arthritis, recent arthroscopic surgery), and recent intra-articular injections of the knee. Compared with baseline, the injection group showed a significant decrease in the Lequesne score and VAS scores for pain at rest and pain on weight bearing, and an improvement in the isokinetic peak torque of the knee extensors and flexors (P < 0.01). The RCT found no significant difference in these outcomes compared with baseline in the control group. It found evaluation of the total work of the knee

flexors and extensors showed a significant difference between the treatment and control group ($P < 0.01$).[82] **Other intra-articular treatments:** Several other intra-articular treatments exist, but we found insufficient evidence on their effects. Treatments include radioactive isotopes, glycosaminoglycan polysulphuric acid, orgotein, and morphine.[4,86,87]

Harms: We found no reports of serious adverse effects. Localised discomfort after injection is common. A theoretical risk of infection exists, but we found no evidence of this.

Comment: There is little evidence of whether simple aspiration of the knee would be as effective as injection.

OPTION OSTEOTOMY

We found no RCTs comparing osteotomy versus conservative treatment. Two RCTs found similar functional outcomes with osteotomy compared with knee replacement. Two RCTs provided insufficient evidence on the effects of different types of osteotomy.

Benefits: **Versus conservative treatment:** We found no systematic reviews. We found no RCTs (see comment below). **Versus other surgical techniques:** We found four RCTs of osteotomy compared with other surgical treatments.[88–91] Subgroup analysis from one RCT (100 people randomised aged 55–70 years with medial osteoarthritis of the knee, grades I–III according to Ahlback's classification, with knee symptoms [mainly pain] regarded as justifying surgical treatment, but not with impairment of hips or ankles; subgroup analysis on 59 people with strictly unilateral knee pain) compared high tibial osteotomy versus unicompartmental prosthetic knee replacement (UKA).[89] Assessment was before, and 1 year after, surgery. It found an overall clinical improvement from baseline on the British Orthopaedic Association score (see glossary, p 1583), pain during walking, and the ability to ascend and descend steps, but the range of knee flexion and the isokinetic thigh muscle torque remained unchanged after 1 year with both osteotomy and UKA. On comparing treatments after 1 year, it found no significant difference between osteotomy and UKA, but walking outcomes were non-significantly better with UKA. The second RCT (60 people) compared high tibial osteotomy versus unicompartmental joint replacement.[88] The inclusion criteria were medial unicompartmental osteoarthritis, age over 60 years, varus malalignment < 10°, flexion contraction < 15°, and ligament instability < 2nd degree. It found no significant difference at latest follow up (range 7–10 years) in knee scores (mean scores of 76 [range 29–100] with osteotomy *v* 74 [range 31–94] with unicompartmental joint replacement using the Knee Society Clinical Rating System; higher scores represent a worse outcome; $P = 0.77$). It found no significant difference in functional score (mean functional score 71 [0 –100] with osteotomy *v* 59 [0–100] with unicompartmental joint replacement; $P = 0.22$). The third RCT (46 people with knee osteoarthritis, 50 operations) compared closed-wedge high tibial osteotomy (HTO) versus an open-wedge procedure based on hemicallotasis technique (HCO).[90] People with medial osteoarthritis of the knee of

Ahlback grade 1–3 were included. The RCT found no significant difference in the median hip–knee–ankle (HKA) angle between the two procedures after 2 years (median HKA angle: 182°, range 174° to 192° with HTO *v* 182°, range 179° to 189° with HCO; P = 0.3).[90] It found no significant difference between the two procedures in the Hospital for Special Surgery, Lysholm, and Wallgren-Tegner activity scores, and the Nottingham Health Profile questionnaire after 2 years. The RCT found that HCO significantly reduced hospital stay compared with closed-wedge HTO (P < 0.001), and significantly reduced convalescence period (P = 0.01).[90] The fourth RCT (63 people aged 49–74 years) compared two-level Mittelmeier osteotomy with lateral closed-wedge high tibial osteotomy using the AO/ASIF L-plate.[91] Inclusion criteria included that people were employed primarily in agriculture and had unicompartmental medial degenerative varus osteoarthritis with no previous history of knee surgery. Exclusion criteria included post-traumatic and rheumatic arthritis, knee extension deficit > 20°, range of motion < 60°, and two-compartment femorotibial arthritis. The RCT found that satisfactory results, using a recognised knee rating system, were similar in both groups (rated as "satisfactory results"; 5 years: 90% with Mittelmeier osteotomy *v* 91% with lateral closed-wedge HTO; 9 years: 70% *v* 73%; 12 years: 54% *v* 57%; differences reported as not statistically significant). After 1 year, the RCT found similar rates of satisfaction in both groups (people "very satisfied" or "satisfied": 91.4% with Mittelmeier osteotomy *v* 96.3% with lateral closed-wedge HTO). On longer term follow up, the RCT found similar rates of satisfaction between the two groups (people reporting "symptoms had improved"; 5 years: 91% with Mittelmeier osteotomy *v* 96% with lateral closed-wedge HTO; 7 years: 89% *v* 93%; 12 years: 66% *v* 68%; differences reported as not statistically significant). It found that 89% of people in each group returned to their previous agricultural activity within 8–12 months.[91]

Harms: The third RCT reported complications in four people in the HTO group resulting in changes in the HKA angle.[90] One person underwent revision surgery and was treated with antibiotics for deep infection. Closed reduction was carried on a second person and a cast maintained for 66 days. A third person was found to have an increased valgus angle 10 weeks after the operation by which time the osteotomy was considered healed. Closed reduction was carried out on a fourth person and the leg was immobilised in plaster for 59 days. This person developed lymphoedema below the knee and was still receiving lymph therapy twice a week at 2 years. Clinical scores at follow up were reported as good to excellent in one person, and fair to good in the remaining three people. In the HCO group, one person was admitted for 2 days with pain. There were no signs of any other complications. The RCT found 18 pin-track infections (classified as grade 1 to 2) in 15 people, which equals a rate of pin infection of 18%. The infections were localised to the tibial metaphysis in 14 people.[90] The fourth RCT reported non-fatal pulmonary embolism (1 person with Mittelmeier osteotomy *v* 0 with lateral closed-wedge HTO), deep vein thrombosis (2 *v* 2), superficial infection (0 *v* 1), skin necrosis (0 *v* 1), subcutaneous haematoma (2

v 1), transient peroneal nerve palsy (1 *v* 0), delayed union (2 *v* 0), pseudarthrosis (1 *v* 1), mechanical failure of hardware (1 *v* 1), enclosed sural nerve in fibula callus (1 *v* 1), and absorption of tibial tuberosity (1 *v* 0).[91] We found no evidence about harms in the other studies.

Comment: We also identified 18 observational studies. Of the observational studies, only one compared osteotomy with another technique (osteotomy *v* UKA). It found UKA had better results than osteotomy and that these results were sustained over long periods.[92] The other observational studies found that osteotomy was effective in subgroups with appropriate site of osteoarthritis, severity of disease, and degree of physical activity.

OPTION TOTAL HIP REPLACEMENT

One systematic review of RCTs and observational studies has found that hip replacement is effective for at least 10 years.

Benefits: We found two systematic reviews.[93,94] In the first systematic review (search date 1995, 17 RCTs, 61 observational studies of hip replacements) the mean ages of people in the trials ranged from 43–71 years.[73] The review found that at least 70% of people without prosthetic failure were rated "good/excellent" for pain and function at 10 years' follow up (see comment below). A second systematic review (search date 1995) identified 11 RCTs and 180 observational studies comparing different prostheses.[94] It found wide variations in outcome, with primary evidence too weak to draw valid conclusions.

Harms: **Death:** We found one systematic review (search date 1995).[95] It pooled data from 130 000 people who had undergone hip replacement and had not received thromboprophylaxis, and found that the rate of fatal pulmonary embolism was 0.1–0.2% and overall mortality was 0.3–0.4%. One retrospective cohort study (11 607 hip replacements) found mortality to be higher in the first 3 months after surgery than in the subsequent 9 months.[96] **Revision and infection:** Two high quality observational studies found that the risk of a revision operation was about 1% per annum, ranging from 0.2–2.0%.[93,97] Most studies found that revisions were not required until at least 10 years after implantation. One large study of a patient register in Sweden found that cumulative 10 year proportion of hip replacements that were revised due to infection fell to less that 0.5% between 1978 and 1990. It also found that after the immediate postoperative period, aseptic loosening accounted for about 80% of all requirements for replacement or revision surgery.[98] Observational studies found that the initial results of revision surgery were only slightly worse than primary surgery but the prostheses deteriorated more quickly.[99–101] One prospective cohort study (39 543 people) on the Norwegian Hip Replacement register found a lower standardised mortality ratio (0.81) for people who had undergone total hip replacement at mean follow up of 5.2 years (range 0–10.4 years).[102]

Comment: One poor quality narrative review of 20 mainly small uncontrolled studies evaluated self assessed quality of life (at least 2 out of the following factors: physical, social, emotional, economic, and overall

satisfaction).[103] It found that improvement in non-physical measures occurred most often within 3 months. Benefit was sustained for up to 5 years after surgery. We found no longer term evidence. Most studies did not distinguish between hip replacement for osteoarthritis and hip replacement for other reasons, which may confound data for osteoarthritis. Outcome of hip replacement for osteoarthritis differs significantly from that for other conditions (e.g. hip fracture in the very elderly and frail, or replacement for rheumatoid arthritis). Hundreds of additional uncontrolled observational studies are available. These studies generally find that hip replacement is effective and beneficial. One recent observational study using the Swedish National Total Hip Arthroplasty register (1056 randomly selected people who had not had revision surgery) found that 10 years after surgery people usually had good health (based on SF-36 measures).[104]

OPTION KNEE REPLACEMENT

Systematic reviews of observational studies have found that knee replacement is effective in relieving pain and improving function. One subsequent RCT found limited evidence that unicompartmental knee replacement is more effective than tricompartmental knee replacement at 5 years' follow up. One systematic review of observational studies found better outcomes with unicompartmental compared with bicompartmental operations.

Benefits: We found one systematic review of tricompartmental prostheses (search date 1992)[105] and one systematic review of bicompartmental and unicompartmental prostheses (search date 1992).[106] **Tricompartmental prostheses:** The review identified 154 studies (4 RCTs, 130 cohort studies, 20 others) of 37 different tricompartmental prostheses in 9879 people (63% with osteoarthritis, mean follow up of 4.1 years).[105] Good or excellent outcomes were reported in 89% of people (improved function 5 years after surgery; pain relief after 5 years; mortality rate at 30 days and at 1 year; thromboembolism by 30 days after surgery; no failure of knee prosthesis). **Bicompartmental prostheses:** The review identified no RCTs but found 18 cohort studies (884 people).[106] The review found that bicompartmental prostheses were effective (based on a global knee rating scale that includes pain, function, and range of movement). **Unicompartmental prostheses:** The review identified no RCTs but 46 cohort studies (2391 people).[106] We found one subsequent RCT.[107] The review found that both unicompartmental and bicompartmental procedures were effective (based on a global knee rating scale that includes measures of pain, function, and range of movement), with better outcomes from unicompartmental operations, particularly since 1987.[106] The subsequent RCT (92 people) found that unicompartmental knee replacement is more effective than tricompartmental knee replacement at 5 years' follow up.[107] Pain relief was good in both groups, but the number of knees able to flex 120° or more was significantly higher in people treated with unicompartmental replacement ($P < 0.001$), and there were more excellent results (90–100 on the Bristol Knee Score) in this group (34/45 [76%] *v* 26/46 [57%]; RR 1.3, 95% CI 0.99 to 1.8).[107] **Quality of life:** Two observational studies published since

the review found improvement in quality of life after all forms of knee replacement.[108,109] The first found that knee replacement improved function (measured by Western Ontario and McMaster osteoarthritis, from 58.2 before surgery to 18.4 at time of survey).[108] The second, a cross-sectional community survey, found that more people had moderate to severe pain (assessed using a modified Knee Society score) before surgery (361/487 [74%]) than 1 or more years afterwards (100/487 [21%]).[109]

Harms: **Death:** In one 6 year cohort of 338 736 US Medicare patients, the death rate within 30 days of hospital admission for total knee replacement was 2147 (0.63%).[110] The same cohort study reported a mean mortality of 1.5% per annum (no comparative data available). One observational study (208 people) found no significant increase in the risk of death after knee arthroplasty for women (standardised mortality ratio 1.03, 95% CI 0.76 to 1.37) or men (standardised mortality ratio 1.14, 95% CI 0.68 to 1.80) after a mean follow up of 6 years (range 0–20 years).[111] **Thrombosis:** We found three studies that reported rates of venous thrombosis.[94,112,113] They found that about 24% of people who had a total knee replacement developed a deep vein thrombosis. **Revision and infection:** This is the main long term risk. The first review found a revision rate of 3.8% during 4.1 years' follow up after tricompartmental replacements.[105] The second review found a revision rate of 9.2% over 4.6 years for unicompartmental prostheses and 7.2% over 3.6 years for bicompartmental prostheses.[106] Large patient register based studies in Sweden found that the cumulative 10 year risk for revision surgery because of infection had fallen to less than 1%.[98] Most implant revision surgery was because of aseptic loosening. For unicompartmental osteoarthritis, unicompartmental knee replacement was an effective alternative to total knee replacement.[114,115] **Postoperative pain:** This was rarely recorded, but seemed to be absent or mild in most people. **Wound infection:** We found no good evidence on the frequency of wound infections. One large retrospective cohort study found lower complication rates in centres with a higher volume of procedures.[116]

Comment: We found hundreds of observational studies that reported the time to prosthesis failure or revision surgery, but less evidence on patient related outcomes. The evidence suggests that benefits and harms of knee replacement now seem to be similar to that of hip replacement.

QUESTION Which people are most likely to benefit from hip replacement?

OPTION HIP REPLACEMENT (WHO IS MOST LIKELY TO BENEFIT)

We found no RCTs. One systematic review of observational studies has suggested younger age (< 45 years), older age (> 75 years), and weight over 70 kg may be associated with worse outcomes in terms of pain relief and function after hip replacement. One cohort study found that younger people were at greater risk of revision, whereas another study found lower rates of implant survival in obese people.

Benefits: We found no RCTs (see comment below).

Harms: **Revision and infection:** One Swedish cohort study found that younger people and people doing heavy physical work were at greater risk of revision.[97] Another study found lower rates of long term survival of the implant in obese people.[99]

Comment: One systematic review (search date not stated) identified 40 observational studies (number of people not stated) relating individual characteristics to outcome after hip replacement.[117] It found that the following factors predicted better outcomes in terms of pain relief and function: age 45–75 years; weight less than 70 kg; good social support; higher educational level; and less preoperative morbidity. **Obesity:** One prospective cohort study (176 people) found no difference in the quality of life after a primary hip replacement between the non-obese and moderately obese either at 1 or 3 years, but the study reported no results in people with a body mass index greater than 40 kg/m^2.[118] **Age:** We found a few large observational studies. They found conflicting evidence, which suggested that older people had good self reported outcomes in terms of pain and function, but spent longer in hospital, needed more rehabilitation, and experienced more perioperative complications.[103,119–125] Consensus groups have reported from Sweden, the USA, Canada, and New Zealand.[126–129] Constant pain, particularly night or rest pain, with or without substantial functional impairment, were the generally agreed criteria for joint replacement (see table 3, p 1588). In practice, most surgeons prefer to have radiographic evidence of joint damage as well.

QUESTION **Which people are most likely to benefit from knee replacement?**

OPTION **KNEE REPLACEMENT (WHO IS MOST LIKELY TO BENEFIT)**

We found no RCTs. We found insufficient evidence from observational studies on the effects of obesity on knee replacement outcomes. We found limited evidence from observational studies that knee replacement is effective in elderly people.

Benefits: We found no RCTs (see comment below).

Harms: None found.

Comment: **Obesity:** We found insufficient evidence from observational studies on the effects of obesity on outcome of knee replacement.[130–133] **Age:** We found limited evidence from observational studies suggesting that knee replacement is effective in elderly people.[125,134,135]

GLOSSARY

Arthritis Self-Efficacy (ASE) The ASE consists of two subscales, one for pain (5 items) and one for other symptoms (6 items). Within each subscale, each item is scored from 0 (very uncertain) to 10 (very certain). Scores are summed across the items for each subscale, producing scores of 5–50 for pain and 6–60 for other symptoms.

Attention only education Information about arthritis but no guidance on self treatment.

Lequesne Index This includes the measurement of pain (5 questions), walking distance (1 question), and activities of daily living (4 questions), with versions available for the hip and knee. Scores for each question are added together to provide a combined disease severity score. Scores of 1–4 are classified as mild osteoarthritis, 5–7 moderate, 8–10 severe, 11–13 very severe, and 14 as extremely severe osteoarthritis.[9]

Modified Knee Society score This instrument combines three different domains (pain, function, and joint status) into a single score (patient function [i.e. walking ability and stair climbing] accounts for about 50% of the total score, with pain and joint status [i.e. stability and deformity] each accounting for about 25%).[5]

Rubefacient An agent that produces mild irritation and redness of the skin.

Self care education Individualised arthritis self care instruction based on patients' needs assessment.

The Brief Pain Inventory (BPI) questionnaire (validated) This measures pain intensity and effect (interference) on quality of life. Intensity (worst and least pain in the last week, average pain, pain right now) are recorded on numerical scales from 0 (no pain) to 10 (pain as bad as you can imagine). The effect of the pain are recorded in terms of how much it interferes with general activity, mood, walking ability, normal work, relations with others, sleep, and enjoyment of life, recorded on a numerical scale from 0 (does not interfere) to 10 (completely interferes).

The British Orthopedic Association (BOA) score This is used as clinical evaluation and has a maximum score of 39 points.

Western Ontario and McMaster osteoarthritis (WOMAC) scale This is a validated instrument for assessing lower limb (hip and knee) osteoarthritis and is sensitive to change. It is a self assessment questionnaire and includes questions on pain, stiffness, and physical function (such as walking ability). WOMAC is disease specific but not intervention specific; it can be used to assess any intervention in osteoarthritis.[6–8]

Competing interests: SL has in the past 5 years received fees for organising education and/or consulting from Aventis, AstraZeneca, Genzyme, Eli Lilly, Negma, Lerads, Pharmacia, Pfizer, and Procter & Gamble. DS, JC and CS none declared.

We would like to acknowledge the previous contributors of this chapter, including Alex Faulkner.

TABLE 1 **Effect sizes (95% CI) of exercise in osteoarthritis of the knee and hip: results of the three highest quality RCTs identified in a systematic review (see text, p 0).[10]**

RCT	Pain	Observed disability
1	0.31 (0.28 to 0.34)	0.31 (0.28 to 0.34)
2	0.47 (0.44 to 0.50)	0.89 (0.85 to 0.93)
3	0.58 (0.54 to 0.62)	0.28 (0.24 to 0.32)

Effectiveness of exercise therapy in patients with osteoarthritis of the hip or knee: a systematic review of randomized clinical trials, Van Baar ME, Assendelft WJ, Dekker J et al, Arthritis Rheum, Copyright © 1999, American College of Rheumatology. Reproduced with permission of John Wiley & Sons, Inc.

TABLE 2 **Estimated relative risk of gastrointestinal adverse effects with the use of individual NSAIDs (pooled data from 12 studies) (see text, p 1570).[51]**

Drug	Pooled RR	95% CI for pooled RR
Ibuprofen (low dose)*	1.0	ND
Fenoprofen	1.6	1.0 to 2.5
Aspirin	1.6	1.3 to 2.0
Diclofenac	1.8	1.4 to 2.3
Sulindac	2.1	1.6 to 2.7
Diflunisal	2.2	1.2 to 4.1
Naproxen	2.2	1.7 to 2.9
Indomethacin	2.4	1.9 to 3.1
Tometin	3.0	1.8 to 4.9
Piroxicam	3.8	2.7 to 5.2
Ketoprofen	4.2	2.7 to 6.4
Azapropazone	9.2	4.0 to 21.0

*Comparative data used low dose ibuprofen as the reference control for calculating the relative risk of other drugs.
ND, no data; NSAIDs, non-steroidal anti-inflammatory drugs.

TABLE 3 **Summary of New Zealand priority criteria for joint replacement (see text, p 0).[129]**

Severity is scored out of a possible 100 on the basis of:

Pain: severity 0–20; duration 0–20
Function: walking difficulty 0–10; other 0–10
Joint damage: pain on passive movement 0–10; other/x ray 0–10
Other: other joints 0–10; work, care giving, independence 0–10

Plantar heel pain and fasciitis

Search date September 2003

QUESTIONS

INTERVENTIONS

See glossary, p 1601

Key Messages

- **Casted orthoses (custom made insoles)** One systematic review found no RCTs on the effects of orthoses versus placebo or no treatment. The review found limited and conflicting evidence from RCTs about the effects of orthoses (with or without heel pads or stretching exercises) versus corticosteroids, corticosteroids plus local anaesthesia, stretching exercises, or other physical supports.
- **Corticosteroid injection (in the short term)** One systematic review identified no RCTs comparing corticosteroid injections alone versus placebo.
- **Corticosteroid injection plus local anaesthetic injection in the short term (with or without non-steroidal anti-inflammatory drugs or heel pads)** One systematic review identified no RCTs comparing corticosteroid injections plus local anaesthesia versus placebo. RCTs provided insufficient evidence about clinically important effects of corticosteroids plus local anaesthesia (alone or combined with non-steroidal anti-inflammatory drugs or heel pads) compared with other treatments.
- **Extracorporeal shock wave therapy** We found one systematic review and four subsequent RCTs of extracorporeal shock wave therapy (ESWT). Seven small RCTs provided insufficient evidence to assess extracorporeal shock wave therapy compared with placebo. Two RCTs found limited evidence that high dose extracorporeal shock wave therapy reduced pain and walking scores compared with low dose therapy. However, the clinical importance of these effects is not clear.

Plantar heel pain and fasciitis

- **Heel pads and heel cups** One systematic review found no RCTs on the effects of heel pads and heel cups compared with placebo or no treatment. The review found limited and conflicting evidence on the effects of heel pads and heel cups (alone or in combination with other treatments) compared with other treatment modalities.
- **Lasers** One small RCT identified by a systematic review found no significant difference between laser treatment and placebo.
- **Local anaesthetic injection** One systematic review identified no RCTs comparing local anaesthesia versus placebo or no treatment.
- **Night splints plus non-steroidal anti-inflammatory drugs** One RCT found no significant difference in pain between a night splint plus non-steroidal anti-inflammatory drugs and non-steroidal anti-inflammatory drugs alone after 3 months. There was insufficient evidence from one RCT comparing night splints versus orthoses.
- **Stretching exercises** One systematic review identified no RCTs comparing stretching exercises versus no treatment in people with heel pain. One RCT found that plantar fascia stretching plus insole was more effective at reducing morning heel pain than Achilles tendon stretching plus insole. One RCT found no significant difference in pain after 8 weeks between stretching alone (Achilles tendon stretching and plantar fascia stretching) and stretching plus orthoses. (One RCT found no significant difference in pain between sustained and intermittent Achilles tendon stretching exercises.
- **Surgery** One systematic review found no RCTs of surgery for heel pain.
- **Ultrasound** One systematic review found one small RCT. It found no significant difference in pain between ultrasound and sham ultrasound.
- **Corticosteroid injection in the medium to long term (with or without heel pad)** One systematic review identified no RCTs comparing corticosteroid injections versus placebo. One small RCT provided insufficient evidence about the long term clinical effects of corticosteroid injection plus heel pad compared with placebo plus heel pad. Observational studies have found a high rate of plantar fascia rupture and other complications associated with corticosteroid injections, which may lead to chronic disability in some people.
- **Corticosteroid injection plus local anaesthetic injection in the medium to long term (with or without non-steroidal anti-inflammatory drugs or heel pads)** One systematic review identified no RCTs comparing corticosteroid injections plus local anaesthesia versus placebo. RCTs provided insufficient evidence about clinically important effects of corticosteroids plus local anaesthesia (alone or combined with non-steroidal anti-inflammatory drugs or heel pads) compared with other treatments. Observational studies have found a high rate of plantar fascia rupture and other complications associated with corticosteroid injections, which may lead to chronic disability in some people.

DEFINITION Plantar heel pain is soreness or tenderness of the heel that is restricted to the sole of the foot. It often radiates from the central part of the heel pad or the medial tubercle of the calcaneum, but may extend along the plantar fascia into the medial longitudinal arch of the foot. Severity may range from an irritation at the origin of the plantar fascia, which is noticeable on rising after rest, to an

incapacitating pain. This review excludes clinically evident underlying disorders, for example, infection, calcaneal fracture, and calcaneal nerve entrapment, which may be distinguished clinically — a calcaneal fracture may present after trauma, and calcaneal nerve entrapment gives rise to shooting pains and feelings of "pins and needles" on the medial aspect of the heel.

INCIDENCE/ PREVALENCE The incidence and prevalence of plantar heel pain is uncertain. Plantar heel pain primarily affects those in mid to late life.[1]

AETIOLOGY/ RISK FACTORS Unknown.

PROGNOSIS One systematic review (search date 2002) found that almost all of the included trials reported an improvement in discomfort regardless of the intervention received (including placebo), suggesting that the condition is at least partially self limiting.[1] A telephone survey of 100 people treated conservatively (average follow up 47 months) found that 82 people had resolution of symptoms, 15 had continued symptoms but no limitations of activity or work, and three had persistent bilateral symptoms that limited activity or changed work status.[2] Thirty one people said that they would have seriously considered surgical treatment at the time that medical attention was sought.

AIMS OF INTERVENTION To reduce pain and immobility, with minimal adverse effects.

OUTCOMES Pain reduction (often measured using visual analogue scales); walking distance.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION What are the effects of treatments for plantar heel pain?

OPTION CORTICOSTEROID INJECTIONS

One systematic review identified no RCTs comparing corticosteroid injections versus placebo. One small RCT provided insufficient evidence about the long term clinical effects of corticosteroid injection plus heel pad compared with placebo plus heel pad. Observational studies have found a high rate of plantar fascia rupture and other complications associated with corticosteroid injections, which may lead to chronic disability in some people.

Benefits: We found one systematic review (search date 2002).[1] **Versus placebo or no treatment:** The review found no RCTs. **Corticosteroid injection plus heel pad versus placebo plus heel pad:** The review found one small RCT (19 people, 22 heels with recalcitrant heel pain but not arthritis) comparing corticosteroid (hydrocortisone acetate 25 mg) injection plus heel pad (see glossary, p 1601) versus saline injection plus heel pad. It found no significant difference between hydrocortisone and placebo in the proportion of heels with no relief of pain assessed between 6–18 months after the injection (3/13 [23%] heels with hydrocortisone *v*

4/9 [44%] heels with placebo; RR 0.52, 95% CI 0.15 to 1.79).[1] **Versus orthoses:** The review found no RCTs. **Versus pads:** The review found no RCTs. **Versus pain medication alone:** The review found no RCTs. **Corticosteroid injection plus local anaesthesia:** The review found no RCTs.

Harms: The RCT identified by the review gave no information on harms.[1] Corticosteroid injections can be painful. Complications observed from local corticosteroid injection throughout the body include infection, subcutaneous fat atrophy, skin pigmentation changes, fascial rupture, peripheral nerve injury, and muscle damage, among others.[3] Observational studies have reported rupture of the plantar fascia in people receiving corticosteroid injections.[4,5] One study reported a 10% incidence of rupture among 122 injected heels.[5] A second study examined 37 people with a presumptive diagnosis of plantar fascia rupture, all of whom had had plantar fasciitis and all of whom had previously been treated with corticosteroid injection.[4] History revealed that in 13/37 (35%) people the rupture had been a sudden event, whereas in the remainder it seemed to be gradual. The study reported that most had resolution of symptoms, but this often took 6–12 months to occur.[4] Rupture may relieve the original heel pain, but may cause arch and mid-foot strain, lateral plantar nerve dysfunction, stress fracture, deformity, and swelling, all of which may persist.

Comment: The evidence from observational studies makes it difficult to define the clinical importance of rupture of the plantar fascia.

OPTION LOCAL ANAESTHETIC INJECTION

One systematic review identified no RCTs comparing local anaesthesia versus placebo or no treatment. RCTs provided insufficient evidence about clinically important effects of corticosteroids plus local anaesthesia (alone or combined with non-steroidal anti-inflammatory drugs or heel pads) compared with other treatments.

Benefits: We found one systematic review (search date 2002).[1] **Versus placebo or no treatment:** The review found no RCTs.[1] **Versus corticosteroids plus local anaesthetic:** See benefits of corticosteroids plus local anaesthesia, p 1593.

Harms: See harms of corticosteroid injections plus local anaesthetic, p 1594.

Comment: Epinephrine (adrenaline) is not recommended in local anaesthetics for procedures that involve the appendages because of the risk of ischaemic necrosis.[6]

OPTION CORTICOSTEROID INJECTIONS PLUS LOCAL ANAESTHESIA

One systematic review identified no RCTs comparing corticosteroid injections plus local anaesthesia versus placebo. RCTs provided insufficient evidence about clinically important effects of corticosteroids plus local anaesthesia (alone or combined with non-steroidal

anti-inflammatory drugs or heel pads) compared with other treatments. Observational studies have found a high rate of plantar fascia rupture and other complications associated with corticosteroid injections, which may lead to chronic disability in some people

Benefits: We found one systematic review (search date 2002), which identified 4 RCTs comparing of corticosteroid plus local anaesthetic injections versus various other treatments.[1] **Versus placebo or no treatment:** The review found no RCTs. **Versus heel pads:** The review found two RCTs.[1] The first RCT (80 people) included people with pain on the plantar aspect of the heel but excluded people on anti-inflammatory medication, people who had had a corticosteroid injection during the past 6 months, people with rheumatoid arthritis, and people with pain that radiated along the plantar fascia more distally. It compared three treatments: a heel pad (see glossary, p 1601) alone; an injection alone (triamcinolone hexacetonide 20 mg plus 2% lidocaine [lignocaine]), and injection plus heel pad (an "anti-pronatory insole"). Analysis was not by intention to treat, and four people (5%) were lost to follow up. The RCT found that, after 1 month, the greatest improvement in pain was in people who received the injection alone (22 people), with the least improvement in people who had the heel pad alone (26 people) (100 mm visual analogue scale: injection alone *v* pad alone, mean difference –45 mm, 95% CI –59 mm to –31 mm). At 24 weeks, there was greater mean pain reduction with the injection alone versus the heel pad alone, but the difference was not significant (85% with injection alone *v* 75% with pad alone). The second RCT (17 people) identified by the review compared triamcinolone 20 mg plus 2% lidocaine injection versus heel pad (prefabricated silicone type). Although more people improved after treatment with the heel pad at 12 weeks (66% with heel pad *v* 33% with injection), the difference in pain was not significant at 1, 2, or 12 weeks. **Versus corticosteroid alone:** The review found no RCTs. **Versus corticosteroid plus local anaesthetic plus heel pad:** The review found one RCT.[1] It found that heel pad plus injection (triamcinolone hexacetonide 20 mg plus 2% lidocaine) significantly worsened pain score compared with injection alone 1 month after treatment, although the clinical importance of these results is unclear (100 mm visual analogue scale: mean difference 1.60 cm, 95% CI 0.07 cm to 3.12 cm). However, at 24 weeks, people treated with pad plus injection had less pain compared with injection alone but this was not significant (94% with pad plus injection *v* 85% with injection alone). **Plus heel pad versus heel pad alone:** The review found one RCT (described above).[1] It found a significantly better response with injection (triamcinolone hexacetonide 20 mg plus 2% lidocaine) plus heel pad (an anti-pronatory insole) versus heel pad alone at 4 weeks and 12 weeks (10 cm visual analogue scale: mean difference at 4 weeks –2.9 cm, 95% CI –4.4 cm to –1.4 cm), but not at 24 weeks (10 cm visual analogue scale: mean difference at 24 weeks –1.07 cm, 95% CI –2.55 cm to +0.41 cm; AR for pain reduction: 94% with injection plus pad *v* 75% with pad alone). However, the clinical importance of these results is unclear. **Plus non-steroidal anti-inflammatory drugs versus heel pad plus paracetamol:** The review[1] found one RCT (103 people with plantar heel tenderness, a history of pain upon rising in the morning [first

step pain], and no history of trauma in the previous 3 months).[7] It compared three interventions: three injections of corticosteroid plus local anaesthetic into the heel plus non-steroidal anti-inflammatory drugs (anti-inflammatory treatment); heel pads plus paracetamol (acetaminophen) as required (accommodative treatment), and a heel pad before fitting of custom made orthoses (see glossary, p 1601) (mechanical treatment). Treatment in the anti-inflammatory group consisted of etodolac 600 mg and 0.5 mL dexamethasone sodium phosphate 4 mg/mL plus 1 mL of 0.5% bupivacaine hydrochloride without adrenaline (epinephrine). If there was no response, 0.2 mL of dexamethasone acetate 16 mg/mL injection was added cumulatively to the second (2nd week) and third (4th week) injections. Analysis was not by intention to treat and 18 people (17.5%) were lost to follow up. The RCT found no significant difference between the groups treated with injection plus anti-inflammatories and that treated with heel pads at three months (10 cm visual analogue scale: mean difference −1.2 cm, 95% CI −2.8 cm to +0.4 cm). **Plus non-steroidal anti-inflammatory drugs versus orthoses plus heel pad:** The review[1] found one RCT (described above).[7] It found that both anti-inflammatory treatment (corticosteroid injection plus local anaesthesia plus non-steroidal anti-inflammatory drugs) and mechanical treatment (orthoses plus heel pad) improved pain at 3 months, but the difference was not significant (10 cm visual analogue scale: mean difference −1 cm, 95% CI −2.5 cm to +0.5 cm). **Versus local anaesthetic alone:** The review[1] found one RCT (91 people with 106 episodes of heel pain; randomisation by heel).[8] It compared a single injection of 1 mL prednisolone acetate 25 mg/mL plus 1 mL lidocaine hydrochloride 2% versus 2 mL lidocaine hydrochloride 2% alone. It found that the combined injection slightly improved pain score at 1 month, although the clinical importance of this result is unclear (10 cm visual analogue scale: mean difference −0.8 cm, 95% CI −1.5 cm to −0.2 cm). However, it found no significant difference in pain thereafter (3 months: mean difference +0.1 cm, 95% CI −1.2 cm to +1.3 cm; and 6 months: +0.5 cm, 95% CI −0.8 cm to +1.7 cm).

Harms: **Versus local anaesthetic alone:** In the RCT identified in the review,[1] participants' heels were injected through the medial aspect of the heel pad.[8] Half of the 106 randomised heels were given a tibial nerve block and half received local injection only. The RCT found no significant difference between these groups in pain at time of injection.[8] The other RCTs did not report on harms. See also harms of corticosteroid injections, p 1592.

Comment: The RCTs had many flaws (lack of intention to treat analysis, lack of power, high withdrawal rates, and lack of placebo control). Limitations of the available evidence make the use of corticosteroid injections in heel pain difficult to categorise in terms of benefits and harms. Heterogeneity of interventions prevented data pooling. A survey of UK rheumatologists found that corticosteroid injections are the most common treatment of heel pain and are used by 98% of UK rheumatologists (Crawford F, personal communication, 2000), confirming the results of similar surveys.[3] We found evidence from two observational studies of high rates of moderately

severe harms from this treatment (see harms of corticosteroid injections, p 1592). This is also consistent with evidence about harms of corticosteroid injections in other areas.[3] These harms are particularly relevant because the evidence of benefit is poor, and spontaneous resolution of symptoms is common.

OPTION STRETCHING EXERCISES

One systematic review identified no RCTs comparing stretching exercises versus no treatment in people with heel pain. One RCT found no significant difference between stretching alone (Achilles tendon stretching and plantar fascia stretching) and stretching plus orthoses in pain after 8 weeks. One RCT found no significant difference in pain between sustained and intermittent Achilles tendon stretching exercises. One RCT found that plantar fascia stretching plus insole was more effective at reducing morning heel pain than Achilles tendon stretching plus insole.

Benefits: We found one systematic review (search date 2002). [1] **Versus no treatment:** The review found no RCTs. **Versus orthoses plus stretching exercises:** The review identified one RCT (236 people with maximal tenderness over the medial calcaneal tuberosity for which they had received no previous treatment. People with systemic disease, sciatica, or local nerve entrapment were excluded. The RCT compared five treatments: stretching exercises alone (Achilles tendon stretching and plantar fascia stretching [see glossary, p 1601] for 10 minutes twice daily); custom made orthoses (see glossary, p 1601) plus stretching exercises, and heel pad (prefabricated shoe inserts) made from three different materials (silicone, felt, or rubber) plus stretching exercises.[9] It found no significant difference in pain improvement at 8 weeks between stretching alone and orthoses plus stretching (100 mm visual analogue scale: difference –3.2 mm, 95% CI –17.4 mm to +11.0 mm; see comment below). **Versus heel pad plus stretching:** The review identified one RCT [9]. **Sustained versus intermittent Achilles tendon stretching:** We found one RCT (94 people with 122 affected heels).[10] It found no significant difference in foot and ankle pain scores (pain score not further described) between sustained Achilles tendon stretching (performed for 3 minutes, three times daily for at least 4 months) and intermittent Achilles tendon stretching (five 20 second repetitions performed in two daily sessions after 4 months; $P = 0.31$).[10] **Plantar fascia stretching plus heel pad versus Achilles tendon stretching plus heel pad:** One RCT (101 people with chronic proximal plantar fasciitis for at least 10 months) found that plantar fascia stretching (held for a count of 10 and repeated three times daily) plus prefabricated full-length heel pads (soft insoles) reduced first step pain after rest compared with Achilles tendon stretching (held for a count of 10 and repeated three times daily) plus prefabricated full-length soft insoles after 8 weeks (WMD in first step pain after rest: –17.9, 95% CI –19.8 to –15.9). The RCT did not report on adherence to either intervention.[11]

Harms: The RCTs did not report on harms.

Comment: Subgroup analysis in the RCT with five treatment arms found that, among people who stood for more than 8 hours daily, a greater reduction in pain was achieved with stretching alone than with customised insoles plus stretching exercises.[9] It found no significant difference in people who stood for less than 8 hours daily. This hypothesis requires testing as the primary outcome in an RCT. Only half of the participants in this subgroup analysis responded to the pain questionnaire.

OPTION CASTED ORTHOSES (CUSTOM MADE INSOLES)

One systematic review found no RCTs comparing the effects of orthoses versus placebo or no treatment. The review found limited and conflicting evidence from RCTs about the effects of orthoses (with or without heel pads or stretching exercises) versus corticosteroids, corticosteroids plus local anaesthesia, stretching exercises, or other physical supports.

Benefits: We found one systematic review (search date 2002).[1] **Versus placebo or no treatment:** The review found no RCTs. **Orthoses plus heel pad versus steroid plus local anaesthesia injections plus non-steroidal anti-inflammatory drugs:** See benefits of corticosteroid injections plus local anaesthesia, p 1593. **Orthoses plus heel pad versus heel pad plus pain medication:** The review[1] found one RCT (103 people with plantar heel tenderness, a history of pain upon rising in the morning [first step pain], and no history of trauma in the previous 3 months).[8] It compared three interventions: three injections of corticosteroid plus local anaesthetic into the heel plus non-steroidal anti-inflammatory drugs (anti-inflammatory treatment); heel pad (viscoelastic) plus paracetamol (acetaminophen) as required (accommodative treatment); and a heel pad for 4 weeks before a custom made orthosis (see glossary, p 1601) was fitted (mechanical treatment). Analysis was not by intention to treat and 18 people (17.5%) were lost to follow up. It found a significantly better pain reduction with heel pad plus orthoses compared with heel pad plus paracetamol (10 cm visual analogue scale: difference −2.2 cm, 95% CI −3.8 cm to −0.5 cm). **Orthoses plus stretching exercises versus heel pad plus stretching exercises:** The review[1] found one RCT (236 people).[9] The RCT compared five treatments: stretching exercises alone (Achilles tendon stretching and plantar fascia stretching [see glossary, p 1601] for 10 minutes twice daily); custom made orthoses plus stretching exercises; and three different types of heel pads (prefabricated shoe inserts) made from silicone, felt, or rubber, plus stretching exercises. It found significantly less pain at 8 weeks in people who were assigned to heel pads plus stretching (results combined for all materials) compared with custom-made orthoses plus stretching ($P = 0.007$). **Orthoses plus stretching exercises versus stretching exercises alone:** See benefits of stretching exercises, p 1595. **Versus night splints:** The review[1] found one RCT.[12] The RCT (255 people) compared custom made orthoses versus night splints. The results were difficult to interpret because there was a large difference in withdrawals between the groups (26% with night splints *v* 7% with orthoses), and we were not able to report intention to treat analysis.[12]

Harms: No RCTs reported on harms.

Comment: We found one RCT comparing heel pads versus custom made orthoses;[13] however, there was a significant difference in weight between the groups at baseline (19 lb [8.6 kg]) and weight was associated with severity of heel pain. This makes the results difficult to interpret.

OPTION HEEL PADS AND HEEL CUPS

One systematic review found no RCTs on the effects of heel pads and heel cups compared with placebo or no treatment. The review found limited and conflicting evidence on the effects of heel pads and heel cups (alone or in combination with other treatments) compared with other treatment modalities.

Benefits: We found one systematic review (search date 2002),[1] which identified RCTs of heel pads (see glossary, p 1601) and heel cups (see glossary, p 1601) compared with various treatments. **Versus placebo or no treatment:** The review found no RCTs.[1] **Versus corticosteroid injection:** The review found no RCTs. **Versus heel pad plus corticosteroid injection:** (See benefits of corticosteroid injections, p 1591**. Versus corticosteroid injections plus local anaesthesia:** See benefits of corticosteroid injections plus local anaesthesia, p 1593. **Heel pad plus pain medication versus corticosteroid injection plus local anaesthesia plus non-steroidal anti-inflammatory drugs:** See benefits of corticosteroids plus local anaesthesia, p 1593. **Heel pad plus stretching exercises versus stretching exercises alone:** See benefits of stretching exercises, p 1596. **Heel pad plus stretching exercises versus orthoses plus stretching exercises:** See benefits of casted orthoses custom made insoles, p 1596. **Heel pad plus orthoses versus heel pad plus pain medication:** See benefits of casted orthoses custom made insoles, p 1596. **Heel pad plus orthoses versus corticosteroid injection plus local anaesthesia plus non-steroidal anti-inflammatory drugs:** See benefits of corticosteroids plus local anaesthesia, p 1593. **Heel pad plus corticosteroid injection plus local anaesthetic versus corticosteroid plus local anaesthetic:** See benefits of corticosteroids plus local anaesthesia, p 1593.

Harms: None of the RCTs reported harms.

Comment: Heel cups and heel pads can be made from several different materials, but rubber, viscoelastic, and silicone can be bought as prefabricated shoe inserts. Podiatrists or orthotists sometimes use felt and foam to construct heel pads. We found one additional RCT of heel pads versus orthoses but the results were difficult to interpret. See comment of casted orthoses (custom made insoles), p 1597.[13]

OPTION EXTRACORPOREAL SHOCK WAVE THERAPY

We found one systematic review and four subsequent RCTs of extracorporeal shock wave therapy in people with heel pain. Seven small RCTs provided insufficient evidence to assess extracorporeal shock wave

therapy compared with placebo. Two RCTs found limited evidence that high dose extracorporeal shock wave therapy reduced pain and walking scores compared with low dose therapy. However, the clinical importance of these effects is unclear.

Benefits: We found one systematic review (search date 2002; 5 RCTs)[1] and four subsequent RCTs of extracorporeal shock wave therapy (ESWT — see glossary, p 1601).[14–17] **Versus placebo:** The review[1] found three RCTs comparing ESWT with placebo or sham treatment and we found four subsequent RCTs.[14–17] The first RCT identified by the review (36 people with recalcitrant heel pain) compared 1000 impulses (0.06 mJ/mm^2) versus placebo (sham ESWT) three times at weekly intervals. It found that pain on manual pressure and pain free walking ability were significantly improved with ESWT compared with placebo at 6 weeks ($P < 0.005$). Six people withdrew from the trial, and analysis was not by intention to treat. The second RCT (260 people with recalcitrant heel pain) compared ESWT for a total of 1500 pulses at 18 kV versus sham treatment.[18] It found that more people receiving ESWT reported improved pain after 12 weeks (improvement of ≥ 50% and ≥ 4 cm on a 10 cm visual analogue scale), but the difference did not reach significance (71/119 [60%] with ESWT *v* 56/116 [48%] with sham treatment; RR 1.24, 95% CI 0.97 to 1.57; results recalculated by *Clinical Evidence*). It also found slightly improved self assessed activity with ESWT, but it was not possible to calculate significance. The third RCT (166 people with plantar fasciitis) found no significant difference in overall pain between ultrasound guided ESWT (1000 mJ/mm^2 weekly for 3 weeks) and placebo at 12 weeks after treatment (mean difference in score measured with 100 mm visual analogue scale [0 mm = no pain; 100 mm = maximal pain]; ESWT *v* placebo: +0.6 mm, 95% CI −10.3 mm to +11.5 mm).[19] The first subsequent RCT (32 people with recalcitrant heel pain) compared 1000 impulses of ESWT at 0.8 mJ/mm^2 versus placebo.[17] It found that ESWT significantly reduced rest pain compared with placebo at 48 weeks (mean score on 10 cm visual analogue scale [0 cm = no pain, 10 cm = maximal pain]: 0.7 cm with ESWT *v* 1.8 cm with placebo; $P = 0.01$). It also found that ESWT improved exercise tolerance (with footwear) compared with placebo at 48 weeks (proportion of people who could walk for longer than 60 minutes: 15/17 [88%] with ESWT *v* 8/15 [53%] with placebo; significance not reported). The second subsequent RCT (272 people with chronic heel pain) compared ESWT versus sham treatment.[14] It found no significant difference between treatments in morning pain or pressure pain at either 6 or 12 weeks (WMD at 6 weeks: +0.03, 95% CI −0.45 to +1.05; WMD at 12 weeks: −0.5, 95% CI −1.30 to +0.30). The third subsequent RCT (45 running athletes) found that ESWT was more effective at reducing morning pain compared with sham treatment (WMD in pain scores: −2.6, 95% CI −3.7 to −1.4).[15] The fourth subsequent RCT (150 people with heel pain) compared a single treatment of ESWT versus sham treatment [16]. It found no significant difference between treatments in the first-step pain scores 3 months after treatment (WMD: −0.70, 95% CI −1.66 to +0.26). **Different doses:** The review[1] identified two RCTs.[20,21] The first RCT (50 people) compared 3 500 impulses of ESWT versus 3 100 impulses (both at intensity 0.08 mJ/mm^2) in people with

recalcitrant heel pain.[20] It found no significant difference in pain on pressure at 6 weeks (10 cm visual analogue scale: mean difference −0.4 cm, 95% CI −2.0 cm to +1.2 cm) or at 12 weeks (mean difference −1.4 cm, 95% CI −3.0 cm to +0.2 cm). It also found no significant difference in walking pain at 6 weeks (mean difference −0.8 cm, 95% CI −2.4 cm to +0.7 cm) or at 12 weeks (mean difference −0.9 cm, 95% CI −2.5 cm to +0.7 cm). Self reported walking pain at 12 months suggested a marginal long term benefit from higher doses of ESWT (10 cm visual analogue scale: mean difference −2.0 cm, 95% CI −3.7 cm to −0.2 cm). The second RCT (119 people with recalcitrant heel pain),[21] compared 1000 impulses of 0.08 mJ/mm^2 versus 10 impulses. All treatments were given three times at weekly intervals. It found greater improvements in pressure pain between weeks 0–12 with the higher dose (100 mm visual analogue scale: mean difference −47 mm, 95% CI −54 mm to −40 mm).

Harms: ESWT without local anaesthetic can be painful. One RCT reported a sensation of heat and numbness or bruising in two people receiving ESWT, and a burning sensation in the heel and ankle in one person receiving placebo.[19] One RCT reported significantly more adverse effects with ESWT than with sham treatment (OR 2.26, 95% CI 1.02 to 5.18).[14] Adverse effects included skin reddening, pain and local swelling, and, less frequently, dizziness, sleep disturbance, haematoma, nausea, and hair loss.

Comment: Availability of ESWT is limited. Pain associated with ESWT and differences in procedures suggest that the single blinding in the first placebo controlled RCT was probably not maintained.[1] One large RCT reported a large increase in the number of people not using pain medications with ESWT (measured as any use between weeks 10 and 12; 70% with ESWT *v* 35% with sham treatment).[18] We found one small RCT reported in abstract only (37 people with recalcitrant heel pain). It found a non-significant reduction in pain associated with ESWT at 1500 pulses at 3 Hz versus sham treatment at 2 months (100 mm visual analogue scale: mean difference −15 mm, 95% CI −45 mm to +15 mm).[22] A long term follow up of one RCT (78/119 [66%] of the people enrolled) found significantly less pain on manual pressure with high dose compared with low dose ESWT at 5 years (100 mm visual analogue scale: mean difference −20 mm, 95% CI −28 mm to −11 mm). However, there are potential confounding effects from additional treatments received by unresponsive people in both groups.[21]

OPTION SURGERY

One systematic review found no RCTs of surgery for heel pain.

Benefits: We found one systematic review (search date 2002),[1] which identified no RCTs of surgery for heel pain.

Harms: We found no RCTs.

Comment: The systematic review identified many observational studies of surgery for chronically painful heels.[1] One of the largest observational studies (76 people) compared postoperative complication

rates after endoscopic fasciotomy compared with traditional plantar fasciotomy.[23] It found that serious complications (recurrent pain, neuritis, infection) were less common in people treated with endoscopic fasciotomy compared with traditional surgery (serious incidents per procedure: 11/66 [17%] with endoscopic fasciotomy *v* 9/26 [35%] with traditional surgery).

OPTION LASERS

One systematic review of one small RCT found no significant difference between laser treatment and placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 2002), which identified one small RCT (32 people with pain of at least 1 month's duration; tenderness to pressure at the origin of the plantar fascia; pain at the mid-anterior inferior border of the calcaneus; and sharp shooting, localised, or both, inferior foot pain made worse with activity or on rising in the morning)[1]. It compared low intensity laser treatment (30 mW continuous-wave diode laser) versus placebo (treatment with a disabled laser) and found no evidence of a significant effect (data not reported).

Harms: The RCT reported that 96% of people had no adverse effects, with 4% reporting a "mild sensation" during or after treatment.[1]

Comment: None.

OPTION ULTRASOUND

One systematic review of one small RCT found no significant difference in pain between ultrasound and sham ultrasound.

Benefits: **Versus placebo:** We found one systematic review (search date 2002) which identified one small RCT (19 people, 7 with bilateral heel pain).[1] It compared ultrasound (8 treatments in 4 weeks; dose 0.5 W/cm^2, pulsed 1:4, 3 MHz for 8 minutes) versus the same number of applications of sham ultrasound (only the timer on the machine was activated). Inclusion criteria were pain radiating from the medial tubercle of the calcaneum in response to both pressure and weight bearing first thing in the morning. It found no significant difference in pain between ultrasound and sham ultrasound (10 cm visual analogue scale; mean difference +0.1 cm, 95% CI −1.8 cm to +2.1 cm).[1]

Harms: The RCT did not assess harms.[1]

Comment: None.

OPTION NIGHT SPLINTS

One RCT found no significant difference in pain between a night splint plus non-steroidal anti-inflammatory drugs and non-steroidal anti-inflammatory drugs alone after 3 months. There was insufficient evidence from one RCT comparing night splints versus orthoses

Benefits: One systematic review (search date 2002) identified two RCTs.[1] **Night splint plus non-steroidal anti-inflammatory drugs versus non-steroidal anti-inflammatory drugs alone:** The first RCT (116 people with recalcitrant heel pain) compared treatment with a night splint that dorsiflexed the ankle joint by 5°, worn nightly for 3 months, versus no night splint. All participants received ankle dorsiflexion exercises and a non-steroidal anti-inflammatory drug (piroxicam 20 mg/day for 30 days). The RCT found no significant difference in pain between night splinting and no splinting (RR 1.0, 95% CI 0.8 to 1.3).[24] **Versus orthoses:** See benefits of casted orthoses (custom made insoles), p 1596.

Harms: The RCTs did not assess harms.[1]

Comment: The first RCT only studied the most symptomatic foot in people with bilateral complaints, because of potential inconvenience and poor compliance from wearing two night splints simultaneously.[1]

GLOSSARY

Casted orthoses Made from polyurethene or similar material to a negative cast of a person's foot.

Extracorporeal shock wave therapy (ESWT) Shock waves are pulsed acoustic waves that dissipate mechanical energy at the interface of two substances with different acoustic impedance.

Heel cups Prefabricated rubber heel cups (firmer than viscoelastic heel pads) that extend up the sides of the heel and enclose the fibro fatty heel pad.

Heel pads Prefabricated viscoelastic heel pads made of malleable material. Heel pads can also be constructed from semi compressed felt, sponge rubber, and silicone.

Plantar fascia stretching A stretch achieved by crossing the affected leg over the other leg from a seated position, placing the fingers of the affected side across the base of the toes (distal to the metatarsal phalangeal joints), and pulling the toes back until a stretch in the arch of the foot can be felt.

Achilles tendon stretching A stretch achieved by hanging the heel from a step while keeping the knee straight or by leaning into the wall from a standing position with the affected leg placed behind the other leg. For people with flat foot arches, the stretch is achieved by hanging the heel from a step and inverting the foot.

Substantive changes

Corticosteroid injection plus local anaesthetic injection option restructured. Corticosteroid injection plus local anaesthetic (short term) categorised as unknown effectiveness and corticosteroid injection plus local anaesthetic (medium to long term) categorised as likely to be ineffective or harmful.

Stretching One RCT added comparing plantar fascia stretching plus heel pad versus Achilles tendon stretching plus heel pad;[11] categorisation unchanged.

Extracorporeal shock wave therapy Three RCTs added comparing extracorporeal shock wave therapy versus placebo;[14–16] categorisation unchanged.

Raynaud's (primary)

Search date February 2003

Janet Pope

QUESTIONS

INTERVENTIONS

Key Messages

- **Nifedipine** Six RCTs found that nifedipine reduced the frequency and severity of attacks over 4–12 weeks compared with placebo, and was rated by participants as more effective than placebo in improving overall symptoms. The RCTs found that nifedipine was associated with higher rates of adverse effects compared with placebo, including flushing, headache, oedema, and tachycardia.
- **Amlodipine; diltiazem; moxisylyte (thymoxamine)** We found no good RCTs of these interventions.
- **Inositol nicotinate; naftidrofuryl oxalate; nicardipine; prazosin** RCTs provided insufficient evidence to assess these interventions.

Raynaud's (primary)

DEFINITION Raynaud's phenomenon is episodic vasospasm of the peripheral arteries, causing pallor followed by cyanosis and redness with pain and sometimes paraesthesia, and, rarely, ulceration of the fingers and toes (and in some cases of the ears or nose). Primary or idiopathic Raynaud's phenomenon (Raynaud's disease) occurs without an underlying disease. Secondary Raynaud's phenomenon (Raynaud's syndrome) occurs in association with an underlying disease — usually connective tissue disorders such as scleroderma, systemic lupus erythematosus, rheumatoid arthritis, or polymyositis. This review excludes secondary Raynaud's phenomenon.

INCIDENCE/ PREVALENCE The prevalence of primary Raynaud's phenomenon varies by gender, country, and exposure to workplace vibration. One large US cohort study (4182 people) found symptoms in 9.6% of women and 8.1% of men, of whom 81% had primary Raynaud's phenomenon.[1] Smaller cohort studies in Spain have estimated the prevalence of Raynaud's phenomenon to be 3.7–4.0%, of which 90% is primary Raynaud's phenomenon.[2,3] One cohort study in Japan (332 men, 731 women) found symptoms of primary Raynaud's phenomenon in 3.4% of women and 3.0% of men.[4]

AETIOLOGY/ RISK FACTORS The aetiology of primary Raynaud's phenomenon is unknown.[5] There is evidence for genetic predisposition,[6,7] most likely in those people with early onset Raynaud's phenomenon (aged < 40 years).[8] One prospective observational study (424 people with Raynaud's phenomenon) found that 73% of sufferers first developed symptoms before age 40 years.[8] Women are more at risk than men (OR 3.0, 95% CI 1.2 to 7.8, in 1 US case control study [235 people]).[9] The other known risk factor is occupational exposure to vibration from tools (symptoms developed in about 8% with exposure *v* 2.7% with no exposure in 2 cohorts from Japan).[10,11] People who are obese may be less at risk.[9] Symptoms are often worsened by cold or emotion.

PROGNOSIS Attacks may last from several minutes to a few hours. One systematic review (search date 1996, 10 prospective observational studies, 639 people with primary Raynaud's phenomenon) found that only 13% of long term sufferers later manifested an underlying disorder such as scleroderma.[12]

AIMS OF INTERVENTION To reduce the number and severity of attacks; to prevent tissue damage; to minimise adverse effects of treatment.

OUTCOMES Frequency and severity of symptoms (as assessed by patient diary); severity assessed by visual analogue scales, Likert scales, or the Raynaud's Condition Score;[13] rates, size, and healing of digital ulceration.

METHODS *Clinical Evidence* search and appraisal February 2003. We found no systematic review. Many RCTs included people with both primary and secondary Raynaud's phenomenon. We excluded RCTs in which less than 50% of people had primary Raynaud's phenomenon or where the type of Raynaud's was unclear. We also excluded RCTs in which attacks were experimentally induced (e.g. by dipping the hands in cold water) or which did not assess clinical outcomes.

Some RCTs compared changes in symptoms from baseline within each treatment group rather than directly comparing outcomes between treatment groups. These have been described in the comment sections.

QUESTION **What are the effects of treatments for primary Raynaud's phenomenon?**

OPTION **NIFEDIPINE**

Six RCTs found that nifedipine reduced the frequency and severity of attacks over 4–12 weeks compared with placebo, and was rated by participants as more effective than placebo in improving overall symptoms. The RCTs found that nifedipine was associated with higher rates of adverse effects compared with placebo, including flushing, headache, oedema, and tachycardia.

Benefits: **Versus placebo:** We found six RCTs comparing nifedipine versus placebo (457 people, 451 with primary Raynaud's phenomenon, 2 parallel, 4 crossover trials) (see table 1, p 1611).[14–19] All RCTs found that nifedipine significantly reduced the mean frequency of attacks over 4–12 weeks compared with placebo.[14–19] One RCT found that nifedipine reduced the mean grade of the most severe attack over 4 weeks compared with placebo,[18] but another RCT found no significant difference in the mean severity of attacks over 6 weeks.[15] Three RCTs found that a significantly higher proportion of people rated nifedipine as more effective than placebo in improving overall symptoms.[14,15,19]

Harms: Five RCTs found higher rates of adverse effects with nifedipine.[14–17,19] The first RCT found that significantly more people taking nifedipine compared with placebo had oedema (24% with nifedipine *v* 0% with placebo; $P < 0.01$) or flushing (8% with nifedipine *v* 0% with placebo; $P < 0.01$).[14] Two people taking nifedipine had tachycardia. The second RCT found that 10/22 (45%) people taking nifedipine 10 mg, 16/22 (72%) people taking nifedipine 20 mg, and 6/22 (27%) people taking placebo had adverse effects (CI not stated).[15] The third RCT found no significant difference between nifedipine and placebo in the overall incidence of adverse effects, but found that nifedipine significantly increased the risk of palpitations (7/18 [38.8%] with nifedipine *v* 1/18 [5.5%] with placebo; $P < 0.05$).[16] The fourth RCT found that significantly more people had adverse effects, including headaches, flushing, and ankle swelling over 8 weeks after crossover with nifedipine compared with placebo (14/23 [61%] with nifedipine *v* 2/23 [9%] with placebo; $P = 0.05$).[17] The fifth RCT found that 16/21 (76%) people had adverse effects with nifedipine, but did not report adverse effects with placebo.[18] The sixth RCT (34 people) found that more people had adverse effects, including flushing, headache, and oedema, with nifedipine over 12 weeks after crossover compared with placebo (26/34 [76%] with nifedipine *v* 5/34 [15%] with placebo; P value not stated).[19]

Comment: One of the RCTs included six people with secondary Raynaud's phenomenon.[19]

OPTION NICARDIPINE

One RCT found that nicardipine decreased the frequency of Raynaud's attacks over 8 weeks after crossover compared with placebo, but found no significant difference in the severity of attacks. Another RCT found no significant difference in frequency, severity, or duration of attacks with nicardipine compared with placebo, but it is likely to have been too small to exclude a clinically important difference in outcomes.

Benefits: We found two RCTs.[20,21] The first RCT (69 people with primary Raynaud's, crossover design, outcomes assessed after crossover; see comment below) found that nicardipine significantly decreased the frequency of attacks over 8 weeks compared with placebo (attacks/week: 4.9 with nicardipine *v* 5.8 with placebo; mean difference 0.9, 95% CI 0 to 2.2; P = 0.02) and reduced overall disability (measured on a visual analogue scale of 10 cm where 0 represented no disability; mean 2.6 with nicardipine *v* 3.3 with placebo; P = 0.018), but found no significant difference in the severity of attacks (measured on a scale of 1–4 where 1 represented mild and 4 highly severe; 1.36 with nicardipine *v* 1.55 with placebo; mean difference in severity 0.2, 95% CI 0 to 0.4; P reported as non-significant; no further data provided).[20] The second RCT (25 people, 16 with primary Raynaud's phenomenon, crossover design, outcomes assessed after crossover; see comment below) found no significant difference in frequency, severity, or duration of attacks at 6 weeks between nicardipine 30 mg twice daily and placebo (analysis in 16 people with primary Raynaud's; mean frequency 4.4 attacks/day with nicardipine *v* 4.4 attacks/day with placebo; mean severity of attacks on a 10 point scale where 0 represented no pain; 3.5 with nicardipine *v* 3.7 with placebo; mean duration of attacks 13 minutes with nicardipine *v* 11 minutes with placebo; reported as non-significant for all outcomes; no further data provided).[21] The RCT is likely to have been too small to exclude a clinically important difference in outcomes.

Harms: The first RCT found that 7/69 (10%) people withdrew from the trial because of adverse effects: five people while taking nicardipine and two while taking placebo.[20] In the second RCT, three people withdrew because of adverse effects (including flushing, headache, and palpitations), two while taking nicardipine, and one while taking placebo.[21]

Comment: The second RCT included nine people with secondary Raynaud's phenomenon.[21] The results of the crossover trials should be viewed with caution as no precrossover results were available and results may not allow for confounding factors such as inadequate washout and the naturally variable course of Raynaud's phenomenon.[20,21]

OPTION AMLODIPINE

We found no good RCTs.

Benefits: We found no RCTs that provided between group comparisons of amlodipine versus placebo (see comment below).

Harms: We found no good RCTs (see comment below).

Comment: We found one RCT that presented within group comparisons of changes in outcomes from baseline (24 people, 15 with primary Raynaud's phenomenon, crossover design, outcomes assessed after crossover).[22] It found that amlodipine significantly reduced the number of acute attacks a week from baseline at 7 weeks (from 11.8 attacks/week at baseline to 8.6 attacks/week after treatment; $P < 0.001$) and reduced the severity of attacks from baseline (from a discomfort score of 7.8 at baseline to 5.1 after treatment). However, the RCT did not assess the significance of the difference in frequency and severity of attacks between groups. It found that amlodipine was associated with ankle oedema (55% of people taking amlodipine *v* 0% of people taking placebo), flushing, and headaches compared with placebo (10–20% with amlodipine *v* 0% with placebo).[22] The RCT included people with secondary Raynaud's phenomenon, so results may not be applicable in people with primary Raynaud's phenomenon.

OPTION DILTIAZEM

We found no good RCTs.

Benefits: We found no good RCTs (see comment below).

Harms: We found no good RCTs (see comment below).

Comment: One crossover RCT (30 people, 19 with primary Raynaud's phenomenon, outcomes assessed after crossover) found that diltiazem significantly reduced the number of attacks compared with placebo (mean reduction in attacks from baseline 22.9/month with diltiazem *v* 4.6/month with placebo; $P = 0.01$) and reduced duration of attacks (mean reduction from baseline 444 minutes/month with diltiazem *v* 160 minutes/month with placebo; $P < 0.01$) over 8 weeks.[23] The results of this RCT should be interpreted with caution as it reported comparisons from baseline, thus removing the benefits of randomisation, and the results are not intention to treat (8/30 [27%] withdrew from the trial). Two people withdrew from the trial because of adverse effects (rash or headache) while taking diltiazem. The RCT included people with secondary Raynaud's phenomenon, so results may not be fully applicable in people with primary Raynaud's phenomenon.

OPTION NAFTIDROFURYL OXALATE

One RCT found that, compared with placebo, naftidrofuryl oxalate reduced the duration and intensity of Raynaud's attacks over 2 months and reduced the impact of attacks on daily activities.

Benefits: We found one RCT (102 people, 87 with primary Raynaud's phenomenon) comparing naftidrofuryl oxalate 600 mg daily versus placebo for 2 months.[24] It found that, over 2 months, naftidrofuryl oxalate significantly reduced the duration of attacks (measured as pain for < 15 minutes, for 15–30 minutes, or for > 30 minutes; overall $P < 0.05$; people who had pain for < 15 minutes; 28/51 [55%] with naftidrofuryl *v* 17/45 [38%] with placebo; P value not stated), intensity of attacks (measured as no pain, mild pain, strong pain; overall $P < 0.001$; people who had no pain 13/50 [26%] with

naftidrofuryl *v* 3/49 [6%] with placebo; P value for this comparison not stated), and reduced the impact of attacks on daily activities compared with placebo (measured as no impact, weak impact, important impact; overall $P < 0.05$; people for whom Raynaud's had no impact on daily life 16/51 [31%] with naftidrofuryl *v* 8/49 [16%] with placebo; P value not stated) over 2 months.[24]

Harms: The RCT found no adverse effects associated with naftidrofuryl oxalate.[24]

Comment: The RCT included people with secondary Raynaud's phenomenon, so results may not be applicable in people with primary Raynaud's phenomenon.[24]

OPTION INOSITOL NICOTINATE

Two RCTs provided insufficient evidence to assess inositol nicotinate.

Benefits: We found two RCTs.[25,26] The first RCT (23 people with primary Raynaud's phenomenon) compared inositol nicotinate (4 g daily) versus placebo for 84 days during the winter.[25] It found that, compared with placebo, people taking inositol nicotinate had fewer and shorter attacks over 84 days, but the difference was not significant (P reported as non-significant; no further data provided). The RCT is likely to have been too small to exclude a clinically important difference.[25] The second RCT (65 people, 54 with primary Raynaud's phenomenon) found that, compared with placebo, more people taking inositol nicotinate 2 g twice daily improved over 12 weeks (as measured by a 5 point scale from 0 [no problem] to 5 [very severe]), but the difference was not significant (19/34 [56%] people scored 0–1 with inositol *v* 11/33 [33%] with placebo; RR 1.58, 95% CI 0.90 to 2.76; calculated from data in the paper; see comment below).[26]

Harms: The first RCT found no adverse effects associated with inositol nicotinate.[25] In the second RCT, three people taking inositol nicotinate withdrew from the trial because of gastrointestinal disturbance or dizziness compared with one person taking placebo.[26]

Comment: The second RCT included people with secondary Raynaud's phenomenon, so results may not be fully applicable in people with primary Raynaud's phenomenon.[26]

OPTION PRAZOSIN

One small crossover RCT found no clear evidence of benefit from prazosin. It found that prazosin reduced the number and duration of attacks over 6 weeks after crossover compared with placebo, but found no significant difference in the severity of attacks.

Benefits: We found one RCT (24 people, 14 with primary Raynaud's phenomenon, crossover design, outcomes assessed after crossover; see comment below) comparing prazosin (1 mg twice daily) versus placebo.[27] It found that, compared with placebo, prazosin significantly reduced the mean number of attacks over 6 weeks after crossover (attacks/day; 2.5 with prazosin *v* 4.1 with placebo;

P = 0.003) and reduced duration of attacks (21.9 minutes with prazosin *v* 29.9 minutes with placebo; P = 0.02), but found no difference in the severity of attacks (measured on a 10 point scale where 0 represented no pain; 4.1 with prazosin *v* 4.8 with placebo; P = 0.11).

Harms: The RCT found that 50% of people taking prazosin had adverse effects, including dizziness and palpitations, compared with 29% of people taking placebo.[27]

Comment: The results of the RCT should be viewed with caution as no precrossover results were available and results may not allow for confounding factors such as inadequate washout and the naturally variable course of Raynaud's phenomenon.[27] The RCT included people with secondary Raynaud's phenomenon, so results may not be fully applicable in people with primary Raynaud's phenomenon.

OPTION MOXISYLYTE (THYMOXAMINE)

We found no good RCTs of moxisylyte (thymoxamine).

Benefits: We found no RCTs of moxisylyte that assessed clinical outcomes.

Harms: We found no good RCTs.

Comment: None.

TABLE 1 **RCTs comparing nifedipine versus placebo in people with primary Raynaud's phenomenon (see text, p 1605).[14–19]**

Ref	Intervention	Number of people	RCT design	Time to outcome (weeks)	Results	Comment
14	Nifedipine (30 mg/day for 2 weeks, adjusted to daily, twice daily, or 0 depending on adverse effects) *v* placebo, biofeedback, or sham biofeedback for 1 year	313 people with primary Raynaud's	Parallel	56	**Frequency of attacks:** mean attacks/day 0.07 with nifedipine *v* 0.21 with placebo; $P < 0.001$ **Subjective assessment:** 51/70 (73%) people rated themselves as "improved" with nifedipine *v* 54/164 (33%) with placebo; $P < 0.001$	**Frequency:** attacks defined as the person reporting a Raynaud's episode at least 30 minutes after a previously recorded diary entry and indicating a corresponding code consistent with a true Raynaud's attack **Subjective assessment:** results not intention to treat; withdrawals not stated
15	Nifedipine (10 mg twice daily for 3 weeks, then 20 mg twice daily for 3 weeks) *v* placebo	22 people with primary Raynaud's	Crossover	6	**Frequency of attacks:** mean attacks/week 4.4 with nifedipine *v* 7.3 with placebo; $P < 0.01$ **Severity of attacks:** mean severity 1.7 with nifedipine *v* 1.9 with placebo; P reported as non-significant **Subjective assessment:** 12/22 (54%) people rated nifedipine *v* placebo as more effective; $P < 0.01$	**Severity:** measured on a scale of 1–3, where 1 represented mild, 2 moderate, and 3 severe attack **Subjective assessment:** measured on a 5 point scale
16	Nifedipine (10 mg 3 times daily increased to 20 mg 3 times daily after 5 weeks if no improvement) *v* placebo for 10 weeks	39 people with primary Raynaud's	Parallel	10	**Frequency of attacks:** mean reduction in frequency of attacks/week 48% with nifedipine *v* 25% with placebo; $P < 0.05$	No direct comparison of nifedipine *v* placebo; results are based on comparing changes in outcomes in each group before and after treatment
17	Nifedipine (5 mg 3 times daily for 1 week followed by 10 mg 3 times daily for 1 week and 15 mg 3 times daily for 2 weeks) *v* placebo	23 women with primary Raynaud's	Crossover	8	**Frequency of attacks:** median number of attacks/week in final 2 weeks of treatment after crossover 2.3 with nifedipine *v* 5.0 with placebo; $P < 0.01$	No precrossover results available*

TABLE 1 continued

Ref	Intervention	Number of people	RCT design	Time to outcome (weeks)	Results	Comment
18	Nifedipine (20 mg twice daily for 1 week followed by 40 mg twice daily for 1 week if no adverse effects, *v* placebo	26 people with primary Raynaud's	Crossover	4	**Frequency of attacks:** mean number of attacks/day after crossover: range 0–3.64 with nifedipine v 0.57–5.71 with placebo; $P < 0.01$ **Severity of attacks:** mean grade of the most severe attack: range 0–7.00 with nifedipine *v* 1.00–8.14 with placebo; $P < 0.01$	**Severity:** measured on a scale of 0–10 where 0 represented minimum and 10 maximum severity. No precrossover results available*
19	Nifedipine (20 mg twice daily for 8 weeks) *v* placebo (2 weeks washout between each 4 weeks of treatment)	34 people; 28 with primary Raynaud's	Crossover	12	**Frequency of attacks:** mean number of attacks/week after crossover 7.5 with nifedipine *v* 10.0 with placebo; $P < 0.001$ **Subjective assessment:** 20/29 (69%) rated nifedipine *v* placebo as more effective; $P < 0.001$	**Subjective assessment:** measured on a 5 point scale. No precrossover results available.* Included people with secondary Raynaud's phenomenon, so results may not be fully applicable in people with primary Raynaud's phenomenon

*Results after crossover may not allow for confounding factors such as inadequate washout and the naturally variable course of Raynaud's phenomenon.

Shoulder pain

Search date June 2003

Cathy Speed and Brian Hazleman

QUESTIONS

INTERVENTIONS

See glossary, p 1629

Key Messages

- Shoulder pain is not a specific diagnosis. Well designed, double blind RCTs of specific interventions in specific shoulder disorders are needed. Systematic reviews have found RCTs mostly with poor methods, and pronounced heterogeneity of study populations and outcome measures. We found insufficient evidence on the effects of most interventions in people with non-specific shoulder pain.
- **Laser treatment** One systematic review found three small RCTs. Two of the RCTs found that laser improved pain after 2–3 weeks compared with placebo, and one RCT found no significant difference at 8 weeks between treatments, although it may have lacked power to detect a difference. One additional RCT found that laser significantly increased recovery rates at 1 month compared with placebo.
- **Physiotherapy (manual treatment and exercises)** One RCT in people with mixed shoulder disorders found that physiotherapy improved function at 4 weeks compared with no treatment. One RCT in people with rotator cuff disease found that a supervised exercise regimen plus advice on pain

management improved pain and function compared with no exercise regimen at 6 months and 2.5 years. One RCT in people with adhesive capsulitis found that intra-articular steroids improved pain and function at 6 weeks compared with physiotherapy, although the magnitude of effect declined by 12 months.

- **Surgical arthoscopic decompression/forced manipulation** One RCT found that arthroscopic decompression by experienced surgeons followed by physiotherapy improved pain and function compared with sham laser but not compared with supervised exercises at 6 months and 2.5 years. One small RCT found that forced manipulation plus intra-articular hydrocortisone injection increased recovery rate at 3 months compared with intra-articular hydrocortisone injection alone.
- **Arthroscopic laser subacromial decompression** One systematic review found no RCTs on arthroscopic subacromial decompression.
- **Electrical stimulation** Three small RCTs provided insufficient evidence about the effects of electrical stimulation in people with shoulder pain.
- **Extracorporeal shock wave therapy** Small and limited RCTs provided insufficient evidence about the effects of extracorporeal shock wave therapy compared with sham treatment or no treatment in people with non-calcifying rotator cuff tendinosis and chronic suprapinatus tendinosis. There was limited evidence of benefit in people with calcific tendinitis.
- **Ice** One small RCT provided insufficient evidence about the effects of ice.
- **Intra-articular corticosteroid injection** We found inconclusive evidence about the effects of intra-articular steroids, with or without local anaesthetic or physiotherapy, compared with placebo or physiotherapy alone in people with shoulder pain.
- **Intra-articular guanethidine** We found no systematic review or RCTs of intra-articular guanethidine in people with non-arthritic shoulder pain.
- **Multidisciplinary biopsychosocial rehabilitation** One systematic review found no good quality RCTs of multidisciplinary biopsychosocial rehabilitation in people with shoulder pain.
- **Oral corticosteroids** Two small RCTs found no evidence of reduced pain or improved abduction with oral corticosteroids compared with placebo or no treatment at 4–8 months. Adverse effects of corticosteroids are well documented (see asthma, p 1966).
- **Oral non-steroidal anti-inflammatory drugs** One systematic review and one additional RCT provided insufficient evidence to draw reliable conclusions about the effects of oral non-steroidal anti-inflammatory drugs compared with placebo in people with non-specific shoulder pain.
- **Phonophoresis** We found no RCTs solely in people with shoulder pain.
- **Subacromial corticosteroid injection** We found no RCTs comparing subacromial injection of steroids versus placebo. Three small RCTs in people with rotator cuff tendinitis and one small RCT in people with subacromial impingement provided insufficient evidence to compare the clinical effects of corticosteroid plus lidocaine versus lidocaine alone. One RCT found no significant difference between subacromial steroid plus lidocaine and physiotherapy in terms of diability or successful outcome at 6 months in people attending their general practitioner because of a new episode of unilateral shoulder pain, but found that steroid injection increased the need for repeat consultation or other interverntions.
- **Transdermal glyceryl trinitrate** We found no reliable RCTs.

- **Ultrasound** One RCT identified by a systematic review found that ultrasound significantly improved pain and quality of life at the end of treatment (6 weeks) in people with calcific tendinitis, but found no significant difference at 9 months. Four other RCTs identified by the review found no significant difference between ultrasound and sham ultrasound, but may have been too small to detect a clinically important difference.
- **Paracetamol or opiates; topical or intra-articular non-steroidal anti-inflammatory drugs** We found no RCTs about these interventions.

DEFINITION Shoulder pain arises in or around the shoulder from the glenohumeral, acromioclavicular, sternoclavicular, "subacromial", and scapulothoracic articulations, and surrounding soft tissues. Regardless of the disorder, pain is the most common reason for consulting a practitioner. In adhesive capsulitis (frozen shoulder), pain is associated with pronounced restriction of movement. For most shoulder disorders, diagnosis is based on clinical features, with imaging studies playing a role in some people. Post-stroke shoulder pain is not addressed in this chapter.

INCIDENCE/ PREVALENCE Each year in primary care in the UK, about 1% of adults aged over 45 years present with a new episode of shoulder pain.[1] Prevalence is uncertain, with estimates from 4–20%.[2–6] One community survey (392 people) found a 1 month prevalence of shoulder pain of 34%.[7] A second community survey (644 people aged ≥ 70 years) reported a point prevalence of 21%, with a higher frequency in women than men (25% *v* 17%).[8] Seventy per cent of cases involved the rotator cuff. One survey of 134 people in a community based rheumatology clinic found that 65% of cases were rotator cuff lesions; 11% were caused by localised tenderness in the pericapsular musculature; 10% acromioclavicular joint pain; 3% glenohumeral joint arthritis; and 5% were referred pain from the neck.[9] One survey found that, in adults, the annual incidence of frozen shoulder was about 2%, with those aged 40–70 years most commonly affected.[10] The age distribution of specific shoulder disorders in the community is unknown.

AETIOLOGY/ RISK FACTORS Rotator cuff disorders are associated with excessive overloading, instability of the glenohumeral and acromioclavicular joints, muscle imbalance, adverse anatomical features (narrow coracoacromial arch and a hooked acromion), cuff degeneration with ageing, ischaemia, and musculoskeletal diseases that result in wasting of the cuff muscles.[11–14] Risk factors for frozen shoulder include female sex, older age, shoulder trauma, surgery, diabetes, cardiorespiratory disorders, cerebrovascular events, thyroid disease, and hemiplegia.[10,15,16] Arthritis of the glenohumeral joint can occur in numerous forms, including primary and secondary osteoarthritis, rheumatoid arthritis, and crystal arthritides.[11]

PROGNOSIS One survey in an elderly community found that most people with shoulder pain were still affected 3 years after the initial survey.[17] One prospective cohort study of 122 adults in primary care found that 25% of people with shoulder pain reported previous episodes and 49% reported full recovery at 18 months' follow up.[18]

AIMS OF INTERVENTION To reduce pain and to improve range of movement and function, with minimal adverse effects.

OUTCOMES Pain scores (overall score, on activity, at night, at rest, during the day, analgesia count); range of movement measures; assessment of overall severity (self assessed or by blinded assessor); functional score; global improvement scores (self assessed or by blinded assessor); tenderness; strength; stiffness; and adverse effects of treatment. The shoulder pain and disability index (SPADI) (see glossary, p 1630) is a validated shoulder related pain and disability questionnaire.[19–24] Other validated participant rated disability scores have been developed.[20]

METHODS *Clinical Evidence* search and appraisal June 2003. We found some articles that were not published in English; these articles are being translated and, if appropriate, will be included in future updates.

QUESTION What are the effects of treatments?

OPTION ORAL NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

One systematic review and one additional RCT provided insufficient evidence to draw reliable conclusions about the effects of oral non-steroidal anti-inflammatory drugs compared with placebo in people with non-specific shoulder pain.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 4 small RCTs, 151 people with shoulder pain for more than 72 hours)[25] and one additional RCT.[26] The review pooled results from RCTs that reported sufficient data (90 people with rotator cuff tendinitis) and found no significant reduction in pain and no significant improvement in abduction between oral non-steroidal anti-inflammatory drugs (NSAIDs — diclofenac, naproxen) and placebo after 4 weeks (pain: visual analogue scale, WMD +3%, 95% CI −19% to +25% where positive values represent deterioration; abduction: WMD +26°, 95% CI −9° to +61° where positive values represent improvement).[27,28] The additional RCT (69 people with acute shoulder pain of less than 96 hours' duration) found that oral flurbiprofen (300 mg daily) improved pain relief judged by the investigator compared with placebo at 14 days (global assessment by investigator: 30/35 [86%] improved with NSAID *v* 19/32 [59%] with placebo; ARR 26%, CI 5% to 46%; NNT 4, 95% CI 3 to 20).[26]

Harms: Withdrawal because of adverse events occurred in less than 10% of people in non-randomised comparative studies, but in up to 20% of people in RCTs. Adverse events were mostly gastrointestinal symptoms, skin rash, headache, or dizziness. The review found no evidence that the incidence or nature of adverse effects varied among NSAIDs (naproxen, diclofenac, flurbiprofen, indometacin [indomethacin], etodolac, ibuprofen, fentiazac, phenylbutazone, piroxicam). We found no systematic review of the adverse effects of cyclo-oxygenase type II selective agents in people with shoulder pain (see differences between NSAIDs under the NSAIDs topic, p 1551).

Comment: Evidence about the effects of NSAIDs in shoulder disorders is limited by the lack of standardised approaches: diverse disorders have been considered under the universal term shoulder pain, different types of NSAIDs were used, and outcome measures and follow up periods vary among RCTs. In addition, pain is a symptom, and so relying on investigator rated pain may not be valid.

OPTION TOPICAL NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

We found no RCTs about the effects of topical non-steroidal anti-inflammatory drugs in people with shoulder pain.

Benefits: We found no systematic review or RCTs of topical non-steroidal anti-inflammatory drugs specifically in people with shoulder pain.

Harms: We found no systematic review or RCTs specifically in people with shoulder pain.

Comment: See topical non-steroidal anti-inflammatory drugs under osteoarthritis, p 1560.

OPTION INTRA-ARTICULAR NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

We found no systematic review or RCTs evaluating intra-articular injection of non-steroidal anti-inflammatory drugs.

Benefits: We found no systematic review or RCTs evaluating intra-articular injection of non-steroidal anti-inflammatory drugs.

Harms: We found no RCTs.

Comment: None.

OPTION PARACETAMOL OR OPIATES

We found no RCTs evaluating paracetamol or opiates in people with shoulder pain.

Benefits: We found no systematic review or RCTs evaluating paracetamol or opiates in people with shoulder pain.

Harms: We found no RCTs.

Comment: None.

OPTION SUBACROMIAL CORTICOSTEROID INJECTIONS

We found no RCTs comparing subacromial injection of steroids versus placebo. Three small RCTs in people with rotator cuff tendinitis and one small RCT in people with subacromial impingement provided insufficient evidence to compare clinical effects of corticosteroid plus lidocaine with lidocaine alone. One RCT found no significant difference between subacromial steroid plus lidocaine and physiotherapy in terms of disability or successful outcome at 6 months in people attending their general practitioner because of a new episode of unilateral shoulder pain, but found that steroid injection increased the need for repeat consultation or other intervention.

Benefits:

Versus placebo: We found no RCTs. **Plus lidocaine versus lidocaine alone:** We found one systematic review (search date 2002, 4 RCTs).[29] The first RCT identified by the review (50 people with rotator cuff tendinitis) compared three treatments: subacromial triamcinolone plus lidocaine (1 mL of 80 mg/mL triamcinolone plus 2 mL of 0.5% lidocaine); subacromial lidocaine (3 mL of 0.5%); and oral diclofenac plus subacromial lidocaine (diclofenac 50 mg 3 times daily plus 3 mL of 0.5% lidocaine). It found that subacromial triamcinolone plus lidocaine significantly increased clinical response rates at 4 weeks compared with lidocaine alone, but it found no significant difference in pain (clinical response defined as improvement in a combination of overall pain severity score, range of active abduction, and limitation of function: 70% for triamcinolone plus lidocaine *v* 0% for lidocaine alone; $P < 0.001$; reduction in pain: WMD +7%, 95% CI −33% to +47%). The second RCT identified by the review (55 people with rotator cuff tendinitis) found no significant difference between subacromial methylprednisolone (40 mg) plus lidocaine (1 mL of 1%) and lidocaine alone for pain or remission rate at 12 weeks (pain using visual analogue scale 0–30: median pain improved by 8 points with active treatment *v* 8 points with placebo; P value not reported; remission defined as score of 0 on pain, active abduction, flexion, and external rotation: 32% in remission with corticosteroids *v* 26% with placebo; P value not reported). The third RCT in the review (published in abstract form only; 52 people with rotator cuff tendinitis or partial tear, of whom results for 41 people reported) found no significant difference between lidocaine (4 mL of 2%) plus betamethasone (1 mL with 6 mg) and lidocaine (5 mL of 2%) alone for clinical response at 6 months (response rate, measured by American Shoulder and Elbow Surgeons criteria: $P = 0.77$; no further data reported). The fourth RCT in the review (40 people with subacromial impingement who received physiotherapy) found that triamcinolone acetonide (2 mL with 40 mg) plus lidocaine (4 mL of 1%) significantly reduced pain compared with lidocaine alone (6 mL of 1%), but found no significant difference in activities of daily living after a mean follow up of about 30 weeks (moderate or severe pain: 3/19 [16%] with corticosteroid plus lidocaine v 15/21 [71%] with lidocaine alone; P value not reported). Loss to follow up was not clear, and it was not clear whether analysis was by intention to treat. The timing of follow up ranged from 12–55 weeks. **Combined intra-articular and subacromial corticosteroid injections:** We found one systematic review (search date 2002, 2 RCTs).[29] The first RCT (100 people with pain or tenderness over supraspinatus during preceding 3 months) compared four treatments: intra-articular plus subacromial triamcinolone plus lidocaine plus oral naproxen; intra-articular plus subacromial triamcinolone plus lidocaine; intra-articular plus subacromial lidocaine plus oral naproxen; and placebo (intra-articular plus subacromial lidocaine).[28] It found that intra-articular plus subacromial triamcinolone plus lidocaine increased remission rates compared with placebo at 4 weeks (remission defined as a perfect score in active abduction, pain, and limitation of function: 28% for triamcinolone *v* 8% for placebo; P value not reported).[28] The second RCT in the review (42 people with adhesive capsulitis and night pain) compared four treatments:

subacromial plus intra-articular steroid; mobilisation; ice therapy; and no treatment. It found no significant difference between treatment groups at 6 months (no data reported).[30] **Plus lidocaine versus physiotherapy:** We found one RCT (207 people attending general practitioner with new episode of unilateral shoulder pain).[31] It found no significant difference between subacromial methylprednisolone (40 mg) plus lidocaine (4 mL of 1%) and physiotherapy (8 sessions over 6 weeks) in disability or successful outcome at 6 months (disability, measured on validated shoulder disability questionnaire from 0 [no disability] to 23 [severe disability]: mean difference 1.4, 95% CI −0.2 to +3.0; successful outcome defined as 50% drop in disability score from baseline: 53% with injection *v* 60% with physiotherapy; difference 7%, 95% CI −6.8% to +20.4%). It found that steroid injection significantly increased the combined outcome of repeat consultation or other intervention for shoulder pain compared with physiotherapy (57% *v* 40%; difference 17%, 95% CI 4% to 31%).

Harms: The first RCT included in the review (50 people with rotator cuff tendinitis) found no adverse effects with subacromial corticosteroid plus lidocaine compared with lidocaine alone, apart from mild discomfort.[27] Another RCT (50 people with rotator cuff tendinitis receiving treatments of interest) found a similar adverse event rate with subacromial plus intra-articular corticosteroid injection and with placebo (3/25 [12%, mild gastrointestinal symptoms; pityriasis rosea 2 days after the injection; increased frequency of urination] with corticosteroid injection *v* 3/25 [12%, mild gastrointestinal symptoms; diarrhoea; vasovagal reaction] with placebo).[28]

Comment: Range of movement is not a satisfactory surrogate measure of function. We found no evidence on the accuracy of placement of subacromial injections.

OPTION INTRA-ARTICULAR CORTICOSTEROID INJECTIONS

We found inconclusive evidence about the effects of intra-articular steroids, with or without local anaesthetic or physiotherapy, compared with placebo or physiotherapy alone in people with shoulder pain.

Benefits: **Versus placebo:** We found no systematic review, but we found one RCT.[32] The RCT (93 people with adhesive capsulitis) compared four treatments: intra-articular steroid injection (40 mg triamcinalone hexacetonide under fluoroscopic control) plus physiotherapy; steroid injection alone; saline injection plus physiotherapy; and saline injection alone.[32] It found that intra-articular steroids (with or without physiotherapy) significantly improved pain and disability at 6 weeks compared with placebo, but found no significant difference at 12 months (improvement in SPADI [see glossary, p 1630] score at 6 weeks: 46.5 with steroid plus physiotherapy v 36.7 with steroid alone v 18.9 with placebo; P = 0.0004 for both steroid treatments v placebo; 12 months: 48.3 with steroid plus physiotherapy v 50.1 with steroid alone v 47.2 with placebo; P value not reported). **Plus lidocaine (lignocaine) versus lidocaine alone:** We found one systematic review (search date 2002, 2 RCTs).[29] The first RCT identified by the review (48 people with frozen shoulder) compared

four treatments: intra-articular methylprednisolone plus lidocaine; intra-articular lidocaine; intra-bursal methylprednisolone plus lidocaine; and intra-bursal lidocaine.[33] It found no significant difference between intra-articular methylprednisolone plus lidocaine and lidocaine alone in pain score or shoulder motion at 24 weeks (pain on 6 point pain scale [0 = no pain; 5 = most severe]: improvement of about 1 in point both groups [absolute score about 3 in both groups]; $P > 0.05$; shoulder motion: improvement of about 50° in both groups [absolute range of movement about 350° in both groups]; $P > 0.05$).[33] The second RCT in the review (60 people with rotator cuff lesions, 12 in each treatment group) compared five treatments: tolmetin plus methyl prednisolone plus lidocaine; methyl prednisolone plus lidocaine; acupuncture; ultrasound; and placebo. It found no significant difference between intra-articular injection and placebo in pain or treatment success at 4 weeks (pain on a 100 mm visual analogue scale: 29.2 mm with intra-articular injection *v* 22.0 mm with placebo; P value not reported). These two RCTs may have been too small to detect a clinically important difference. **Combined intra-articular and subacromial corticosteroid injections versus placebo:** See sub-acromial corticosteroid injection, p 1618. **Versus physiotherapy:** The systematic review identified one RCT and we found one subsequent RCT.[29,32] The RCT identified by the review (109 people with adhesive capsulitis) compared up to three injections of 40 mg intra-articular triamcinalone acetonide versus 12 physiotherapy sessions over 6 weeks.[34] It found that steroid injection significantly increased success rates at 7 weeks compared with physiotherapy, but the difference in severity score was less significant at 52 weeks (success defined as complete recovery or much improved at 7 weeks: 40/52 [77%] with steroids v 26/56 [46%] with physiotherapy; RR 1.66, 95% CI 1.21 to 2.28: mean improvement in severity score at 52 weeks: 70 with steroids v 59 with physiotherapy; difference 11, 95% CI 1 to 23). The subsequent RCT (93 people with adhesive capsulitis) compared four treatments: 40 mg intra-articular triamcinalone hexacetonide under fluoroscopic control plus physiotherapy; steroid injection alone; saline injection plus physiotherapy; and saline injection alone.[32] It found that steroid alone significantly improved pain and disability at 6 weeks compared with physiotherapy alone, but found no significant difference at 12 months (improvement in SPADI score at 6 weeks: 36.7 with steroid alone v 22.2 with physiotherapy alone; $P < 0.05$; 12 months: 50.1 with steroid alone v 45.5 with physiotherapy alone; P value not reported).

Harms: Intra-articular injections are rarely associated with infection (estimated at 1/14 000 to 1/50 000 injections).[35,36] An acute self limited synovitis was reported in up to 2% of people. Prevalence of tendon rupture, including rupture of the bicipital tendon and rotator cuff, was reported in less than 1% of people after local injection of corticosteroids.[35] Subcutaneous fat necrosis or skin atrophy was found in less than 1%. Corticosteroid arthropathy and osteonecrosis were rare (< 0.8%) and seem to affect mostly weight bearing joints.[27] One RCT identified by the systematic review[29] compared corticosteroid injection versus physiotherapy in painful stiff shoulders, and reported that corticosteroids were associated with more

facial flushing (9/52 [17%] people treated with corticosteroid injections *v* 1/56 [2%] treated with physiotherapy) and more new menstrual irregularities (6/52 [12%] people treated with local corticosteroid injections *v* 0/56 [0%] after physiotherapy).[34] The RCT comparing steroid with and without physiotherapy versus placebo did not report harms.[32]

Comment: Few RCTs of interventions in shoulder pain used high quality methods. One case control study found that clinical outcome correlated with accuracy of injection.[37] Another case control study found that only 10% of intra-articular injections were placed correctly even by experienced operators.[38] Confirmation of injection accuracy can be obtained with fluoroscopy or ultrasound. **Different doses:** We found one RCT (57 people with frozen shoulder).[39] It found that higher dose (40 mg) compared with lower dose (10 mg) triamcinolone injection significantly reduced pain after 6 weeks (change on 100 mm visual analogue scale: 31 mm with low dose *v* 49 mm with high dose; CI not reported; $P < 0.01$), movement restriction, and self rated functional impairment (change on 4 point ordinal scale: 0.7 with low dose *v* 1.3 with high dose; CI not reported; $P = 0.03$), but did not significantly improve sleep disturbance. The RCT found no significant difference in any outcome after 6 months.

OPTION ORAL CORTICOSTEROIDS

Two small RCTs found no evidence of reduced pain or improved abduction with oral corticosteroids compared with placebo. Adverse effects of corticosteroids are well documented.

Benefits: **Versus placebo:** We found no systematic review but found one RCT (32 people with frozen shoulder), which compared oral corticosteroids (cortisone acetate, 200 mg a day for first 3 days, 100 mg up to day 14, then 12.5 mg every 2 days up to 4 weeks) versus placebo.[40] It found no evidence that oral corticosteroids reduced pain more than placebo after 18 weeks, but inter-group comparisons were not reported (mean improvement of 4 point rating scale [0 = no pain, 3 = severe pain]: from 1.4 at baseline to 0.5 with oral corticosteroids *v* 1.4 at baseline to 0.6 with placebo; P values not reported).[40] **Plus home exercise versus home exercise alone:** We found one small RCT (40 people with frozen shoulder).[41] People in both groups also took non-salicylate analgesics and diazepam (5 mg) at night as needed. It found no significant difference between oral corticosteroids (10 mg for 4 weeks and 5 mg for a further 2 weeks) plus advice on home pendular excercises and advice alone for pain at 8 months (no figures available).[41]

Harms: Adverse effect of corticosteroids are well documented (see rheumatoid arthritis, p 000 and asthma, p 1966). One RCT (40 people with frozen shoulder) reported mild indigestion in two people, which settled after reducing the dose of oral corticosteroids below 10 mg.[41] No other adverse events were reported. The other RCT did not report adverse events.[40]

Comment: None.

OPTION PHYSIOTHERAPY (MANUAL TREATMENT AND EXERCISES)

One RCT in people with mixed shoulder disorders found that physiotherapy improved function at 4 weeks compared with no treatment. One RCT in people with rotator cuff disease found that a supervised exercise regimen plus advice on pain management improved pain and function compared with no exercise regimen at 6 months and 2.5 years. One RCT in people with adhesive capsulitis found that intra-articular steroids improved pain and function at 6 weeks compared with physiotherapy, although the magnitude of effect declined by 12 months.

Benefits: **Versus placebo or no treatment:** We found one systematic review (search date 2002, 3 RCTs).[42] The first RCT identified by the review (66 people with mixed shoulder disorders) found that physiotherapy plus home exercises significantly increased recovery and improved function at 4 weeks compared with no treatment (recovery RR 7.74, 95% CI 1.97 to 30.32; improved function RR 1.53, 95% CI 0.98 to 2.39).[43] The second RCT identified by the review (125 people with rotator cuff disease) compared three treatments: exercise supervised by an experienced physiotherapist plus home exercises plus pain management; arthroscopic decompression plus physiotherapy; and sham laser over 6 weeks.[44] It found that physiotherapy significantly improved Neer score (see glossary, p 1630) compared with sham laser at 6 months (median Neer score 86 with physiotherapy *v* 66 with sham laser: $P < 0.001$). Long term follow up of 110 participants from the RCT found that physiotherapy significantly increased success rate compared with sham laser at 2.5 years (success defined as Neer score > 80: 27/44 [61%] with physiotherapy *v* 7/28 [25%] with sham laser; $P < 0.01$).[45] The third small RCT identified by the review (42 people with adhesive capsulitis and night pain) compared four treatments: subacromial plus intra-articular steroid; Maitland mobilisation (see glossary, p 1629) ; ice therapy; and no treatment. It found no significant difference in pain or range of motion between treatment groups at 3 months (no data reported). The RCT may have lacked power to detect a clinically important difference.[30] **Versus surgical arthoscopic decompression:** See surgery, p 1628. **Versus intra-articular corticosteroids:** See intra-articular corticosteroids, p 1619.

Harms: One RCT comparing physiotherapy versus corticosteroid injection in people with painful stiff shoulders found frequent adverse effects in both groups (32/57 [56%] with physiotherapy *v* 30/57 [53%] with corticosteroid injection). After physiotherapy, these effects lasted longer than 2 days in 13% of people.[34] Fever during treatment was found in 1% of people and local skin irritation in 2% of people; 4% of people reported tingling, radiation of pain down the arm, or slight swelling after treatment.

Comment: Studies on the effects of physiotherapy in shoulder disorders are limited by the lack of standardised approaches. Diverse disorders are considered under the universal term shoulder pain, diverse forms of physiotherapy have been evaluated, and outcome measures and follow up periods vary.

OPTION ULTRASOUND

One RCT identified by a systematic review found that ultrasound significantly improved pain and quality of life at the end of treatment (6 weeks) in people with calcific tendinitis but found no significant difference at 9 months. Four other RCTs identified by the review found no significant difference between ultrasound and sham ultrasound but may have been too small to detect a clinically important difference.

Benefits:

Versus placebo or no treatment: We found one systematic review (search date 2002, 5 RCTs).[42] The review included studies in people with different clinical conditions.[42] The first RCT in the review (180 people with either pain over deltoid on movement or reduced range of shoulder movement, who had failed to respond to 6 sessions of exercise) compared five treatments: pulsed ultrasound; dummy ultrasound; bipolar interferential electrotherapy; dummy electrotherapy; and dummy electrotherapy plus dummy ultrasound.[46] It assessed recovery using a 7 point Likert scale scored from "very large improvement, including recovery" to "very much worse". It found no significant difference in the proportion rating themselves as "very large improvement" between ultrasound and either no treatment or dummy ultrasound at 6 weeks (26% with ultrasound *v* 19% with dummy ultrasound; difference 7%, 95% CI −7% to +20%; 26% with ultrasound *v* 20% with no treatment; difference 6%, 95% CI −16% to +17%). Similarly, it found no significant difference between ultrasound and control for functional status, pain, or range of movement after 12 months. The second RCT in the review (randomised 70 shoulders in 63 people with calcific tendinitis) compared pulsed ultrasound (frequency 890 Hz; intensity 2.5 W/cm^2; pulsed mode 1 : 4) versus sham treatment over the area of calcification.[47] The first 15 treatments were given daily (5 times weekly) and the remainder three times weekly for 3 weeks. The treating therapist was blind to treatment allocation. Nine people (9 shoulders) did not complete the treatment: three in the ultrasound group and six in the sham group, two in the latter because of pain. The RCT found that ultrasound significantly improved pain and quality of life at the end of treatment (6 weeks) but found no significant difference at 9 months (6 weeks: mean improvement in 15 point pain score was 6.4 with ultrasound *v* 1.6 with sham; $P < 0.001$; mean improvement in 10 point quality of life score was 2.6 with ultrasound *v* 0.4 with sham; $P = 0.002$; 9 months: mean improvement in 15 point pain score 5.7 points with ultrasound *v* 4.0 points with sham; $P = 0.23$; mean improvement in 10 point quality of life score 2.4 with ultrasound *v* 1.9 with sham; $P = 0.52$).[47] The third RCT in the review (60 people with rotator cuff lesions) compared five treatments: ultrasound (no details reported); tolmetin plus methyl prednisolone plus lidocaine; methyl prednisolone plus lidocaine; acupuncture; and placebo. It found no significant difference between ultrasound and placebo in pain or treatment success at 4 weeks, although the study may have lacked power to detect clinically important differences (mean pain score on a 100 mm visual analogue scale from baseline to 4 weeks: 48.2 to 41.2 with ultrasound *v* 52.2 to 22.0 with placebo; P value not reported).[48] The fourth RCT in the review (20 people with shoulder

pain and limited movement for > 1 month) found similar proportions of people with either minimal or no pain after 4 weeks between ultrasound (1 MHz, 1.2 W/cm^2, for 6 minutes) compared with sham ultrasound, although the study may have lacked power to detect clinically important effects (7/11 [64%] with ultrasound *v* 4/9 [44%] with placebo; P value not reported).[49] The fifth RCT in the review (61 people with rotator cuff disease without tear) found no significant difference between pulsed ultrasound (1.0 MHz, on : off ratio 1 : 4, intensity 1.0 W/cm^2, 10 minutes) and placebo in pain or function after 12 months (difference in pain scored using index from 1 to 5, no further details: 0.1, 95% CI –0.1 to +0.3; difference in function using Activities of Daily Living index scored from 2 to 10, no further details: –0.2, 95% CI –0.5 to +0.1).[50]

Harms: None of the RCTs included in the review assessed harms of ultrasound.[42]

Comment: In most RCTs, with the exception of the most recent (second RCT in the review[47]), there was considerable heterogeneity of the groups, interventions, and follow up duration among the RCTs. It is not clear whether ultrasound machines were always adequately calibrated before use.

OPTION LASER TREATMENT

One systematic review found three small RCTs. Two of the RCTs found that laser improved pain in rotator cuff tendinitis after 2–3 weeks compared with placebo, and one RCT found no significant difference at 8 weeks between treatments, although it may have lacked power to detect a difference. One additional RCT found that laser significantly increased recovery rates at 1 month compared with placebo.

Benefits: **Versus placebo:** We found one systematic review[42] (search date 2002, 4 RCTs) and one additional RCT.[51] The first RCT in the review (35 people with rotator cuff tendinitis) found no significant difference between continuous irradiation laser and dummy laser (10 minute sessions, twice weekly for 8 weeks) for pain or abduction at 8 weeks (pain on 10 cm visual analogue scale: improved by 3.6 cm with laser *v* 1.2 cm with placebo; P = 0.34; range of movement improved by 36° with laser *v* 29° with placebo; P = 0.23).[52] The second RCT in the review (20 people with rotator cuff tendinitis) compared three treatments: low level infrared laser (5 minutes 3 times weekly for 2 weeks); sham laser; and naproxen. It found that laser significantly reduced pain after 2 weeks compared with sham laser (pain score difference on 10 cm visual analogue scale 2.5%, 95% CI 2.0% to 3.0%).[53] The third RCT in the review (24 people with supraspinatus tendinitis) found that low level laser (9 treatments over a 3 week period) significantly improved pain at 3 weeks compared with dummy laser (pain improved: 80% with laser *v* 20% with dummy laser; P < 0.05).[54] A fourth RCT in the review (40 people with shoulder periarthritis) compared 15 laser treatments with sham laser and is awaiting translation.[55] The additional RCT (91 people with rotator cuff tendinitis) found that laser significantly increased recovery rates at 1 month compared with placebo (42/47 [89%] *v* 18/44 [41%]; ARR 48%, 95% CI 31% to 65%).[51]

Harms: None of the RCTs included in the review assessed harms of laser therapy.[42]

Comment: The quality of studies on the effects of laser treatment in shoulder disorders is limited by the lack of standardised approaches.

OPTION ELECTRICAL STIMULATION

Three small RCTs provided insufficient evidence about the effects of electrical stimulation in people with shoulder pain.

Benefits: **Versus placebo:** We found one systematic review (search date 2002, 3 RCTs).[42] The first RCT in the review (180 people with pain over deltoid or reduced movement not improved by 6 exercise sessions) compared electrical stimulation (bipolar interferential electrical stimulation [see glossary, p 1629]) with dummy electrical stimulation, and compared pulsed ultrasound with dummy ultrasound in a blinded two by two factorial design (see benefits of ultrasound, p 1623). It found no significant difference in the proportion of people who reported a "large improvement" at 6 weeks (AR 17/73 [23%] with electrical stimulation *v* 16/72 [22%] with control; ARR +1%, 95% CI −13% to +15%). The second RCT in the review (60 people with symptomatic calcific tendinitis) found that pulsed electromagnetic field significantly improved calcific tendinitis at 6 weeks compared with sham treatment (see comment). The third RCT in the review (29 people with rotator cuff tendinitis not cured by corticosteroid injection) compared electrical stimulation induced by pulsed electromagnetic fields (5–9 hours/day for 4 weeks) versus placebo, but it did not report on clinical improvement or resolution.

Harms: The review provided no evidence on harms.

Comment: The quality of studies on the effects of electrical treatments in shoulder disorders is limited by the lack of standardised approaches. We found no good evidence that different forms of electrical stimulation produce different effects. Further details of the outcomes in the second RCT in the review should be available when this RCT is translated.[56]

OPTION ICE

One small RCT provided insufficient evidence about the effects of ice.

Benefits: We found one small RCT (42 people with adhesive capsulitis and night pain), which compared four treatments: subacromial plus intra-articular steroid; mobilisation (see glossary, p 1629); ice therapy; and no treatment. It found no significant difference in pain or range of motion between treatment groups at 3 months (no data reported).[30] However, the study may have lacked power to detect clinically important effects of treatment.

Harms: The RCT provided no evidence on harms.

Comment: None.

OPTION INTRA-ARTICULAR GUANETHIDINE

We found no systematic review or RCTs of intra-articular guanethidine in people with non-arthritic shoulder pain.

Benefits: We found no systematic review or RCTs of intra-articular guanethidine in people with non-arthritic shoulder pain (see comment below).

Harms: We found no RCTs.

Comment: We found one RCT (18 people with resistant shoulder pain, including 6 people with rheumatoid arthritis, 5 with osteoarthritis, 5 with frozen shoulder, 1 with rotator cuff tendinitis, and 1 with psoriatic arthritis) comparing intra-articular guanethidine versus intra-articular saline.[57] It found that guanethidine significantly reduced pain compared with placebo after 8 weeks but found no significant difference in the range of movement (pain improvement on a 10 cm visual analogue scale: 36% with guanethidine *v* 16% with placebo; $P < 0.05$; range of abduction 53° at baseline and 52° at 8 weeks with guanethidine *v* 57° at baseline and 56° at 8 weeks with placebo; CI not reported).

OPTION TRANSDERMAL GLYCERYL TRINITRATE

We found no reliable RCTs.

Benefits: We found no systematic review but found one small RCT (20 people with supraspinatus tendinitis), which compared local transdermal glyceryl trinitrate with placebo.[58] The RCT did not report direct comparisons between the treatment and placebo groups (see comment below).

Harms: Headaches were reported in 20% of the treatment group 24 hours after the treatment was started (no comparative figures available).[58]

Comment: The RCT[58] found that glyceryl trinitrate significantly reduced pain at 24 hours compared with baseline (mean pain intensities with active treatment measured on a 0–10 analogue scale: 7.1 at baseline; 4.5 at 24 hours, $P < 0.001$; 2.0 at 48 hours, $P < 0.001$). Changes in the placebo group were not reported. Relief was maintained after 15 days (figures not available). Mean duration of pain was also significantly reduced with active treatment (figures not available). Mean mobility (assessor rated 4 point scale) significantly improved with active treatment (2.0 at baseline *v* 0.1 at 5 days; $P < 0.0001$), but not with placebo (1.2 at baseline *v* 1.2 at 15 days). The significance figures quoted are not direct comparisons. Significance figures for treatment versus placebo were not stated.

OPTION PHONOPHORESIS

We found no RCTs solely in people with shoulder pain.

Benefits: **Versus placebo or sham phonophoresis:** See glossary, p 1629. We found no RCTs solely in people with shoulder pain (see comment below). **Versus other treatment:** We found no RCTs.

Harms: Adverse effects were not reported.

Comment: One RCT (24 people, 13 with rotator cuff tendinitis, 1 with biceps tendinitis, 1 triceps tendinitis, 9 with knee tendinitis) compared active phonophoresis (see glossary, p 1629) using topical dexamethasone, lidocaine (lignocaine), and aqueous gel with placebo phonophoresis using aqueous gel only (5 sessions over 5–10 days).[59] It found no significant difference in perceived pain (visual analogue scale [0 cm = no pain, 10 cm = extreme pain]; pain changed from 2.4 cm to 1.3 cm with active treatment *v* from 2.6 cm to 1.5 cm with placebo; not significant, P value not reported). It found no significant effect for tenderness (localised force needed to elicit pain: 198 g, 95% CI 164 g to 235 g at session 1 to 204 g, 95% CI 170 g to 238 g at session 5 with active phonophoresis *v* 196 g, 95% CI 153 g to 235 g at session 1 to 249 g, 95% CI 221 g to 275 g at session 5 with placebo phonophoresis).

OPTION EXTRACORPOREAL SHOCK WAVE THERAPY

Small and limited RCTs provided insufficient evidence about the effects of extracorporeal shock wave therapy compared with sham treatment or no treatment in people with non-calcifying rotator cuff tendinosis and chronic suprapinatus tendinosis. There was limited evidence of benefit in people with calcific tendinitis.

Benefits: We found no systematic review but found three RCTs.[60–62] The first RCT (115 people with calcific tendinitis) compared three different extracorporeal shock wave therapy regimens (low energy treatment in a single session *v* a single high energy session *v* 2 high energy sessions 1 week apart) versus no treatment.[60] It found that high energy treatment increased subjective improvement of pain compared with low energy treatment or placebo at 3 months (81 people analysed; AR for improvement 14/20 [70%] with 2 high energy sessions *v* 12/20 [60%] with 1 high energy session *v* 6/21 [29%] with low energy treatment *v* 0/20 [0%] with placebo; NNT 2 for high energy treatment compared with placebo, 95% CI 1 to 21 for single session and 1–14 for 2 session treatment). It also found that high energy treatment significantly improved a combined measure of pain and function in activities of daily living compared with placebo (the Constant score difference; $P < 0.0001$). However, results should be interpreted with caution because of the high drop out rate and lack of an intention to treat analysis. The second RCT (74 people with chronic non-calcifying rotator cuff tendinitis) found no significant difference between extracorporeal shock wave therapy (1500 pulses at 0.12 mJ/mm) and sham treatment (3 sessions at monthly intervals) in shoulder pain or night pain at 3 or 6 months (improvement of 50% from baseline for shock wave therapy versus sham at 3 months on SPAD index [see glossary, p 1630]: OR 1.760, 95% CI 0.081 to 0.710; night pain OR 0.94, 95% CI 0.65 to 1.36).[61] The RCT may have lacked power to exclude clinically important effects. The third RCT (40 people with chronic suprapinatus tendinosis, 38 analysed) found no significant difference between extracorporeal shock wave therapy (6000 pulses at 0.11 mJ/mm) and sham treatment (2 sessions weekly for 3 weeks)

in function or pain at 12 weeks (difference treatment *v* control: pain at rest on 10 point visual analogue scale +1.4, 95% CI −1.0 to +3.9; pain during activity on 10 point scale: +2.5, 95% CI −0.81 to +3.33).[62] The RCT may have lacked power to exclude clinically important effects.

Harms: High intensity extracorporeal shock wave therapy can be painful during treatment. Small haematomas were reported in the first RCT, but the incidence was not stated and they could have been related to subcutaneous infiltration of local anaesthetic before treatment.[60]

Comment: The first RCT found no significant difference between two sessions and a single session of extracorporeal shock wave therapy for continued pain (91 people analysed; 23/49 [47%] with 2 sessions *v* 23/42 [55%] with 1 session; RR of continued pain 0.85, 95% CI 0.50 to 1.23).[60] The mechanism of action of extracorporeal shock wave therapy remains unclear. There was radiological disappearance or disintegration of calcium deposits in a significantly greater proportion of people who received high energy treatment than placebo; 77% of those receiving two sessions of treatment had radiological disappearance or disintegration of calcium deposits after 6 months compared with 47% who had one session ($P = 0.05$).[60] Technical factors and the dosing regimen of shock-wave administration are likely to be important to clinical outcome.

OPTION SURGICAL ARTHROSCOPIC DECOMPRESSION/FORCED MANIPULATION

One RCT found that arthroscopic decompression by experienced surgeons followed by physiotherapy improved pain and function compared with sham laser, but not compared with supervised exercises at 6 months and 2.5 years. One small RCT found that forced manipulation plus intra-articular hydrocortisone injection increased recovery rate at 3 months compared with intra-articular hydrocortisone injection alone.

Benefits: **Versus placebo:** We found one RCT (125 people with rotator cuff disease), which compared three treatments: arthroscopic decompression by experienced surgeons plus physiotherapy; exercise supervised by experienced physiotherapist plus home exercises plus pain management; and sham laser for 6 weeks.[44] It found that surgery significantly improved Neer score (see glossary, p 1630) compared with sham laser at 6 months (median Neer score 87 with surgery *v* 66 with sham laser; $P < 0.001$). Long term follow up of 110 people in the RCT found that surgery significantly increased success rate compared with sham laser at 2.5 years (success defined as Neer score > 80: 27/44 [61%] with physiotherapy *v* 7/28 [25%] with sham laser; $P < 0.01$).[45] **Versus physiotherapy:** The same RCT (125 people with rotator cuff disease) found no significant difference in Neer score between arthroscopic decompression and supervised exercises at 6 months (median Neer score 87 with surgery *v* 86 with exercises, difference 4.0; 95% CI −2 to +11).[44] Long term follow up of 110 people found no significant difference in success rates at 2.5 years (success defined as Neer score > 80: 26/38 [68%] with physiotherapy *v* 7/28 [25%] with sham laser; $P < 0.01$).[45] **Forced manipulation plus intra-articular hydrocortisone injection versus intra-articular**

hydrocortisone injection alone: We found one RCT (30 people with frozen shoulder).[63] It found that forced manipulation under sedation plus intra-articular hydrocortisone injection alone increased recovery rates compared with intra-articular hydrocortisone injection at 3 months (recovery defined as no disability: 7/15 [47%] with forced manipulations *v* 2/15 [13%] with control; ARI 33%, 95% CI 1% to 65%).[63]

Harms: The RCTs did not report adverse effects.[44,63]

Comment: None.

OPTION MULTIDISCIPLINARY BIOPSYCHOSOCIAL REHABILITATION

One systematic review found no good quality RCTs in people with shoulder pain of multidisciplinary biopsychosocial rehabilitation.

Benefits: We found one systematic review (search date 2002).[64] If found no good quality RCTs solely in people with shoulder pain of multidisciplinary biopsychosocial rehabilitation (see glossary, p 1629) compared with usual treatment (see comment below).

Harms: The review found no reliable RCTs.[64]

Comment: The systematic review found one low quality RCT (70 people aged 20–55 years) in people with chronic neck and shoulder pain.[64] Co-interventions were not avoided, blinding of therapists was not specified, analysis was not by intention to treat, and treatment groups were dissimilar at baseline. It found no significant difference for multidisciplinary biopsychosocial rehabilitation versus usual treatment. The rehabilitation combined physiotherapy with psychological, behavioural, and educational interventions.

OPTION ARTHROSCOPIC LASER SUBACROMIAL DECOMPRESSION

One systematic review found no RCTs about arthroscopic subacromial decompression with a holmium:YAG laser.

Benefits: We found one systematic review (search date 2000) of arthroscopic subacromial decompression with holmium:YAG laser for people with shoulder pain due to impingement syndrome.[65] It identified no RCTs.

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Interferential electrical stimulation Typically a high frequency current (4000 Hz) amplitude modulated at a lower frequency (60–100 Hz) given in bursts of 4 seconds and repeated for up to 15 minutes.

Maitland mobilisation A graded system of manipulations and exercises intended to increase mobility of specific joints.

Multidisciplinary biopsychosocial rehabilitation Combined physical, social, and psychological rehabilitation.

Phonophoresis The application of topical medication followed by ultrasound to the same area; the theory being that the ultrasound energy drives the medication through the skin.

Shoulder pain

Shoulder pain and disability index (SPADI) A self administered instrument for measuring pain (5 items) and disability (8 items).
Neer score Assesses pain during the past week, clinical testing of shoulder function, active range of movement, and anatomical or radiological examination. Scores range from 0–100 points.

Substantive changes

Subacromial corticosteroid injections One systematic review added;[29] conclusions unchanged.
Subacromial corticosteroid injections One RCT added;[31] conclusions unchanged.
Intra-articular corticosteroid injections One systematic review and one RCT added;[29,32] conclusions unchanged.
Physiotherapy One systematic review added.[42] Intervention recategorised from Unknown effectiveness to Likely to be beneficial.
Ultrasound One systematic review added;[42] conclusions unchanged.
Laser treatment One systematic review added.[42] Intervention recategorised from Unknown effectiveness to Likely to be benefitical.
Electrical stimulation One systematic review added;[42] conclusions unchanged.
Surgical arthroscopic decompression One RCT and follow up study added.[44,45] Intervention recategorised from Unknown effectiveness to Likely to be beneficial.

Tennis elbow

Search date April 2003

Willem Assendelft, Sally Green, Rachelle Buchbinder, Peter Struijs, and Nynke Smidt

QUESTIONS

INTERVENTIONS

Key Messages

- **Topical non-steroidal anti-inflammatory drugs for short term pain relief** One systematic review has found that topical non-steroidal anti-inflammatory drugs improve pain in the short term compared with placebo. Minor adverse effects have been reported. We found no RCTs comparing oral versus topical non-steroidal anti-inflammatory drugs.
- **Oral non-steroidal anti-inflammatory drugs for short term pain relief** One systematic review found limited evidence that an oral non-steroidal anti-inflammatory drug reduced pain and improved function compared with placebo in the short term, although we found limited evidence that it was less effective than corticosteroid injection in the short term.
- **Corticosteroid injections** One systematic review and subsequent RCTs of corticosteroid injections found limited evidence of a short term improvement in symptoms with steroid injections compared with placebo, a local anaesthetic, orthoses (elbow strapping), physiotherapy, or oral non-steroidal anti-inflammatory drugs. We found no good evidence on long term effects of corticosteroids compared with placebo, local anaesthetic, physiotherapy (mobilisation plus massage) or elbow strapping, and found limited evidence that corticosteroid injection was less effective than physiotherapy or oral non-steroidal anti-inflammatory drugs in the long term.
- **Acupuncture** We found insufficient evidence from small, methodologically weak RCTs about effects of needle acupuncture, laser acupuncture, or electro-acupuncture in people with tennis elbow.

Tennis elbow

- **Exercise and mobilisation** One small RCT identified by a systematic review found limited evidence that exercise reduced symptoms at 8 weeks compared with ultrasound plus friction massage. However, we were unable to draw reliable conclusions from this small study.
- **Non-steroidal anti-inflammatory drugs for longer term pain relief** We found insufficient evidence to assess the longer term effects of oral or topical non-steroidal anti-inflammatory drugs, although one RCT found that oral non-steroidal anti-inflammatory drugs were more effective than corticosteroid injections in the long term.
- **Orthoses** One systematic review found insufficient evidence about the effects of orthoses (braces) compared with placebo or physiotherapy. It found limited evidence of a short term improvement in symptoms compared with corticosteroid infections.
- **Surgery** One systematic review found no RCTs of surgical treatment.
- **Extracorporeal shock wave therapy** One systematic review and one subsequent RCT found no significant difference in symptoms between extracorporeal shock wave therapy and sham treatment at 3 months.

DEFINITION Tennis elbow has many analogous terms, including lateral elbow pain, lateral epicondylitis, rowing elbow, tendonitis of the common extensor origin, and peritendinitis of the elbow. Tennis elbow is characterised by pain and tenderness over the lateral epicondyle of the humerus and pain on resisted dorsiflexion of the wrist, middle finger, or both. For the purposes of this review, tennis elbow is restricted to lateral elbow pain or lateral epicondylitis.

INCIDENCE/ PREVALENCE Lateral elbow pain is common (population prevalence 1–3%).[1] Peak incidence is at 40–50 years of age, and for women of 42–46 years of age the incidence increases to 10%.[2,3] The incidence of lateral elbow pain in general practice is 4–7/1000 people a year.[3–5]

AETIOLOGY/ RISK FACTORS Tennis elbow is considered to be an overload injury, typically after minor and often unrecognised trauma of the extensor muscles of the forearm. Despite the title tennis elbow, tennis is a direct cause in only 5% of those with lateral epicondylitis.[6]

PROGNOSIS Although lateral elbow pain is generally self limiting, in a minority of people symptoms persist for 18 months to 2 years and in some cases for much longer.[7] The cost is therefore high, both in terms of lost productivity and healthcare use. In a general practice trial of an expectant waiting policy, 80% of the people with elbow pain of already greater than 4 weeks' duration had recovered after 1 year.[8]

AIMS OF INTERVENTION To reduce lateral elbow pain and improve function, with minimal adverse effects.

OUTCOMES Pain at rest, with activities and resisted movements (visual analogue scale or Likert scale); function (validated disability questionnaire, includes 30 point Disabilities of the Arm, Shoulder, and Hand questionnaire, or visual analogue scale or Likert scale); quality of life (validated questionnaire); grip strength (dynamometer); return to work, normal activities, or both; overall participant reported improvement; adverse effects (participant or researcher report); Roles–Maudsley subjective pain score where 1 = excellent, no

pain, full movement, full activity; 2 = good, occasional discomfort, full movement and full activity; 3 = fair, some discomfort after prolonged activity; and 4 = poor, pain limiting activities.

METHODS *Clinical Evidence* search and appraisal April 2003. We included all RCTs and quasi-RCTs of any of the listed interventions in (1) people older than 16 years of age with (2) lateral elbow pain for greater than 3 weeks' duration and (3) no history of significant trauma or systemic inflammatory conditions such as rheumatoid arthritis. We included trials in people with various soft tissue diseases and pain due to tendinitis at all sites, provided that the lateral elbow pain results were presented separately or that greater than 90% of people had lateral elbow pain.

QUESTION What are the effects of treatments?

OPTION ACUPUNCTURE

Sally E Green and Rachelle Buchbinder

We found insufficient evidence from small, methodologically weak RCTs about effects of needle acupuncture, laser acupuncture, or electro-acupuncture in people with tennis elbow.

Benefits: **Versus placebo** We found one systematic review (search date 2001, 4 RCTs, 239 people with tennis elbow defined as lateral elbow pain aggravated by wrist and finger dorsiflexion)[9] and one subsequent RCT.[10] None of the RCTs evaluated the effects of acupuncture on quality of life or return to work. The review found that there were important problems with the methodology of the included trials (particularly small populations, uncertain allocation concealment, and substantial loss to follow up) and clinical differences between trials. Results could not be combined in a meta-analysis. The first RCT (48 people) comparing needle acupuncture with sham acupuncture (with needles not inserted) found that acupuncture significantly increased the duration of pain relief and significantly increased the proportion of people with at least 50% reduction in pain after one treatment (duration of pain relief: WMD 18.8 hours, 95% CI 10.1 hours to 27.5 hours; pain reduction: 19/24 [79%] with acupuncture *v* 6/24 [25%] with sham treatment; RR 3.2, 95% CI 1.5 to 6.5; see comment below).[11] The second RCT found that needle acupuncture significantly increased the proportion of people with a self reported good or excellent result compared with sham treatment (22/44 [50%] with needle acupuncture *v* 8/38 [21%] with sham treatment; RR 2.4, 95% CI 1.2 to 4.7) after 10 treatments.[12] However, it found no significant difference in the longer term (after 3 or 12 months). The third RCT found no significant difference between laser acupuncture and sham treatment in the proportion of participants reporting no improvement or worsening of symptoms (after 10 sessions: 6/23 [26.1%] with laser *v* 5/26 [19.2%] with sham treatment; RR 1.36, 95% CI 0.48 to 3.86; at 3 months: 2/22 [9.1%] with laser *v* 6/25[24%] with sham treatment; RR 0.38, 95% CI 0.09 to 1.69; after 12 months: 1/18 [5.6%] *v* 0/21 [0%] with sham treatment; RR 3.47, 95% CI 0.15 to 80.36).[9] The fourth RCT found no significant difference in cure rate (definition of cure not reported) between vitamin B12 injection plus

acupuncture and vitamin B12 injection alone (risk of cure with B12 injection alone: RR 0.44, 95% CI 0.15 to 1.29).[9] The subsequent RCT (45 people) compared 10 treatments of acupuncture with sham acupuncture.[10] It found significantly greater reductions in pain intensity and functional impairment with acupuncture compared with sham treatment at 2 weeks (on 30 mm visual analogue scale pain improved by 8.43 with acupuncture *v* 4.89 with sham treatment, $P < 0.05$; Disabilities of the Arm, Shoulder, and Hand questionnaire improved by 23.70 with acupuncture *v* 8.54 with sham treatment, $P < 0.05$). **Manual versus electro-acupuncture:** We found one small RCT (20 people) comparing manual versus electro-acupuncture and assessed pain immediately following a course of six treatments over 2 weeks.[13] It found that electro-acupuncture significantly reduced pain compared with manual acupuncture (pain scored on 10 cm visual analogue scale; pain reduction: 50% with electro-acupuncture *v* 32% with manual acupuncture, $P < 0.001$). We found no RCT on the effect of acupuncture on quality of life, strength, or return to work.

Harms: Long term follow up of one RCT[10] found that one person (1/45) withdrew due to pain from acupuncture.[14] It found no other adverse events. The other RCTs did not report on harms.

Comment: **Versus placebo:** Although statistically significant, an increase of 18 hours in pain relief after needle acupuncture may not be clinically important.[9]

OPTION ORTHOSES (BRACES)

Willem JJ Assendelft and Peter AA Struijs

One systematic review found insufficient evidence about the effects of orthoses (braces) compared with placebo or physiotherapy. It found limited evidence of a short term improvement in symptoms compared with corticosteroid injections.

Benefits: We found one systematic review (search date 1999).[15] Results were not pooled because of considerable heterogeneity among trials. **Versus placebo or no treatment:** The review identified no RCTs.[15] We found no subsequent RCTs. **Versus corticosteroid injections:** The review found two RCTs comparing orthoses versus corticosteroid injections.[15] The first RCT (16 people) compared an orthotic device versus corticosteroid injections. It found no significant difference in short term improvement in pain (improvement: 27.1 with corticosteroid *v* 13.6 with orthotic device; 100 mm visual analogue score difference +13.5, 95% CI −4.6 to +31.6).[15] The second RCT (70 people, 4 treatment groups) found that corticosteroid injection significantly increased the proportion of people having a good or excellent self reported outcome at 2 weeks compared with a splint or elbow band but found no significant difference at 6 or 12 months (2 weeks: AR 34/37 [92%] pooled results for splint and elbow band group *v* 6/19 [32%] with injection; RR 2.9, 95% CI 1.8 to 5.7; 6 months: 19/37 [51%] *v* 14/19 [74%]; RR 0.7, 95% CI 0.46 to 1.05; 12 months: 22/37 [59%] *v* 13/19 [68%]; RR 0.9, 95% CI 0.6 to 1.03).[15] **Versus physiotherapies:** The review found one RCT (84 people) comparing an elbow support

versus an unspecified physical therapy.[15] It found no significant difference in short term self reported satisfaction (23/49 [47%] with elbow support *v* 16/35 [46%] with unspecified physical therapy; RR 1.03, 95% CI 0.64 to 1.64). This study provided insufficient information to assess pain improvement. It also had a withdrawal rate of 30%. **Versus non-steroidal anti-inflammatory cream:** The review found one RCT (17 people) comparing a non-steroidal anti-inflammatory cream (details of cream not reported in review) versus an elbow strap.[15] It found greater short term pain reduction with the cream (WMD [scale not specified] 0.38, 95% CI 0.02 to 0.70).

Harms: The review did not report on harms.[15]

Comment: The review reported that validity scores for the RCTs ranged from low to medium.[15] The review identified three RCTs comparing adding an orthotic device to corticosteroid injections or ultrasound. All three RCTs reported only short term results and there were insufficient data or the power of the study was too low to indicate the effect of orthoses.

OPTION CORTICOSTEROID INJECTIONS

Willem JJ Assendelft and Nynke Smidt

One systematic review and subsequent RCTs of corticosteroid injections found limited evidence of a short term improvement in symptoms with steroid injections compared with placebo, a local anaesthetic, orthoses (elbow strapping), physiotherapy, or oral non-steroidal anti-inflammatory drugs. We found no good evidence on long term effects of corticosteroids compared with placebo, local anaesthetic, physiotherapy (mobilisation plus massage), or elbow strapping, and found limited evidence that corticosteroid injection was less effective than physiotherapy or oral non-steroidal anti-inflammatory drugs in the long term.

Benefits: We found one systematic review (search date 1999)[16] and two subsequent RCTs.[17,18] None of the RCTs evaluated the effects of corticosteroid injections on quality of life or return to work. **Versus placebo or no treatment:** The review identified two RCTs comparing corticosteroid injection (1 mL methylprednisolone acetate) versus injection of saline solution. The first RCT (29 people in smallest group; see comment below) found that corticosteroid significantly increased short term global improvement compared with saline injection (timescale not further specified; RR 0.11, 95% CI 0.04 to 0.33). The RCT did not measure pain or grip strength. The second RCT (10 people in smallest group) found no significant difference in short term pain, global improvement, or grip strength. The first subsequent RCT (39 people with symptoms > 4 weeks) compared corticosteroid injection versus a control injection.[17] All people received rehabilitation. It found that corticosteroid injection significantly improved pain compared with control from 8 weeks to 6 months (improvement on 100 point visual analogue scale: 24.3 with steroid injection *v* 8.9 with control injection; P = 0.04; CI not reported). It found no significant difference in other pain outcomes or grip strength. The second subsequent RCT (59 people in smallest group) compared corticosteroid injection with no treatment and

with physiotherapy.[18] It found corticosteroid injection significantly improved mean "main complaint" and functional disability at 3 and 6 weeks compared with no treatment (at 6 weeks, mean difference in "main complaint" 24%, 95% CI 14% to 35%). It found no significant difference at 12, 26, and 52 weeks (at 52 weeks, mean difference in "main complaint" −9%, 95% CI −19% to +2%). **Versus local anaesthetic:** The review identified three RCTs comparing corticosteroid injections versus local anaesthetic alone.[16] Two RCTs (18 and 35 people in smallest groups) found greater global improvement in the short term (4 weeks; follow up not stated) with corticosteroid injections (1 mL hydrocortisone acetate 25 mg and 1 mL methylprednisolone acetate 10 mg), but data could not be pooled because of heterogeneity. The third RCT (7 people in smallest group) reported only medium term results. It found no significant difference in global improvement at 9–17 weeks (chance of not getting a good outcome: RR 0.97, 95% CI 0.41 to 2.32). **Versus orthoses:** See benefits of orthoses, p 1636. **Versus physiotherapies:** The review identified two RCTs comparing corticosteroid injections (1 mL triamcinolone acetate 1% plus 1 mL lidocaine [lignocaine]) versus physiotherapies,[16] and we found one additional RCT.[18] The first RCT identified by the review (53 people in smallest group) found that friction massage and a manipulation technique significantly reduced the chance of overall improvement compared with steroid injection (overall improvement: RR 0.45, 95% CI 0.29 to 0.69). It found no significant difference in any outcome at 52 weeks. The review was unable to report measured results for the second RCT (12 people in smallest group). The additional RCT (59 people in smallest group) compared a corticosteroid injection with no treatment and with physiotherapy consisting of nine sessions of ultrasound, deep friction massage, and an exercise programme over 6 weeks (see versus placebo or no treatment above).[18] It found that corticosteroid injection significantly improved the "main complaint" and functional disability at 3 and 6 weeks compared with physiotherapy (at 6 weeks, mean difference in "main complaint" 20%, 95% CI 10% to 31%). However, there was no significant difference at 12 weeks, and at 26 and 52 weeks physiotherapy significantly improved the "main complaint" compared with corticosteroid injection (at 52 weeks, mean difference in "main complaint" 15%, 95% CI 5% to 25%). **Versus non-steroidal anti-inflammatory drugs:** See oral non-steroidal anti-inflammatory drugs versus corticosteroid injections, p 1639.

Harms: The review (8 RCTs) found no significant difference in adverse events between corticosteroid injections and control interventions (including facial flushes, post-injection pain, and local skin atrophy).[16] However, the review did not report P values.

Comment: The review provided the number of people in the smallest group for each trial rather than the total number of people in the trial. The review found that in the longer term there was a high rate of improvement in all groups.[16] It found that in general the quality of the methodology of the RCTs was poor to modest. The corticosteroid suspensions used in these trials were methylprednisolone (2 RCTs), triamcinolone (4 RCTs), betamethasone (2 RCTs), hydrocortisone (5 RCTs), and dexamethasone (1 RCT). In one RCT, two different

substances were used. The RCTs with longer term results for corticosteroid compared with non-steroidal anti-inflammatory drugs and with physiotherapy suggested that a steroid injection improved outcomes in the short term but increased recurrences in the medium term.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

Sally E Green and Rachelle Buchbinder

One systematic review has found that topical non-steroidal anti-inflammatory drugs improve symptoms in the short term compared with placebo. Minor adverse effects have been reported. The review found limited evidence that oral non-steroidal anti-inflammatory drugs improved symptoms in the short term compared with placebo, although we also found limited evidence that it was less effective than corticosteroid injection in the short term. We found insufficient evidence to assess the longer term effects of non-steroidal anti-inflammatory drugs compared with placebo, although one RCT found that oral non-steroidal anti-inflammatory drugs were more effective than corticosteroid injections in the long term. We found no RCTs comparing oral versus topical non-steroidal anti-inflammatory drugs.

Benefits: We found one systematic review (search date 2001)[19] and no subsequent RCTs. None of the RCTs in the review evaluated the effect of non-steroidal anti-inflammatory drugs (NSAIDs) on return to work or quality of life. **Topical NSAIDs versus placebo:** The review found that topical NSAIDs significantly improved pain at up to 4 weeks compared with placebo and significantly reduced participant opinion of no benefit (3 RCTs, 130 people; pain: WMD –1.88, 95% CI –2.54 to –1.21; scale 0 [no pain] to 10 [maximum pain]; no benefit: 2 RCTs; RR 0.39, 95% CI 0.23 to 0.66).[19] Inclusion of unblinded trials did not significantly change the results. It found no significant differences between topical NSAIDs and placebo for grip strength (reported as non-significant, further data not reported) or range of motion (RR for limitation of movement 1.01, 95% CI 0.80 to 1.28). It found that NSAIDs significantly improved the doctor's opinion of effect on pain and in tenderness with placebo (pain: WMD –1.88, 95% CI –2.54 to –1.21; scale 0 [no pain] to 10 [maximum pain]; RR for tenderness 0.83, 95% CI 0.70 to 0.99). The topical NSAIDs used were diclofenac (2 RCTs) and benzydamine (1 RCT). **Oral NSAIDs versus placebo:** The review found two RCTs.[19] The RCTs were not pooled because one reported means and standard deviations and the other medians and ranges. One RCT found limited evidence that diclofenac improved short term pain and function compared with placebo but did not assess long term results (WMD –13.9, 95% CI –23.2 to –4.6 on 100 point scale). The second RCT found no significant difference in pain over 28 days, 6 months, or 1 year or for function at 6 months or 1 year (median [range] pain score, 28 days: 4 [2–6] with naproxen *v* 3.5 [2–6] with placebo; 6 months: 1 [0–3] with NSAIDs *v* 1 [0–2.2] with placebo; 12 months: 0 [0–2] with NSAIDs *v* 0 [0–2] with placebo; function at 6 months: 0 [0–2.75] with NSAIDs *v* 0.5 [0–2] with placebo; at 12 months: 1 [0–1] with NSAIDs *v* 0 [0–0] with placebo). **Oral NSAIDs versus corticosteroid injection:** The review found three RCTs.[19] Only two RCTs were included in the

meta-analysis because of incomplete reporting of results. The first of these RCTs compared 20 mg methylprednisolone plus lidocaine versus 500 mg naproxen, and the second compared 6 mg betamethasone plus prilocaine plus placebo tablets versus 500 mg naproxen (initial high dose, then 250 mg). Meta-analysis of self reported perception of benefit found a significant difference in favour of injection at 4 weeks (RR of participant perceived benefit of injection 3.06, 95% CI 1.55 to 6.06). One RCT was not included in the meta-analysis because of skewed data; it found less functional limitation at 4 weeks in the injection group (median [range] 0 [0–2] with injection *v* 3 [1–5] with NSAIDs). The greater benefit of injection compared with naproxen was only found in the short term. The largest RCT (53 people in smallest group) found significantly greater improvement in pain at 26 weeks with an NSAID (RR 1.71, 95% CI 1.17 to 2.51). It found no significant difference in grip strength and results were not reported for global improvement.

Harms: **Topical NSAIDs:** One RCT identified by the review found that topical NSAIDs significantly increased any adverse event compared with placebo (RR 2.26, 95% CI 1.04 to 4.94).[20] Adverse effects were mild and no one was withdrawn from the study. Adverse effects reported in the published trials were foul breath and minor skin irritation. **Oral NSAIDs:** One trial of oral NSAIDs found an increased risk of abdominal pain and diarrhoea (pain: RR 3.17, 95% CI 1.35 to 7.41; diarrhoea: RR 1.92, 95% CI 1.08 to 3.14). One systematic review (search date 1994, 12 RCTs of NSAIDs in a variety of disorders)[21] found that the overall relative risk of complications from oral NSAIDs was 3.0–5.0. Adverse effects were predominantly gastrointestinal. See important differences between available NSAIDs in the NSAIDs chapter, p 1551.

Comment: Both topical and oral NSAIDs may provide short term relief of pain in tennis elbow, although topical NSAIDs may be associated with fewer adverse effects. Further placebo controlled and comparative trials of oral compared with topical NSAIDs would help to clarify the effects of NSAIDs in the treatment of tennis elbow. Few trials used intention to treat analysis, and the sample size of most was small (populations range from 18–128 people for trials included in the meta-analysis).[19]

OPTION EXERCISE AND MOBILISATION

Willem JJ Assendelft and Nynke Smidt

One small RCT identified by a systematic review found limited evidence that exercise reduced symptoms at 8 weeks compared with ultrasound plus friction massage. However, we were unable to draw reliable conclusions from this small study. We found no RCTs of mobilisation.

Benefits: We found one systematic review (search date 1999, 1 RCT, 19 people).[22] The small RCT found that exercise significantly improved symptoms at 8 weeks compared with ultrasound plus friction massage (SMD –0.95, 95% CI –1.64 to –0.26). Four other RCTs were either of poor validity or provided insufficient data on relevant outcome measures. We found no RCTs of mobilisation.

Harms: No harms were described in the systematic review.[22]

Comment: None.

OPTION EXTRACORPOREAL SHOCK WAVE THERAPY

Rachelle Buchbinder and Sally E Green

One systematic review and one subsequent RCT found no significant difference in symptoms between extracorporeal shock wave therapy and sham treatment at 3 months.

Benefits: **Versus placebo:** We found one systematic review (search date 2001, 2 RCTs, 286 people)[23] and one subsequent RCT comparing extracorporeal shock wave therapy (ESWT) versus placebo.[24] Both RCTs identified by the review had similar study populations (mean age 41.9–46.9 years, slightly more women) with chronic symptoms (mean duration 21.9–27.6 months) who had not improved on at least 6 months of conservative treatment, including non-steroidal anti-inflammatory drugs, injections, brace or taping, casting, and physiotherapy. The frequency, doses, and technique of ESWT application were similar in both trials. The first RCT in the review used 1000 impulses of 0.08 mJ/mm^2 of ESWT at weekly intervals for 3 weeks.[23] The second RCT in the review used "low energy" ESWT with 2000 pulses under local anaesthesia (3 mL mepivacaine 1%) at weekly intervals for 3 weeks using device dependent energy flux density (ED+) between 0.07 and 0.09 mJ/mm^2.[23] The review found no significant difference in treatment failure (defined as Roles–Maudsley subjective pain score of 4) between ESWT and placebo at 6 weeks and at 1 year (6 weeks: RR 0.40, 95% CI, 0.08 to 1.91; 1 year: RR 0.44, 95% CI 0.09 to 2.17). After 6 weeks, it found no significant improvement in pain at rest, pain with resisted wrist extension, or pain with resisted middle finger extension (pain scored out of 100 points; pain at rest: WMD −11.4, 95% CI −26.1 to +3.3; pain with resisted wrist extension: WMD −16.2, 95% CI −47.8 to +15.4; pain with resisted middle finger extension: WMD −20.5, 95% CI −56.6 to +15.6). At 12 and 24 weeks, it found no significant difference between treatments in pain at 12 to 24 weeks (pain scored out of 100 points; improvement in pain at rest: WMD −14.7, 95% CI −35.4 to +6.1; pain with resisted wrist extension: WMD −14.70, 95% CI −43.4 to +14.0; pain with resisted middle finger extension: WMD −21.1, 95% CI −58.3 to +16.1). The effect of ESWT on function, quality of life, and return to work was not reported. The effect of ESWT on grip strength was reported in both trials but the results were difficult to interpret in one RCT. The other RCT found no difference in improvement in grip strength between groups at 6 weeks, 12 weeks, or 1 year. The subsequent RCT (75 people) found no significant difference between ESWT (1500 pulses at 0.18 mJ/mm^2 at weekly intervals for 3 weeks) and sham treatment in pain at 3 months (50% or greater improvement in pain measured on 10 mm visual analogue scale: 14/40 [35%] with ESWT *v* 12/35 [34%] with sham; RR 1.3, 95% CI 0.75 to 2.4).[24]

Harms: One RCT in the review did not report adverse events.[23] The other RCT in the review reported significantly more adverse effects in the EWST group compared with placebo (OR 4.3, 95% CI 2.9 to 6.3). However, there were no treatment discontinuations or dosage adjustments related to adverse effects. The most frequently

reported adverse effects in the ESWT treated group were transitory reddening of the skin (21.1% with ESWT *v* 4.7% with placebo); pains (4.8% with ESWT *v* 1.7% with placebo); and petechiae, bleeding, or haematomas (4.5% with ESWT *v* 1.7% with placebo). Migraine occurred in four people and syncope in three people after ESWT, compared with no people treated with placebo. No significant adverse effects were reported in the subsequent RCT.[24]

Comment: The two RCTs in the review found conflicting results.[23] When data from both trials were pooled, the benefits observed in the first trial were no longer apparent. This RCT, which found a significant improvement, had uncertain allocation concealment and no analysis of early withdrawals (15/115 [13%]).

OPTION SURGERY

Rachelle Buchbinder and Sally E Green

One systematic review found no RCTs of surgical treatment.

Benefits: We found one systematic review (search date 2001), which identified no RCTs.[25] We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: Various open and percutaneous operations for lateral elbow pain have been described based upon the surgeon's concept of the pathological entity. The most commonly described surgical procedures involve excision of abnormal tissue (comprising microscopic degeneration, rupture, or both, and immature reparative tissue) within the origin of extensor carpi radialis brevis, release of the extensor carpi radialis brevis from the lateral epicondyle region, or both. Additional procedures include release of the anterior capsule, removal of inflamed synovial folds, resection of a third of the orbicular ligament, debridement of articular damage, release of the posterior interosseous nerve, denervation of the lateral epicondyle, denervation of the radiohumeral joint, and excision of a radiohumeral bursa.[26–38]

Substantive changes

Acupuncture One RCT added;[13] categorisation unchanged.
Extracorporeal shock wave therapy One additional RCT found no significant difference in pain between ESWT and sham treatment.[24] ESWT recategorised as Unlikely to be beneficial.

QUESTIONS

INTERVENTIONS

*Although we found no RCTs on the effects of these interventions, there is a general consensus that they are effective

Key Messages

Prevention

- **Acetazolamide** One systematic review has found that acetazolamide reduces the incidence of acute mountain sickness compared with placebo. The review found that acetazolamide caused polyuria and/or paraesthesia in over a third of people. We found no good RCTs comparing acetazolamide versus dexamethasone.
- **Dexamethasone** One systematic review and further RCTs have found that dexamethasone is more effective than placebo for preventing acute mountain sickness. However, the review found that adverse effects (including depression) occurred in a quarter of people on withdrawal of dexamethasone. We found no good RCTs comparing dexamethasone versus acetazolamide.
- **Slow ascent (or acclimatisation)** We found no RCTs evaluating different rates of ascent or acclimatisation. One non-randomised trial, observational studies, and consensus opinion suggest that slower ascent reduces the risk of acute mountain sickness compared with more rapid ascent.

Treatment

- **Descent compared with resting at the same altitude** We found no RCTs on the effects of descent compared with resting at the same altitude in people with acute mountain sickness. Consensus opinion suggests that people with acute mountain sickness should descend if possible. However, we found no RCTs examining effects of different distances of descent, or about the balance of risks and benefits in people who might find it difficult to descend.

Altitude sickness

- **Dexamethasone** One small RCT in climbers with symptoms and signs of acute mountain sickness found that dexamethasone reduced mean acute mountain sickness scores compared with placebo.
- **Acetazolamide** We found no good RCTs on the effects of acetazolamide compared with placebo for treating people with acute mountain sickness.

DEFINITION

Altitude sickness (or high altitude illness) includes acute mountain sickness, high altitude pulmonary oedema, and high altitude cerebral oedema. Acute mountain sickness typically occurs at altitudes greater than 2500 metres (about 8000 feet) and is characterised by the development of some or all of the symptoms of headache, weakness, fatigue, listlessness, nausea, insomnia, breathlessness on exertion, suppressed appetite, and peripheral oedema. Symptoms may take days to develop or may occur within hours, depending on the rate of ascent and the altitude attained. More severe forms of altitude sickness have been identified. High altitude pulmonary oedema is characterised by symptoms and signs typical of pulmonary oedema such as shortness of breath, coughing, and production of frothy or blood stained sputum. High altitude cerebral oedema is characterised by confusion, ataxia, and decreasing conscious level. This review covers only acute mountain sickness.

INCIDENCE/ PREVALENCE

The incidence of acute mountain sickness increases with absolute height attained and with the rate of ascent. One survey in Taiwan (93 people ascending above 3000 metres) found that 27% of people experienced acute mountain sickness.[1] One survey in the Himalayas (278 unacclimatised hikers at 4243 metres) found that 53% of people developed acute mountain sickness.[2] One survey in the Swiss Alps (466 climbers at 4 altitudes between 2850 metres and 4559 metres) found the prevalence of two or more symptoms of acute mountain sickness to be 9% of people at 2850 metres; 13% of people at 3050 metres; 34% of people at 3650 metres; and 53% of people at 4559 metres.[3]

AETIOLOGY/ RISK FACTORS

The Himalayan study identified the rate of ascent and absolute height attained as the only risk factors.[2] It found no evidence of a difference in risk between men and women, or that previous episodes of altitude experience, load carried, or recent respiratory infections affected risk. However, the study was too small to exclude these as risk factors or to quantify risks reliably. One systematic review of RCTs (search date 1999) comparing prophylactic agents versus placebo found that, among people receiving placebo, the incidence of acute mountain sickness was higher with a faster rate of ascent (54% of people at a mean ascent rate of 91 metres/hour; 73% at a mean ascent rate of 1268 metres/hour; 89% at a simulated ascent rate in a hypobaric chamber of 1647 metres/hour).[4]

PROGNOSIS

We found no reliable data on prognosis. It is widely held that if no further ascent is attempted, the symptoms of acute mountain sickness tend to resolve over a few days. We found no reliable data about long term sequelae in people whose symptoms have completely resolved.

AIMS OF INTERVENTION

To prevent acute mountain sickness; to achieve rapid resolution of acute mountain sickness; with minimal adverse effects.

OUTCOMES **Prevention:** incidence of acute mountain sickness, incidence of individual symptoms. **Treatment:** clinical resolution of acute mountain sickness, resolution of individual symptoms.

METHODS *Clinical Evidence* search and appraisal May 2003. We excluded RCTs with fewer than 10 people in each treatment arm, and crossover trials that did not report pre-crossover results. We excluded RCTs if rates of ascent and absolute altitude were different between treatment groups. We excluded individual RCTs that examined effects of simulated altitude in hypobaric chambers. However, one systematic review (search date 1999; 18 RCTs) included three RCTs that simulated altitude in this way.[4] We have not adjusted its meta-analysis to exclude these studies.

QUESTION What are the effects of interventions to prevent acute mountain sickness? New

OPTION SLOW ASCENT (OR ACCLIMATISATION)

We found no RCTs evaluating different rates of ascent or acclimatisation. One non-randomised trial, observational studies, and consensus opinion suggest that slower ascent reduces the risk of acute mountain sickness compared with more rapid ascent.

Benefits: We found no RCTs (see comment below).

Harms: We found no RCTs. Slow ascent is, in itself, unlikely to be harmful.

Comment: We found one non-randomised controlled trial (60 male soldiers without previous high altitude exposure) comparing faster versus slower ascent to an altitude of 3500 metres.[5] Faster ascent was achieved by flying people to the target altitude (ascent time 1 hour) and slower ascent by driving them (ascent time 4 days). The trial found that slower ascent reduced the risk of any symptom of acute mountain sickness compared with faster ascent ("one symptom or another": 51% with slower ascent *v* 84% with faster ascent; P value not reported). Observational data suggest that faster ascent is a risk factor for acute mountain sickness (see aetiology/risk factors, p 1646).[4] Consensus opinion suggests that slower ascent helps to prevent acute mountain sickness.

OPTION ACETAZOLAMIDE

One systematic review has found that acetazolamide reduces the incidence of acute mountain sickness compared with placebo. The review found that acetazolamide caused polyuria and/or paraesthesia in over a third of people. We found no good RCTs comparing acetazolamide versus dexamethasone.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 9 RCTs, 295 people) which compared acetazolamide (500 mg or 750 mg daily) versus placebo at altitudes above 4000 metres.[4] It found that acetazolamide significantly increased the proportion of people who remained free of acute mountain sickness

compared with placebo (AR for freedom from acute mountain sickness: 67% of people with acetazolamide *v* 42% with placebo; RR 1.58, 95% CI 1.27 to 1.96; see comment below). **Versus dexamethasone:** We found no systematic reviews or RCTs of sufficient quality.

Harms: The review found that polyuria and paraesthesia were significantly more common with acetazolamide compared with placebo (AR for polyuria: 33% with acetazolamide *v* 6% with placebo; RR 4.24, 95% CI 1.92 to 9.37; AR for paraesthesia: 43% with acetazolamide *v* 10% with placebo; RR 4.02, 95% CI 1.71 to 9.43).[4] The review reported that the adverse effects with acetazolamide were of "minor severity": the term "minor" was not further defined.[4]

Comment: The review undertook subgroup analysis for different doses of acetazolamide.[4] It found that acetazolamide 750 mg was significantly more effective than placebo, but it found no significant difference between acetazolamide 500 mg and placebo (AR for freedom from acute mountain sickness: 66% of people with acetazolamide 750 mg *v* 32% with placebo; RR 2.18, 95% CI 1.52 to 3.15; AR for freedom from acute mountain sickness: 68% of people with acetazolamide 500 mg *v* 54% with placebo; RR 1.22, 95% CI 0.93 to 1.59). However, the analysis comparing 500 mg acetazolamide versus placebo may have lacked power to exclude clinically important effects. Ascent rates varied among RCTs, and the lack of effect of acetazolamide 500 mg versus placebo may be due to lower ascent rates in RCTs included in the analysis at that dosage.

OPTION DEXAMETHASONE

One systematic review and further RCTs have found that dexamethasone is more effective than placebo for preventing acute mountain sickness. However, the review found that adverse effects (including depression) occurred in a quarter of people on withdrawal of dexamethasone. We found no good RCTs comparing dexamethasone versus acetazolamide.

Benefits: **Versus placebo:** We found one systematic review,[4] two additional RCTs (reported in one publication),[6] and one subsequent RCT.[7] The systematic review (search date 1999, 8 RCTs, 161 people) compared dexamethasone (8, 12, or 16 mg daily) versus placebo at altitudes above 4000 metres.[4] It found that dexamethasone significantly increased the proportion of people who were free of acute mountain sickness compared with placebo (AR for freedom from acute mountain sickness: 62% with dexamethasone *v* 26% with placebo; RR 2.50, 95% CI 1.71 to 3.66). The two additional RCTs were excluded from the review because they compared dexamethasone versus placebo at altitudes below 4000 metres.[6] Both RCTs were undertaken in health professionals aged 18 to 65 years, who normally lived at altitudes less than 450 metres, and who were participating in continuing medical education programmes in the Rocky Mountains. The first additional RCT (73 people; altitude 2700 metres) found that dexamethasone (4 mg every 6 hours for a total of 6 doses) significantly reduced the incidence of acute mountain sickness compared with placebo (3/38 [8%] developed acute mountain sickness with dexamethasone *v* 14/35 [40%] with

placebo; ARR 32%, 95% CI 14% to 50%; RR 0.20, 95% CI 0.06 to 0.65).[6] The second additional RCT (50 people; altitude 2050 metres) found no significant difference in the incidence of acute mountain sickness between dexamethasone (4 mg every 6 hours for a total of 6 doses) and placebo (5/25 [20%] with dexamethasone *v* 4/25 [16%] with placebo; ARI +4%, 95% CI −17% to +25%; RR 1.25, 95% CI 0.62 to 1.78; see comment below).[6] The subsequent RCT (50 men, aged 19–24 years, normally resident at sea level) compared five different treatments (3 different dosages of prednisolone, dexamethasone, and placebo).[7] One arm (10 men) compared dexamethasone 0.5 mg daily versus placebo.[7] Acute mountain sickness was assessed using a scoring system based on symptoms and clinical assessment. People in the RCT were airlifted to an altitude of 3450 metres. The RCT found that dexamethasone significantly reduced the mean acute mountain sickness score after 2 days compared with placebo ($P < 0.001$, results presented graphically, further details not reported). **Versus acetazolamide:** We found no systematic reviews or RCTs of sufficient quality.

Harms: The review reported that adverse effects, mainly depression, occurred on withdrawal of dexamethasone.[4] The review found that withdrawal of dexamethasone significantly increased the incidence of all adverse effects compared with placebo (adverse reactions on withdrawal: 27% of people with dexamethasone *v* 0% with placebo; RR 4.45, 95% CI 1.08 to 18.3). The severity of depression was not reported.[4]

Comment: In the RCT conducted at 2050 metres, event rates were low in both groups, probably because of the relatively low altitude.[6] The study may therefore have lacked power to detect clinically important differences between dexamethasone and placebo.

QUESTION What are the effects of treatments for acute mountain sickness? New

OPTION ACETAZOLAMIDE

We found no good RCTs on the effects of acetazolamide compared with placebo for treating people with acute mountain sickness.

Benefits: We found no systematic reviews or RCTs of sufficient quality.

Harms: We found no RCTs. See harms of acetazolamide in prevention, p 1648.

Comment: None.

OPTION DEXAMETHASONE

One small RCT in climbers with symptoms and signs of acute mountain sickness found that dexamethasone reduced mean acute mountain sickness scores compared with placebo.

Benefits: We found no systematic review. We found one RCT (35 climbers arriving at an alpine hut with symptoms of acute mountain sickness, altitude of 4559 metres) comparing dexamethasone (8 mg initially,

then 4 mg after 6 and 12 hours) versus placebo without concurrent descent in either group.[8] Acute mountain sickness was assessed using a scoring system based on symptoms and clinical assessment (score 0 to 14, where 14 was the most severe). The RCT found that after treatment for 12 hours at the same altitude, dexamethasone improved mean symptoms scores significantly more than placebo (improvement in mean score: 4.1 with dexamethasone *v* 0.4 with placebo; difference between groups 3.7, 95% CI 2.2 to 5.3).

Harms: The RCT did not report on harms.[8] See harms of dexamethasone in prevention, p 1649.

Comment: None.

OPTION DESCENT COMPARED WITH RESTING AT THE SAME ALTITUDE

We found no RCTs on the effects of descent compared with resting at the same altitude in people with acute mountain sickness. Consensus opinion suggests that people with acute mountain sickness should descend if possible. However, we found no RCTs examining effects of different distances of descent, or about the balance of risks and benefits in people who might find it difficult to descend.

Benefits: We found no systematic reviews or RCTs.

Harms: We found no RCTs.

Comment: Consensus opinion suggests that people with acute mountain sickness should descend if possible. However, we found no RCTs examining effects of different distances of descent, or about the balance of risks and benefits in people who might find it difficult to descend (for example, due to symptoms of acute mountain sickness or unrelated injury).

Bell's palsy

Search date November 2002

Rodrigo Salinas

QUESTIONS

INTERVENTIONS

Unknown effectiveness

See glossary, p 1654

Key Messages

- **Antiviral treatment** Two systematic reviews found no RCTs of aciclovir versus placebo. One RCT found limited evidence that aciclovir plus prednisone improved facial function compared with prednisone alone after 4 months.
- **Corticosteroids** One systematic review found no clear evidence that corticosteroid improved the recovery of facial motor function or cosmetically disabling sequelae compared with placebo after 6 months.
- **Facial nerve decompression surgery** One systematic review identified no RCTs of facial nerve decompression.

DEFINITION Bell's palsy is an acute, unilateral paresis or paralysis of the face in a pattern consistent with peripheral facial nerve dysfunction, without detectable causes.[1] Additional symptoms may include pain in or behind the ear, numbness in the affected side of the face, impaired tolerance to ordinary levels of noise, and disturbed taste on the anterior part of the tongue.[2–5]

INCIDENCE/ PREVALENCE The incidence is about 23/100 000 people a year, or about 1/60–70 people in a lifetime.[6] Bell's palsy affects men and women more or less equally, with a peak incidence between the ages of 10 and 40 years. It occurs with equal frequency on the right and left sides of the face.[7]

AETIOLOGY/ RISK FACTORS The cause is unclear. Viral infection, ischaemia, autoimmune inflammatory disorders, and heredity factors have been proposed as underlying causes.[2,8,9] A viral cause has gained popularity since the isolation of the herpes simplex virus-1 genome from facial nerve endoneurial fluid in people with Bell's palsy.[10]

PROGNOSIS More than two thirds of people with Bell's palsy achieve full spontaneous recovery. The largest series of people with Bell's palsy who received no specific treatment (1011 people) found the first signs of improvement within 3 weeks of onset in 85% of people.[11] For the other 15%, some improvement occurred 3–6 months later. The same series found that 71% of people recovered normal function of the face, 13% had insignificant sequelae, and the remaining 16% had permanently diminished function, with contracture of facial muscles and synkinesis (see glossary, p 1654). These figures are roughly similar to those of other series of people receiving no specific treatment for Bell's palsy.[7,8,12]

AIMS OF INTERVENTION To maximise recovery of facial function; to reduce the risk of complications, with minimum adverse effects.

OUTCOMES Grade of recovery of motor function of the face; presence of sequelae (motor synkinesis, autonomic dysfunction, hemifacial spasm); time to full recovery.

METHODS *Clinical Evidence* search and appraisal November 2002. Trials used different scoring systems for reporting outcomes.

QUESTION **What are the effects of treatments in adults and children?**

OPTION **CORTICOSTEROIDS**

One systematic review found no clear evidence that corticosteroid improved the recovery of facial motor function or cosmetically disabling sequelae compared with control after 6 months.

Benefits: **Versus placebo or no specific treatment:** We found one systematic review (search date 2000, 3 RCTs, 117 people).[13] In the review, one RCT (26 people aged 12–76 years) compared cortisone acetate versus placebo, one RCT (51 people, ages not specified) compared prednisone plus vitamins versus vitamins alone, and one

RCT (42 children aged 24–74 months) compared methylprednisolone versus no specific treatment. The review found no significant difference between corticosteroid (cortisone acetate, prednisone, methylprednisolone) and control in the number of people with incomplete recovery of facial motor function after 6 months (3 RCTs: 13/59 [22%] of people with corticosteroid *v* 15/58 [26%] of people with control; RR 0.86, 95% CI 0.47 to 1.59). When data from two quasi-randomised trials found by the review[12,14] were added to the pooled estimate, the result remained non-significant (RR 0.69, 95% CI 0.42 to 1.16; absolute numbers not provided; see comment below). The review also found no significant difference between corticosteroid and control in the number of people with cosmetically disabling sequelae after 6 months (8/59 [14%] of people with corticosteroid *v* 9/58 [16%] of people with control; RR 0.86, 95% CI 0.38 to 1.98). When data from two quasi-randomised trials found by the review[12,14] were added to the pooled estimate, the result remained non-significant (RR 0.82, 95% CI 0.39 to 1.73; absolute numbers not provided). **Versus aciclovir:** See benefits of antiviral treatment, p 1653.

Harms: No adverse effects were reported in the trials.

Comment: Of the two quasi-randomised trials identified by the review, one compared corticosteroids (preparation not stated) versus supportive therapy only, and used alternation in matched participants as the method of allocation.[12] The other compared dexamethasone versus placebo, and used allocation according to the day of admission.[14]

OPTION ANTIVIRAL TREATMENT

Two systematic reviews found no RCTs of aciclovir versus placebo. One RCT found limited evidence that aciclovir plus prednisone improved facial function compared with prednisone alone after 4 months.

Benefits: We found two systematic reviews (search date 2000, 2 RCTs, 200 people;[15] search date 2000, 3 RCTs, 230 people[16]). Neither review found RCTs of aciclovir versus placebo. Both included the same RCT (119 people) of aciclovir (400 mg 5 times daily for 10 days) plus prednisone versus prednisone alone (see comment below). The first review found that aciclovir plus prednisone versus prednisone alone significantly decreased the number of people with incomplete recovery of facial function (measured using a facial function scoring system) after 4 months (4/53 [8%] of people with aciclovir plus steroid had moderate or moderately severe dysfunction *v* 11/46 [24%] with steroid alone; RR 0.32, 95% CI 0.11 to 0.92; see comment below).[15]

Harms: The RCT reported mild to moderate gastrointestinal complaints, which did not require treatment. No numbers were reported.[15]

Comment: In the RCT, 20/119 (17%) of people enrolled in the trial were lost to follow up. It is not clear to which treatment group these belonged. Results were calculated from the 99/119 (83%) of people who completed the trial. The systematic reviews identified two further RCTs of aciclovir that were not of sufficient quality.

OPTION FACIAL NERVE DECOMPRESSION SURGERY

One systematic review found no RCTs of facial nerve decompression surgery for people with Bell's palsy.

Benefits: We found one systematic review (search date 2000), which found no RCTs of facial nerve decompression surgery for people with Bell's palsy.[16]

Harms: The systematic review found reports of permanent unilateral deafness in four non-randomised prospective studies of facial nerve decompression in people with Bell's palsy.[16] One study of people with complete facial palsy undergoing facial nerve decompression found that 4/41 (10%) people had conductive deafness and 2/41 (5%) people had perceptive deafness after 1 year.[12]

Comment: None.

QUESTIONS

INTERVENTIONS

Beneficial

Likely to be beneficial

Trade off between benefits and harms

Unknown effectiveness

To be covered in future updates

Treatment of drug resistant generalised epilepsy

*We found no placebo controlled RCTs. However, widespread consensus holds that these drugs are effective.

See glossary, p 1667

Key Messages

- **Addition of second line drugs for drug resistant partial epilepsy** Systematic reviews in people with drug resistant partial epilepsy have found that adding gabapentin, levetiracetam, lamotrigine, oxcarbazepine, tiagabine, topiramate, vigabatrin, or zonisamide to usual treatment reduces seizure frequency compared with adding placebo. The reviews have found that adding any of the drugs increases the frequency of adverse effects compared with adding placebo. We found no good evidence from RCTs on which to base a choice among drugs.

Epilepsy

- **Antiepileptic monotherapy in generalised epilepsy** We found no placebo controlled trials of the main antiepileptic drugs (carbamazepine, phenobarbital, phenytoin, sodium valproate), but widespread consensus holds that these drugs are effective. Systematic reviews found no good evidence on which to base a choice among these drugs in terms of seizure control.
- **Antiepileptic monotherapy in partial epilepsy** We found no placebo controlled RCTs of the main antiepileptic drugs (carbamazepine, phenobarbital, phenytoin, sodium valproate) used as monotherapy in people with partial epilepsy, but widespread consensus holds that these drugs are effective. Systematic reviews found no reliable evidence on which to base a choice among drugs in terms of seizure control. Systematic reviews have found that phenobarbital is more likely to be withdrawn than phenytoin or carbamazepine and that phenytoin is more likely to be withdrawn than carbamazepine.
- **Educational programmes** One RCT found that a 2 day education programme reduced seizure frequency at 6 months compared with waiting list control, although it found no significant difference in health related quality of life. Two RCTs found that an educational package improved knowledge and understanding of epilepsy, adjustment to epilepsy, and psychosocial functioning compared with control.
- **Antiepileptic drug withdrawal for people in remission** One systematic review of observational studies and one RCT have found that antiepileptic drug withdrawal for people in remission is associated with a higher risk of seizure recurrence than is continued treatment. Clinical predictors of relapse after drug withdrawal include age, seizure type, number of antiepileptic drugs being taken, whether seizures have occurred since antiepileptic drugs were started, and the period of remission before drug withdrawal.
- **Antiepileptic drugs after a single seizure** RCTs have found that immediate treatment of a single seizure with antiepileptic drugs reduces seizure recurrence at 2 years compared with no treatment. However, we found no evidence that treatment alters long term prognosis. Long term antiepileptic drug treatment is potentially harmful.
- **Cognitive behavioural therapy** We found insufficient evidence about the effects of cognitive behavioural therapy in people with epilepsy from two small RCTs.
- **Family counselling** We found insufficient evidence on family counselling from one small RCT that employed weak methods.
- **Relaxation plus behavioural modification therapy** RCTs found insufficient evidence about the effects of combined relaxation and behavioural modification on seizures.
- **Biofeedback; relaxation therapy; yoga** Systematic reviews found insufficient evidence on the effects of these interventions.

DEFINITION Epilepsy is a group of disorders rather than a single disease. Seizures can be classified by type as partial (categorised as simple partial, complex partial, and secondary generalised tonic clonic seizures), or generalised (categorised as generalised tonic clonic, absence, myoclonic, tonic, and atonic seizures).[1] See glossary, p 1667.

INCIDENCE/ PREVALENCE Epilepsy is common, with an estimated prevalence in the developed world of 5–10/1000, and an annual incidence of 50/100 000 people.[2] About 3% of people will be given a diagnosis of epilepsy at some time in their lives.[3]

AETIOLOGY/ RISK FACTORS Epilepsy can also be classified by cause.[1] Idiopathic generalised epilepsies (such as juvenile myoclonic epilepsy or childhood absence epilepsy) are largely genetic. Symptomatic epilepsies result from a known cerebral abnormality; for example, temporal lobe epilepsy may result from a congenital defect, mesial temporal sclerosis, or a tumour. Cryptogenic epilepsies are those that cannot be classified as idiopathic or symptomatic and in which no causative factor has been identified, but is suspected.

PROGNOSIS For most people with epilepsy the prognosis is good. About 70% go into remission, defined as being seizure free for 5 years on or off treatment. This leaves 20–30% who develop chronic epilepsy, which is often treated with multiple antiepileptic drugs.[4] About 60% of untreated people have no further seizures in the 2 years after their first seizure.[5]

AIMS OF INTERVENTION To reduce the risk of subsequent seizures and to improve the prognosis of the seizure disorder; in people in remission, to withdraw antiepileptic drugs without causing seizure recurrence; to minimise adverse effects of treatment.

OUTCOMES For treatment after a single seizure: time to subsequent seizures, time to achieve remission, proportion achieving remission. For treatment of newly diagnosed epilepsy: retention on allocated treatment or time to withdrawal of allocated treatment, time to remission, time to first seizure after treatment. For treatment of drug resistant epilepsy: percentage reduction in seizure frequency, proportion of responders (response defined as ≥ 50% reduction in seizure frequency). For drug withdrawal: time to seizure recurrence. Improvement in quality of life; reduction in anxiety, depression, and fear of seizures; coping or adjustment to epilepsy (assessed by validated measures).

METHODS *Clinical Evidence* search and appraisal for systematic reviews March 2003, and additional searches for RCTs by the contributors.

QUESTION Should single seizures be treated?

OPTION ANTIEPILEPTIC DRUGS AFTER A SINGLE SEIZURE

RCTs have found that treatment of a single seizure with antiepileptic drugs reduces seizure recurrence at 2 years compared with no treatment. However, we found no evidence that treatment alters long term prognosis. Long term antiepileptic drug treatment is potentially harmful.

Benefits: We found no systematic review. We found three RCTs, the largest of which (419 people, 42% women, 28% aged ≤ 16 years, 66% aged 16–60 years, 6% aged ≥ 60 years) compared immediate treatment after a first unprovoked seizure versus no immediate treatment.[6] People were randomised within 7 days of their first tonic clonic seizure (see glossary, p 1668). Longer term follow up of the RCT found that there were half as many second seizures with immediate treatment compared with no treatment at 2 years (HR 0.36, 95%

CI 0.24 to 0.53).[7] However, it found no significant difference in the proportion of people achieving a 2 year remission in seizures (AR 60% *v* 68%; RR 0.82, 95% CI 0.64 to 1.03; RR adjusted for time of starting treatment 0.96, 95% CI 0.77 to 1.22).[7]

Harms: The RCT gave no information on adverse effects of antiepileptic drugs.[6,7] However, these are well known and include idiosyncratic reactions, teratogenesis, and cognitive effects.

Comment: One systematic review of prospective observational studies (search date not stated, about 2500 people, 30% receiving treatment) concluded that, within 2 years of their first seizure, 40% (95% CI 37% to 43%) of people have further seizures.[5] The RCT was too small to rule out the possibility that treating a first seizure alters the long term prognosis of epilepsy.[6,7]

QUESTION What are the effects of monotherapy in newly diagnosed partial epilepsy?

OPTION ANTIEPILEPTIC MONOTHERAPY IN NEWLY DIAGNOSED PARTIAL EPILEPSY

We found no placebo controlled RCTs of the main antiepileptic drugs (carbamazepine, phenobarbital, phenytoin, sodium valproate) used as monotherapy in people with partial epilepsy, but widespread consensus holds that these drugs are effective. Systematic reviews found no reliable evidence on which to base a choice among drugs in terms of seizure control. Systematic reviews have found that phenobarbital is more likely to be withdrawn than phenytoin or carbamazepine and that phenytoin is more likely to be withdrawn than carbamazepine.

Benefits: We found no systematic reviews or RCTs comparing antiepileptic drugs versus placebo or no treatment (see comment below). We found five systematic reviews that compared antiepileptic drugs versus each other.[8–12] **Sodium valproate versus carbamazepine:** The first systematic review (search date 1999, 5 RCTs, 1265 people, of whom 830 had partial epilepsy and 395 had generalised epilepsy, age 3–83 years, follow up < 5 years) compared sodium valproate versus carbamazepine.[8] The systematic review included a meta-analysis of the subgroup of people with partial epilepsy (with results expressed as HRs; HR > 1 for an event that is more likely with sodium valproate). It found no significant difference for treatment withdrawal between sodium valproate and carbamazepine (HR 1.00, 95% CI 0.79 to 1.26). Sodium valproate decreased 12 month remission compared with carbamazepine and significantly increased risk of first seizure (remission: HR 0.82, 95% CI 0.67 to 1.00; first seizure: HR 1.22, 95% CI 1.04 to 1.44). A test for statistical interaction was performed and was significant for time to first seizure but not for time to 12 month remission. These subgroup analyses must therefore be treated with caution. **Sodium valproate versus phenytoin:** The second systematic review (search date 2000, 5 RCTs, 250 people with partial epilepsy, and 419 with generalised epilepsy, age 3–95, follow up < 5 years) compared sodium valproate versus phenytoin.[9] It included a meta-analysis in people with partial epilepsy (with results expressed as

HRs; HR > 1 for an event that is more likely with phenytoin). It found no significant difference in treatment withdrawal, 12 month remission, or first seizure (treatment withdrawal: HR 1.23, 95% CI 0.77 to 1.98; 12 month remission: HR 1.02, 95% CI 0.68 to 1.54; first seizure: HR 0.81, 95% CI 0.59 to 1.11). **Phenobarbital versus phenytoin:** The third systematic review (search date 1998, 3 RCTs, 599 people with partial or generalised epilepsy, age 3–77 years) compared phenobarbital versus phenytoin.[10] Results were expressed as HRs (HR > 1 for an event more likely with phenobarbital), but it did not undertake subgroup analyses for people with partial or generalised epilepsy. Overall, it found no significant difference in 12 month remission or first seizure (12 month remission: HR 0.93, 95% CI 0.70 to 1.23; first seizure: HR 0.84, 95% CI 0.68 to 1.05). It found that treatment withdrawal was greater with phenobarbital than with phenytoin, presumably because it was less well tolerated (HR 1.62, 95% CI 1.22 to 2.14). **Carbamazepine versus phenobarbital:** The fourth systematic review (search date 2002, 4 RCTs, 680 people, of whom 523 had partial epilepsy) compared carbamazepine versus phenobarbital.[11] Results were expressed as HRs (HR > 1 for an event more likely on phenobarbital). For people with partial epilepsy it found that phenobarbital was significantly more likely to be withdrawn than carbamazepine (HR 1.60, 95% CI 1.18 to 2.17). It found no significant difference in remission during the next 12 months (HR 1.03, 95% CI 0.72 to 1.49), but it found that phenobarbital significantly increased time to first seizure compared with carbamazepine (HR 0.71, 95% CI 0.55 to 0.91). **Carbamazepine versus phenytoin:** The fifth systematic review (search 2002, 3 RCTs, 552 adults and children, of whom 431 had partial epilepsy) compared carbamazepine versus phenytoin.[12] The review did not present results separately for people with partial epilepsy (see comment below).

Harms: Two RCTs found similar prevalence of adverse effects with carbamazepine and sodium valproate.[13,14] Rashes occurred more often with carbamazepine than with sodium valproate (11% *v* 1.7%, $P < 0.05$; 6.3% *v* 3.4%, NS). Weight gain was more common with sodium valproate (12% *v* 1.1%, $P < 0.05$; 10% *v* 3.9%, NS), usually after at least 3 months of treatment. Other adverse events with carbamazepine included dizziness (6.7% *v* 2.9%, NS; 6.3% *v* 0.8%, $P < 0.05$), headaches (6.1% *v* 3.4%), ataxia (2.2% *v* 0%), somnolence (20% *v* 9.3%, $P < 0.05$), fatigue (10% *v* 5.1%, NS), diplopia (3.9% *v* 0%, NS), and insomnia (3.9% *v* 0%, NS). Other drug related adverse events with sodium valproate were tremor (5.2% *v* 1.7%, NS), alopecia (2.9% *v* 0.6%, NS; 4.2% *v* 1.6%, NS), and appetite increase (2.3% *v* 0%, NS; 9.3% *v* 0%, $P < 0.01$). Treatment was withdrawn because of adverse events in 9% of people taking sodium valproate compared with 18% taking carbamazepine (18 *v* 15 people).[13,14]

Comment: Placebo controlled trials of these drugs would now be considered unethical. The meta-analysis provides weak evidence in support of the consensus view to use carbamazepine as the drug of choice in people with partial epilepsy.[8] The systematic review comparing carbamazepine versus phenytoin did not present results separately

for people with generalised epilepsy and people with partial epilepsy.[12] Overall, however, it found no significant difference between carbamazepine and phenytoin for treatment withdrawal, first seizure, or 12 month remission (treatment withdrawal: HR 0.97, 95% CI 0.74 to 1.28; first seizure: HR 0.91, 95% CI 0.74 to 1.12; time to 12 month remission: HR 1.00, 95% CI 0.78 to 1.29).

QUESTION **What are the effects of monotherapy in newly diagnosed generalised epilepsy (generalised tonic clonic seizures with or without other generalised seizure types)?**

OPTION **ANTIEPILEPTIC MONOTHERAPY IN NEWLY DIAGNOSED GENERALISED EPILEPSY**

We found no placebo controlled trials of the main antiepileptic drugs (carbamazepine, phenobarbital, phenytoin, sodium valproate) used as monotherapy in people with generalised epilepsy, but widespread consensus holds that these drugs are effective. Systematic reviews found no evidence on which to base a choice among drugs in terms of seizure control.

Benefits:

Versus placebo: We found no systematic review or RCTs comparing antiepileptic drugs versus placebo. We found four systematic reviews that compared different antiepileptic drugs.[8,9,11,12] The first two reviews were of RCTs that recruited people if they had generalised onset tonic clonic seizures (see glossary, p 1668) with or without other generalised seizure types (e.g. absence or myoclonus).[8,9] **Carbamazepine versus sodium valproate:** The first systematic review compared carbamazepine versus sodium valproate (search date 1999, 5 RCTs, 4 of the RCTs included 395 people with generalised epilepsy, age 3–79 years, follow up < 5 years).[8] Results were expressed as HRs (HR > 1 indicates that an event is more likely with sodium valproate). A meta-analysis of the generalised epilepsy subgroup found no significant difference between sodium valproate and carbamazepine for treatment withdrawal (HR 0.89, 95% CI 0.62 to 1.29), 12 month remission (HR 0.96, 95% CI 0.75 to 1.24), or first seizure (HR 0.86, 95% CI 0.68 to 1.67; see comment below). **Phenytoin versus sodium valproate:** The second systematic review compared phenytoin and sodium valproate (search date 2000, 5 RCTs, 419 people aged 3–95 years with generalised epilepsy).[9] Results were expressed as HRs (HR > 1 indicates that an event is more likely with phenytoin). A meta-analysis of the generalised epilepsy subgroup found no significant difference between sodium valproate and phenytoin for time to treatment withdrawal, 12 month remission, or first seizure (treatment withdrawal: HR 0.98, 95% CI 0.60 to 1.58; 12 month remission: HR 1.06, 95% CI 0.71 to 1.57; first seizure: HR 1.03, 95% CI 0.77 to 1.39; see comment below). **Carbamazepine versus phenobarbital:** The third systematic review (search date 2002, 4 RCTs, 680 people, of whom 157 had generalised epilepsy) compared carbamazepine versus phenobarbital.[11] Subgroup analysis in people with a generalized epilepsy found no significant differences for first seizure, 12 month remission, or treatment withdrawal (first seizure: HR 0.61, 95% CI 0.36 to 1.03; 12 month

remission: HR 0.61, 95% CI 0.36 to 1.03; treatment withdrawal: HR 1.78, 95% CI 0.87 to 3.62). **Carbamazepine versus phenytoin:** The fourth systematic review (search 2002, 3 RCTs, 552 people, of whom 121 had generalized epilepsy) compared carbamazepine versus phenytoin.[12] It did not present results separately for people with generalised epilepsy (see comment under antiepileptic monotherapy in newly diagnosed partial epilepsy, p 1667).

Harms: See harms under antiepileptic monotherapy in newly diagnosed partial epilepsy, p 1667.

Comment: Although no difference was found in the systematic reviews between sodium valproate and either carbamazepine or phenytoin, the confidence intervals are wide and these results do not establish equivalence of sodium valproate and carbamazepine or phenytoin.[8,9] Also, the age distribution of people classified as having generalised epilepsy suggests errors in the classification of epilepsy type. Failure of the RCTs to document generalised seizures other than tonic clonic seizures is an important limitation. The meta-analysis does not provide evidence to support or refute the use of sodium valproate for people with generalised tonic clonic seizures as part of generalised epilepsy.

QUESTION Does the addition of second line drugs benefit people with drug resistant partial epilepsy?

OPTION ADDITION OF SECOND LINE DRUGS IN PEOPLE WITH DRUG RESISTANT PARTIAL EPILEPSY

Systematic reviews in people with drug resistant partial epilepsy have found that adding gabapentin, levetiracetam, lamotrigine, oxcarbazepine, tiagabine, topiramate, vigabatrin, or zonisamide to usual treatment reduces seizure frequency compared with adding placebo. The reviews have found that adding any of the drugs increases the frequency of adverse effects compared with adding placebo. We found no good evidence from RCTs on which to base a choice among drugs.

Benefits: We found eight systematic reviews that compared the addition of active drugs versus placebo in people who have not responded to usual drug treatment.[15–22] **Gabapentin versus placebo:** One systematic review (search date 2002, 5 RCTs, 997 people) found that adding gabapentin to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 1, p 1671).[15] **Levetiracetam versus placebo:** One systematic review (search date 2003, 4 RCTs, 1023 people) found that adding levetiracetam to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 2, p 1672).[16] **Lamotrigine versus placebo:** One systematic review (search date 2002, 11 RCTs, 1243 people) found that adding of lamotrigine to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 2, p 1672).[17] **Oxcarbazepine versus placebo:** One systematic review (search date 2002, 2 RCTs, 961 adults and children) found that adding oxcarbazepine to usual treatment significantly reduced seizure frequency compared

with adding placebo (see table 2, p 1672).[18] **Tiagabine versus placebo:** One systematic review (search date 2002, 3 RCTs, 769 people) found that adding tiagabine to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 2, p 1672).[22] **Topiramate versus placebo:** One systematic review (search date 2002, 6 RCTs, 743 people) found that adding topiramate to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 1, p 1671).[20] **Vigabatrin versus placebo:** One systematic review (search date 1995, 4 RCTs, 495 people) found that adding vigabatrin to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 1, p 1671).[19] **Zonisamide versus placebo:** One systematic review (search date 2002, 3 RCTs, 499 people) found that adding zonisamide to usual treatment significantly reduced seizure frequency compared with adding placebo (see table 2, p 1672).[21]

Harms: Adverse effects and treatment withdrawal were more frequent with additional treatment than with placebo (see table 1, p 1671 and table 2, p 1672).[15,20] Lamotrigine is associated with a rash, which may be avoided by slower titration of the drug. Vigabatrin causes concentric visual field abnormalities in about 40% of people, which are probably irreversible.[23]

Comment: Few RCTs have compared these drugs directly with each other. Because of the irreversible visual field abnormalities associated with vigabatrin, the consensus view among neurologists is not to recommend this drug.

QUESTION Which people in remission from seizures are at risk of relapse on withdrawal of drug treatment?

OPTION ANTIEPILEPTIC DRUG WITHDRAWAL FOR PEOPLE IN REMISSION

One RCT in people who had been seizure free for at least 2 years found that further seizures were more likely if people stopped treatment than if they continued antiepileptic medication. Observational studies have found that nearly a third of people will relapse within 2 years if antiepileptic drugs are withdrawn. Clinical predictors of relapse after drug withdrawal include age, seizure type, number of antiepileptic drugs being taken, whether seizures have occurred since antiepileptic drugs were started, and the period of remission before drug withdrawal.

Benefits: One large RCT (1013 people who had been seizure free for > 2 years) compared continued antiepileptic treatment with slow antiepileptic drug withdrawal.[24,25] At 2 years, 78% of people who continued treatment remained seizure free compared with 59% in the withdrawal group. There were no significant differences in psychosocial outcomes between groups. Risk reductions with 95% confidence intervals for the main factors predicting recurrence of seizures are tabulated (see table 3, p 1673).[24] One systematic review of observational studies (search date not stated) found that, at 2 years, 29% (95% CI 24% to 34%) of people in remission from all types of epilepsy would relapse if antiepileptic drugs were withdrawn.[26]

Harms: Sixteen people died during the trial, 10 in the continued treatment group and six in the withdrawal group.[25] Only two deaths were attributed to epilepsy, and both of these occurred in people randomised to continued treatment.

Comment: People with a seizure recurrence were less likely to be in paid employment at 2 years.[24,25]

QUESTION What are the effects of behavioural and psychological treatments for people with epilepsy?

OPTION RELAXATION THERAPY

One systematic review found insufficient evidence about the effects of relaxation therapy compared with control in people with epilepsy.

Benefits: **Seizure frequency:** We found one systematic review (search date 2002,[27] 3 small unblinded controlled trials,[28–30] 50 people, including 32 women). The trials used weak methods (see comment below). Two of the studies found a non-significant reduction in seizure frequency with relaxation therapy (see glossary, p 1668) compared with no relaxation therapy, and one study found a significantly reduced seizure frequency. The weak methods preclude reliable conclusions.

Harms: The RCTs gave no information on adverse effects.[28–30]

Comment: All three trials used weak methods.[28–30] The treatment allocation methods were strict alternation,[30] alternation in blocks of five,[29] or were not stated.[28] The baseline seizure frequency varied considerably among the allocated groups in all of the trials. In one trial, two people in the treatment group had new antiepileptic medication added during the study period and one of these had a greater than 50% reduction in seizure frequency; another person discontinued antiepileptic medication.[29] Antiepileptic drug treatment was also adjusted during the trial, making it difficult to conclude whether the observed results were because of changes in drug treatment or because of the intervention. The trial duration and follow up was short. The possibility of publication bias cannot be excluded. The effects of relaxation therapy remain unclear.

OPTION YOGA

We found insufficient evidence from one systematic review about effects of yoga in people with epilepsy.

Benefits: **Seizure frequency:** We found one systematic review (search date 2002,[31] 1 quasi randomised trial,[32] 32 people). The RCT compared sahaja yoga (10 people) versus control (sham yoga 10 people, no intervention 12 people). The trial found that yoga reduced seizure frequency compared with control but it used weak methods, which precludes reliable conclusions.

Harms: The trial gave no information on adverse effects.[32]

Comment: The baseline seizure frequency and duration varied among the groups, making results difficult to interpret.[32]

OPTION BIOFEEDBACK

We found insufficient evidence from one systematic review about the effects of electroencephalographic feedback.

Benefits: **Seizure frequency:** We found one systematic review (search date 2002,[27] 1 controlled trial,[33] 24 people with uncontrolled epilepsy) of electroencephalographic (EEG) biofeedback (see glossary, p 1667) compared with control treatment. The trial compared three treatments: EEG biofeedback, sham (non-contingent) feedback, and no intervention (8 people in each group). It found a significant reduction in seizure frequency compared with the baseline frequency in people given biofeedback (median seizure reduction with biofeedback 61%; $P < 0.005$ *v* baseline; see comment below).

Harms: The trial gave no information on harms.[33]

Comment: The RCT did not provide data about seizure frequency in the control group.[33] We were therefore unable to compare the EEG biofeedback and control groups. The RCT did not report the number of people who had greater than 50% reduction in seizure frequency. The study was not blinded and the randomisation method is not clear. The duration of follow up was only 6 weeks. The evidence is insufficient to draw reliable conclusions about the effects of EEG biofeedback.

OPTION COGNITIVE BEHAVIOURAL TREATMENT

We found insufficient evidence about the effects of cognitive behavioural therapy in people with epilepsy. One small RCT found no significant difference in seizure frequency between group cognitive behavioural treatment and control treatment. The RCT found no significant improvement in psychosocial function. Another small RCT found that cognitive behavioural treatment improved a depression score in people with epilepsy plus depressed mood compared with control treatment.

Benefits: **Seizure frequency:** We found one systematic review (search date 2002)[27] that found one RCT (30 people)[34] comparing cognitive behavioural therapy (see glossary, p 1667) versus control treatment. The RCT found no significant difference between cognitive behavioural therapy and control treatment in seizure frequency, but the RCT was too small to exclude a clinically important difference. **Psychosocial functioning:** The RCT included in the review found no significant differences between cognitive behavioural therapy and control treatments in various psychological scales, such as the Washington Psycho Social Inventory, the Minnesota Multiphasic Inventory, and the Beck Depression Inventory (see glossary, p 1667).[34] Another RCT (15 people with epilepsy and depression) found that cognitive behavioural therapy significantly reduced depression and self reported anxiety or anger, and significantly increased involvement in social activities compared with control treatment.[35] The RCT did not report seizure frequencies, or specify the intervention given to controls or the concomitant antidepressant treatment.

Harms: The trial gave no information on harms.[34]

Comment: The method of randomisation concealment is not known for these small RCTs.[34,35] Publication bias cannot be excluded. The evidence is insufficient to define the effects of cognitive behavioural therapy on people with epilepsy.

OPTION EDUCATIONAL PROGRAMMES

One RCT found that a 2 day education programme reduced seizure frequency at 6 months compared with waiting list control, although it found no significant difference in health related quality of life. Two RCTs found that an educational package improved knowledge and understanding of epilepsy, adjustment to epilepsy, and psychosocial functioning compared with control.

Benefits: We found one systematic review (search date 2002,[27] 2 RCTs[36,37]) and one subsequent RCT.[38] **Seizure frequency:** The two RCTs included in the review did not report on seizure frequency.[36,37] The subsequent RCT (242 people) found that a 2 day educational programme significantly reduced seizure frequency at 6 months compared with waiting list control (proportion of people with at least 2 point reduction in seizure frequency on a 6 point scale [0 = no seizures in last 6 months, 5 = at least one seizure daily]: 19% with education *v* 7.2% with control; P value not reported).[38] However, the clinical importance of this effect is unclear. **Psychosocial functioning:** One RCT included in the review (100 adults with epilepsy) found that a specific 2 day educational programme significantly improved responses to a 50 item true/false questionnaire compared with control intervention (overall understanding of epilepsy, significant decrease in fear of seizures, significant decrease in hazardous medical self management) and significantly improved compliance with current medication (demonstrated by serum antiepileptic drug levels).[36] The second RCT included in the review (252 children with epilepsy aged 7–14 years) found that a child centred, family focused educational programme significantly improved questionnaire responses compared with control intervention (knowledge about what to do during a seizure, purpose of the electroencephalographic [see glossary, p 1667] examination, and minimal restriction in activities), increased the proportion of children likely to participate in normal activities, improved perceived academic and social competencies of the children, and reduced the anxiety of parents (see comment below).[37] The subsequent RCT found that a 2 day educational programme had no significant effect on SF-36 questionnaire scores (see glossary, p 1668) 6 months after the programme compared with waiting list control (SF-36 mental health component score 43.7 with educational package *v* 42.5 with control, P value not stated; SF-36 physical component score 50.4 with educational package *v* 52.0 with control, P value not stated).[38] Scales validated using the study population revealed significant improvement in epilepsy knowledge and coping with epilepsy.

Harms: None reported.

Comment: In one RCT, randomisation was by random number assignment, but only a proportion of medical records were available to the authors (65% in the experimental group *v* 47% of controls).[36] In the other

RCT the method of randomisation was not stated.[37] A minority of the people in the first RCT actively participated in the interventions (23/50 in the treatment group *v* 20/50 in the control group) or completed the study (20/50 in the treatment group *v* 18/50 in the control group).[36] In the subsequent RCT, the method of randomisation was not stated, and among 383 patients randomised 242 (113 in the treatment group and 119 in control group) completed the study.[38]

OPTION RELAXATION PLUS BEHAVIOURAL MODIFICATION THERAPY

Two RCTs found insufficient evidence about the effects of combined relaxation and behavioural modification treatment on seizures. One of the RCTs found that the intervention improved anxiety and adjustment compared with control.

Benefits: **Seizure frequency:** We found one systematic review[27] (search date 2002) that identified two RCTs of relaxation plus behaviour therapy versus control.[39,40] The first small RCT (18 children with uncontrolled epilepsy) compared three interventions for 6 weeks: behaviour modification (broad spectrum behaviour modification programme, which included teaching of symptom discrimination, relaxation, and countermeasure techniques to interrupt and abort seizures during early cues of the onset of a seizure); attention control (non-directive discussion around and experience of seizures, other people's reactions to seizures, and current problems); and control (usual care).[39] Both active treatments were given in six 1 hour sessions. It found that behaviour modification significantly reduced the median seizure index (the product of the seizure frequency and the seizure duration in seconds) compared with baseline after 1 year and that the median seizure index was increased compared with baseline in the control groups after 1 year. Long term follow up of the RCT found that behaviour modification significantly reduced the median seizure index after 8 years.[41] The RCT did not report actual values for these observations, so comparison of groups is not possible. The second RCT (150 adults with uncontrolled epilepsy) compared Jacobson's muscle relaxation plus behavioural therapy versus control treatment.[40] It reported separately the mean seizure frequencies for each seizure type but did not specify the number in each category. It reported separately the mean seizure frequencies for those people with fewer than 20 seizures and those with more than 20 seizures per month at baseline. We were unable to analyse these results in a meaningful way. **Psychological outcomes:** The second RCT found that relaxation plus behavioural modification significantly improved anxiety (Spielberger's self assessment questionnaire for trait and state anxiety; $P < 0.01$), and home, health, social, and emotional adjustment compared with control (assessed by adjustment inventory; P values not reported).[40]

Harms: The RCTs gave no information on harms.[39,40]

Comment: The randomisation method was not stated for one study and was by alternate allocation in the other. The seizure index reported in one study is not an ideal outcome measure.[39] One of the RCTs recruited

only 18 children and the groups would not be expected to be balanced for baseline characteristics.[39] It is possible that the results of the psychological interventions on psychosocial functioning may depend on the baseline personality of the persons included in the study, and their education and intelligence.

OPTION FAMILY COUNSELLING

We found insufficient evidence on family counselling from one small RCT that employed weak methods.

Benefits: We found no systematic review but found one small RCT (36 people with epilepsy and job loss) that compared three interventions: family therapy (no detailed description but it appears that the family was present for discussion of problems for a mean of 7.8 sessions); one family session (in which information about the seizure profile was given); and usual care (vocational assistance in obtaining a job with no follow up other than site visit).[42] It did not report seizure frequencies, but found a significantly improved psychosocial inventory score with family therapy (Washington Psycho Social Inventory [see glossary, p 1668], 27 completers: improved perceived acceptance by family, emotional adjustment, interpersonal adjustment, adjustment to seizures, and overall psychosocial function). It found a trend toward improvement in job stability.

Harms: The study did not report harms.[42]

Comment: The method of concealment of randomisation was not described in the RCT.[42] Nine of the 36 people did not complete the study and withdrawal was uneven across the groups (2 with family therapy, 6 with 1 family session, 1 with no intervention). The available evidence is insufficient to define the effects of family counselling.

GLOSSARY

Absence seizure Previously known as "petit mal". Brief episodes of unconsciousness with vacant staring, sometimes with fluttering of the eyelids, as if "daydreaming". People with absence seizure do not fall to the ground and generally have a rapid recovery. The condition is rare in adults.

Atonic seizure Momentary loss of limb muscle tone causing sudden falling to the ground or drooping of the head.

Beck Depression Inventory Standardised scale to assess depression.

Cognitive behavioural therapy A broad category of interventions designed to identify and control stress and minimise its effects, often by using intellectual experience to correct damaging thoughts and behaviour.

Complex partial seizure Consciousness is impaired and memory of the episode is distorted, but the person may not collapse. The person may exhibit automatic behaviours ("automatisms", such as chewing, scratching the head, undressing). Complex partial seizures can spread to the rest of the brain to become a secondary generalised tonic clonic seizure (see below). The electrical abnormality commonly starts in the temporal lobes.

Electroencephalographic (EEG) biofeedback A technique of making EEG activity apparent to a person, who is then taught to produce certain EEG waves that are believed to increase the threshold for seizures.

Minnesota Multiphasic Personality Inventory (MMPI) A battery of standardised tests to assess personality (psychopathology).

Myoclonic seizure Sudden, symmetrical, shock like limb movements with or without loss of consciousness.

Relaxation therapy Techniques to train people to control muscle tension.

SF-36 score A scale that assesses health related quality of life across eight domains: limitations in physical activities (physical component); limitations in social activities; limitations in usual role activities due to physical problems; pain; psychological distress and wellbeing (mental health component); limitations in usual role activities because of emotional problems; energy and fatigue; and general health perceptions.

Simple partial seizure Electrical activity confined to one localised part of the brain causing symptoms and signs that depend on the part of the brain affected. The person remains conscious and fully aware.

Tonic clonic seizure Also known as a convulsion or "grand mal" attack. The person will become stiff (tonic) and collapse, and have generalised jerking (clonic) movements. Breathing might stop and the bladder might empty. Generalised jerking movements lasting typically for a few minutes are followed by relaxation and deep unconsciousness, before the person slowly comes round. People are often tired and confused, and may remember nothing. Tonic clonic seizures may follow simple partial or complex partial seizures (see above), where they are classified as secondary generalised tonic clonic seizures. Tonic clonic seizures occurring without warning and in the context of generalised epilepsy are classified as generalised tonic clonic seizures.

Tonic seizure Stiffening of the whole body with or without loss of consciousness.

Washington Psycho Social Inventory (WPSI) A standardised battery of tests to assess adjustment in various spheres (measure of psychosocial difficulties) in people with epilepsy.

TABLE 1 **Effects of additional drug treatment in people not responding to usual treatment: results of systematic reviews (see text, p 1669).**

Drug	Daily dose (mg)	Percentage responding (95% CI)*	RR treatment withdrawal (95% CI)	RR adverse effects with CI (95% unless otherwise stated)	Comment
Gabapentin	**Adults only**				
	Placebo	9.9 (7.2 to 13.5)	1.4 (0.8 to 2.5)	Dizziness 2.25 (1.3 to 4)	5 RCTs (1 in children, 4 in adults)
	600	14.4 (12.0 to 17.3)		Fatigue 2.25 (1.1 to 4.6)	Efficacy increased with increasing dose. No plateauing of response, so doses tested may not have been optimal
	900	17.3 (14.6 to 20.3)		Somnolence 2.04 (1.2 to 3.4)	
	1200	20.6 (17.1 to 24.6)			
	1800	28.5 (21.5 to 36.7)			
	Adults and children		**Adults and children**	**Adults and children**	
	600–1800	RR 1.81 (1.32 to 2.49)	1.04 (0.71 to 1.52)	Dizziness 2.19 (1.24 to 3.89) Fatigue 2.30 (1.11 to 4.75) Somnolence 1.91 (1.20 to 3.05)	
Topiramate	Placebo 200	11.7 (8.7 to 15.7)	2.06 (1.38 to 3.08)	Ataxia 1.95 (99% CI 1.04 to 3.65)	9 RCTs
	400–1000	26.8 (15.8 to 41.3)		Dizziness 1.55 (99% CI 1.07 to 2.24)	
		46.5 (42.5 to 50.5)		Fatigue 2.21 (99% CI 1.42 to 3.45)	
				Somnolence 2.26 (99% CI 1.48 to 3.46)	
				Difficulty thinking 5.54 (99% CI 2.34 to 13.12)	
Vigabatrin (adults)	Placebo	13.8 (9.7 to 19.2)	2.95 (1.25 to 7.00)	No adverse effects significantly more frequent but 40% develop concentric visual field abnormalities[23]	3 RCTs
	1000 or 2000	22.8 (14.5 to 34.9)			
	3000 or 6000	45.9 (39.5 to 52.5)			

Results show percentage responding at particular daily doses, but results for treatment withdrawal and adverse effects are calculated for all doses.
*50% reduction in seizure frequency.

TABLE 2 **Effects of additional drug treatment in people not responding to usual treatment: results of systematic reviews (see text, p 1669).**

Drug	Daily dose (mg)	Percentage responding (95% CI)*	RR treatment withdrawal (95% CI)	RR adverse effects (95% CI)	Comment
Levetiracetam (adults)	1000–3000	3.78 (2.62 to 5.44)	1.21 (0.88 to 1.66)	Dizziness 2.50 (1.16 to 5.41) Infection 1.76 (1.03 to 3.02)	4 RCTs. Results of regression models with CI (95% unless otherwise stated) do not provide reliable estimates for a response to individual doses.
Lamotrigine (adults)	200–500	2.32 (1.67 to 3.23)	1.10 (0.81 to 1.50)	Ataxia 3.23 (1.93 to 5.42) Diplopia 3.47 (1.91 to 6.31) Dizziness 2.05 (1.52 to 2.78) Nausea 1.76 (1.18 to 2.64)	11 RCTs
Oxcarbazepine (adults and children)	600–2400	2.51 (1.88 to 3.33)	1.72 (1.35 to 2.18)	Ataxia 3.54 (1.75 to 7.13) Dizziness 2.87 (1.82 to 4.52) Fatigue 1.81 (1.00 to 3.29) Nausea 3.09 (1.74 to 5.49) Somnolence 2.36 (1.54 to 3.62) Diplopia 7.25 (3.12 to 16.80)	2 RCTs
Tiagabine	16–56	RR 3.67 (2.30 to 5.86)	1.81 (1.25 to 2.62)	Dizziness 1.69 (99% CI 1.13 to 2.51)	3 RCTs. Results of regression models do not provide accurate estimates for a response to individual doses
Zonisamide	400	2.46 (1.61 to 3.76)	1.64 (1.02 to 2.62)	Ataxia 4.50 (99% CI 1.05 to 19.22) Somnolence 1.91 (99% CI 1.08 to 3.38) Aggitation/irritability 2.37 (99% CI 1.00 to 5.64) Anorexia 3.00 (99% CI 1.31 to 6.88)	3 RCTs

*50% reduction in seizure frequency. All results are calculated for all doses.

TABLE 3 **Relative risks of seizure recurrence within 2 years of treatment withdrawal, according to prognostic variable (see text, p 1670).[24,25]**

Prognostic variable	RR (95% CI) of seizure recurrence within 2 years
Age < 16 years	1.8 (1.3 to 2.4)
Tonic clonic seizures	1.6 (1.1 to 2.2)
Myoclonus	1.8 (1.1 to 3.0)
Treatment with more than one antiepileptic drug	1.9 (1.4 to 2.4)
Seizures since antiepileptic drugs were started	1.6 (1.2 to 2.1)
Any electroencephalographic abnormality	1.3 (1.0 to 1.8)

Risk of recurrence also declined as the seizure free period increased, but in a complex manner.

Key Messages

- **Propranolol (increases response rates at 6 weeks)** Small RCTs have found that propranolol (60–240 mg) for 1 month improves clinical scores, tremor amplitude, and self evaluation of severity at up to 6 weeks compared with placebo. RCTs provided insufficient evidence to compare propranolol versus other β blockers.
- **Botulinum A toxin–haemagglutinin complex (improves clinical rating scales at 4–12 weeks but associated with hand weakness)** Two RCTs in people with essential hand tremor found that botulinum A toxin–haemagglutinin complex improved clinical rating scales at 4–12 weeks but found no consistent improvement in motor tasks or functional disability. Hand weakness, which is dose dependent and transient, is a frequent adverse effect.

- **Phenobarbital (improves tremor at 5 weeks but associated with depression and cognitive adverse effects)** One small RCT found that phenobarbital improved tremor scores at 5 weeks compared with placebo, but two RCTs found no significant difference in tremor scores at 4–5 weeks between phenobarbital and placebo. Phenobarbital is associated with depression and cognitive and behavioural adverse effects.
- **Primidone (improves tremor and function at 5 weeks but associated with depression and cognitive adverse effects)** Three small, short term RCTs found limited evidence that primidone improved tremor and functional ability over 4–5 weeks compared with placebo. Primidone is associated with depression and cognitive and behavioural adverse effects.
- **Topiramate (improves tremor scores after 2 weeks' treatment but associated with appetite suppression, weight loss, and paraesthesias)** One RCT found that topiramate improved observer rated tremor score after 2 weeks' treatment compared with placebo but was associated with adverse effects, including appetite suppression, weight loss, and paraesthesias. The clinical importance of the difference in tremor score is uncertain.
- **All treatment options in the long term** We found no RCTs that assessed long term effects of drug treatments for essential tremor.
- **β Blockers other than propranolol (atenolol, metoprolol, nadolol, pindolol, sotalol)** Three small RCTs found weak evidence that atenolol or sotalol improved symptoms and self evaluated measures of tremor at 5 days to 4 weeks compared with placebo. One small RCT found no significant difference in symptoms between metoprolol and placebo and another small RCT found that pindolol worsened tremor amplitude compared with placebo. A third very small RCT provided insufficient evidence to compare nadolol versus placebo. RCTs provided insufficient evidence to compare other β blockers versus propranolol.
- **Benzodiazepines** Two small short term RCTs found weak evidence that alprazolam may improve tremor and function at 2–4 weeks compared with placebo. However, we were unable to draw reliable conclusions about effects. One very small RCT provided insufficient evidence to compare clonazepam versus placebo. Adverse effects with benzodiazepines, including dependency, sedation and cognitive and behavioural effects, have been well described for other conditions (see panic disorder, p 1335).
- **Calcium channel blockers (dihydropyridine)** Poor quality RCTs provided insufficient evidence to compare the dihydropyridine calcium channel blockers nicardipine and nimodipine versus placebo.
- **Carbonic anhydrase inhibitors** Small RCTs provided insufficient evidence to assess methazolamide or acetazolamide in people with essential tremor.
- **Clonidine** One RCT found no significant difference between clonidine and placebo in essential hand tremor. However, the study lacked power to rule out a clinically important difference.
- **Flunarizine** One small RCT found weak evidence that flunarizine may reduce the symptoms of essential hand tremor after 1 months' treatment compared with placebo.
- **Gabapentin** Small crossover RCTs provided insufficient evidence to compare gabapentin versus placebo.
- **Isoniazid** One RCT found no significant difference between isoniazid and placebo in essential hand tremor, but it may have lacked power to detect a clinically important difference.

Essential tremor

DEFINITION Tremor is a rhythmic, mechanical oscillation of at least one body region. The term essential tremor is used when there is either a persistent bilateral tremor of hands and forearms, or an isolated tremor of the head without abnormal posturing, and when there is no evidence that the tremor arises from another identifiable cause. The diagnosis is not made if there are abnormal neurological signs, known causes of enhanced physiological tremor, a history or signs of psychogenic tremor, sudden change in severity, primary orthostatic tremor, isolated voice tremor, isolated position specific or task specific tremors, and isolated tongue, chin, or leg tremor.[1]

INCIDENCE/ PREVALENCE Essential tremor is one of the most common movement disorders throughout the world, with a prevalence of 0.4–3.9% in the general population.[2]

AETIOLOGY/ RISK FACTORS Essential tremor is sometimes inherited with an autosomal dominant pattern. About 40% of people with essential tremor have no family history. Alcohol ingestion provides symptomatic benefit in 50–70% of people.[3]

PROGNOSIS Essential tremor is a persistent and progressive condition. It usually begins during early adulthood and the severity of the tremor increases slowly. Only a small proportion of people with essential tremor seek medical advice, but the proportion in different surveys varies from 0.5–11%.[2] Most people with essential tremor are only mildly affected. However, most of the people who seek medical care are disabled to some extent, and most are socially handicapped by the tremor.[4] A quarter of people receiving medical care for the tremor change jobs or retire because of essential tremor induced disability.[3,5]

AIMS OF INTERVENTION To reduce tremor; to minimise disability and social embarrassment; to improve quality of life, with minimal adverse effects from treatment.

OUTCOMES Severity of symptoms and disability measured by clinical rating scales or patient self evaluation. Clinical rating scales are often composite scores that grade tremor amplitude in each body segment in specific postures or tasks. Few scales have been formally validated. Accelerometer recordings are reported in many trials but they are proxy outcomes that have been included in this review only when clinical outcomes were not available.

METHODS *Clinical Evidence* search and appraisal May 2003. We excluded single dose studies and RCTs lasting under 1 week.

QUESTION **What are the effects of drug treatments in people with essential tremor of the hand?**

OPTION **PROPRANOLOL**

Small RCTs have found that propranolol (60–240 mg) for 1 month improves clinical scores, tremor amplitude, and self evaluation of severity at up to 6 weeks compared with placebo. RCTs provided insufficient evidence to compare propranolol versus other β blockers. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** We found 11 small (10–24 people), brief (up to 6 weeks) RCTs, many of which had a crossover design.[6–16,28] Four RCTs compared three interventions: propranolol, metoprolol, and placebo in one RCT,[11] propranolol, atenolol, and placebo in the second,[16] propranolol, pindolol, and placebo in the third,[15] and propranolol, nicardipine, and placebo in the fourth.[28] One RCT compared four interventions: propranolol, atenolol, sotalol, and placebo, each for 2 weeks' treatment.[12] Ten RCTs evaluated clinical outcomes, including self evaluation of severity,[6–8,10,11-14,28] the other three assessed accelerometer readings.[9,15,16] All RCTs found that propranolol improved symptoms compared with placebo ($P < 0.05$).[6–8,10-14,28] Four of the RCTs found that, compared with placebo, propranolol (60–160 mg/day) significantly increased the proportion of people categorised as "responders". The precise definition of responder varied among the RCTs, but the results were similar (AR 22/23 [96%] with propranolol *v* 5/23 [22%] with placebo, ARR 69%, 95% CI 49% to 89%[6]; ARR 80%, 95% CI 69% to 91%;[7] ARR 64%, 95% CI 33% to 95%, NNT 2, 95% CI 2 to 4;[8] AR 10/16 [63%] with propranolol *v* 5/16 [31%] with placebo, ARR 32%, 95% CI 17% to 47%, NNT 4, 95% CI 2 to 6[14]). **Versus beta-blockers other than propranolol:** See benefits of β blockers other than propranolol, p 1678.

Harms: **Versus placebo:** Withdrawals (mainly because of fatigue and bradycardia) were rare (e.g. 1/10 [10%] people in 1 RCT).[8] Depression, diarrhoea, breathlessness, sedation, blurred vision, and sexual problems were each reported in fewer than 5% of people taking propranolol. **Versus beta-blockers other than propranolol:** See harms of β blockers other than propranolol, p 1678.

Comment: We found no RCTs addressing long term outcomes. All trials were analysed as "on treatment" rather than by intention to treat, and this may have biased results. Accelerometry is a proxy outcome that was reported in several RCTs. All accelerometry results were in favour of propranolol, but there is an inconsistent relationship between accelerometry and clinical measures of effectiveness. People with congestive heart failure, second degree heart block, asthma, severe allergy, and insulin dependent diabetes were generally excluded from the RCTs. All the studies were small. The possibility of publication bias has not been excluded.

OPTION β BLOCKERS OTHER THAN PROPRANOLOL

Three small RCTs found weak evidence that atenolol or sotalol improved symptoms and self evaluated measures of tremor at 5 days to 4 weeks compared with placebo. One small RCT found no significant difference in symptoms between metoprolol and placebo and another small RCT found that people taking pindolol had worse tremor amplitude compared with people taking placebo. A third very small RCT provided insufficient evidence to compare nadolol versus placebo. RCTs provided insufficient evidence to compare other β blockers versus propranolol. We found no RCTs addressing long term outcomes.

Essential tremor

Benefits: We found no systematic review. **Versus placebo:** We found six small (9–24 people) brief (5 days to 4 weeks) RCTs of different β blockers (sotalol, atenolol, metoprolol, nadolol, pindolol) versus placebo.[11,12,15–18] Three RCTs compared three interventions: propranolol, metoprolol, placebo in one RCT,[11] propranolol, atenolol, and placebo in another,[16] and propranolol, pindolol, and placebo in a third.[15] One RCT compared four interventions: propranolol, atenolol, sotalol, and placebo, each for 2 weeks' treatment.[12] Two RCTs selected participants known to be responders or non-responders to propranolol.[12,17] One RCT (9 people, crossover design) found that both sotalol and atenolol significantly reduced symptom scores compared with placebo ($P < 0.01$ with sotalol; $P < 0.02$ with atenolol).[12] Another RCT found that sotalol significantly improved self evaluated measures of tremor compared with placebo ($P < 0.05$).[18] A third RCT (24 people, crossover design) compared three interventions propranolol, atenolol, and placebo.[16] It found that atenolol significantly improved tremor intensity measured by accelerometer readings compared with placebo (P 0.001). A fourth RCT (16 people, crossover design) compared three interventions: propranolol (120–240 mg/day), metoprolol (150–300 mg/day), and placebo.[11] The RCT reported three outcomes: a composite clinical score, self evaluation, and accelerometer records. It found no significant difference between metoprolol and placebo in any outcomes (reported as non-significant, CI not reported). A fifth crossover RCT comparing propranolol (120 mg/day), pindolol (30 mg/day), and placebo found that people taking pindolol had significantly worse tremor amplitude accelerometer recordings (see glossary, p 1685) ($P < 0.05$) compared with people taking placebo.[15] It found no significant difference between pindolol and placebo in tremor frequency (reported as non-significant, CI not reported). A sixth small RCT (10 people) comparing nadolol versus placebo found significant results at 4 weeks only with a subgroup analysis in six people who had previously responded to propranolol.[17] **Versus propranolol:** We found no systematic review but found three small (16–24 participants) crossover, double blind RCTs.[11,15,16] The first crossover RCT (16 people) compared three interventions: propranolol (120–240 mg/day), metoprolol (150–300 mg/day) and placebo.[11] It found that, compared with metoprolol (150 mg), propranolol (120 mg) significantly improved clinical scores ($P < 0.05$) and self assessment ($P < 0.01$). It also found that propranolol (240 mg) significantly improved self assessment ($P < 0.05$) compared with metoprolol (300 mg). The second crossover RCT (24 people) compared three interventions: propranolol, atenolol, and placebo. It found no significant difference between propranolol and atenolol in tremor intensity measured by accelerometer readings (reported as non-significant, CI not reported), but more people preferred propranolol to atenolol (12/24 [50%] *v* 1/24 [4%]; CI not reported).[16] The third crossover RCT (24 people) compared three interventions: propranolol (120 mg/day), pindolol (30 mg/day), and placebo.[15] It found that pindolol significantly worsened tremor amplitude measured by accelerometer readings compared with propranolol ($P < 0.005$).

Harms: See harms of propranolol, p 1677.

Comment: People with congestive heart failure, second degree heart block, asthma, severe allergy, and insulin dependent diabetes were generally excluded from the RCTs. The weak evidence suggests but does not confirm that β blockers other than propranolol improve essential tremor compared with placebo. We found no RCTs addressing long term outcomes.

OPTION BARBITURATES

Three small, short term RCTs found limited evidence that primidone improved tremor and functional ability over 4–5 weeks compared with placebo. One small RCT found that phenobarbital improved tremor scores at 5 weeks compared with placebo, but two RCTs found no significant difference in tremor scores at 4–5 weeks between phenobarbital and placebo. Phenobarbital and primidone are associated with depression and cognitive and behavioural adverse effects. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Primidone versus placebo:** We found three crossover RCTs.[19–21] All were small (8–22 people) and brief (2–5 weeks' treatment). The first crossover RCT (16 people) compared three interventions: primidone (up to 750 mg/day), phenobarbital (phenobarbitone) (up to 150 mg/day), and placebo.[19] It found that primidone significantly improved a clinical score and self evaluation of tremor at 5 weeks after crossover compared with placebo ($P < 0.05$). The second RCT (22 people) also found that, at 10 weeks after crossover, primidone (up to 750 mg/day) significantly improved hand tremor measured by clinical scores ($P < 0.02$), functional tests ($P < 0.01$), and self evaluation ($P < 0.01$) compared with placebo. The results of this trial should be interpreted with caution as no intention to treat analysis was performed and only 16/22 (73%) people completed the trial.[20] The third RCT (22 people) compared four interventions: primidone (up to 750 mg/day, mean dose 402 mg), alprazolam, acetazolamide, and placebo for 4 weeks' treatment with a 2 week washout between treatments.[21] It found that primidone improved function compared with placebo at 4 weeks before crossover (observer rated score based on ability to write, feed and function socially [0 = normal, 11 = unable to keep pencil on paper, needs help to feed, and no social activity]; 5.2 with primidone *v* 7.8 with placebo; P value not reported). **Phenobarbital versus placebo:** We found three small, short term, crossover RCTs.[13,22,19] The first RCT (12 people) found that, compared with placebo, phenobarbital (120 mg/day) significantly improved accelerometer recordings (see glossary, p 1685) ($P < 0.01$) and a symptom rating scale ($P < 0.05$) after 5 weeks, but found no significant difference in handwriting tests or self evaluation of tremor.[22] It found that phenobarbital significantly increased the proportion of people who responded compared with placebo (response defined as decrease in tremor score measured by accelerometer of ≥15%: 11/11 [100%] with phenobarbital *v* 6/11 [55%] with placebo; ARR 45%, 95% CI 15% to 75%; NNT 3, 95% CI 2 to 7).[22] The second RCT (17 people) compared three treatments phenobarbital (1.25 mg/kg/day), propranolol (1.7 mg/kg/day), and placebo.[13] It found no significant difference in a clinical tremor score or functional tests at 4 weeks between phenobarbital

and placebo. The results of this trial should be interpreted with caution as no intention to treat analysis was performed and only 12/17 (70%) people completed the trial.[20] The third RCT (16 people) compared three interventions: phenobarbital, primidone, and placebo. It found no significant difference in clinical score and self evaluation of tremor at 5 weeks between phenobarbital and placebo (reported as non-significant, CI not reported).[19]

Harms: **Primidone:** In one RCT, 5/22 [23%] people taking primidone withdrew because of adverse effects (first dose acute toxic reaction, sedation, daytime sleepiness, tiredness, and depression).[20] In another RCT, 8/24 people receiving primidone discontinued treatment because of adverse effects, including nausea, ataxia, dizziness, or confusion.[21] **Barbiturates:** Both primidone (metabolised to phenobarbital) and phenobarbital are associated with depression and cognitive and behavioural effects (particularly in children, elderly people, and people with neuropsychiatric problems). See epilepsy, p 1655.

Comment: The RCTs were short term, small, and many randomised people did not complete the trials. We found no RCTs addressing long term outcomes.

OPTION BENZODIAZEPINES

Two small RCTs found weak evidence that alprazolam may improve tremor and function at 2–4 weeks compared with placebo. However, we were unable to draw reliable conclusions about effects. One very small RCT provided insufficient evidence to compare clonazepam versus placebo. Adverse effects with benzodiazepines, including dependency, sedation and cognitive and behavioural effects, have been well described for other conditions (see panic disorder, p 1335). We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Alprazolam versus placebo:** We found two RCTs.[21,23] The first RCT (24 people) found that alprazolam (up to 3 mg/day) improved observer rated global impression at 2 weeks compared with placebo, but found no significant difference in clinical scores, functional tests, or self evaluation of tremor.[23] The second RCT (22 people) compared four interventions: alprazolam (up to 1.5 mg/day, mean dose 0.75 mg), acetazolamide, primidone, and placebo.[21] It found that alprazolam improved function compared with placebo after 4 weeks (observer rated score based on ability to write, feed and function socially [0 = normal, 11 = unable to keep pencil on paper, needs help to feed, and no social activity]; 6.0 with alprazolam *v* 7.8 with placebo; P value not reported). **Clonazepam versus placebo:** We found one RCT (15 people), which found no significant difference between clonazepam and placebo in any outcome.[24] However, nine people withdrew during an open run-in period with clonazepam, so only six entered the double blind phase; the trial is therefore likely to have been underpowered to detect a clinically important difference in outcomes.

Harms: We found no data addressing harms of benzodiazepines specifically in populations with essential tremor. Adverse effects with benzodiazepines, including dependency, sedation and cognitive and behavioural effects, have been well described for other conditions (see panic disorder, p 1335).

Comment: We found no RCTs addressing long term outcomes.

OPTION CARBONIC ANHYDRASE INHIBITORS

Small RCTs provided insufficient evidence to assess methazolamide or acetazolamide in people with essential tremor. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Methazolamide versus placebo:** We found one crossover RCT (25 people), which found no significant difference between methazolamide (up to 300 mg/day) and placebo in clinical score, functional tasks, or self evaluation (7/18 [39%] improved with methazolamide *v* 4/18 [22%] with placebo; ARR +16%, 95% CI −15% to +45%; see comment below).[25] **Acetazolamide versus placebo:** We found one RCT (22 people) comparing acetazolamide (up to 750 mg/day, mean dose 562 mg) versus alprazolam versus primidone versus placebo.[21] It found that fewer people taking acetazolamide than taking placebo had improved function after 4 weeks compared with placebo (observer rated score based on ability to write, feed and function socially [0 = normal, 11 = unable to keep pencil on paper, needs help to feed, and no social activity]; 7.3 with acetazolamide *v* 7.8 with placebo; P value not reported).

Harms: **Methazolamide versus placebo:** The RCT gave no information on adverse effects.[25] **Acetazolamide versus placebo:** In the RCT, 3/19 people receiving acetazolamide complained of tolerable paraesthesias.[21]

Comment: In the first RCT, the results were analysed on treatment rather than by intention to treat.[25] Seven people withdrew from the trial. We found no RCTs addressing long term outcomes.

OPTION CALCIUM CHANNEL BLOCKERS (DIHYDROPYRIDINE)

Poor quality RCTs provided insufficient evidence to compare dihydropyridine calcium channel blockers versus placebo. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Nicardipine versus placebo:** One double blind, crossover RCT (11 people) found no significant difference in accelerometer recordings (see glossary, p 1685) after 1 month between nicardipine and placebo.[26] No clinical outcomes were assessed. Another crossover RCT (14 people) compared three interventions: nicardipine (1 mg/kg/day), propranolol (160 mg/day), and placebo for 1 month.[28] It found that nicardipine improved a symptom score at 1 month compared with placebo (CI not reported). **Nimodipine versus placebo:** We found one double blind, crossover RCT (15 people), which found no significant difference in clinical scores after 2 weeks' treatment between nimodipine (90 mg/day) and placebo (ARR +20%, 95% CI −15% to +55%).[27]

Harms: Nicardipine and nimodipine can provoke or aggravate heart failure. They are associated with dizziness, flushing, peripheral oedema, lethargy, headache, and fatigue. Adverse gastrointestinal effects (nausea/vomiting, loss of appetite, constipation, weight gain, thirst, indigestion, or altered taste) are reported by 1–3% of people. Abnormalities of laboratory tests (liver function tests) have been observed, usually within 1–8 weeks after starting treatment.

Comment: The possibility of publication bias has not been excluded. The evidence is too weak to assess the role of calcium channel blockers in essential hand tremor. We found no RCTs addressing long term outcomes.

OPTION FLUNARIZINE

One small RCT found weak evidence that flunarizine may reduce the symptoms of essential hand tremor after 1 months' treatment compared with placebo. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** We found one crossover RCT (17 people), which found that flunarizine (10 mg/day) significantly improved clinical scores and tremor amplitude after 1 month of treatment compared with placebo ($P = 0.0006$).[29] Most of the people who completed the RCT were considered improved with flunarizine (13/15 [87%]), but the number improving with placebo was not reported.[9]

Harms: Observational studies suggest that flunarizine is associated with adverse neuropsychiatric effects, and with the development of parkinsonism and other movement disorders.[30–33]

Comment: The RCT was small and brief. The evidence is inconclusive. We found no RCTs addressing long term outcomes.

OPTION CLONIDINE

One RCT found no significant difference between clonidine and placebo in essential hand tremor. However, the study lacked power to rule out a clinically important difference. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** One crossover RCT (10 people) found no significant difference in the proportion of people who improved between clonidine (up to 0.6 mg/day) and placebo (1/10 [10%] with clonidine *v* 1/10 [10%] with placebo).[34]

Harms: The RCT gave no information on adverse effects.[34] Clonidine has been associated in other studies with sedation, lethargy, drowsiness, constipation, dry mouth, headache, dizziness, fatigue, and weakness.

Comment: We found no RCTs addressing long term outcomes.

OPTION ISONIAZID

One RCT found no significant difference between isoniazid and placebo in essential hand tremor, but it may have lacked power to detect a clinically important difference. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** One brief, crossover RCT (15 people, 11 with essential tremor) comparing isoniazid (up to 1200 mg/day) versus placebo found similar clinical scores and accelerometer recordings (see glossary, p 1685) between treatments.[35]

Harms: In other studies, isoniazid has been associated with hepatotoxicity and peripheral neuropathy.

Comment: We found no RCTs addressing long term outcomes.

OPTION GABAPENTIN

Small crossover RCTs provided insufficient evidence to compare gabapentin versus placebo. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** We found three small crossover RCTs (16–25 people).[14,36,37] The first RCT (20 people) compared gabapentin (1800 mg/day) versus placebo for 2 weeks' treatment. It found no significant difference in clinical scores, activities of daily living, or self evaluation at 6 weeks after crossover (reported as non-significant, CI not reported).[36] The second RCT (16 people) compared three interventions: gabapentin (up to 1200 mg/day), propranolol (up to 120 mg/day), and placebo. It found that, compared with placebo, gabapentin significantly improved response rate (10/16 [63%] responded with gabapentin *v* 5/16 [31%] with placebo; ARR 32%, 95% CI 17% to 47%; NNT 4, 95% CI 2 to 6), clinical scores ($P < 0.05$), disability ($P < 0.01$), self evaluation ($P < 0.006$), and accelerometer recordings (see glossary, p 1685) ($P < 0.05$) at 2 weeks before crossover.[14] The third RCT (25 people) compared three interventions: gabapentin (1800 mg/day), gabapentin (3600 mg/day), and placebo. It found that, compared with placebo, gabapentin (at either dose) significantly improved participants' global assessments ($P < 0.05$), water pouring scores ($P < 0.05$), and scores of activities of daily living ($P < 0.005$). It found no significant difference between gabapentin and placebo in accelerometry scores, spirographs, or investigator global impression scores.[37] The RCT also found no significant difference between high and low doses of gabapentin in the 20 people who completed the trial.

Harms: The RCTs reported fatigue, drowsiness, nausea, dizziness, and decreased libido in people taking gabapentin.[14,36,37] See epilepsy, p 1655.

Comment: The results of the three RCTs differ. It is unclear whether the difference arose by chance or whether confounding variables, such as prior use of antitremor medications, baseline severity, or assessment rating scales, explain the difference. We found no RCTs addressing long term outcomes.

OPTION BOTULINUM A TOXIN–HAEMAGGLUTININ COMPLEX

Two RCTs in people with essential hand tremor found that botulinum A toxin–haemagglutinin complex improved clinical rating scales at 4–12 weeks but found no consistent improvement in motor tasks or functional disability. Hand weakness, which is dose dependent and transient, is a frequent adverse effect. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[38,39] The first RCT (25 people with essential hand tremor unresponsive to "optimal medical therapy"; see comment below) compared botulinum A toxin–haemagglutinin complex versus placebo.[38] Botulinum toxin (50 U) was injected in forearm muscles and repeated if necessary after 1 month (100 U). The RCT found that botulinum toxin significantly increased the proportion of people who responded to the first injection compared with placebo (12/13 [92%] with botulinum toxin *v* 1/12 [8%] with placebo; $P < 0.001$). After 4 weeks, mild to moderate improvement was significantly more likely with botulinum toxin (75% with botulinum toxin *v* 27% with placebo; ARR 48%, 95% CI 30% to 66%; NNT 3, 95% CI 2 to 4). It also found that botulinum toxin significantly improved clinical scores compared with placebo ($P < 0.05$), but found no significant difference in functional tests and accelerometer recordings (see glossary, p 1685). The second RCT (133 people with essential tremor of the hand by the Tremor Investigation Group criteria, 16 weeks' follow up) compared three interventions: single injections of low dose botulinum A toxin–haemagglutinin complex (50 U), high dose botulinum A toxin–haemagglutinin complex (100 U), and placebo into the wrist flexors and extensors. It found that botulinum toxin type A at either dose significantly improved postural tremor on clinical rating scales was after 12 weeks ($P = 0.004$ with low dose, $P = 0.0003$ with high dose). It found no significant difference between botulinum toxin at either dose in kinetic tremor, motor task performance, or functional disability.[39]

Harms: The main adverse effect of botulinum A toxin–haemagglutinin complex is dose dependent transient hand weakness.

Comment: The first RCT stated that participants were unresponsive to "optimal medical therapy" but did not state what this involved.[38] We found no RCTs addressing long term outcomes.

OPTION TOPIRAMATE

One RCT found that topiramate improved observer rated tremor score after 2 weeks' treatment compared with placebo but was associated with adverse effects, including appetite suppression, weight loss, and paraesthesias. The clinical importance of the difference in tremor score is uncertain. We found no RCTs addressing long term outcomes.

Benefits: We found no systematic review. **Versus placebo:** We found one crossover RCT (24 people with tremor of hand, head, or voice), which compared topiramate (400 mg/day or maximum tolerated dose; mean dose 333 mg/day) versus placebo for two weeks'

treatment with a two week washout between treatments.[40] It found that topiramate significantly improved observer rated tremor score at 6 weeks after crossover compared with placebo (tremor score improvement 0.88 with topiramate *v* 0.15 with placebo; P = 0.015).

Harms: Nine out of the 24 people withdrew from the RCT; six because of adverse effects (5 with topiramate, 1 with placebo).[40] The most common adverse effects with topiramate were appetite suppression, weight loss, and paraesthesias (see epilepsy, p 1655).

Comment: The RCT did not report tremor scores specifically for the hand. However, 23 of the 24 patients had hand tremor and only four patients also had tremor in other locations. The primary outcome of observer rated tremor was assessed by a non-validated scale developed by Fahn et al.[41] The clinical relevance of the difference is uncertain. We found no RCTs addressing long term outcomes.

GLOSSARY

Accelerometer recording Recording of the movements from a body segment to allow measurement of frequency, amplitude, or intensity of a tremor. Intensity of tremor is a measure of the overall magnitude of movement; it often refers to the product of the amplitude of tremor multiplied by its frequency.

Competing interests: CS has accepted reimbursement for attending symposia, fees for speaking, fees for organising education, and funds for a member of staff from Allergan (Botox) and IPSEN (Dysport). JF has been paid by Allergen (Botox) and IPSEN (Dysport) for running educational programmes. JF declares involvement in the design and conduct of multiple clinical trials testing antiparkinsonian, antidystonic, and antiepileptic drugs developed by multiple companies. He declares no previous or present participation in trials in the field of tremor.

Headache (chronic tension-type)

Search date February 2003

Peter J Goadsby

QUESTIONS

INTERVENTIONS

See glossary, p 1693

Key Messages

- We found only limited evidence about the treatment of chronic tension-type headache.
- **Amitriptyline (only short term evidence)** One systematic review and three small, short duration RCTs have found that amitriptyline reduces duration and frequency of chronic tension-type headache compared with placebo.
- **Cognitive behavioural therapy** One systematic review of three small RCTs and one subsequent RCT found limited evidence that cognitive behavioural therapy reduced symptoms at 6 months compared with no treatment.
- **Acupuncture** We found insufficient evidence from heterogeneous RCTs about effects of acupuncture compared with placebo in people with episodic or chronic tension-type headache. Many of the RCTs were of poor quality. Some of the RCTs may have lacked power to exclude a clinically important effect.
- **Benzodiazepines** Two RCTs found insufficient evidence about the effects of benzodiazepines compared with placebo or other treatments. Benzodiazepines are commonly associated with adverse effects if taken regularly.
- **Regular acute pain relief medication** We found no RCTs. We found insufficient evidence from one non-systematic review of observational studies about benefits of common analgesics in people with chronic tension-type headache. It found that sustained and frequent use of some analgesics was associated with chronic headache and reduced the effectiveness of prophylactic treatment.
- **Botulinum toxin; relaxation and electromyographic biofeedback therapy; serotonin reuptake inhibitors; tricyclic antidepressants other than amitriptyline** We found insufficient evidence about the effects of these interventions.

Headache (chronic tension-type)

DEFINITION The 1988 International Headache Society criteria for chronic tension-type headache (CTTH) are headaches on 15 or more days a month (180 days/year) for at least 6 months; pain that is bilateral, pressing, or tightening in quality, of mild or moderate intensity, which does not prohibit activities and is not aggravated by routine physical activity; presence of no more than one additional clinical feature (nausea, photophobia, or phonophobia) and no vomiting.[1] CTTH is distinguished from chronic daily headache, which is simply a descriptive term for any headache type that occurs for 15 days or more a month that may be due to CTTH as well as migraine or analgesic associated headache.[2] In contrast to CTTH, episodic tension-type headache can last for 30 minutes to 7 days and occurs for fewer than 180 days a year. Terms based on assumed mechanisms (muscle contraction headache, tension headache) are not operationally defined. Old studies that used these terms may have included people with many different types of headache. The greatest obstacle to studying tension-type headache is the lack of any single proved specific or reliable, clinical, or biological defining characteristic of the disorder.

INCIDENCE/ PREVALENCE The prevalence of chronic daily headache from a survey of the general population in the USA was 4.1%. Half of sufferers met the International Headache Society criteria for CTTH.[3] In a survey of 2500 undergraduate students in the USA, the prevalence of CTTH was 2%.[4] The prevalence of CTTH was 2.5% in a Danish population based survey of 975 individuals.[5] One community based survey in Singapore (2096 people from the general population) found that prevalence was 1.8% in females and 0.9% in males.[6]

AETIOLOGY/ RISK FACTORS Tension type headache is more prevalent in women (65% of cases in one survey).[7] Symptoms begin before the age of 10 years in 15% of people with CTTH. Prevalence declines with age.[8] There is a family history of some form of headache in 40% of people with CTTH,[9] although a twin study found that risk of CTTH was similar for identical and non-identical twins.[10]

PROGNOSIS The prevalence of CTTH declines with age.[8]

AIMS OF INTERVENTION To reduce frequency, severity, and duration of headache, with minimal adverse effects from treatment.

OUTCOMES Headache frequency, intensity, and duration.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION What are the effects of treatments for chronic tension-type headache?

OPTION REGULAR ACUTE PAIN RELIEF MEDICATION

We found no RCTs. We found insufficient evidence from one non-systematic review of observational studies about effects of common analgesics in people with chronic tension-type headache. It found that sustained frequent use of some analgesics was associated with chronic headache and reduced effectiveness of prophylactic treatment.

Benefits: We found no RCTs but found one non-systematic review of 29 observational studies (2612 people), which found no evidence of benefits of common analgesia for chronic tension-type headache.[11]

Harms: We found no RCTs but found one non-systematic review of 29 observational studies (2612 people), which found that sustained frequent use (2–3 times/week) of some common analgesics in people with episodic headache was associated with chronic headache and reduced effectiveness of prophylactic treatment.[11] Many, but not all people improved over 1–6 months after withdrawal of the acute relief medication (73% of 1101 people, not all of whom had chronic tension-type headache).

Comment: Observational studies are difficult to interpret.

OPTION BENZODIAZEPINES

Two RCTs found insufficient evidence about any benefits of benzodiazepines versus placebo or other treatments that might outweigh the harms associated with regular use.

Benefits: We found no systematic review but found two RCTs.[12,13] One small RCT (16 people) found that diazepam versus placebo produced modest improvement over 12 weeks.[12] The dose of diazepam was not stated, and the International Headache Society criteria were not used. The other RCT, a crossover study (62 people), compared alprazolam (250 μg three times daily) versus placebo over 16 weeks, and also found a modest short term improvement ($P < 0.05$).[13] Fourteen people withdrew from the trial at various stages, and six of those withdrew before the trial started. It was not reported whether analysis was by intention to treat.

Harms: The harms of benzodiazepines found in studies for other indications include increased risk of motor vehicle accidents, falls and fractures, fatal poisonings, depression, dependency, decline in functional status, cognitive decline, confusion, bizarre behaviour, and amnesia.[14]

Comment: None.

OPTION SEROTONIN REUPTAKE INHIBITORS

We found insufficient evidence from two RCTs about effects of serotonin reuptake inhibitors compared with placebo or other treatments.

Benefits: We found two RCTs.[15,16] The first RCT (50 people) compared sertraline versus placebo.[15] It found no significant difference in symptoms (measured by headache frequency or headache index, a combined measure of frequency, severity, and duration of pain; quantitative data for between-group comparison and P value not reported). The second RCT compared serotonin reuptake inhibitors versus tricyclic antidepressants or placebo.[16] It found no significant benefit from citalopram versus placebo in headache duration, frequency, or severity. It found that amitriptyline significantly improved headache duration, frequency, and severity compared with citalopram (see table 1, p 1695).

Headache (chronic tension-type)

Harms: One small cohort study found that four of eight people taking fluvoxamine had transient nausea, two complained of anorexia, and three complained of irritability.[19] The RCT comparing sertraline versus placebo reported nausea in six people taking sertraline and four taking placebo (no further data provided).[15]

Comment: One cohort study found significant benefit from fluvoxamine, but the people recruited were not randomised and those responding to placebo were excluded from the study.[19]

OPTION TRICYCLIC ANTIDEPRESSANTS

We found one systematic review and three small, short duration RCTs that found benefit from amitriptyline versus placebo for treating chronic tension-type headache.

Benefits: **Tricyclic antidepressants versus placebo:** We found one systematic review[20] (search date 1994, 1 RCT[21]) and three subsequent RCTs[16–18] of amitriptyline versus placebo (dosage range 10–150 mg; treatment duration 4–32 weeks). All four RCTs[16–18,21] found that amitriptyline significantly improved headache duration and frequency in people with moderate to severe, properly defined chronic tension-type headache. See table A on web extra.[1,22–25]

Harms: One RCT (53 people) found increased rates of dry mouth (54% with amitriptyline 75 mg/day *v* 17% with placebo; $P < 0.05$), drowsiness (62% with amitriptyline *v* 27% with placebo; $P < 0.05$), and weight gain (16% with amitriptyline *v* 0% with placebo; $P > 0.05$).[17] Similar results have been found in other studies for amitriptyline[16] and other tricyclic antidepressants.[19,22]

Comment: Most recent RCTs were small, short term, and used different outcome measures. Observational data were difficult to interpret. For example, one cohort study excluded those responding to placebo before the trial.[19] The trials finding benefit from amitriptyline were of short duration. Currently, they only reliably apply to people with properly defined, moderate to severe chronic tension headache, rather than to people with milder forms of headache. It is not clear whether benzodiazepines alone might contribute to daily headache. The modest benefit found in two small RCTs is unlikely to outweigh the risk of dependence with prolonged use.

OPTION RELAXATION AND ELECTROMYOGRAPHIC BIOFEEDBACK

We found insufficient evidence that electromyographic biofeedback or relaxation are effective.

Benefits: We found two systematic reviews (search dates 1994[20] and not stated[26]), which did not distinguish between RCTs and observational studies. Appraisal of the papers within the reviews identified 10 relevant RCTs (see table B on web extra).[27–36] We found one subsequent RCT.[4] The RCTs were generally of low quality, and included a variety of different electromyographic biofeedback and relaxation (see glossary, p 1693) techniques. Clear conclusions could not be drawn. One larger RCT included people with chronic tension headache and migraine and did not provide intention to treat analysis.[18]

Harms: The identified studies did not report adverse effects of electromyographic biofeedback or relaxation.

Comment: Relaxation and electromyographic biofeedback require additional trained staff and are time consuming.

OPTION COGNITIVE BEHAVIOURAL THERAPY

One systematic review of three small RCTs and one subsequent RCT have found limited evidence that cognitive behavioural therapy versus no treatment reduced the intensity of chronic tension-type headache.

Benefits: **Versus placebo:** We found one systematic review[20] and one subsequent RCT.[15] The systematic review (search date 1994, 3 small RCTs) found greater improvement with cognitive behavioural therapy than with no treatment, sham treatment, or no usual care.[20] The subsequent RCT (203 adults with chronic tension-type headache [CTTH]) compared cognitive behavioural therapy (relaxation [see glossary, p 1693] and cognitive coping) versus antidepressant (amitriptyline up to 100 mg/day or nortriptyline up to 75 mg/day) versus combined cognitive therapy plus antidepressant versus placebo.[18] It found that cognitive behavioural therapy versus placebo significantly reduced the headache index score after 6 months (WMD 0.79 U, 95% CI 0.30 U to 1.28 U), but found a non-significant increase in the frequency of clinically important improvement (at least 50% reduction in headache index score: 17/49 [35%] with cognitive behavioural therapy *v* 14/48 [29%] with placebo; RR 1.19, 95% CI 0.66 to 2.13). **Versus another treatment:** The review found nine additional comparative studies of relaxation or electromyographic biofeedback therapy (see glossary, p 1693) or both versus either cognitive therapy alone (2 studies) or in combination with relaxation or electromyographic biofeedback therapy (7 studies).[20] Results were inconclusive. **Versus antidepressants:** We found no systematic review but found one RCT (203 adults with CTTH)[18] comparing cognitive behavioural therapy (and cognitive coping) versus antidepressant (amitriptyline up to 100 mg/day or nortriptyline up to 75 mg/day) versus combined cognitive therapy plus antidepressant. It found no difference between cognitive behavioural therapy versus antidepressant treatment in either the headache index score after 6 months (score is the mean of pain ratings [0–10 scale] recorded by participants in a daily diary 4 times daily [higher scores represent more severe pain]; WMD –0.13 U, 95% CI –0.61 U to +0.35 U) or in the frequency of clinically important improvement after 6 months (at least 50% reduction in headache index score: 17/49 [35%] with cognitive behavioural therapy *v* 20/53 [38%] with antidepressant; RR 0.92, 95% CI 0.55 to 1.54).

Harms: The identified studies did not report any adverse effects of cognitive behavioural therapy.

Comment: The studies in the systematic review were small and had as few as five people in each group. Although the RCT found that the headache index score was reduced, it found no convincing reduction in the number of people who had a clinically important response. The evidence is too limited to define the role of cognitive therapy in CTTH.

Headache (chronic tension-type)

OPTION ACUPUNCTURE

We found insufficient evidence from heterogeneous RCTs to compare acupuncture versus placebo in people with episodic or chronic tension-type headache. Many of the RCTs were of poor quality and some may have lacked power to exclude a clinically important effect.

Benefits: We found two systematic reviews.[37,38] The first systematic review (search date 1998, 6 RCTs, 182 people) found important heterogeneity among studies, making it difficult to summarise the results. A meta-analysis found no significant difference in response rates (defined as > 33% index reduction); however, this only included two RCTs (48 people, 17/24 [71%] with acupuncture *v* 11/24 [46%] with sham acupuncture; RR 1.49, 95% CI 0.96 to 2.03).[37] The meta-analysis might have had insufficient power to find clinically important differences. The second systematic review (search date 1998, 4 RCTs, 91 people) found insufficient evidence comparing the effectiveness of acupuncture versus placebo. The summary of results of the heterogeneous RCTs was not clear enough to allow appropriate meta-analysis.[38] A subsequent small RCT (47 people with chronic tension-type headache, 21 people with episodic headache) compared acupuncture versus sham, non-penetrative acupuncture.[39] Two treatments were given weekly over 5 weeks. The RCT found no significant differences with acupuncture versus sham in headache frequency immediately after treatment (mean 13.1 days/month with acupuncture *v* 16.6 days/month with sham) or at 5 months after the end of the treatment (mean 16.7 days/month with acupuncture *v* 17.2 days/month with sham). It also found no significant differences in pain intensity, as measured using a visual analogue scale.

Harms: Adverse effects were not reported.[37–39]

Comment: Many of the RCTs were of poor quality. Some may have lacked power to exclude a clinically important effect.

OPTION BOTULINUM TOXIN

We found insufficient evidence from three small RCTs about effects of botulinum toxin compared with placebo in people with chronic tension-type headache.

Benefits: We found no systematic review but found three double blind RCTs that compared pericranial intramuscular injection of botulinum toxin type A versus placebo in people with chronic tension-type headache.[40,41] The first RCT (59 people) found no significant difference between treatments in pain relief 8 weeks after treatment (> 25% pain relief at 8 weeks: 54% with botulinum *v* 38% with placebo; CI not reported; P > 0.05).[40] The second, smaller RCT (21 people) also found no significant differences between botulinum versus placebo for headache intensity, duration, and frequency at 4, 8, and 12 weeks (pain on 10 point visual analogue score [10 = most severe pain] about 6 for both groups at baseline; at 12 weeks pain score about 5 for botulinum toxin *v* about 4.5 for

placebo; results presented graphically).[41] The third RCT (37 people) found that botulinum toxin A improved headache score more than placebo (AR for at least 25% improvement: 13/22 [59%] with botulinum *v* 2/15 [13%] with placebo; statistical significance not stated).[42]

Harms: The first RCT found no significant difference between treatments.[40] After 4 weeks, the following symptoms were noted: vertigo (2 with botulinum *v* 1 person with placebo) and pain at injection site (3 with botulinum *v* 1 person with placebo). By 8 weeks, the symptoms had resolved. Botulinum toxin may be associated with facial weakness, difficulty with swallowing, and disturbed local sensation. Adverse effects were not reported in the second RCT.[41] The third RCT found no significant difference in adverse events between botulinum toxin A and placebo (statistical analysis not presented).[42] The complaints reported were muscle cramps, flu-like symptoms, and subjective feelings of weakness in the neck muscles.

Comment: The RCTs were too small to exclude a clinically important difference between botulinum and placebo.

GLOSSARY

Electromyographic biofeedback Feedback of the amplified electromyographic signal from forehead and neck muscles through earphones or a loudspeaker to enable people to reduce the amount of muscle contraction.

Relaxation Includes Jacobson's progressive relaxation exercises, meditation, passive relaxation, autogenic training, and functional relaxation.[41]

Key Messages

- **Eletriptan** One systematic review and subsequent RCTs have found that eletriptan increases headache relief at 2 hours compared with placebo. One systematic review and subsequent RCTs have found that eletriptan 40 and 80 mg increases headache relief at 2 hours compared with sumatriptan 50 and 100 mg. One RCT found that eletriptan 40 and 80 mg increased headache relief at 2 hours compared with ergotamine plus caffeine.
- **Ibuprofen** Five RCTs have found that ibuprofen improves migraine symptoms compared with placebo.
- **Naratriptan** One systematic review and subsequent RCTs have found that naratriptan increases headache relief at 2 hours compared with placebo. One systematic review has found that sumatriptan 100 mg increases headache relief at 2 hours compared with naratriptan 2.5 mg. However, one subsequent RCT found no significant difference in headache recurrence. One RCT found no significant difference between naratriptan 2.5 mg and zolmitriptan 2.5 mg in headache relief at 4 hours. One RCT identified by a systematic review found that naratriptal reduced headache relief at 2 hours compared with rizatriptan.
- **Rizatriptan** One systematic review and subsequent RCTs have found that rizatriptan improves headache relief compared with placebo. Two RCTs found no significant difference between rizatriptan and zolmitriptan in headache relief at 2 hours. One RCT identified by a systematic review found that rizatriptan increased headache relief at 2 hours compared with naratriptan. One RCT found that rizatriptan increased headache relief and reduced nausea and vomiting at 2 hours compared with ergotamine plus caffeine.

- **Salicylates** RCTs have found that oral or intravenous salicylates (alone or in combination with metoclopramide, paracetamol, or caffeine) increase headache relief compared with placebo. One RCT found no significant difference between aspirin and paracetamol plus codeine in headache relief. One RCT found no significant difference between aspirin plus metoclopramide and sumatriptan in headache relief. One RCT found that oral lysine acetylsalicylate plus metoclopramide increased headache relief and reduced nausea and vomiting at 2 hours compared with ergotamine plus caffeine. One RCT found no significant difference in headache relief between aspirin plus metoclopramide and zolmitriptan.
- **Sumatriptan** Systematic reviews and subsequent RCTs have found that subcutaneous, oral, or intranasal sumatriptan increases headache relief compared with placebo. RCTs found no significant difference in headache relief between sumatriptan and aspirin plus metoclopramide, tolfenamic acid, or zolmitriptan. RCTs have found that oral or nasal sumatriptan increase headache relief compared with oral or nasal ergotamine. One systematic review has found that sumatriptan 100 mg increases headache relief at 2 hours compared with naratriptan 2.5 mg. However, one subsequent RCT found no significant difference in headache recurrence. One systematic review and subsequent RCTs have found that eletriptan 40 and 80 mg increases headache relief at 2 hours compared with sumatriptan 50 and 100 mg.
- **Zolmitriptan** One systematic review and two subsequent RCTs have found that oral zolmitriptan increases headache relief compared with placebo. One systematic review and two subsequent RCTs found no significant difference between zolmitriptan and sumatriptan in headache relief. One RCT found no significant difference in headache relief between aspirin plus metoclopramide and zolmitriptan. One RCT found no significant difference between naratriptan 2.5 mg and zolmitriptan 2.5 mg in headache relief at 4 hours.
- **Diclofenac** RCTs have found that oral or intramuscular diclofenac improves headache symptoms compared with placebo. One RCT found that intramuscular diclofenac improved migraine symptoms compared with intramuscular paracetamol.
- **Ergotamine** One systematic review found limited evidence from four RCTs that ergotamine (with or without caffeine) improved headache relief compared with placebo. One overview of harms suggested that ergotamine increased nausea and vomiting compared with placebo. RCTs have found that ergotamine (or its derivatives, with or without caffeine and cyclizine) is less effective for migraine symptoms than sumatriptan. They found limited evidence that it was less effective than naproxen. RCTs found that thalergotarine plus caffeine reduced headache relief and increase nausea and vomiting at 2 hours compared with oral lysine acetylsalicylate plus metoclopramide and rizatriptan.
- **Naproxen** Three small RCTs found that naproxen reduced migraine symptoms compared with placebo. Two RCTs found that naproxen reduced symptoms compared with ergotamine (with or without caffeine plus cyclizine). However, one further RCT found no significant difference between naproxen and ergotamine in pain relief after 1 hour.
- **Tolfenamic acid** RCTs found limited evidence that tolfenamic acid improved duration and severity of headache compared with placebo. RCTs found no significant difference in symptom relief between tolfenamic acid and sumatriptan or paracetamol.

Migraine headache

DEFINITION Migraine is a primary headache disorder manifesting as recurring attacks usually lasting for 4–72 hours and involving pain of moderate to severe intensity, often with nausea, sometimes vomiting, and/or sensitivity to light, sound, and other sensory stimuli. The 1988 International Headache Society criteria (see glossary, p 1716) include separate criteria for migraine with and migraine without associated aura.[1] Unless stated otherwise, RCTs used International Headache Society criteria for migraine with or without aura.

INCIDENCE/ PREVALENCE Migraine is common worldwide. Prevalence has been reported to be 5–25% in women and 2–10% in men. Overall, the highest incidence for migraine without aura has been reported between the ages of 10 and 11 years (10/1000 person years). The peak incidence of migraine without aura in males is between ages 10 and 11 years (10/1000 person years) and in females between ages 14 and 17 years (19/1000 person years).[2] The incidence of migraine with aura peaks in males at age 5 years (7/1000 person years) and in females at age 12–13 years (14/1000 person years).[2] Female prevalence of migraine with or without aura has a declining trend after age 45–50 years.

AETIOLOGY/ RISK FACTORS Data from independent representative samples from Canada,[3,4] the USA,[5,6] several countries in Latin America,[7] and several countries in Europe,[8–11] Hong Kong,[12] and Japan[13] show a female to male predominance and a peak in middle aged women. Migraine has been reported to be 50% more likely in people with a family history of migraine.[14]

PROGNOSIS Acute migraine is self limiting and only rarely results in permanent neurological complications. Chronic recurrent migraine may cause disability through pain, and may affect daily functioning and quality of life.

AIMS OF INTERVENTION To reduce frequency of migraine, intensity of accompanying symptoms, and duration of headache, with minimal adverse effects.

OUTCOMES Headache relief or being pain free (see glossary, p 1717) at different times after medication. Pain relief at specific post-dose times. In this review, headache relief is reported at 2 hours unless otherwise stated. Some RCTs include the need for rescue medication and headache recurrence (see glossary, p 1716) as outcome measures.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION What are the effects of drug treatments for acute migraine?

OPTION SALICYLATES

RCTs have found that oral or intravenous salicylates (alone or in combination with metoclopramide, paracetamol, or caffeine) increase headache relief compared with placebo. One RCT found no significant difference between aspirin and paracetamol plus codeine in headache relief. One RCT found no significant difference between aspirin plus metoclopramide and sumatriptan in headache relief. One RCT found that

oral lysine acetylsalicylate plus metoclopramide increased headache relief and reduced nausea and vomiting at 2 hours compared with ergotamine plus caffeine. One RCT found no significant difference in headache relief between aspirin plus metoclopramide and zolmitriptan.

Benefits: We found no systematic review but found 12 RCTs.[15–26] **Oral lysine acetylsalicylate (L-ASA):** One RCT (266 people, 475 migraine attacks) found that oral L-ASA 1620 mg plus metoclopramide 10 mg significantly increased headache relief (see glossary, p 1716) compared with placebo (AR 56% with L-ASA *v* 28% with placebo; RR 2.0, 95% CI 1.6 to 2.5).[15] A second RCT compared three treatments: oral L-ASA 1620 mg plus metoclopramide 10 mg, oral sumatriptan 100 mg, and placebo.[16] It found that L-ASA plus metoclopramide significantly increased headache relief compared with placebo (AR 57% with L-ASA *v* 24% with placebo; RR 2.4, 95% CI 1.7 to 3.3). The difference between active treatment groups was not significant (AR 57% with L-ASA *v* 54% with sumatriptan; P = 0.50). **Intravenous L-ASA:** One RCT (278 people) compared three treatments: L-ASA 1800 mg intravenously, sumatriptan 6 mg subcutaneously, and placebo.[17] It found that both L-ASA and sumatriptan significantly increased headache relief compared with placebo, and that sumatriptan significantly increased headache relief compared with L-ASA (AR 74% with L-ASA *v* 91% with sumatriptan *v* 24% with placebo; RR for L-ASA *v* placebo 3.1, 95% CI 1.8 to 5.4; RR for L-ASA *v* sumatriptan 0.8, 95% CI 0.7 to 0.9). A second, smaller, crossover RCT (112 attacks in 56 people) compared L-ASA 1000 mg intravenously versus ergotamine 0.5 mg subcutaneously.[18] It found no significant difference between groups in pain intensity score on a visual analogue scale. **Effervescent aspirin:** One crossover RCT (120 people) compared effervescent aspirin 650 mg with and without metoclopramide 10 mg versus placebo.[19] At 2 hours aspirin with or without metoclopramide reduced headache significantly more than placebo (P < 0.001). A second RCT (374 people) compared effervescent aspirin 1000 mg versus placebo.[20] It found that aspirin significantly increased headache relief compared with placebo (AR 55% with aspirin *v* 37% with placebo; RR 1.5, 95% CI 1.2 to 1.9). **Dispersible aspirin:** One crossover RCT (101 people with migraine, 73 of whom received both treatments) compared mouth dispersible aspirin 900 mg versus placebo in two consecutive attacks.[21] It found that aspirin significantly increased headache relief at 2 hours compared with placebo, and significantly reduced need for rescue medication (see glossary, p 1717) (AR for headache relief 48% with aspirin *v* 19% with placebo; P = 0.0005; difference in need for rescue medication: P < 0.01). **Other combinations:** One large RCT (1357 people with non-disabling migraine) compared oral paracetamol 250 mg plus aspirin 250 mg plus caffeine 65 mg versus placebo.[22] Combination treatment improved headache relief compared with placebo (AR 59% with combination *v* 33% with placebo; RR 1.8, 95% CI 1.6 to 2.1). A second, crossover RCT (198 people treated for 3 consecutive migraine attacks) found no significant difference in headache relief between aspirin 1000 mg orally and paracetamol 400 mg plus codeine 25 mg.[23] However, both improved headache relief compared with placebo (P = 0.0003 with aspirin and P = 0.0002 with paracetamol plus codeine). **Aspirin versus**

sumatriptan: One RCT (358 people) found no significant difference between oral aspirin 900 mg plus metoclopramide 10 mg and oral sumatriptan 100 mg in headache relief at 2 hours (AR 45% with aspirin plus metoclopramide *v* 56% with sumatriptan; P = 0.078).[24] **Aspirin versus tolfenamic acid:** See benefits of tolfenamic acid, p 1703. **Aspirin versus zolmitriptan:** See benefits of zolmitriptan, p 1714. **Aspirin versus ergotamine:** See benefits of ergotamine, p 1704.

Harms: One RCT reported adverse effects related to L-ASA in 2%, to sumatriptan in 15%, and to placebo in 2% of people treated.[17] In this trial, severe harms were related to L-ASA in 3%, to sumatriptan in 5%, and to placebo in 2% of people treated. Another trial reported premature withdrawal of treatment in 1% with L-ASA, 3% with sumatriptan, and 2% with placebo.[16] The most frequently reported harms for L-ASA were somnolence, abdominal pain, nausea or vomiting, fatigue, and headache. The RCT comparing the combination of paracetamol, aspirin, and caffeine versus placebo reported no serious adverse effects.[22] **Versus zolmitriptan:** See harms of zolmitriptan, p 1715. **Versus ergotamine:** See harms of ergotamine, p 1706.

Comment: None.

OPTION DICLOFENAC

RCTs have found that oral or intramuscular diclofenac improves headache symptoms compared with placebo. One RCT found that intramuscular diclofenac improved migraine symptoms compared with intramuscular paracetamol.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs of oral diclofenac[27,28,30] and one RCT of intramuscular diclofenac.[29] The first RCT (170 people) found that diclofenac improved treatment success compared with placebo (success defined at 2 hours as a visual analogue scale score < 10 mm or headache duration of < 2 hours without need for rescue medication [see glossary, p 1717] within this period: AR 27% with diclofenac *v* 19% with placebo; RR 1.5, 95% CI 1.0 to 2.2).[27] The second RCT (72 people) found that diclofenac 50 or 100 mg significantly increased headache relief (see glossary, p 1716) compared with placebo (AR 39% with 50 mg *v* 44% with 100 mg *v* 22% with placebo; RR diclofenac 50 mg *v* placebo 1.8, 95% CI 1.0 to 3.1; RR diclofenac 100 mg *v* placebo 1.9, 95% CI 1.1 to 3.3).[28] The RCT found no significant difference between 50 mg and 100 mg doses of diclofenac. However, it found that diclofenac 100 mg significantly reduced need for rescue medication compared with placebo (AR 37% with diclofenac *v* 58% with placebo; RR 0.64, 95% CI 0.44 to 0.93). The third RCT (120 people with migraine with or without aura) compared intramuscular diclofenac 75 mg versus placebo.[29] At 1 hour, it found that diclofenac improved headache relief and reduced need for rescue medication compared with placebo in people with and without aura (headache relief in people without aura: AR 43.3% with diclofenac *v* 16.7% with placebo; P < 0.01; headache relief in people with aura: AR 50% with

diclofenac *v* 13.3% with placebo; P < 0.01; rescue medication in people without aura: 20% with diclofenac *v* 50% with placebo; P < 0.05; rescue medication in people with aura: 11% with diclofenac *v* 42% with placebo; P < 0.05). The fourth RCT (156 people meeting International Headache Society criteria (see glossary, p 1716) for migraine with or without aura) compared three treatments: diclofenac potassium 50 or 100 mg, oral sumatriptan 100 mg, and placebo.[30] The trial found that diclofenac significantly reduced headache pain (measured on a visual analogue scale) at 2 hours compared with placebo (P < 0.001). **Versus sumatriptan:** The RCT comparing diclofenac, sumatriptan, and placebo found no significant difference between either dose of diclofenac and sumatriptan.[30] **Versus paracetamol:** One RCT (86 people) compared intramuscular diclofenac 75 mg versus intramuscular paracetamol in people with paroxysmal headaches accompanied by at least two of the following features: unilateral pain, nausea, visual and limb symptoms, and positive family history.[31] The trial found that diclofenac increased the proportion of people with partial relief of overall migraine symptoms (intensity and duration) within 35 minutes compared with paracetamol (AR 89% with diclofenac *v* 17% with paracetamol; RR 4.9, 95% CI 2.5 to 9.8).

Harms: In one RCT (72 people), 33% of people reported one or more adverse effects during one or more attacks.[28] Most adverse effects were rated as mild or moderate (gastrointestinal complaints were the most common, followed by tiredness and fatigue), but 12% of people rated adverse experiences as severe. In another RCT (170 people), 14% of people reported at least one adverse effect, with gastrointestinal effects being the most common (50%).[27] Only three people withdrew because of gastrointestinal symptoms. See non-steroidal anti-inflammatory drugs, p 1551.

Comment: None.

OPTION IBUPROFEN

Five RCTs have found that ibuprofen improves migraine symptoms compared with placebo.

Benefits: **Versus placebo:** We found no systematic review but found five RCTs comparing ibuprofen versus placebo.[32–36] The first RCT (729 people) found that oral ibuprofen (400 and 600 mg in gel formulation) significantly improved headache relief (see glossary, p 1716) compared with placebo (AR 72% with 400 mg *v* 72% with 600 mg *v* 50% with placebo; ibuprofen 400 mg *v* placebo RR 1.4, 95% CI 1.2 to 1.7; ibuprofen 600 mg *v* placebo RR 1.4, 95% CI 1.2 to 1.7).[32] It found no significant difference in the need for rescue medication (see glossary, p 1717). The second RCT (25 people, 146 migraines) found that ibuprofen significantly improved migraine index (see glossary, p 1717) (25 with ibuprofen *v* 46 with placebo; P = 0.0014) and reduced the need for rescue medication 4 hours after treatment (26% with ibuprofen *v* 56% with placebo; P = 0.007) compared with placebo.[33] The third RCT (40 people with common and classic migraine, 345 migraines) compared ibuprofen 800–1200 mg orally versus placebo.[34] The trial found

that significantly more attacks were rated as mild with ibuprofen compared with placebo ($P < 0.001$) and significantly fewer attacks were rated as moderate ($P < 0.05$) or severe ($P < 0.05$). It also found that ibuprofen reduced the need for rescue medication compared with placebo (AR 22% with ibuprofen *v* 81% with placebo; RR 0.27, 95% CI 0.20 to 0.36). One RCT (660 people with headache intensity (see glossary, p 1716) not requiring bed rest or inhibiting daily activities in more than 50% of attacks) compared ibuprofen 200 or 400 mg versus placebo with a follow up of 6 hours.[35] It found that ibuprofen significantly increased headache relief at 2 hours compared with placebo (AR 41.7% with ibuprofen 400 mg *v* 40.8% with ibuprofen 200 mg *v* 28.1% with placebo; $P = 0.006$ for both doses *v* placebo). The fifth RCT (40 people) compared an ibuprofen arginine preparation (400 mg orally) versus placebo.[36] It found that more people taking ibuprofen arginine versus placebo achieved "considerable" or "complete" relief within 2 hours (51% with ibuprofen *v* 7% with placebo; $P < 0.01$). Fewer people taking ibuprofen arginine received rescue medication (31% with ibuprofen *v* 48% with placebo) but no statistical analysis was performed.

Harms: One RCT did not report adverse effects.[34] Another RCT reported pain and stomach discomfort in 12% of people on treatment, which was not considered serious.[33] Another reported no significant difference in adverse events among treatment groups, and no serious adverse events.[35] See non-steroidal anti-inflammatory drugs, p 1551.

Comment: None.

OPTION NAPROXEN

Three small RCTs found that naproxen reduced migraine symptoms compared with placebo. Two RCTs found that naproxen reduced symptoms compared with ergotamine (with or without caffeine plus cyclizine). However, one further RCT found no significant difference between naproxen and ergotamine in pain relief after 1 hour.

Benefits: We found no systematic review. **Versus placebo:** We found one crossover RCT (37 people with classic or common migraine) comparing oral naproxen 750–1250 mg versus placebo.[37] It found that naproxen significantly reduced headache intensity (see glossary, p 1716) ($P = 0.047$). However, it found no significant difference in need for rescue medication (see glossary, p 1717) (absolute numbers not reported; $P = 0.13$). A second crossover RCT (40 people with common or classic migraine) comparing naproxen 750–1000 mg versus placebo found that naproxen reduced overall pain intensity (rated as mild, moderate, or severe; $P = 0.011$; time of evaluation not reported).[38] The need for rescue medication after 2 hours was also significantly lower for naproxen (AR 47% with naproxen *v* 72% with placebo; $P = 0.002$; insufficient data for calculation of RR). A third RCT compared three treatments: naproxen, ergotamine (plus caffeine plus cyclizine), and placebo.[39] It found that naproxen significantly increased pain relief compared with ergotamine at 1 hour after the first dose ($P = 0.032$). **Versus**

ergotamine: We found three RCTs, which compared oral naproxen 750–1750 mg versus ergotamine 2–4 mg alone or with caffeine 91.5 mg plus cyclizine chlorhydrate 50 mg.[39–41] The first RCT (114 people) found that naproxen significantly reduced migraine intensity (rated as mild, moderate, severe, or incapacitating) compared with ergotamine plus caffeine plus cyclizine (P = 0.014). However, it found no significant difference in need for rescue medication.[39] The second RCT (37 people with classic or common migraine) compared naproxen versus ergotamine.[40] In this trial, 47% of people were reported to have terminated the study prematurely. The trial found that naproxen significantly reduced migraine intensity (rated as none, mild, moderate, or severe) compared with ergotamine (P = 0.04). However, it found no significant difference in need for rescue medication (23% with naproxen *v* 29% with ergotamine). The third RCT (41 people) compared three treatments: naproxen, ergotamine, and placebo.[41] It found no significant difference in pain relief at 1 hour after the first dose between naproxen and ergotamine (P = 0.65).

Harms: In one RCT, adverse effects were reported in 5/32 (16%) people taking naproxen; four had stomach pain and dyspepsia, and one withdrew from the trial because of severe stomach pain.[37] One RCT comparing naproxen versus ergotamine found that vomiting was more frequent with ergotamine (10% with naproxen *v* 34% with ergotamine; P = 0.0083), and more people taking ergotamine withdrew because of severe symptoms (diarrhoea, vomiting, dizziness, nausea, shivering, and sweating) compared with those taking naproxen (2% with naproxen *v* 8% with ergotamine).[41] In another RCT, more people taking naproxen versus ergotamine discontinued medication (6/19 [32%] with naproxen *v* 2/17 [12%] with ergotamine).[40] One RCT found that more people taking ergotamine versus naproxen had severe adverse effects (1/48 [2%] with naproxen *v* 8/48 [17%] with ergotamine), and two people taking ergotamine withdrew from the study.[52] See non-steroidal anti-inflammatory drugs, p 1551.

Comment: None of the RCTs used the International Headache Society criteria (see glossary, p 1716) to identify cases.

OPTION TOLFENAMIC ACID

RCTs found limited evidence that tolfenamic acid improved duration and severity of headache compared with placebo. RCTs found no significant difference in symptom relief between tolfenamic acid and sumatriptan or paracetamol.

Benefits: We found no systematic review. **Versus placebo or sumatriptan:** One RCT (141 people, 289 migraine attacks) compared three treatments: tolfenamic acid 200 mg, sumatriptan 100 mg, and placebo.[42] The trial found that tolfenamic acid significantly increased headache relief (see glossary, p 1716) compared with placebo (AR 77% with tolfenamic acid *v* 29% with placebo; RR 2.6, 95% CI 1.5 to 4.2). However, it found no significant difference between tolfenamic acid and sumatriptan. The use of rescue medication (see glossary, p 1717) was not significantly different

between any of the three arms. **Versus placebo or aspirin or ergotamine:** One crossover RCT (20 women with common or classic migraine, 160 migraines) compared tolfenamic acid 200 mg, aspirin 500 mg, and ergotamine 1 mg versus placebo.[43] The RCT found that tolfenamic acid significantly reduced the duration of attacks compared with placebo ($P < 0.001$; time of evaluation not reported). The mean duration of attack was shortest with tolfenamic acid compared with the other treatments, but this was not significantly shorter than the mean duration of attack with the other drugs combined (P values not reported). The need for rescue medication after 2 hours was not significantly different. **Versus paracetamol:** One RCT (149 people with common or classic migraine) compared tolfenamic acid 400 mg versus paracetamol 1000 mg.[44] It found no significant difference between treatments in headache intensity (see glossary, p 1716), adverse effects, strength, effect duration, or need for additional medication after 3 hours. **Combination preparations:** One crossover RCT (49 people with common or classic migraine, 482 migraines) compared tolfenamic acid alone or in combination with either caffeine or metoclopramide versus placebo.[45] The trial found that tolfenamic acid, either alone or in combination, significantly reduced headache intensity (measured on a scale of no, slight, moderate, or severe symptoms) compared with placebo. All combinations of tolfenamic acid significantly reduced the need for rescue medication compared with placebo ($P < 0.01$).

Harms: In one RCT comparing tolfenamic acid versus sumatriptan, the frequency of adverse effects was similar (30% *v* 41%).[41] See non-steroidal anti-inflammatory drugs, p 1551.

Comment: None.

OPTION ERGOTAMINE

One systematic review found limited evidence from four RCTs that ergotamine (with or without caffeine) improved headache relief compared with placebo. One overview of harms suggested that ergotamine increased nausea and vomiting compared with placebo. RCTs have found that ergotamine (or its derivatives, with or without caffeine and cyclizine) is less effective for migraine symptoms than sumatriptan. They found limited evidence that it was less effective than naproxen. RCTs found that ergotamine plus caffeine reduced headache relief and increased nausea and vomiting at 2 hours compared with oral lysine acetylsalicylate plus metoclopramide and rizatriptan.

Benefits: **Versus placebo:** We found one systematic review (search date 1991, 7 RCTs, 588 people).[46] Ergotamine was given orally at doses between 1 and 6 mg. Ergotamine was given alone in three RCTs, combined with caffeine in three RCTs, and combined with alkaloids and barbiturates in one RCT. The RCT of ergotamine plus alkaloids plus barbiturates was not evaluable. None of the trials used International Headache Society criteria (see glossary, p 1716) for participant inclusion, and defined responders according to a variety of 3 point to 10 point scales. Two RCTs identified by the review found that ergotamine alone significantly increased headache relief (see

glossary, p 1716) compared with placebo ($P < 0.01$ in 1 RCT; reported as "significant" in the other RCT; P value not reported) and one RCT found that ergotamine alone significantly reduced the duration of attacks compared with placebo ($P < 0.001$). Two RCTs identified by the review found a similar use of rescue medication (see glossary, p 1717) with ergotamine alone and with placebo (P value not reported; no further data reported). Two RCTs identified by the review measuring nausea or vomiting associated with migraine found similar results with ergotamine alone and placebo (P value not reported). One RCT identified by the review found that ergotamine plus caffeine significantly increased headache relief (reported as "significant"; P value not reported) compared with placebo, but another RCT found no significant difference (P value not reported). The RCTs comparing ergotamine plus caffeine versus placebo did not assess duration of attack. Two RCTs identified by the review found that ergotamine plus caffeine significantly reduced need for rescue medication ($P < 0.05$ in 1 RCT; reported as "significant" in the other, P value not reported). Two RCTs identified by the review measuring nausea or vomiting found that placebo reduced these symptoms compared with ergotamine plus caffeine (no statistical analysis reported). **Versus sumatriptan:** One RCT (580 people) compared oral ergotamine 2 mg plus oral caffeine 100 mg with oral sumatriptan 100 mg.[47] The trial found that ergotamine plus caffeine significantly reduced headache relief compared with sumatriptan (AR 48% with ergotamine plus caffeine *v* 66% with sumatriptan; RR 0.73, 95% CI 0.62 to 0.85; $P < 0.001$). Significantly more people required rescue medication with ergotamine plus caffeine than with sumatriptan (AR 44% with ergotamine plus caffeine *v* 24% with sumatriptan; RR 1.82, 95% CI 1.38 to 2.39). A second RCT (crossover design; 368 people treating 2 attacks) compared dihydroergotamine nasal spray (1 or 2 mg) with sumatriptan nasal spray (20 mg).[48] It found that sumatriptan significantly increased headache relief at 1 and 2 hours, and significantly reduced nausea at 1 hour compared with dihydroergotamine (headache relief at 1 hour: 53% with sumatriptan *v* 41% with dihydroergotamine; $P < 0.001$; headache relief at 2 hours: $P = 0.003$; relief of nausea at 1 hour: 64% with sumatriptan *v* 40% with dihydroergotamine; $P = 0.006$). However, the RCT found no significant differences between treatments with respect to relief from vomiting, photophobia, or phonophobia. **Versus eletriptan:** See benefits of eletriptan, p 1707. **Versus rizatriptan:** See benefits of rizatriptan, p 1710. **Plus metoclopramide:** One RCT (24 women with common or classic migraine, 176 migraines) found no significant difference between ergotamine alone and ergotamine plus metoclopramide in headache intensity (see glossary, p 1716) (measured on a 3 point scale as more than usual, usual, or less than usual) or need for rescue medication.[49] **Versus naproxen:** See benefits of naproxen, p 1702. **Plus caffeine versus salicylates:** One RCT (250 people randomised, 227 in efficacy analysis) found that lysine acetylsalicylate (L-ASA) 1620 mg plus metoclopramide 10 mg significantly increased headache relief compared with ergotamine 2 mg plus caffeine 200 mg (86/112 [77%] with L-ASA plus metoclopramide *v* 70/115 [61%] with ergotamine plus caffeine; $P = 0.01$).[25] It found that L-ASA plus

metoclopramide significantly reduced nausea and vomiting compared with ergotamine plus caffeine after 2 hours (people free from nausea or vomiting: 73/112 [65%] with L-ASA plus metoclopramide *v* 46/115 [40%] with ergotamine plus caffeine; P = 0.001).

Harms: **Versus placebo:** In the systematic review comparing ergotamine versus placebo, two RCTs measuring nausea and vomiting found that ergotamine alone increased nausea and vomiting compared with placebo (no statistical analysis reported), and two RCTs found that ergotamine plus caffeine increased nausea and vomiting compared with placebo (no statistical analysis conducted).[46] We found one overview of the safety of dihydroergotamine mesylate (DHE) and ergotamine tartrate.[50] This overview identified two trials (24 and 311 people), which found that adverse effects with intramuscular DHE occurred in fewer than 10% of people (with leg cramps and pain at the injection site being most common) and that harms resolved within 1 hour. Three RCTs in the overview found that nausea and vomiting were the most common adverse effects, which subsided within 15 minutes. In another open trial (300 people), 32% of people taking DHE complained of nausea. Post-marketing surveillance studies have reported ischaemic complications, nausea, vomiting, seizures, cardiac and non-cardiac vascular disorders such as vasospasm and infarction, liver abnormalities, leg pain, chest pain, hypertensive crisis, injection site reactions, head and shoulder pain, and paraesthesia. Treatment related phenomena were reported in fewer than 4% of people receiving intranasal DHE. A bitter or unpleasant taste was reported by 2%. Dizziness and muscle pain were reported by less than 1%. Discontinuation of treatment occurred in 1% of people included in the RCTs. Worsening of baseline nausea or vomiting was suggested in 5/7 RCTs comparing acute administration of ergotamine tartrate versus placebo. Single case reports of less common adverse effects include abdominal discomfort, numbness or tingling of fingers or toes, ischaemic complications, swollen fingers, and leg cramps. With chronic use in excessive doses, ischaemic neuropathy, anorectal ulcers following suppository use, habituation, and overuse headaches have been reported.[50] **Versus sumatriptan:** In the RCT comparing sumatriptan versus dihydroergotamine nasal sprays, the incidence of adverse events was similar (about 10%) in both treatment groups after the first dose. The most common were disturbance of taste after sumatriptan, and nasal or sinus symptoms such as congestion, irritation, and rhinitis after dihydroergotamine. These were reported as being mild and self limiting.[48] **Plus caffeine versus salicylates:** One RCT found no significant difference in the proportion of people reporting at least one adverse event between L-ASA 1620 mg plus metoclopramide 10 mg and ergotamine 2 mg plus caffeine 200 mg (17% with L-ASA plus metoclopramide *v* 23% with ergotamine plus caffeine).[25] It found that the most common adverse events with the L-ASA regimen were somnolence (3.2%), dizziness (1.6%), and dry mouth (1.6%) and that abdominal pain (6.65), malaise (3.3%), anxiety (2.5%), and nervousness (1.7%) were the most common adverse events with the ergotamine regimen.

Comment: None.

OPTION ELETRIPTAN

One systematic review and subsequent RCTs have found that eletriptan increases headache relief at 2 hours compared with placebo. One systematic review and subsequent RCTs have found that eletriptan 40 and 80 mg increases headache relief at 2 hours compared with sumatriptan 50 and 100 mg. One RCT has found that eletriptan 40 and 80 mg increases headache relief at 2 hours compared with ergotamine plus caffeine.

Benefits:

Versus placebo: We found one systematic review (search date 2000, 8 RCTs, 5370 people)[51] and six subsequent RCTs.[52–57] The review found that all doses of eletriptan significantly increased headache relief (see glossary, p 1716) compared with placebo at 2 hours (eletriptan 20 mg, 499 people; eletriptan 40 mg, 1870 people; eletriptan 80 mg, 1393 people; total placebo groups 1113 people; AR for 20 mg: 48.9%; for 40 mg: 60.2%; for 80 mg: 65.8%; AR for placebo about 25%; ARR for 80 mg *v* placebo 42%, 95% CI 36% to 48%; for 40 mg *v* placebo 35.2%, 95% CI 29.8% to 40.7%). All six subsequent RCTs found that eletriptan significantly improved headache relief compared with placebo (see table A on web extra).[52–57] **Versus sumatriptan:** We found one systematic review[51] and two subsequent RCTs.[52,54] The review (search date 2000, 2 RCTs) found that eletriptan 40 and 80 mg significantly increased headache relief at 2 hours compared with sumatriptan 100 mg. It found no significant difference between eletriptan 20 mg and sumatriptan 100 mg (ARI for complete headache relief: eletriptan 80 mg: 18%, 95% CI 9% to 26%; eletriptan 40 mg: 11%, 95% CI 2% to 19%; eletriptan 20 mg: −1%, 95% CI −13% to +12%).[51] It found that eletriptan 40 and 80 mg significantly increased headache relief at 2 hours compared with sumatriptan 50 mg (ARI for eletriptan 80 mg: 15%, 95% CI 8% to 23%; eletriptan 40 mg: 10%, 95% CI 3% to 18%). The first subsequent RCT (1008 people) compared two doses of eletriptan (40 and 80 mg), two doses of sumatriptan (50 and 100 mg), and placebo.[52] It found that both doses of eletriptan significantly increased headache relief compared with sumatriptan at 2 hours (AR 108/169 [64%] with eletriptan 40 mg *v* 107/160 [67%] with eletriptan 80 mg *v* 88/176 [50%] with sumatriptan 50 mg *v* 85/160 [53%] with sumatriptan 100 mg; $P < 0.01$ for either dose eletriptan *v* sumatriptan 50 mg; $P < 0.05$ for either dose eletriptan *v* sumatriptan 100 mg). The second subsequent RCT (2113 people) compared three treatments: eletriptan 40 mg, sumatriptan 100 mg, and placebo.[54] It found that that eletriptan 40 mg significantly increased headache relief compared with sumatriptan 100 mg at 2 hours (67% with eletriptan *v* 59% with sumatriptan; $P < 0.001$). It found that eletriptan significantly reduced nausea compared with sumatriptan 100 mg at 2 hours (nausea absent: 74% with eletriptan *v* 67% with sumatriptan; $P < 0.01$). **Versus ergotamine plus caffeine:** We found one RCT (733 people treated included in the systematic review[51]) that compared two doses of eletriptan (40 and 80 mg), ergotamine plus caffeine, and placebo. It found that both doses of

eletriptan significantly increased headache relief and reduced nausea at 2 hours compared with ergotamine plus caffeine (headache relief: 111/206 [54%] with eletriptan 40 mg *v* 142/209 [68%] with eletriptan 80 mg *v* 65/197 [33%] with ergotamine plus caffeine; $P < 0.05$; nausea: results presented graphically; $P \leq 0.0001$ for both comparisons).[51]

Harms:

Versus placebo: We found one systematic review (search date 2000)[51] and four subsequent RCTs[54–57] that reported harms. The review found that higher doses of eletriptan 40 and 80 mg significantly increased any adverse event and central nervous system (CNS) adverse events (see glossary, p 1716) compared with placebo. It found no significant difference in adverse event rates with eletriptan 20 mg (ARI compared with placebo for any adverse event: 20 mg +1.9%, 95% CI −15.5% to +19.3%; 40 mg 7.3%, 95% CI 2.7% to 11.8%; 80 mg 18.9%, 95% CI 11.2% to 26.6%; CNS events: 20 mg +2.6%, 95% CI −6.6% to +11.7%; 40 mg 7.5%, 95% CI 4.5% to 10.6%; 80 mg 14.6%, 95% CI 10.2% to 19.0%). It found that 80 mg eletriptan significantly increased chest symptoms compared with placebo. It found no significant difference with 40 and 20 mg eletriptan (ARR compared with placebo, 20 mg −0.3%, 95% CI −3.1% to +2.6%; 40 mg +0.9%, 95% CI −0.2% to +2.0%; 80 mg 2.6%, 95% CI 0.6% to 4.5%).[51] The first subsequent RCT (2113 people analysed) found similar rates of adverse events between eletriptan 40 and 80 mg and placebo (about 30% in each group, P value not reported).[54] The second subsequent RCT (309 people analysed) found that eletriptan 20, 40, and 80 mg increased adverse events compared with placebo (16.3% with eletriptan 20 mg *v* 62.5% with eletriptan 40 mg *v* 45.5% with eletriptan 80 mg *v* 15.5% with placebo; P value not reported).[55] The most common adverse events were asthenia, nausea, and somnolence (asthenia: 1.3% with eletriptan 20 mg *v* 2.5% with eletriptan 40 mg *v* 11.7% with eletriptan 80 mg *v* 1.2% with placebo; nausea: 3.8% with eletriptan 20 mg *v* 7.5% with eletriptan 40 mg *v* 10.4% with eletriptan 80 mg *v* 2.4% with placebo; somnolence: 6.3% with eletriptan 20 mg *v* 10.0% with eletriptan 40 mg *v* 16.9% with eletriptan 80 mg *v* 3.6% with placebo, P value not reported).The third subsequent RCT found that eletriptan 40 and 80 mg increased nausea, chest symptoms, and asthenia compared with placebo (nausea: 5% with eletriptan 40 mg *v* 11% with eletriptan 80 mg *v* 8% with placebo; chest symptoms: 4% with eletriptan 40 mg *v* 5% with eletriptan 80 mg *v* 0% with placebo; asthenia: 5% with eletriptan 40 mg *v* 12% with eletriptan 80 mg *v* 2% with placebo, P value not reported).[56] The fourth subsequent RCT found that the most common adverse event was somnolence (2.8% with eletriptan 20 mg *v* 7.1% with eletriptan 40 mg *v* 8.7% with eletriptan 80 mg *v* 4.5% with placebo, P value not reported).[57] Other common adverse events with higher doses of eletriptan were asthenia and dizziness (asthenia: 3.1% with eletriptan 20 mg *v* 3.4% with eletriptan 40 mg *v* 7.1% with eletriptan 80 mg *v* 2.7% with placebo; dizziness: 2.8% with eletriptan 20 mg *v* 5.1% with eletriptan 40 mg *v* 6.1% with eletriptan 80 mg *v* 3.1% with placebo, P value not reported). **Versus sumatriptan:** The systematic review (search date 2000, 2 RCTs) found no significant difference between eletriptan 40 mg and sumatriptan 100 mg in adverse events or CNS

related events (ARI, any event: 0%, 95% CI −11% to +11%; CNS events: −3%, 95% CI −13% to +8%).[51] It found that sumatriptan 50 mg significantly reduced adverse events and CNS related events compared with eletriptan 40 mg (ARR, any event: 8%, 95% CI 1% to 15%; CNS events: 8%, 95% CI 2% to 13%).[51] One subsequent RCT found similar rates of adverse events with eletriptan 40 mg and with sumatriptan 100 mg (31% with eletriptan *v* 37% with sumatriptan).[54] **Versus ergotamine plus caffeine:** One RCT (733 people treated) that compared two doses of eletriptan (40 and 80 mg), ergotamine 1 mg plus caffeine 100 mg, and placebo found that the most common adverse events were nausea and asthenia (nausea: 5% with eletriptan 40 mg *v* 10% with eletriptan 80 mg *v* 7% with ergotamine plus caffeine; asthenia: 4% with eletriptan 40 mg *v* 10% with eletriptan 80 mg *v* 3% with ergotamine plus caffeine, P value not reported).[51]

Comment: None.

OPTION NARATRIPTAN

One systematic review and subsequent RCTs have found that naratriptan increases headache relief at 2 hours compared with placebo. One systematic review has found that sumatriptan 100 mg increases headache relief at 2 hours compared with naratriptan 2.5 mg. However, one subsequent RCT found no significant difference in headache recurrence. One RCT found no significant difference between naratriptan 2.5 mg and zolmitriptan 2.5 mg in headache relief at 4 hours. One RCT identified by a systematic review found that naratriptan reduced headache relief at 2 hours compared with rizatriptan.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 5 RCTs, 1077 people)[51] and two subsequent RCTs.[58,59] The review found that naratriptan significantly increased headache relief (see glossary, p 1716) compared with placebo (ARI 22.2%, 95% CI 16.9% to 27.5%).[51] The first subsequent RCT (643 people) found that naratriptan 2.5 mg or sumatriptan 100 mg significantly increased headache relief at 4 hours compared with placebo (AR 63% with naratriptan *v* 80% with sumatriptan *v* 31% with placebo; $P < 0.05$ for either drug compared with placebo).[58] In the second subsequent RCT a subgroup of 206 people with a poor response to sumatriptan 50 mg in a first attack were randomised 1 week later to either naratriptan 2.5 mg orally or placebo.[59] Naratriptan significantly increased headache relief at 2 hours (AR 25% with naratriptan *v* 10% with placebo; RR 2.5, 95% CI 1.3 to 4.7) and at 4 hours (AR 41% with naratriptan *v* 19% with placebo; RR 2.2, 95% CI 1.4 to 3.5) compared with placebo. **Versus sumatriptan:** We found one systematic review (search date 2000, 2 RCTs, 480 people)[51] and one subsequent RCT.[60] The review found that sumatriptan 100 mg significantly increased headache relief at 4 hours compared with naratriptan 2.5 mg (AR not reported; ARI: 8%, 95% CI 0% to 16%).[51] The subsequent RCT comparing naratriptan 2.5 mg orally with sumatriptan 100 mg orally found no significant difference in headache recurrence (see glossary, p 1716).[60] **Versus zolmitriptan:** We found one systematic

review (search date 2000, 1 RCT, 179 people).[51] It found no significant difference between naratriptan 2.5 mg and zolmitriptan 2.5 mg in headache relief at 4 hours (difference: +1%, 95% CI −15% to +17%). **Versus rizatriptan:** See benefits of rizatriptan, p 1710.

Harms: **Versus placebo:** The systematic review found no significant difference in overall adverse events, central nervous system (CNS) adverse events, and chest related adverse events (see glossary, p 1716) between naratriptan 2.5 mg and placebo (ARI for naratriptan *v* placebo; any event: +2.4%, 95% CI −2.2% to +7.0%; CNS events: +1.9%, 95% CI −12.2% to +5.0%; chest symptoms: +0.4%, 95% CI −0.8% to +1.6).[51] One subsequent RCT found similar adverse effects with naratriptan 2.5 mg orally and placebo (21% with naratriptan *v* 23% with placebo; significance not reported).[58] **Versus sumatriptan:** The systematic review (search date 2000, 2 RCTs) found that sumatriptan 100 mg significantly increased adverse events compared with naratriptan 2.5 mg (difference: 11.3%, 95% CI 1% to 22.5%).[51] **Versus zolmitriptan:** The systematic review (search date 2000, 1 RCT) found that naratriptan 2.5 mg significantly reduced adverse events compared with zolmitriptan 2.5 mg (difference: −23%, 95% CI −37% to −8%).[51] **Versus rizatriptan:** See harms of rizatriptan, p 1711.

Comment: Naratriptan or a different triptan in a second attack may be beneficial in people responding poorly to sumatriptan in a first attack, but this requires confirmation in further RCTs.

OPTION RIZATRIPTAN

One systematic review and subsequent RCTs have found that rizatriptan improves headache relief compared with placebo. Two RCTs found no significant difference between rizatriptan and zolmitriptan in headache relief at 2 hours. One RCT identified by a systematic review found that rizatriptan increased headache relief at 2 hours compared with naratriptan. One RCT found that rizatriptan increased headache relief and reduced nausea and vomiting at 2 hours compared with ergotamine plus caffeine.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 12 RCTs, 6395 people)[51] and one subsequent RCT.[61] The systematic review found that rizatriptan significantly increased headache relief (see glossary, p 1716) at 2 hours compared with placebo (AR: 62.4% with rizatriptan 5 mg *v* 68.6% with rizatriptan 10 mg *v* about 34% with placebo; ARI compared with placebo presented graphically: about 28% with rizatriptan 5 mg *v* 35% with rizatriptan 10 mg). The subsequent RCT (727 people) compared three treatments: rizatriptan 10 mg, zolmitriptan 2.5 mg, and placebo.[61] It found that rizatriptan significantly increased headache relief compared with placebo (AR 71% with rizatriptan *v* 30% with placebo; $P < 0.05$).[61] **Versus zolmitriptan:** We found one systematic review (search date 2000, 1 RCT, 435 people)[51] and one subsequent RCT.[61] The systematic review found no significant difference between rizatriptan 10 mg and zolmitriptan 2.5 mg in headache relief at 2 hours (difference: +4%, 95% CI −4% to

+11%).[51] The subsequent RCT (727 people) comparing rizatriptan 10 mg, zolmitriptan 2.5 mg, and placebo found no significant difference between rizatriptan and zolmitriptan in headache relief (AR 71% with rizatriptan *v* 67% with zolmitriptan; P = 0.23).[61] **Versus naratriptan:** One systematic review (search date 2000; 1 RCT 522 people) found that rizatriptan 10 mg significantly increased headache relief at 2 hours compared with naratriptan 2.5 mg (ARI 20%, 95% CI 11% to 30%).[51] **Versus ergotamine:** One RCT (439 people) compared oral rizatriptan 10 mg with ergotamine 2 mg plus caffeine 100 mg for the first migraine attack with the other treatment for a second attack.[62] It found that rizatriptan significantly increased headache relief and reduced nausea and vomiting at 2 hours compared with ergotamine plus caffeine (headache relief: 75.9% with rizatriptan *v* 47.3% with ergotamine plus caffeine; P ≤ 0.001; no nausea: 82.7% with rizatriptan *v* 56.2% with ergotamine plus caffeine; P ≤ 0.001; no vomiting: 96.2% with rizatriptan *v* 89.5% with ergotamine plus caffeine; P ≤ 0.001).

Harms: **Versus placebo:** We found one meta-analysis (search date 2000, 1963 people given rizatriptan 5 mg, 2783 people given rizatriptan 10 mg, and 1649 given placebo) that used individual patient data from published and unpublished RCTs.[51] It found that rizatriptan (5 and 10 mg) significantly increased overall and chest related adverse events (see glossary, p 1716) compared with placebo (placebo subtracted events: any event 7.9%, 95% CI 4.7% to 11.1% with rizatriptan 5 mg and 13.5%, 95% CI 10.6% to 16.3% with 10 mg rizatriptan; CNS events: 6.1%, 95% CI 3.2% to 9.0% with rizatriptan 5 mg and 9.4%, 95% CI 7.2% to 11.6% with rizatriptan 10 mg).[51] It found no significant difference in chest related adverse events between rizatriptan 5 mg and placebo but found that rizatriptan 10 mg significantly increased chest related adverse events compared with placebo (placebo subtracted chest symptoms: +0.9%, 95% CI −0.04 to +1.8 with rizatriptan 5 mg and 1.5%, 95% CI 0.8% to 2.3% with rizatriptan 10 mg). **Versus zolmitriptan:** The meta-analysis (search date 2000, 1 RCT) found no significant difference in adverse events between rizatriptan 10 mg and zolmitriptan 2.5 mg (difference: −8%, 95% CI −15% to 0%).[51] **Versus naratriptan:** The meta-analysis (search date 2000, 1 RCT) found that rizatriptan 10 mg significantly increased adverse events compared with naratriptan 2.5 mg (difference: 10%, 95% CI 1% to 19%).[51] **Versus ergotamine:** One RCT comparing rizatriptan 10 mg with ergotamine 2 mg plus caffeine 100 mg found no significant difference in adverse events (35.4% with rizatriptan *v* 34.5% with ergotamine plus caffeine).[62] The most common adverse events were dizziness, nausea, and somnolence (dizziness: 6.7% with rizatriptan *v* 5.3% with ergotamine; nausea: 4.2% with rizatriptan *v* 8.5% with ergotamine; somnolence: 5.5% with rizatriptan *v* 2.3% with ergotamine, P values not reported).

Comment: None.

OPTION SUMATRIPTAN

Systematic reviews and subsequent RCTs have found that subcutaneous, oral, or intranasal sumatriptan increases headache relief compared with placebo. RCTs found no significant difference in headache relief between

sumatriptan and aspirin plus metoclopramide, tolfenamic acid, or zolmitriptan. RCTs have found that oral or nasal sumatriptan increases headache relief compared with oral or nasal ergotamine. One systematic review has found that sumatriptan 100 mg increases headache relief at 2 hours compared with naratriptan 2.5 mg. However, one subsequent RCT found no significant difference in headache recurrence. One systematic review and subsequent RCTs have found that eletriptan 40 and 80 mg increases headache relief at 2 hours compared with sumatriptan 50 and 100 mg.

Benefits:

Subcutaneous sumatriptan: We found one systematic review (search date 1997),[63] one additional RCT,[64] and one subsequent RCT.[65] The review found that subcutaneous sumatriptan 6 mg significantly increased headache relief (see glossary, p 1716) at 1 hour compared with placebo (12 RCTs, 3127 people; 69% with sumatriptan *v* 19% with placebo; RR 3.7, 95% CI 3.3 to 4.2).[63] One additional crossover RCT (246 people with up to 12 migraines) comparing subcutaneous sumatriptan 6 mg with usual headache treatment (49% combinations, 24% ergotamine, 19% non-steroidal anti-inflammatory drugs, and 7% dihydroergotamine) found that sumatriptan significantly improved headache relief (78% with sumatriptan *v* 34% with usual treatment; $P < 0.001$).[64] The subsequent RCT (200 people consisting of 50 white people and 150 non-white people) compared headache relief across multiple attacks.[65] It analysed results by ethnic group. It found that subcutaneous sumatriptan 6 mg significantly increased headache relief in non-white people and white people (non-white: 87% with sumatriptan *v* 37% with placebo; white: 87% with sumatriptan *v* 19% with placebo; sumatriptan *v* placebo $P < 0.001$ in either ethnic group). **Oral sumatriptan:** We found one systematic review (search date 2000, 11 RCTs, 3185 people),[51] one additional RCT[66] and two subsequent RCTs.[52,54] The review found that sumatriptan significantly increased headache relief at 2 hours compared with placebo (AR 56.0% with sumatriptan 25 mg *v* 62.7% with sumatriptan 50 mg *v* 59.0% with sumatriptan 100 mg *v* about 30% with placebo; ARI about 25% with sumatriptan 25 mg [presented graphically] *v* about 33% with sumatriptan 50 mg [presented graphically] *v* 29%, 95% CI 26% to 34% with sumatriptan 100 mg).[51] The additional RCT (495 people) found that oral sumatriptan 50 mg significantly increased the proportion of people with headache relief after 4 hours in people with one attack compared with placebo (62% with sumatriptan *v* 32% with placebo; $P < 0.001$).[66] The first subsequent RCT (1008 people randomised, 774 people treated) compared two doses of eletriptan (40 and 80 mg), two doses of sumatriptan (50 and 100 mg), and placebo.[52] At 2 hours it found that both doses of sumatriptan significantly increased headache relief compared with placebo (50% with sumatriptan 50 mg *v* 53% with sumatriptan 100 mg *v* 31% with placebo; $P < 0.01$ for either dose of sumatriptan *v* placebo). The second subsequent RCT (2113 people) compared three treatments: eletriptan 40 mg, sumatriptan 100 mg, and placebo.[54] It found that that sumatriptan 100 mg significantly increased headache relief at 2 hours compared with placebo (59% with sumatriptan 100 mg *v* 26% with placebo; $P < 0.0001$). It found that sumatriptan 100 mg significantly reduced nausea at 2 hours

compared with placebo (nausea absent: 67% with sumatriptan 100 mg *v* 57% with placebo; P < 0.001). **Intranasal sumatriptan:** We found one review (search date 1997)[63] and three additional RCTs.[67–69] The review found that intranasal sumatriptan 20 mg significantly increased headache relief compared with placebo (6 RCTs, 1420 people; 61% with sumatriptan *v* 30% with placebo; RR 2.1, 95% CI 1.8 to 2.4).[63] The three additional RCTs (2475 people) found that intranasal sumatriptan significantly increased headache relief compared with placebo (60–64% with sumatriptan *v* 25–35% with placebo).[67–69] **Versus aspirin plus metoclopramide:** See benefits of salicylates, p 1699. **Versus tolfenamic acid:** See benefits of tolfenamic acid, p 1703. **Versus ergotamine:** See benefits of ergotamine, p 1704. **Versus naratriptan:** See benefits of naratriptan, p 1709. **Versus zolmitriptan:** See benefits of zolmitriptan, p 1714. **Versus eletriptan:** See benefits of eletriptan, p 1707. **Versus ergotamine derivatives:** See benefits of ergotamine, p 1704.

Harms: **Subcutaneous sumatriptan:** In one systematic review (search date 1997), 7/12 RCTs found that adverse effects were more common with subcutaneous sumatriptan 6 mg than with placebo (65% with sumatriptan *v* 32% with placebo; OR 4, 95% CI 3 to 5).[63] The subsequent RCT found that subcutaneous sumatriptan increased adverse events compared with placebo in both non-white and white people (non-white: 63% with sumatriptan *v* 30% with placebo; white: 63% with sumatriptan *v* 23% with placebo; P value not reported).[65] It found nine serious adverse events with sumatriptan compared with none with placebo (no details reported and number exposed was not clear). **Oral sumatriptan versus placebo:** The systematic review found that sumatriptan 25, 50, and 100 mg) significantly increased overall adverse events compared with placebo (ARI: any event 4.4%, 95% CI 0.1% to 8.8% with sumatriptan 25 mg; 7.8%, 95% CI 2.6% to 13.1% with sumatriptan 50 mg; and 13.2%, 95% CI 8.6% to 17.8% with sumatriptan 100 mg).[51] It found that the two higher doses of sumatriptan (50 and 100 mg) significantly increased central nervous system (CNS) adverse events and chest related adverse events (see glossary, p 1716) compared with placebo. However, it found no significant difference between low dose sumatriptan 25 mg and placebo (ARI; CNS events: +1.7%, 95% CI −1.2% to +4.7% with sumatriptan 25 mg; 3.7%, 95% CI 1.0% to 6.5% with sumatriptan 50 mg; 6.3%, 95% CI 3.2% to 9.5% with sumatriptan 100 mg; chest related events: +0.8%, 95% CI −1.0% to +2.6% with sumatriptan 25 mg; 1.9%, 95% CI 0.4% to 3.3% with sumatriptan 50 mg; 1.7%, 95% CI 0.8% to 2.5% with sumatriptan 100 mg). One subsequent RCT found similar rates of adverse effects between sumatriptan and placebo (37% with sumatriptan *v* 34% with placebo, P value not reported).[54]

Comment: There is a consensus that sumatriptan should not be used in people with ischaemic heart disease or concomitantly with ergotamine.

OPTION ZOLMITRIPTAN

One systematic review and two subsequent RCTs have found that oral zolmitriptan increases headache relief compared with placebo. One systematic review and two subsequent RCTs found no significant difference between zolmitriptan and sumatriptan in headache relief. One RCT found no significant difference in headache relief between aspirin plus metoclopramide and zolmitriptan. One RCT found no significant difference between naratriptan 2.5 mg and zolmitriptan 2.5 mg in headache relief at 4 hours.

Benefits:

Versus placebo: We found one systematic review (search date 2000, 9 RCTs , 4641 people)[51] and two subsequent RCTs.[70,71] The systematic review found that zolmitriptan significantly increased headache relief (see glossary, p 1716) at 2 hours compared with placebo (AR: 63.5% with zolmitriptan 2.5 mg *v* 62.8% with zolmitriptan 5 mg *v* about 30% with placebo; ARI: about 30% with zolmitriptan 2.5 mg *v* about 33% with zolmitriptan 5 mg; results presented graphically). The first subsequent RCT (289 people, 229 in analysis) compared three doses of zolmitriptan (1, 2.5, and 5 mg) versus placebo.[70] It found that zolmitriptan 2.5 mg significantly increased headache relief at 2 hours compared with placebo (53.3% with zolmitriptan 1 mg; 55.6% with zolmitriptan 2.5 mg; 65.4% with zolmitriptan 5 mg; 37.5% with placebo; P = 0.032 for zolmitriptan 2.5 mg *v* placebo, other P values not reported; analysis not by intention to treat). The second subsequent RCT (471 people) found that orally dispersible zolmitriptan 2.5 mg significantly increased headache relief at 2 hours compared with placebo (63% with zolmitriptan *v* 22% with placebo; OR 6.1, 95% CI 4.0 to 9.3).[71] It found that zolmitriptan reduced nausea at 2 hours compared with placebo, but the statistical significance was not reported (no nausea: 52% with zolmitriptan *v* 32% with placebo). **Versus sumatriptan:** We found one systematic review (search date 2000, 3 RCTs)[51] and two subsequent RCTs.[72,73] The review found no significant difference between zolmitriptan 2.5 and 5 mg and sumatriptan 25, 50, and 100 mg in headache relief at 2 hours (ARR for sumatriptan 100 mg *v* zolmitriptan 5 mg: +1%, 95% CI −4% to +6%; sumatriptan 50 mg *v* zolmitriptan 2.5 mg: +2%, 95% CI −6% to +9%; sumatriptan 50 mg *v* zolmitriptan 5 mg: +1%, 95% CI −4% to +6%; sumatriptan 25 mg *v* zolmitriptan 2.5 mg: −8%, 95% CI −16% to 0%; sumatriptan 25 mg *v* zolmitriptan 5 mg: −7%, 95% CI −15% to 0%).[51] In the first subsequent RCT (1522 people), up to six consecutive attacks were treated with zolmitriptan 2.5 mg (500 people, 2671 attacks), zolmitriptan 5 mg (514 people, 2744 attacks), or sumatriptan 50 mg (508 people, 2693 attacks).[72] The RCT found no significant difference among groups for headache relief at 2 hours (AR 62.9% with zolmitriptan 2.5 mg *v* 65.7% with zolmitriptan 5 mg zolmitriptan *v* 66.6% with sumatriptan 50 mg). The second subsequent RCT (1445 people) compared zolmitriptan 2.5–5 mg versus sumatriptan 25–50 mg.[73] The trial found no significant difference in headache relief between treatments at any dose. **Versus salicylates:** One RCT (666 people) found no significant difference between aspirin 900 mg plus metoclopramide 10 mg and zolmitriptan 2.5 mg in headache relief at 2 hours over

three migraine attacks. However, it found that zolmitriptan significantly increased the proportion of people who were pain free (see glossary, p 1717) at 2 hours (headache relief: 32.9% with salicylates *v* 33.4% with zolmitriptan; OR 1.06, 95% CI 0.77 to 1.47; pain free: 10.7% with zolmitriptan *v* 5.3% with salicylates; OR 2.19, 95% CI 1.23 to 4.03).[26] It found that rates of nausea were similar with both treatments but the statistical significance was not reported (about 30% in each group). **Stratified care versus step care:** One RCT (835 people) randomised people into three arms.[74] The first arm, named "stratified care", randomised people with low disability scores to aspirin 800–1000 mg plus metoclopramide 10 mg, and people with higher disability scores to zolmitriptan 2.5 mg. The second arm, named "step care", involved treating initial attacks with aspirin plus metoclopramide and then switching to zolmitriptan 2.5 mg for the remaining two to three attacks. The third arm involved "step care within attacks", whereby all attacks were initially treated with aspirin plus metoclopramide, and non-responders were given zolmitriptan after 2 hours. It found that stratified care significantly increased the proportion of people with headache relief compared with either of the step care groups (AR 53% with stratified care *v* 40% with step care *v* 36% with step care within attacks; RR stratified care *v* step care 1.3, 95% CI 1.1 to 1.7; stratified care *v* step care within attacks 1.4, 95% CI 1.2 to 1.7). **Versus naratriptan:** See benefits of naratriptan, p 1709.

Harms:

Versus placebo: The systematic review found that zolmitriptan 2.5 and 5 mg significantly increased overall adverse events, central nervous system (CNS) adverse events, and chest related adverse events (see glossary, p 1716) compared with placebo (ARI compared with placebo; any adverse event: 15.9%, 95% CI 9.6% to 22.1% with 2.5 mg *v* 24.5%, 95% CI 15.3% to 33.5% with 5 mg; CNS events: 9.9%, 95% CI 4.3% to 15.5% with 2.5 mg *v* 11.5%, 95% CI 6.1% to 16.8% with 5 mg; chest related events: 2.0%, 95% CI 0.7% to 3.3% with 2.5 mg *v* 2.9%, 95% CI 1.2% to 4.6% with 5 mg).[51] The first subsequent RCT (289 Japanese people) found that zolmitriptan 5 mg increased asthenia, hypoaesthesia, and abdominal pain compared with placebo (asthenia: 7.0% with zolmitriptan 5 mg *v* 1.6% with 2.5 mg *v* 1.7% with placebo; hypoaesthesia: 7.0% with zolmitriptan 5 mg *v* 1.6% with 2.5 mg *v* 0% with placebo; abdominal pain: 7.0% with zolmitriptan 5 mg *v* 1.6% with 2.5 mg *v* 1.7% with placebo, P values not reported).[70] The second subsequent RCT found that zolmitriptan increased asthenia, throat tightness, and somnolence compared with placebo (asthenia: 3.5% with zolmitriptan *v* 1.3% with placebo; throat tightness: 2.6% with zolmitriptan *v* 0% with placebo; somnolence: 3.0% with zolmitriptan *v* 1.7% with placebo, P values not reported).[71] **Versus sumatriptan:** The systematic review (search date 2000, 3 RCTs) found no significant difference in adverse events between zolmitriptan 5 mg and sumatriptan 50 or 100 mg (ARI for zolmitriptan 5 mg *v* sumatriptan 100 mg: −2%, 95% CI −8% to +4%; zolmitriptan 2.5 mg *v* sumatriptan 50 mg: 4%, 95% CI 0% to 8%; zolmitriptan 5 mg *v* sumatriptan 50 mg: −2%, 95% CI −6% to +2%).[51] However, it found that sumatriptan 25 mg significantly reduced adverse events compared with zolmitriptan 5 mg (ARR: 12%, 95% CI 6% to 18%). The first subsequent RCT comparing

zolmitriptan 2.5 and 5 mg with sumatriptan 50 mg found no significant difference in adverse events.[72] **Versus salicylates:** One RCT found that zolmitriptan increased adverse events compared with salicylates plus metoclopramide but found no difference between treatments in withdrawals due to adverse events (adverse events: 40.8% with zolmitriptan *v* 29.1% with salicylates plus metoclopramide, P value not reported; withdrawal due to adverse events: 0.9% with zolmitriptan *v* 1.5% with salicylates plus metoclopramide, P value not reported).[26] It found that zolmitriptan increased paraesthesia (4.3% with zolmitriptan *v* 1.5% with salicylates plus metoclopramide), dizziness (2.8% with zolmitriptan *v* 0.6% with salicylates plus metoclopramide), and tightness (3.7% with zolmitriptan *v* 0.6% with salicylates plus metoclopramide) and that salicylates plus metoclopramide increased abdominal pain (2.8% with zolmitriptan *v* 5.0% with salicylates plus metoclopramide) and diarrhoea (1.2% with zolmitriptan *v* 2.1% with salicylates plus metoclopramide).

Comment: None.

GLOSSARY

Central nervous system (CNS) adverse events Events associated with triptans, including asthenia, abnormal dreams, agitation, aphasia, ataxia, confusion, dizziness, somnolence, speech disorders, abnormal thinking, tremor, vertigo, and other focal neurological symptoms.

Chest related adverse events Events associated with triptans, including chest pressure, chest pain, radiating pain to the arms, other chest discomfort, heavy arms, shortness of breath, palpitations, and anxiety.

Headache intensity Mild: normal activity allowed. Moderate: disturbing, but not prohibiting normal activity; bed rest not necessary. Severe: normal activity discontinued; bed rest may be necessary.

Headache recurrence In responders, change in headache intensity (see above) from mild/none to moderate/severe within 24 hours of study medication initial dose.

Headache relief Change in headache intensity (see above) score from severe/moderate to mild/none.

International Headache Society criteria (1988) *Migraine without aura (common migraine)* is defined as five or more headache attacks lasting for 4–72 hours with accompanying symptoms of either nausea/vomiting and/or phonophobia and photophobia. Pain should comply with at least two of the following four characteristics: unilateral, throbbing, moderate to severe intensity, and increase with physical activity. For *migraine with aura (classic migraine)*, two or more headache attacks are required that comply with three of the following four characteristics: one or more fully reversible aura symptom indicating focal cerebral cortical and/or brainstem dysfunction; at least one aura symptom developing gradually over more than 4 minutes or two or more symptoms occurring in succession; no aura symptom should last more than 1 hour; and headache follows aura with a pain free (see below) interval of less than 60 minutes. In both migraine with and without aura, secondary causes of headache should be excluded; if any structural damage is found, then it should not explain headache characteristics. Less stringent criteria for migraine without aura can be used. In clinical practice, the so called borderline migraine can be diagnosed when one of the above criteria is not met. International Headache Society criteria were not developed with the intention of identifying potential responders to different medications.

Major and minor adverse effect A major adverse effect is defined as death, serious illness, or any adverse effect of sufficient severity to cause withdrawal from the study. A minor adverse effect is defined as any adverse effect that does not fulfil the criteria for a major harm.
Migraine index Pain scale for migraine resulting from duration times intensity of migraine where intensity is classified as 0 = none, 1 = mild, 2 = moderate, and 3 = severe.
Pain free Change in headache intensity (see above) score from severe/moderate to none.
Rescue medication Additional medications different to study medication permitted in non-responders, usually limited to the habitual medications a person uses to treat their migraine headache.

Substantive changes

Ergotamine One RCT added;[25] categorisation unchanged.
Eletriptan One systematic review[51] and four RCTs added;[54–57] categorisation unchanged but benefits data enhanced.
Naratriptan One systematic review added;[51] categorisation unchanged but benefits data enhanced.
Rizatriptan One systematic review[51] and one RCT added;[62] categorisation unchanged but benefits data enhanced.
Sumatriptan One systematic review[51] and two RCTs added;[54,65] categorisation unchanged but benefits data enhanced.
Zolmitriptan One systematic review[51] and three RCTs added;[26,70,71] categorisation unchanged but benefits data enhanced.

QUESTIONS

INTERVENTIONS

Key Messages

Reducing relapse rates and disability

- We found no evidence from RCTs that any treatment alters long term outcome in multiple sclerosis.
- **Glatiramer acetate** One RCT in people with relapsing and remitting multiple sclerosis found that, compared with placebo, glatiramer acetate reduced relapse rates over 2 years, but had no effect on disability. We found no good quality RCTs in people with secondary progressive multiple sclerosis.

- **Interferon beta** Two RCTs in people experiencing a first demyelinating event found that interferon beta-1a decreased the risk of conversion to clinically definite multiple sclerosis over 2–3 years compared with placebo. One systematic review in people with active relapsing remitting multiple sclerosis found limited evidence that, compared with placebo, interferon beta-1a/b reduced exacerbations and disease progression over 2 years. One subsequent RCT in people with relapsing remitting multiple sclerosis found that interferon beta-1b reduced the proportion of people with relapse over 2 years compared with interferon beta-1a. We found conflicting evidence from three RCTs about the effects of interferon beta on disease progression in people with secondary progressive multiple sclerosis.
- **Azathioprine** One systematic review in people with relapsing and remitting or progressive multiple sclerosis comparing azathioprine versus placebo or no treatment found a modest reduction in relapse rates over 2 years, but no evidence of a difference in disability. However, we were unable to draw reliable conclusions because of clinical heterogeneity among included RCTs.
- **Intravenous immunoglobulin** One RCT in people with relapsing and remitting multiple sclerosis found limited evidence from baseline comparisons that intravenous immunoglobulin may reduce disability over 2 years compared with placebo. However, the clinical importance of this difference is unclear. We found no good quality RCTs in people with secondary progressive multiple sclerosis.
- **Methotrexate** We found insufficient evidence from one small RCT about the effects of methotrexate in people with multiple sclerosis.
- **Mitoxantrone** One RCT in people with worsening, relapsing, remitting, or progressive multiple sclerosis found that mitoxantrone reduced progression of disability compared with placebo. One small RCT in people with active multiple sclerosis found limited evidence that mitoxantrone plus methylprednisolone reduced relapse compared with methylprednisolone alone. However, mitoxantrone is associated with leukopenia, menstrual disorders, and arrhythmia.

Treating acute relapses

- **Corticosteroids (methylprednisolone or corticotrophin)** One systematic review in people with multiple sclerosis requiring treatment for acute exacerbations has found that corticosteroids (methylprednisolone or corticotrophin) improves symptoms compared with placebo within the first 5 weeks of treatment. The optimal dose, route, and duration of treatment are unclear.
- **Plasma exchange** One small RCT provided insufficient evidence to assess plasma exchange in people with acute relapses of multiple sclerosis.

Fatigue

- **Amantadine** We found insufficient evidence from one systematic review of poor quality RCTs about the effects of amantadine in people with multiple sclerosis.
- **Behaviour modification** We found no RCTs on the effects of behavioural modification treatment in people with multiple sclerosis related fatigue.
- **Exercise** We found insufficient evidence from two RCTs about the effects of exercise in people with multiple sclerosis related fatigue.
- **Pemoline** One systematic review found no significant difference in the self reporting of fatigue with pemoline compared with placebo.

Multiple sclerosis

Spasticity

- **Botulinum toxin** We found insufficient evidence from one small RCT about the effects of botulinum toxin on functional outcomes in people with spasticity due to multiple sclerosis.
- **Intrathecal baclofen** One small crossover RCT provided insufficient evidence to assess functional effects of intrathecal baclofen.
- **Oral drug treatments** One systematic review found insufficient evidence about the effects of oral drugs on functional outcomes in people with spasticity due to multiple sclerosis. RCTs provided insufficient evidence to assess other oral drug treatments.
- **Physiotherapy** We found insufficient evidence from two small RCTs about the effects of physiotherapy. One of the RCTs found limited evidence that twice weekly hospital or home based physiotherapy for 8 weeks briefly improved mobility compared with no physiotherapy. The other, in people with progressive multiple sclerosis, found no significant difference between early versus delayed physiotherapy in mobility or activities of daily living.

Multidisciplinary care

- **Inpatient rehabilitation** Two small RCTs provided insufficient evidence to assess the effectiveness of inpatient rehabilitation. Both RCTs found short term benefit, but no reduction in neurological impairment. Longer term effects are uncertain.
- **Outpatient rehabilitation** One small RCT provided insufficient evidence to assess the effectiveness of outpatient rehabilitation.

DEFINITION Multiple sclerosis is a chronic inflammatory disease of the central nervous system. Diagnosis requires evidence of lesions that are separated in both time and space, and the exclusion of other inflammatory, structural, or hereditary conditions that might give a similar clinical picture. The disease takes three main forms: relapsing and remitting multiple sclerosis, characterised by episodes of neurological dysfunction interspersed with periods of stability; primary progressive multiple sclerosis, where progressive neurological disability occurs from the outset; and secondary progressive multiple sclerosis, where progressive neurological disability occurs later in the course of the disease.

INCIDENCE/ PREVALENCE Prevalence varies with geography and racial group; it is highest in white populations in temperate regions.[1] In Europe and North America, prevalence is 1/800 people, with an annual incidence of 2–10/100 000, making multiple sclerosis the most common cause of neurological disability in young adults. Age of onset is broad, peaking between 20 and 40 years.[2]

AETIOLOGY/ RISK FACTORS The cause remains unclear, although current evidence suggests that multiple sclerosis is an autoimmune disorder of the central nervous system resulting from an environmental stimulus in genetically susceptible individuals. Multiple sclerosis is currently regarded as a single disorder with clinical variants, but there is some evidence that it may consist of several related disorders with distinct immunological, pathological, and genetic features.[1,3]

PROGNOSIS In 90% of people, early disease is relapsing and remitting. Although some people follow a relatively benign course over many years, most develop secondary progressive disease, usually 6–10 years

after onset. In 10% of people, initial disease is primary progressive. Apart from a minority of people with "aggressive" multiple sclerosis, life expectancy is not greatly affected and the disease course is often of more than 30 years' duration.

AIMS OF INTERVENTION To prevent or delay disability; to improve function; to alleviate symptoms of spasticity; to prevent complications (contractures, pressure sores); to optimise quality of life.

OUTCOMES Neurological disability, spasticity, fatigue, general health, relapse rate, and quality of life. **Neurological disability:** In clinical trials, disability in multiple sclerosis is usually measured using the disease specific Expanded Disability Status Scale, which ranges from 0 (no disability) to 10 (death from multiple sclerosis) in half point increments.[4] Lower scores (0–4) reflect specific neurological impairments and disability; higher scores reflect reducing levels of mobility (4–7) and upper limb and bulbar function (7–9.5). The scale is non-linear and has been criticised for indicating change poorly, for emphasising neurological examination and mobility, and for failing to reflect other disabilities (e.g. fatigue, sexual disability). Some timed outcomes include ambulation (time taken to walk a specified short distance), the nine-hole peg test (time taken to place some pegs into holes in a block), and the box and block test (time taken to transfer blocks between boxes). **Sustained disease progression:** This is reported when an increase in disability from either disease progression or incomplete recovery from relapse is sustained for 3 or 6 months. A relapse that resolves within this time period constitutes non-sustained progression. **Spasticity:** A variety of clinical measures are used, the most common being the Ashworth Scale, which scores muscle tone on a scale of 0–4, with 0 representing normal tone and 4 severe spasticity. For the purposes of this review, the Ashworth Scale was considered to represent an appropriate clinical outcome and was selected over other outcome measures for spasticity (e.g. neurophysiological measures, examination ratings) that represent proxy clinical outcomes. **General health:** Attempts have been made to customise generic health status scales, but these scales have not been widely used.[5]

METHODS *Clinical Evidence* search and appraisal March 2003. We included only trials focusing on clinical outcomes (disability, relapses, and symptoms).

QUESTION What are the effects of interventions aimed at reducing relapse rates and disability?

OPTION INTERFERON BETA

Two RCTs in people experiencing a first demyelinating event found that interferon beta-1a decreased the risk of conversion to clinically definite multiple sclerosis over 2–3 years compared with placebo. One systematic review in people with active relapsing remitting multiple sclerosis found limited evidence that, compared with placebo, interferon beta-1a/b reduced exacerbations and disease progression over 2 years. One subsequent RCT in people with relapsing remitting multiple sclerosis found that interferon

beta-1b reduced the proportion of people with relapse over 2 years compared with interferon beta-1a. We found conflicting evidence from three RCTs about the effects of interferon beta on disease progression in people with secondary progressive multiple sclerosis.

Benefits:

First demyelinating event: We found two placebo controlled RCTs examining the effects of interferon beta-1a in people experiencing a first demyelinating event with evidence of subclinical demyelination on magnetic resonance imaging of the brain.[6,7] Both RCTs found that interferon beta-1a significantly reduced the risk of a second clinical event and, therefore, of conversion to a definite diagnosis of multiple sclerosis. The first RCT (383 people) found that interferon beta-1a significantly decreased the risk of conversion to clinically definite multiple sclerosis after 3 years compared with placebo (cumulative probability of conversion to clinically definite multiple sclerosis: 35% with interferon beta-1a *v* 50% with placebo; HR 0.56, 95% CI 0.38 to 0.81).[6] The second RCT (308 people) found that interferon beta-1a significantly decreased the proportion of people with clinically definite multiple sclerosis after 2 years compared with placebo (52/154 [34%] with interferon beta-1a *v* 69/154 [45%] with placebo; OR 0.61, 95% CI 0.37 to 0.99).[7] **Relapsing and remitting multiple sclerosis:** We found one systematic review (search date 2000, 1215 people), which identified seven RCTs comparing interferon beta-1a/b versus placebo in people with active relapsing remitting multiple sclerosis (2 relapses in previous 2 or 3 years).[8] The systematic review found that, over 2 years, interferon significantly reduced the risk of exacerbations and disease progression (3 RCTs, 919 people, RR for exacerbation 0.80, 95% CI 0.73 to 0.88; RR for disease progression, defined as 1 point progression on the Expanded Disability Status Scale sustained over 3 or 6 months 0.69, 95% CI 0.55 to 0.87). The review found results for exacerbation or disease progression were not significant if a sensitivity analysis assumed that all people lost to follow up had exacerbation or experienced disease progression (worst case scenario).[8] One subsequent RCT (188 people with relapsing remitting multiple sclerosis) compared interferon beta-1b (250 μg given on alternate days) versus interferon beta-1a (30 μg given once weekly).[9] Over 2 years, the proportion of people remaining relapse free was significantly higher with interferon beta-1b given on alternate days than with interferon beta-1a given once a week (relapse free: 49/96 [51%] with interferon beta-1b *v* 33/92 [36%] with interferon beta-1a; RR of relapse 0.76, 95% CI 0.59 to 0.99). Analysis was by intention to treat. Investigators were not blinded to treatment allocation. **Secondary progressive multiple sclerosis:** We found three RCTs.[10–12] The first RCT (718 people) compared interferon beta-1b (8 MIU on alternate days) versus placebo in people with secondary progressive multiple sclerosis and an Expanded Disability Status Scale score of 3.0–6.5.[10] After a median of 30 months' follow up, the trial found that interferon delayed sustained progression of disability (measured by the Expanded Disability Status Scale) by 9–12 months, reduced risk of progression, and reduced risk of being wheelchair bound (OR for confirmed progression 0.65, 95% CI 0.52 to 0.83; NNT to prevent 1 additional person becoming wheelchair bound 13, 95% CI 8 to 49). The treatment effect was apparent in people of all levels of baseline disability. There was a large number of withdrawals from each group (27% placebo and 25% interferon), and no data on quality of life were reported. The second RCT (618 people)

compared subcutaneous interferon beta-1a (22 or 44 μg, 3 times weekly) versus placebo.[11] It found no significant difference for confirmed progression of disability, although interferon reduced risk of relapse compared with placebo (HR for progression of disability 0.83, 95% CI 0.65 to 1.07; AR for relapse in 1 year 50% with interferon *v* 71% with placebo; $P < 0.001$). The third RCT (436 people) found no significant difference in Expanded Disability Status Scale between interferon beta (60 μg once weekly) and placebo after 2 years.[12] However, Expanded Disability Status Scale was a secondary outcome measure. The RCT also found that interferon beta reduced progression compared with placebo after 2 years (progression measured by Multiple Sclerosis Functional Composite score comprising a 25-foot timed walk, nine-hole peg test, and the paced auditory serial addition test; difference between groups $P = 0.033$). However, this outcome has not been assessed in other RCTs and its clinical importance is uncertain.

Harms: The RCTs did not report any major adverse effects.[10,13–15] Mild to moderate effects included early flu-like symptoms (50% of people) and, rarely, leukopenia and asymptomatic elevation of transaminases. Injection site reactions occurred with subcutaneous administration in 80% of people. The RCT comparing interferon beta-1b versus interferon beta-1a found that most adverse events (flu-like syndrome, fever, fatigue, increased liver enzymes) were most frequent during the first months of treatment and reduced in frequency after the first 6 months.[9] Frequency of adverse events was similar in both groups. However, local skin reactions occurred more frequently in the interferon beta-1b group with one case of skin necrosis that caused treatment withdrawal.[9]

Comment: None.

OPTION GLATIRAMER ACETATE

One RCT in people with relapsing and remitting multiple sclerosis found that, compared with placebo, glatiramer acetate reduced relapse rates over 2 years, but found no effect on disability. We found no good quality RCTs in people with secondary progressive multiple sclerosis.

Benefits: We found no systematic review. **Relapsing and remitting multiple sclerosis:** We found one RCT (251 people, Expanded Disability Status Scale 0–5) comparing glatiramer acetate versus placebo.[16] The RCT found that glatiramer acetate (copolymer 1) 20 mg daily significantly reduced relapse rates over 2 years compared with placebo (mean relapse rate over 24 months: 1.19 with glatiramer acetate *v* 1.68 with placebo; ARR 29%; $P = 0.007$). It found no significant effect on disability. **Secondary progressive multiple sclerosis:** We found no good quality RCTs.

Harms: A self limiting allergic type reaction (flushing, chest tightness, and anxiety) lasting up to 30 minutes was reported by 15% of people on active treatment on at least one occasion (maximum 7 reactions).[16]

Comment: None.

OPTION INTRAVENOUS IMMUNOGLOBULIN

One RCT in people with relapsing and remitting multiple sclerosis found limited evidence from baseline comparisons that intravenous immunoglobulin may reduce disability scores over 2 years compared with placebo. However, the clinical importance of this difference is unclear. We found no good quality RCTs in people with secondary progressive multiple sclerosis.

Benefits: We found no systematic review. **Relapsing and remitting multiple sclerosis:** We found one RCT (150 people with relapsing and remitting multiple sclerosis) comparing intravenous immunoglobulin 0.2 g/kg monthly versus placebo.[17] Treatment was for a maximum of 2 years, but average duration was 21 months. It found that the level of disability significantly decreased from baseline in the experimental group (change in Expanded Disability Status Scale –0.23, 95% CI –0.43 to –0.03) compared with no significant change from baseline in the placebo group (change in Expanded Disability Status Scale +0.12, 95% CI –0.13 to +0.37).[17] The RCT found that the between group difference in the mean change of the Expanded Disability Status Scale was significant (P = 0.008). The RCT did not report the time to development of sustained progression of disability. **Secondary progressive multiple sclerosis:** We found no RCTs meeting our quality criteria.

Harms: No significant adverse effects were reported.[17] However, higher doses of intravenous immunoglobulin have been associated with aseptic meningitis and other systemic reactions.[18]

Comment: The reduction in disability score with intravenous immunoglobulin was modest. The clinical importance of this small effect is unclear.

OPTION AZATHIOPRINE

One systematic review in people with relapsing and remitting or progressive multiple sclerosis comparing azathioprine versus placebo or no treatment found a modest reduction in relapse rates over 2 years, but no evidence of a difference in disability. However, we were unable to draw reliable conclusions because of clinical heterogeneity among included RCTs.

Benefits: We found one systematic review of azathioprine (search date 1989, 7 RCTs, 793 people with relapsing and remitting multiple sclerosis or progressive multiple sclerosis).[19] The systematic review found that azathioprine significantly reduced the relapse rate at 2 years compared with placebo or no treatment (5 RCTs; OR of remaining relapse free 2.04, 95% CI 1.42 to 2.93) and reduced disability scores but the difference did not quite reach significance (4 RCTs; Expanded Disability Status Scale mean score difference –0.22, 95% CI –0.43 to +0.003).

Harms: About 10% of people were unable to tolerate therapeutic doses of azathioprine. Well documented adverse effects include hepatotoxicity and bone marrow suppression.[19] There are concerns about long term cancer risk.[20] In one large RCT, 21% of people on azathioprine withdrew after 1 year compared with 12% on placebo.[20]

Comment: The methods used in the multiple sclerosis trials have improved, making it hard to compare older and more recent RCTs. Trials in the systematic review included people with different categories of multiple sclerosis and used different definitions of relapse.[21] We were therefore unable to draw reliable conclusions about the effects of azathioprine.

OPTION METHOTREXATE

We found insufficient evidence from one small RCT about the effects of methotrexate in people with multiple sclerosis.

Benefits: We found no systematic review. We found one RCT (60 people with primary or secondary progressive multiple sclerosis) comparing low dose methotrexate (7.5 mg weekly) versus placebo.[22] The RCT found that methotrexate significantly reduced the risk of progression compared with placebo (ARR 31%; P = 0.01), defined by a composite outcome measure, including Expanded Disability Status Scale, ambulation, nine-hole peg test, and box and block test. However, the clinical importance of these results is unclear (see comment below).

Harms: No major toxicity was reported in the RCT, but bone marrow suppression and hepatotoxicity can occur with low dose methotrexate; regular monitoring is advised.[22]

Comment: The findings of the RCT mainly reflected changes in upper limb function.[22] RCTs of other drugs have not used composite outcome measures, which makes comparisons difficult. Relative risks for treatment failure were not reported.

OPTION MITOXANTRONE

One RCT in people with worsening, relapsing, remitting, or progressive multiple sclerosis found that mitoxantrone reduced progression of disability compared with placebo. One small RCT in people with active multiple sclerosis found limited evidence that mitoxantrone plus methylprednisolone reduced relapse compared with methylprednisolone alone. However, mitoxantrone is associated with leukopenia, menstrual disorders, and arrhythmia.

Benefits: We found no systematic review. We found two RCTs.[23,24] The first RCT studied 194 people with worsening relapsing, remitting, or secondary progressive multiple sclerosis and an Expanded Disability Status Scale of 3.0–6.0.[23] It compared mitoxantrone (5 mg/m^2 or 12 mg/m^2 intravenously every 3 months) versus placebo for 24 months. It found that the higher dose of mitoxantrone improved disability compared with placebo after 24 months (mean change in the Expanded Disability Status Scale from baseline: –0.13 with 12 mg/m^2 mitoxantrone *v* 0.23 with placebo; difference between groups 0.24, 95% CI 0.04 to 0.44). The RCT reported that lower dose mitoxantrone also improved disability compared with placebo (P = 0.01; no further data provided). A second, smaller unblinded RCT (42 people with active multiple sclerosis) compared monthly intravenous mitoxantrone (20 mg) plus methylprednisolone (1 g) versus methylprednisolone alone.[24] It found that, compared with

methylprednisolone alone, mitoxantrone plus methylprednisolone significantly reduced disease activity after 6 months (as assessed by appearance on magnetic resonance imaging) and significantly lowered annual clinical relapse rates (mitoxantrone plus methylprednisolone 0.7 *v* methylprednisolone alone 3.0; $P < 0.01$).[24]

Harms: The major risk is dose related cardiotoxicity, but this is rare at the doses used in multiple sclerosis (see comment below). Leukopenia, nausea, and amenorrhoea are commonly reported.[25] The RCT comparing higher and lower dose mitoxantrone versus placebo found that nausea, alopecia, urinary tract infection, menstrual disorder, leukopenia, and arrhythmia were more common with the higher dose of mitoxantrone than with placebo (nausea: 20% with placebo *v* 76% with higher dose mitoxantrone; alopecia: 31% *v* 61%; urinary tract infection: 13% *v* 32%; menstrual disorder: 26% *v* 61%; leukopenia: 0% *v* 19%; arrhythmia: 8% *v* 18%).[23]

Comment: One retrospective case series of 1378 people with multiple sclerosis treated with mitroxantrone reported two cases of cardiotoxicity[26] and one case of acute leukaemia.[27]

QUESTION What are the effects of treatments for acute relapse?

OPTION CORTICOSTEROIDS

One systematic review in people with multiple sclerosis requiring treatment for acute exacerbations has found that corticosteroids (methylprednisolone or corticotrophin) improves symptoms compared with placebo within 5 weeks of treatment. The optimal dose, route, and duration of treatment are unclear.

Benefits: We found one systematic review (search date 1999, 377 people with multiple sclerosis requiring treatment for acute exacerbations, 4 RCTs of methylprednisolone, 2 RCTs of corticotrophin *v* placebo).[28] The systematic review found that, compared with placebo, methylprednisolone or corticotrophin significantly reduced the proportion of people whose symptoms were worse or unimproved within 5 weeks of treatment (5 RCTs; worse or unimproved within 5 weeks from randomisation: 63/175 [36%] with methylprednisolone or corticotrophin *v* 94/155 [60%] with placebo; OR 0.37, 95% CI 0.24 to 0.57). A small subgroup analysis using an indirect comparison suggested no difference between 5 days and 15 days of treatment with methylprednisolone.[28] One of the included RCTs (51 people) found no difference between oral methylprednisolone and placebo in the prevention of new relapses or in disability after 1 year.

Harms: Gastrointestinal symptoms and psychic disorders were significantly more common in people receiving oral high dose methylprednisolone than in people receiving placebo.[28] Weight gain and oedema were significantly more frequent in people receiving corticotrophin than in people receiving placebo.[28]

Comment: None.

OPTION PLASMA EXCHANGE

One small RCT provided insufficient evidence to assess plasma exchange in people with acute relapses of multiple sclerosis.

Benefits: We found no systematic review. We found one small, double blind, crossover RCT comparing plasma exchange versus sham treatment in people with acute relapses of multiple sclerosis (12 people) or other demyelinating disease (10 people; see comment below).[29] Analysing pre-crossover results, the RCT found a non-significant increase in moderate or greater improvement in neurological disability in people receiving plasma exchange compared with sham treatment (pre-crossover: 5/11 [46%] with plasma exchange *v* 1/11 [9%] with sham treatment; P = 0.0743).[29]

Harms: The RCT reported no major adverse effects.[29]

Comment: At the time of randomisation, all people had failed to respond to standard doses of intravenous corticosteroids and were within 3 months of onset of the acute deficit.[29]

QUESTION What are the effects of treatments for fatigue?

OPTION AMANTADINE

We found insufficient evidence from one systematic review of poor quality RCTs about the effects of amantadine in people with multiple sclerosis.

Benefits: We found one systematic review (search date 1999).[30] The review found one parallel and three crossover RCTs (236 people with multiple sclerosis; see comment below). It found limited evidence favouring amantadine compared with placebo. However, there were important methodological weaknesses in the included RCTs (see comment below). The parallel RCT included in the review found that amantadine significantly improved fatigue measured by "preferred treatment 2 weeks after end of trial", and "MS-specific Fatigue Scale" ($P < 0.05$), but found no significant difference measured by "preferred treatment at the end of trial", "Fatigue Severity Scale", or "Rand Index of Vitality".[30] The three crossover RCTs included in the review found different results with different measures of fatigue. One RCT found amantadine significantly improved fatigue measured by "effects on most affected activity VAS", "effects on activities of daily living", "response over previous period", and "preferred treatment" ($P < 0.05$), but not by "effects on fatigue VAS"; one found amantadine significantly improved fatigue measured by "preferred treatment" ($P < 0.05$); and one found amantadine significantly improved fatigue measured by "preferred treatment" ($P < 0.05$), but not by "fatigue; daily ratings; point scale 1–5".[30]

Harms: The review reported that there were no important differences in adverse effects between amantadine and placebo.[30]

Comment: The RCTs used a variety of methods to assess fatigue, and the significance of the results was sensitive to the scales or measures used.[30] The systematic review stated that all the RCTs were open to

bias (arising from lack of clarity about the randomisation methods, blinding, incompleteness of follow up, and difficulties with interpretation of crossover RCTs). It found insufficient evidence about the effects of amantadine on the quality of life of people with multiple sclerosis.

OPTION PEMOLINE

One systematic review of poor quality RCTs found no significant difference in fatigue with pemoline compared with placebo.

Benefits: We found one systematic review (search date 1999).[30] It found one parallel and one crossover RCT (126 people with multiple sclerosis). The review found no significant difference with pemoline in the self reporting of fatigue compared with placebo.

Harms: The review found more reports of adverse effects (sleep disturbance, nausea, mood change, palpitations, irritability, insomnia, anorexia) with pemoline than with placebo.[30]

Comment: The RCTs used a variety of methods to assess fatigue, and the significance of the results was sensitive to the scales or measures used.[30] The systematic review stated that all the RCTs were open to bias (arising from lack of clarity about the randomisation methods, blinding, incompleteness of follow up, and difficulties with interpretation of crossover RCTs).[30]

OPTION BEHAVIOURAL MODIFICATION TREATMENT

We found no RCTs on the effects of behavioural modification treatment in people with multiple sclerosis related fatigue.

Benefits: We found no systematic reviews or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION EXERCISE

We found insufficient evidence from two RCTs about the effects of exercise in people with multiple sclerosis related fatigue.

Benefits: We found no systematic review. We identified two RCTs.[31,32] The first RCT (46 people, Expanded Disability Status Scale 0–6) compared 15 weeks of aerobic training versus no exercise.[31] Using a scale that measures mental and physical fatigue, the RCT found a significant reduction in fatigue at 10 weeks but not after completion of the exercise programme. A different scale that measured only physical fatigue remained unchanged in both groups of people. The RCT found significant improvements in other measures of emotional behaviour and quality of life (Profile of Mood States depression and anger score, Sickness Impact profile scores). The second RCT (26 people with clinically definite multiple sclerosis taking part in an inpatient rehabilitation programme, Expanded Disability Status

Scale 1–6.5) compared adding aerobic exercise training (five supervised training sessions/week for 3–4 weeks) to the usual rehabilitation programme versus the usual rehabilitation programme alone.[32] The RCT did not compare the two groups directly. Its results were expressed as changes from baseline within each group before and after intervention using a recognised fatigue severity scale. The RCT found no significant change in fatigue from baseline in either group.

Harms: None reported.

Comment: People with moderate disability or severe fatigue may have difficulty adhering to an aerobic exercise programme.

QUESTION What are the effects of treatments for spasticity?

OPTION PHYSIOTHERAPY

We found insufficient evidence from two small RCTs about the effects of physiotherapy. One of the RCTs found limited evidence that twice weekly hospital or home based physiotherapy for 8 weeks briefly improved mobility compared with no physiotherapy. The other, in people with progressive multiple sclerosis, found no significant difference between early versus delayed physiotherapy in mobility or activities of daily living.

Benefits: We found no systematic review. One single blind crossover RCT (40 people) comparing hospital based or home based physiotherapy (45 minutes, twice weekly for 8 weeks) versus no physiotherapy found significantly improved mobility assessed 1 week after treatment (hospital physiotherapy *v* no physiotherapy: Rivermead mobility index increased by 1.4 units, 95% CI 0.6 units to 2.1 units, $P < 0.001$; home physiotherapy *v* no physiotherapy: Rivermead mobility index increased by 1.5 units, 95% CI 0.7 units to 2.2 units, $P < 0.001$).[33] The treatment effect was short lived, being largely lost 8 weeks after treatment. One unblinded RCT (45 people with progressive multiple sclerosis) compared early versus delayed physiotherapy (9 weeks of inpatient treatment).[34] It found no significant difference in mobility (timed walk, Rivermead mobility index) or activities of daily living. It found treated people reported reduced mobility related stress ($P < 0.001$).

Harms: None reported.

Comment: None.

OPTION ORAL DRUG TREATMENT

One systematic review found insufficient evidence about the effects of oral drugs on functional outcomes in people with spasticity due to multiple sclerosis. RCTs provided insufficient evidence to assess other oral drug treatments.

Benefits: We found one systematic review (search date 2001, 36 RCTs of duration > 7 days).[35] Of these, only 13 RCTs used an appropriate outcome measure (the Ashworth score). **Oral baclofen versus placebo:** The systematic review identified one crossover RCT that

used the Ashworth score.[36] The RCT (30 people) used baclofen (20 mg) with or without an exercise programme and found significant benefit from exercise plus baclofen compared with placebo.[35] It found no significant effect of exercise alone compared with placebo. **Dantrolene versus placebo:** The review found no RCTs that used a validated outcome measure.[35] **Tizanidine versus placebo:** The review identified two RCTs that used the Ashworth score. One RCT (220 people, tizanidine 2–36 mg/day) found no significant difference in Ashworth score but found that tizanidine reduced self reported clonus and spasm.[37] The other RCT (187 people, tizanidine 24–36 mg/day) found that tizanidine significantly reduced muscle tone, although it found no impact on mobility related activities of daily living.[38] **Baclofen versus tizanidine:** Seven RCTs comparing baclofen and tizanidine were identified, three of which used the Ashworth score. No significant differences on this or unvalidated measures of spasticity were found with baclofen and tizanidine. No other comparative RCTs used validated outcome measures.[35]

Harms: Comparative RCTs of baclofen and tizanidine found similar levels of adverse effects (including muscle weakness, sedation, and dry mouth), but tizanidine may be less likely than baclofen to cause muscle weakness.[39]

Comment: The review concluded that the absolute and comparative efficacy of antispasmodic drugs in multiple sclerosis is poorly documented.[35] The major difficulty in planning and designing future RCTs is the lack of a functionally relevant, well validated measure of spasticity.

OPTION INTRATHECAL BACLOFEN

One small crossover RCT provided insufficient evidence to assess functional effects of intrathecal baclofen.

Benefits: We found no systematic review. We found one small crossover RCT comparing intrathecal baclofen versus intrathecal saline (19 non-ambulant people with multiple sclerosis or spinal cord injury and with spasticity resistant to oral baclofen).[40] Baclofen significantly reduced spasticity and spasm frequency. Average Ashworth scores fell from 4.0 at baseline to 1.2 after 3 days of treatment ($P < 0.0001$), with scores for all people improving from baseline.[40]

Harms: Potential problems include pump failure, infection, and, rarely, baclofen overdose.

Comment: We found no evidence about intrathecal baclofen in ambulant people.

OPTION BOTULINUM TOXIN

We found insufficient evidence from one small RCT about the effects of botulinum toxin on functional outcomes in people with spasticity due to multiple sclerosis.

Benefits: We found no systematic review but found one RCT.[41] The RCT (74 people) compared three different doses of intramuscular botulinum toxin (500, 1000, or 1500 units) versus placebo for the treatment

of hip adductor spasticity in multiple sclerosis.[41] The RCT did not examine functional outcomes. It found that the 1500 unit dose (17 people) compared with placebo (16 people) significantly improved maximum distance between the knees at 4 weeks ($P = 0.02$).[41] The 1000 unit (20 people) and 1500 unit (17 people) doses improved median hygiene scores from baseline at 4 weeks.

Harms: Botulinum toxin can cause local weakness. Adverse events were reported in 55% of all people with botulinum toxin compared with 63% of all people with placebo.[41] The most frequent were hypertonia (22% of all people with botulinum toxin *v* 25% of all people with placebo), weakness of non-injected muscles (14% *v* 6%), fatigue (7% *v* 13%), urinary tract infection (5% *v* 19%), headache (5% *v* 13%), micturition frequency (5% *v* 13%), back pain (5% *v* 0%), and diarrhoea (5% *v* 0%).[41] Twice as many adverse events were reported by the 1500 unit group (mean 2.7/person) compared with the 500 unit group (mean 1.1/person) and the 1000 unit group (mean 1.2/person).[41] Six people had serious adverse events (2 with botulinum toxin, 4 with placebo). The events (hospital admissions with diarrhoea, multiple infections, bowel spasticity, gastroparesis, pulmonary embolism, and blocked catheter) were considered to be unrelated to the study medication.[41]

Comment: None.

QUESTION What are the effects of multidisciplinary management?

OPTION INPATIENT REHABILITATION

Two small RCTs provided insufficient evidence to assess the effectiveness of inpatient rehabilitation. Both RCTs found short term benefit, but no reduction in neurological impairment. Longer term effects are uncertain.

Benefits: We found no systematic review but found two RCTs.[42,43] The first RCT compared brief inpatient rehabilitation (average 25 days) versus remaining on the waiting list (non-treatment control group) in 66 people with progressive multiple sclerosis who were selected as "good candidates" for rehabilitation.[42] Rehabilitation significantly improved disability at 6 weeks assessed by the functional independence measure ($P < 0.001$) and the London Handicap Scale ($P < 0.01$), despite unchanged levels of neurological impairment (Expanded Disability Status Scale). Benefit persisted for up to 9 months. The second RCT compared 3 weeks of inpatient rehabilitation versus exercises at home in 50 ambulant people with multiple sclerosis (Expanded Disability Status Scale 3–7).[43] The RCT found improvements in disability, assessed by the functional independence measure ($P < 0.004$), which persisted at 9 but not at 15 weeks' follow up.

Harms: None reported.

Comment: None.

OPTION OUTPATIENT REHABILITATION

One small RCT provided insufficient evidence to assess the effectiveness of outpatient rehabilitation.

Benefits: We found no systematic review. We found one RCT comparing outpatient rehabilitation (5 hours/week for 1 year) versus remaining on the waiting list (non-treatment control group) in 46 people with progressive multiple sclerosis. Rehabilitation reduced the frequency of fatigue (effect size –0.27) and multiple sclerosis symptoms (effect size –0.32), despite no significant change in neurological impairment in either group.[44]

Harms: None reported.

Comment: Future trials need to record effects on disability and quality of life as well as impairment.

See glossary, p 1750

*We have used the term "levodopa" to refer to a combination of levodopa and a peripheral decarboxylase inhibitor.

Key Messages

Drug treatments in people with early stage Parkinson's disease

- **Selegiline** RCTs have found that selegiline improves the symptoms of Parkinson's disease and delays the need for levodopa compared with placebo. One of the RCTs found weak evidence of increased mortality in people treated with selegiline.
- **Dopamine agonists (reduce dyskinesia and motor fluctuations compared with levodopa, but are associated with increased treatment withdrawal and poorer motor scores)** One systematic review and one subsequent RCT found that dopamine agonist monotherapy reduced the incidence of dyskinesias and fluctuations in motor response compared with levodopa monotherapy. However, the subsequent RCT found that dopamine agonist monotherapy was associated with poorer motor scores than was levodopa monotherapy, and with an increased risk of treatment withdrawal.
- **Dopamine agonists plus levodopa (reduce dyskinesia compared with levodopa alone, but increase disability)** One systematic review and subsequent RCTs have found that dopamine agonist treatment plus levodopa reduces dyskinesia compared with levodopa alone. However, some RCTs found that levodopa alone improved motor impairments and disability compared with dopamine agonist plus levodopa.
- **Levodopa** We found no placebo controlled RCTs, although experience suggests that levodopa improves motor function, but that dyskinesias and fluctuations in motor response are related to long term levodopa treatment and are irreversible.
- **Modified release levodopa (no more effective than immediate release levodopa)** RCTs found no significant difference with modified versus immediate release levodopa in motor complications or disease control after 5 years. One RCT found that modified release co-careldopa was better tolerated than immediate release co-careldopa.

Adding a dopamine agonist to levodopa in people with a fluctuating response to levodopa

- **Adding a dopamine agonist to levodopa** Systematic reviews have found that, in people with response fluctuations to levodopa, adjuvant dopamine agonists reduce "off" time, improve motor impairment and activities of daily living, and reduce levodopa dose, but increase dopaminergic adverse effects and dyskinesias.

Surgery in people with later stage Parkinson's disease

- **Pallidal surgery** One systematic review found evidence that unilateral pallidotomy improved motor examination and activities of daily living compared with medical treatment. There is a high incidence of adverse effects with pallidotomy. One RCT found insufficient evidence to assess the effects of pallidotomy compared with those of deep brain stimulation. We found no systematic review or RCTs comparing pallidal deep brain stimulation versus medical treatment. One small RCT found insufficient evidence to assess the effects of pallidal deep brain stimulation compared with those of subthalamic deep brain stimulation.
- **Subthalamic surgery** One systematic review found no RCTs comparing subthalamic surgery versus medical treatment. One small RCT comparing subthalamic deep brain stimulation versus pallidal deep brain stimulation found no significant difference in motor scores.

- **Thalamic surgery** Systematic reviews identified no RCTs comparing thalamic surgery versus medical treatment. One RCT found that thalamic deep brain stimulation improved functional status and caused fewer adverse effects compared with thalamotomy. Case series found that, in 14–23% of people, thalamotomy was associated with permanent complications, including speech disturbance, apraxia, and death.

Rehabilitation treatments in people with later stage Parkinson's disease

- **Occupational therapy; physiotherapy; speech and language therapy for speech disturbance; swallowing therapy for dysphagia** Systematic reviews of poor quality RCTs provided insufficient evidence about the effects of these interventions.

DEFINITION

Idiopathic Parkinson's disease is an age related neurodegenerative disorder, which is associated with a combination of asymmetrical bradykinesia, hypokinesia, and rigidity, sometimes combined with rest tremor and postural changes. Clinical diagnostic criteria have a sensitivity of 80% and a specificity of 30% compared with the gold standard of diagnosis at autopsy.[1] The primary pathology is progressive loss of cells that produce the neurotransmitter dopamine from the substantia nigra in the brainstem. Treatment aims to replace or compensate for the lost dopamine. A good response to treatment supports, but does not confirm the diagnosis. Several other catecholaminergic neurotransmitter systems are also affected in Parkinson's disease. There is no consistent definition of early and late stage Parkinson's disease. In this chapter we consider people with early stage disease to be those who have not yet developed motor complications associated with long term levodopa treatment (such as dyskinesias [see glossary, p 1750] and "on/off" fluctuations). Late stage Parkinson's disease is taken to mean that motor complications of long term levodopa treatment are present.

INCIDENCE/ PREVALENCE

Parkinson's disease occurs worldwide with equal incidence in both sexes. In 5–10% of people who develop Parkinson's disease the condition appears before the age of 40 years (young onset), and the mean age of onset is about 65 years. Overall age adjusted prevalence is 1% worldwide and 1.6% in Europe, rising from 0.6% at age 60–64 years to 3.5% at age 85–89 years.[2,3]

AETIOLOGY/ RISK FACTORS

The cause is unknown. Parkinson's disease may represent different conditions with a final common pathway. People may be affected differently by a combination of genetic and environmental factors (viruses, toxins, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, well water, vitamin E, and smoking).[4–7] First degree relatives of affected people may have twice the risk of developing Parkinson's disease (17% chance of developing the condition in their lifetime) compared with people in the general population.[8–10] However, purely genetic varieties probably affect a small minority of people with Parkinson's disease.[11,12] The parkin gene on chromosome 6 may be associated with Parkinson's disease in families with at least one member with young onset Parkinson's disease, and multiple genetic factors, including the tau gene on chromosome 17q21, may be involved in idiopathic late onset disease.[13,14]

PROGNOSIS Parkinson's disease is currently incurable. Disability is progressive and associated with increased mortality (RR of death compared with matched control populations ranges from 1.6–3.0).[15] Treatment can reduce symptoms and slow progression but it rarely achieves complete control. The question of whether treatment reduces mortality remains controversial.[16] Levodopa seemed to reduce mortality in the UK for 5 years after its introduction, before a "catch up" effect was noted and overall mortality rose toward previous levels. This suggested a limited prolongation of life.[17] An Australian cohort study followed 130 people treated for 10 years.[18] The standardised mortality ratio was 1.58 ($P < 0.001$). At 10 years, 25% had been admitted to a nursing home and only four were still employed. The mean duration of disease until death was 9.1 years. In a similar Italian cohort study conducted over 8 years, the relative risk of death for affected people compared with healthy controls was 2.3 (95% CI 1.60 to 3.39).[19] Age at initial census date was the main predictor of outcome (for people aged < 75 years: RR of death 1.80, 95% CI 1.04 to 3.11; for people aged > 75 years: RR of death 5.61, 95% CI 2.13 to 14.80).

AIMS OF INTERVENTION To improve symptoms and quality of life; to slow disease progression; to limit short and long term adverse effects of treatment, such as motor fluctuations (see glossary, p 1750).

OUTCOMES Disease severity; severity of drug induced symptoms or signs; rate of progression of symptoms; need for levodopa or other treatment; adverse effects of treatment; withdrawals from treatment; and quality of life measures. There are no universal scales, but commonly used scales are the Unified Parkinson's Disease Rating Score (UPDRS) (see glossary, p 1751), the Hoehn and Yahr disability staging scale, Webster scale, the Core Assessment Programme for Intracerebral Transplantation,[20,21] the Parkinson's Disease Quality of Life questionnaire,[22] and the Parkinson's Disease Quality of Life questionnaire 39.[23]

METHODS *Clinical Evidence* search and appraisal August 2003. Unless stated otherwise, we have used the term "levodopa" to refer to a combination of levodopa and a peripheral dopa decarboxylase inhibitor.

QUESTION What are the effects of drug treatments in people with early stage Parkinson's disease?

OPTION SELEGILINE

RCTs have found that selegiline improves the symptoms of Parkinson's disease and delays the need for levodopa compared with placebo. One of the RCTs found weak evidence of increased mortality in people treated with selegiline.

Benefits: We found no systematic review. **Versus placebo:** We found nine RCTs comparing selegiline versus placebo in people with early Parkinson's disease.[24–32] The first RCT (54 people) found that selegiline significantly delayed the need for levodopa compared with placebo (549 days to levodopa with selegiline *v* 312 days to

levodopa with placebo; P < 0.002).[24] The second RCT (800 people) found that selegiline significantly delayed the need for levodopa compared with placebo for 9 months (HR 0.50 for requiring levodopa in each time period, 95% CI 0.41 to 0.62).[25] The third RCT (101 people newly diagnosed with Parkinson's disease) found that selegiline significantly improved total Unified Parkinson's Disease Rating Scale (UPDRS) (see glossary, p 1751) score after 12 months of treatment and 2 months of washout compared with placebo (P < 0.001; CI not reported).[26] The fourth RCT (782 people) found no significant difference between selegiline and placebo in disability scores after 4 years (P = 0.95; CI not reported).[27] The fifth RCT (116 people) found that selegiline significantly reduced the proportion of people who required an increase in levodopa of 50% or more compared with placebo over a 5 year period (50% with selegiline *v* 74% with placebo; P = 0.03; CI not reported).[28] The sixth RCT (163 people) found that selegiline significantly improved motor function after 5 years compared with placebo (UPDRS 3 motor score 16.6 with selegiline *v* 23.8 with placebo; P < 0.01).[29] The seventh RCT (157 people) found that selegiline significantly delayed the need for levodopa compared with placebo (12.7 months with selegiline *v* 8.6 months with placebo; P = 0.028).[30] The eighth RCT (93 people) found that selegiline significantly improved overall function and motor function scores compared with placebo, but found no significant difference in activities of daily living scores at 3 months (outcomes measured by UPDRS; results presented graphically; total UPDRS, P = 0.008; UPDRS 3 motor score, P = 0.03; UPDRS 2 activities of daily living score, P = 0.08).[31] The final RCT (44 people) found that selegiline significantly delayed the need to start levodopa compared with placebo (median time to levodopa 545 days with selegiline *v* 372 days with placebo; P = 0.03).[32] **Versus other drugs:** We found one RCT (475 people) that compared selegiline versus levodopa, bromocriptine, and lisuride.[33] It found that the decline in functional ability was significantly less with selegiline than with all other drugs after a mean of 2 months (mean decline in UPDRS 2 activities of daily living score: 1.4 with selegiline *v* 2.5 with levodopa *v* 1.9 with bromocriptine *v* 2.6 with lisuride; comparison between selegiline and all other treatments, P = 0.03). However, the trial found no significant difference in decline in motor function between selegiline and other treatments (decline in UPDRS 3 motor score 2.4 with selegiline *v* 3.4 with levodopa *v* 2.3 with bromocriptine *v* 3.2 with lisuride; P not reported).[33] The RCT did not report separate statistical differences for selegiline compared with each of the other drugs. The clinical importance of the results is therefore unclear.

Harms: One non-systematic review (5 RCTs, 589 people) found no significant difference between selegiline and placebo in mortality at 2.5–4.0 years (15% with selegiline *v* 6% with placebo; HR 1.02, 95% CI 0.44 to 2.37).[34] Extended follow up of one large RCT[25] found no significant difference between selegiline and placebo in mortality at 35 months (no further data reported).[35] Another RCT found that selegiline versus placebo significantly increased mortality at interim analysis after 5.6 years' follow up (HR 1.57, 95% CI 1.07 to 2.31).[27] Consequently, the selegiline arm of the trial was terminated early. Updated analysis (including blinded assessment

of cause specific mortality) found that the increase in mortality did not quite reach significance (HR 1.30, 95% CI 0.99 to 1.72).[36,37] One retrospective observational study in 12 621 people who had taken an antiparkinsonian drug (excluding those also taking antipsychotic drugs) found increased mortality in people prescribed selegiline, but the increase was of borderline significance (ARI 11%, 95% CI 0% to 23%).[38]

Comment: One RCT (163 people) found that there was no deterioration in symptoms on withdrawal of selegiline after 5 years.[29] This could indicate that it was ineffective. Other studies of early selegiline treatment were either too small or too short to reach a conclusion regarding either the efficacy or safety of selegiline.[34] A systematic review and a large RCT are under way (Clarke C, personal communication, 2003).

OPTION MODIFIED RELEASE LEVODOPA

Two RCTs in people with early Parkinson's disease found no significant difference between modified and immediate release levodopa (see methods, p 1739) in motor complications or disease control after 5 years. One RCT found that modified release co-careldopa was better tolerated than immediate release co-careldopa.

Benefits: **Versus immediate release levodopa:** We found no systematic review but found two RCTs.[39,40] The first RCT (134 people with early Parkinson's disease) compared modified versus immediate release co-beneldopa.[39] It found no significant difference at 5 years in the incidence of dyskinesia (see glossary, p 1750) (41% with modified release *v* 34% with immediate release; RR 1.21, 95% CI 0.59 to 1.92), incidence of motor fluctuations (see glossary, p 1750) (59% with modified release *v* 57% with immediate release; RR 1.03, 95% CI 0.60 to 1.39), motor impairment, or activities of daily living. The second RCT (618 people with early Parkinson's disease) compared modified versus immediate release co-careldopa.[40] It found no significant difference in dyskinesia or motor fluctuations measured by diary data at 5 years (22% of people taking modified release *v* 21% of people taking immediate release; P value not reported), but it found that modified versus immediate release co-careldopa significantly improved activities of daily living (actual scores at 5 years not provided; P = 0.03; CI not reported).

Harms: The RCT of co-careldopa found that immediate release co-careldopa significantly increased withdrawals because of nausea compared with modified release co-careldopa (P = 0.007; CI not reported).[40]

Comment: The RCT comparing modified versus immediate release co-beneldopa with a 5 year follow up had a high withdrawal rate (42% with immediate release *v* 54% with modified release; analyses were per protocol).[39]

OPTION DOPAMINE AGONISTS VERSUS LEVODOPA IN EARLY DISEASE

Experience suggests that levodopa improves motor function, but that dyskinesias and fluctuations in motor response are related to long term levodopa treatment and are irreversible. One systematic review and one subsequent RCT found that dopamine agonist monotherapy reduced the incidence of dyskinesias and fluctuations in motor response compared with levodopa monotherapy. However, the subsequent RCT found that dopamine agonist monotherapy was associated with poorer motor scores than levodopa monotherapy, and an increased risk of treatment withdrawal.

Benefits: We found one systematic review (search date 1999, 6 RCTs, 1170 people)[41] and one subsequent RCT.[42] The review compared bromocriptine versus levodopa (see methods, p 1739).[41] It found that bromocriptine delayed motor complications and dyskinesias (see glossary, p 1750), but it did not report effects on disability or motor impairment. The subsequent RCT (294 people), which was published as an abstract, found that pergolide significantly reduced the proportion of people experiencing one or more motor complications compared with levodopa at 3 years (16% with pergolide *v* 33% with levodopa; $P < 0.004$; CI not reported).[42] Motor Unified Parkinson's Disease Rating Scale (see glossary, p 1751) scores were worse in the pergolide group.

Harms: The systematic review did not discuss harms.[41] The RCT comparing pergolide versus levodopa found that significantly more people in the pergolide group withdrew from treatment (18% with pergolide *v* 10% with levodopa; $P < 0.05$; CI not reported).[42]

Comment: Experience suggests that levodopa improves motor function, but that dyskinesias and fluctuations in motor response are related to long term levodopa treatment and are irreversible. A large UK based RCT is examining quality of life and health economic outcomes of agonist monotherapy in people likely to develop motor complications (Clarke C, personal communication, 2003). A multicentre North American study is investigating the effect of levodopa on dopaminergic cell death.[43]

OPTION DOPAMINE AGONISTS PLUS RESCUE LEVODOPA VERSUS LEVODOPA ALONE IN EARLY DISEASE

Experience suggests that levodopa improves motor function, but that dyskinesias and fluctuations in motor response are related to long term levodopa treatment and are irreversible. One systematic review and subsequent RCTs have found that dopamine agonist treatment plus levodopa reduces dyskinesia compared with levodopa alone. However, some of the RCTs found that levodopa alone improved motor impairments and disability compared with dopamine agonist plus levodopa. One subsequent RCT found no significant difference between lisuride (lysuride) plus levodopa and levodopa alone in motor complications at 5 years.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 803 people)[44] and five additional RCTs.[45–49] The review compared bromocriptine plus levodopa versus levodopa alone and found a

trend toward reduced dyskinesia (see glossary, p 1750) with combination treatment but no difference in duration of "off" time (see glossary, p 1750) (no further data provided).[44] The review did not report effects on disability or motor impairment. The first additional RCT (268 people) found that ropinirole plus rescue levodopa if needed significantly reduced dyskinesias compared with levodopa alone after 5 years (20% with ropinirole *v* 45% with levodopa; RR 0.44, 95% CI 0.31 to 0.64).[45] It found no significant difference in disability after 5 years (Unified Parkinson's Disease Rating Scale [UPDRS; see glossary, p 1751], activities of daily living scale) and a small increase in motor impairments with ropinirole. The second additional RCT (301 people) found that pramipexole plus rescue levodopa significantly reduced the risk of motor complications compared with levodopa alone at 2 years (AR for motor complications: 28% with pramipexole plus rescue levodopa *v* 51% with levodopa alone; HR 0.45, 95% CI 0.30 to 0.66).[46] Improvements in UPDRS motor and activities of daily living scores were greater in the levodopa group. The third additional RCT (419 people), which was published as an abstract, compared cabergoline plus rescue levodopa versus levodopa alone.[47] It found that cabergoline significantly reduced motor complications compared with levodopa at 5 years (22% with cabergoline *v* 34% with levodopa; $P < 0.05$; CI not reported). Activities of daily living scores were worse with cabergoline. The fourth additional RCT (90 people, unblinded), comparing lisuride plus rescue levodopa versus levodopa alone, found fewer motor complications in the lisuride group after 4 years, although total Parkinsonian disability was worse with lisuride alone than with levodopa alone (dyskinesia: 64% with levodopa *v* 0% with lisuride alone ($P < 0.05$); 19% with levodopa + lisuride, ($P < 0.001$ compared with levodopa alone); 20% with lisuride + levodopa, $P < 0.01$ compared with levodopa alone; improvement in Columbia University Rating Scale score: 33 with lisuride *v* 25 with levodopa; P value not reported).[48] The fifth additional RCT (82 people, double blinded for first year and subsequently unblinded) found no significant difference between lisuride plus levodopa and levodopa alone in motor complications after 5 years (UPDRS 4 subscore change: 0.49 to 0.96 with levodopa alone *v* 0.32 to 0.73 with levodopa plus lisuride; P reported as non-significant).[49]

Harms: The RCT comparing ropinirole plus rescue levodopa versus levodopa alone found that adverse events, including nausea, vomiting, dizziness, confusion, hallucinations, and delusions, were similar in both treatment groups.[45] The RCT comparing pramipexole plus rescue levodopa versus levodopa alone found that pramipexole significantly increased somnolence ($P = 0.003$) and hallucinations ($P = 0.03$; CIs not reported).[46]

Comment: Experience suggests that levodopa improves motor function, but that dyskinesias and fluctuations in motor response are related to long term levodopa treatment and are irreversible. The subsequent RCTs with 5 years of follow up had withdrawal rates of about 50%.[45,47,49] In the RCT comparing lisuride plus levodopa versus levodopa alone, the levodopa doses used were low.[48] We found no direct comparisons of individual dopamine agonists in people with early stage Parkinson's disease. See comment under dopamine agonists versus levodopa in early disease, p 1742.

QUESTION **What are the effects of adding a dopamine agonist in people with a fluctuating response to levodopa?**

OPTION **ADDING A DOPAMINE AGONIST TO LEVODOPA**

Systematic reviews have found that, in people with response fluctuations to levodopa, certain dopamine agonists significantly reduce "off" time, improve motor impairment and activities of daily living, and reduce levodopa dose, but increase dopaminergic adverse effects and dyskinesia.

Benefits:

Versus placebo: We found six systematic reviews.[50–55] The first review (search date not reported, 7 RCTs, 396 people with later Parkinson's disease taking levodopa) compared adjuvant bromocriptine versus placebo.[50] Heterogeneity in trial design and outcomes made it impossible to draw reliable conclusions. The second review (search date not reported) comparing lisuride versus placebo identified no RCTs.[51] The third review (search date 1998, 1 RCT, 376 people with Parkinson's disease taking levodopa) found that pergolide significantly reduced daily "off" time (see glossary, p 1750) compared with placebo (mean difference: 1.6 hours; $P < 0.001$), significantly reduced daily levodopa dose (mean reduction in dose: 235 mg/day with pergolide *v* 51 mg/day with placebo; $P < 0.001$), and improved activities of daily living scores (CIs not reported).[52] The fourth review (search date not reported, 4 RCTs, 669 people with Parkinson's disease taking levodopa) found that pramipexole versus placebo significantly reduced daily "off" time (WMD 1.8 hours, 95% CI 1.2 hours to 2.3 hours), reduced levodopa dose (WMD 115 mg, 95% CI 87 mg to 143 mg), and improved activities of daily living scores.[53] The fifth review (search date not reported, 1 RCT, 149 people with Parkinson's disease taking levodopa) compared ropinirole versus placebo.[54] It found no significant difference between ropinirole and placebo in "off" time (WMD 180 mg, 95% CI 106 mg to 253 mg) but found that ropinirole reduced the required dose of levodopa. Complete information on motor impairments and disability was not available. The sixth review (search date not reported, 3 RCTs, 268 people with Parkinson's disease taking levodopa) found no significant difference between cabergoline and placebo in "off" time (WMD +1.1 hours, 95% CI –0.06 hours to +2.33 hours) but it found that cabergoline significantly reduced the required dose of levodopa (WMD 150 mg, 95% CI 94 mg to 205 mg).[55] Small but significant benefits in Unified Parkinson's Disease Rating Score (see glossary, p 1751), activities of daily living, and motor scores were seen with cabergoline in one study only. **Versus each other:** We found five systematic reviews.[56–60] The first systematic review (search date not reported, 1 RCT, 20 people) compared lisuride versus bromocriptine.[56] It found no significant difference in change in motor fluctuations (see glossary, p 1750) and the Columbia University Rating Scale after 12 weeks (no quantitative data reported; no P values or CIs reported). Follow up may have been too short and the study too small to detect significant differences. The second systematic review (search date 1997, 3 RCTs, 293 people) compared pergolide versus bromocriptine.[57] It found that pergolide significantly

increased the number of people with "marked or moderate improvement" compared with bromocriptine, as measured using a seven point clinician's global assessment scale, but it found no significant difference in reduction in levodopa dose after 8–12 weeks (clinician's global assessment scale, 2 RCTs, "marked or moderate improvement": AR 43% with pergolide *v* 30% with bromocriptine; RR 1.45, 95% CI 1.08 to 1.95; difference in reduction in levodopa dose, 3 RCTs: WMD +3 mg/day, 95% CI −4 mg/day to +10 mg/day). Two of the RCTs found that pergolide significantly improved motor impairment compared with bromocriptine. The third systematic review (search date not reported, 1 RCT, 163 people) compared pramipexole versus bromocriptine.[58] It found that pramipexole reduced "off" time compared with bromocriptine (WMD 1.4 hours/day, 95% CI 0 hours/day to 2.8 hours/day). There were no differences in Unified Parkinson's Disease Rating Score or dyskinesias (see glossary, p 1750) (no quantitative data provided; no P values or CIs reported). The fourth systematic review (search date not reported, 3 RCTs, 482 people) compared ropinirole versus bromocriptine.[59] It found that ropinirole improved "off" time and levodopa dose reduction compared with bromocriptine after 8–25 weeks, but these differences were not significant ("off" time: WMD +0.8 hours/day, 95% CI −0.1 hours/day to +1.7 hours/day; difference in levodopa dose reduction: +50 mg/day, 95% CI −49 mg/day to +150 mg/day). The fifth systematic review (search date not reported, 5 RCTs, 1071 people) compared cabergoline versus bromocriptine.[60] Cabergoline improved "off" time compared with bromocriptine after 12–36 weeks, but the difference was not significant ("off" time: WMD +0.3 hours/day, 95% CI −0.1 hours/day to +0.7 hours/day). Four of the RCTs found no difference in motor scores or activities of daily living scores.

Harms:

Versus placebo: The systematic reviews found that agonist treatment significantly increased dopaminergic adverse effects (see glossary, p 1750) compared with placebo.[50–55] In particular, dyskinesia was significantly increased with pergolide (OR 4.6, 95% CI 3.1 to 7.0), pramipexole (OR 2.1, 95% CI 1.5 to 2.9), and ropinirole (OR 2.9, 95% CI 1.4 to 6.2).[52–54] Withdrawal from treatment was significantly lower with pramipexole than with placebo (OR 0.64, 95% CI 0.44 to 0.93) but not with pergolide, ropinirole, or cabergoline.[52,54,55] **Versus each other:** Systematic reviews found no significant difference in adverse events between pergolide and bromocriptine, or between pramipexole and bromocriptine,[57,58] but nausea was significantly less frequent with ropinirole (OR 0.5, 95% CI 0.3 to 0.8).[59] Dyskinesias and confusion were reported as adverse events more commonly with cabergoline than with bromocriptine, but there was no significant difference in the frequency of other dopaminergic adverse events (dyskinesia: OR 1.6, 95% CI 1.1 to 2.4; confusion: OR 2.0, 95% CI 1.1 to 3.8).[60] We found no studies that directly compared other dopamine agonists.

Comment: None.

QUESTION What are the effects of surgery in people with later Parkinson's disease?

OPTION PALLIDAL SURGERY

One systematic review found evidence that unilateral pallidotomy improved motor examination and activities of daily living compared with medical treatment. There is a high incidence of adverse effects with pallidotomy. One RCT found insufficient evidence to assess the effects of pallidotomy compared with those of deep brain stimulation. We found no RCTs comparing pallidal deep brain stimulation versus medical treatment. One small RCT found insufficient evidence to assess the effects of pallidal deep brain stimulation compared with those of subthalamic deep brain stimulation.

Benefits:

Pallidotomy versus medical treatment: We found one systematic review (search date 1999, 2 RCTs) that evaluated mainly unilateral posteroventral pallidotomy (see glossary, p 1750) in people with later stage Parkinson's disease.[61] The first RCT in the systematic review was initially published as an abstract.[62] The full report, which was published subsequently, found that pallidotomy significantly improved total Unified Parkinson's Disease Rating Scale (UPDRS) (see glossary, p 1751) scores compared with medical therapy at 6 months (mean score change: −25.5 with pallidotomy *v* +3.8 with medical therapy; $P < 0.0001$).[63] It also found that pallidotomy significantly improved tremor, bradykinesia, rigidity, gait, postural stability, motor fluctuations, dyskinesias, and "off" time (see glossary, p 1750) compared with medical therapy. The second RCT in the systematic review (37 people) compared unilateral pallidotomy versus medical treatment.[64] It found that pallidotomy significantly improved "off" phase motor examination (UPDRS 3) and activities of daily living (Barthel Index, UPDRS 2, and Schwab and England scale), but not pain on a visual analogue scale at 6 months (UPDRS 3: decreased from 47 to 33 with pallidotomy *v* increased from 53 to 57 with medical treatment, $P < 0.001$; Barthel Index: increased by 2.5 with pallidotomy *v* decreased by 0.5 with medical treatment, $P = 0.004$; UPDRS 2: decreased from 30 to 21 with pallidotomy *v* increased from 32 to 35 with medical treatment, $P = 0.002$; Schwab and England scale: increased from 35 to 70 with pallidotomy *v* decreased from 35 to 30 with medical treatment, $P < 0.001$; pain score on a 100 mm visual analogue scale: decreased from 27 mm to 14 mm with pallidotomy *v* increased from 15 mm to 22 mm with medical treatment, $P = 0.13$; CIs not reported). **Pallidotomy versus pallidal deep brain stimulation:** We found one systematic review (search date 2000, 1 RCT).[65] The RCT (13 people) in the systematic review found no significant difference between pallidotomy and deep brain stimulation (see glossary, p 1750) for symptoms, activities of daily living, and adverse effects over 3 months, but was too small to exclude clinically important differences.[66] **Pallidal deep brain stimulation versus medical treatment:** We found one systematic review (search date 2000) that identified no RCTs comparing pallidal deep brain stimulation versus medical treatment.[65] We found no subsequent RCTs. **Pallidal deep brain stimulation**

versus subthalamic deep brain stimulation: We found one RCT (10 people) comparing bilateral pallidal deep brain stimulation versus bilateral subthalamic nucleus deep brain stimulation.[67] It found no difference in motor scores after 12 months (UPDRS 3 improvement: 39% with pallidal stimulation *v* 44% with subthalamic stimulation), but it may have lacked power to exclude clinically important effects.

Harms: The abstract describing the first RCT in the review comparing pallidotomy versus medical treatment gave no information on adverse effects.[62] The full report published subsequently reported that two participants receiving pallidotomy had seizures and one participant had subcortical haemorrhage and transient speech impairment.[63] In the second RCT in the review, comparing pallidotomy versus medical treatment, 6/19 (31.5%) people who had unilateral pallidotomy had adverse effects persisting for 6 months after surgery, including dysarthria, dysphasia, facial paresis, and urinary incontinence.[64] We found three RCTs assessing neuropsychological, cognitive, or behavioural effects of pallidotomy versus medical treatment.[68–70] The first RCT (35 people) found that left sided, but not right sided, pallidotomy reduced verbal fluency.[68] The second RCT found subtle changes on measures of frontal lobe function after 6 months in people with unilateral pallidotomy.[69] The third RCT (33 people) found that surgery, particularly left sided surgery, reduced letter fluency compared with medical management at 3 months ($P = 0.011$).[70] One systematic review of case series (search date 1998) found that the incidence of permanent adverse effects of unilateral pallidotomy was 4–46%, with a risk of a serious complication (including death) of 3–10%.[71] Another systematic review of case series (search date 1998) estimated a 10–15% incidence of persistent adverse effects with unilateral pallidotomy.[72] One RCT (6 people) compared bilateral pallidotomy versus unilateral pallidotomy plus contralateral pallidal deep brain stimulation.[73] It found that all three people with bilateral pallidotomy experienced severe adverse effects. This led to discontinuation of the study. In general, complication rates decline as surgeons develop experience in performing pallidotomy.[74] Adverse effects linked with deep brain stimulation include haemorrhage, lead displacement, visual deficit, speech, motor or sensory disturbances, psychosis, confusion, and disorientation. Follow up can be expensive and time consuming. Eventually, equipment or battery replacement may be needed, which will require further surgery.

Comment: One cohort study found that the improvements seen after unilateral pallidotomy were maintained for 12 months.[75] One recent non-systematic review and consensus statement suggested that gait, balance disorders, and hypophonia were less responsive to surgery than other features of parkinsonism (no further data reported).[74] Transplants and implants of dopaminergic tissue remain experimental. Uncontrolled studies and limited RCT information suggest that adverse effects may be more frequent after lesioning procedures than deep brain stimulation and are more likely to be permanent. Bilateral lesioning is likely to carry a high risk of adverse axial effects (see glossary, p 1750). Some surgeons propose that if bilateral procedures are required then deep brain stimulation rather than lesioning should be carried out on one side of the brain.

OPTION THALAMIC SURGERY

Systematic reviews identified no RCTs comparing thalamic surgery versus medical treatment. One RCT found that thalamic deep brain stimulation improved functional status and caused fewer adverse effects compared with thalamotomy. Case series found that, in 14–23% of people, thalamotomy was associated with permanent complications, including speech disturbance, apraxia, and death.

Benefits: **Thalamotomy versus medical treatment:** We found two systematic reviews (search date 1999,[61] and search date 1998[72]) that identified no RCTs of thalamotomy versus medical treatment for Parkinson's disease (see comment below). **Thalamic deep brain stimulation versus medical treatment:** We found one systematic review (search date 2000).[65] It found no RCTs of thalamic deep brain stimulation (see glossary, p 1750) versus medical treatment. We found no subsequent RCTs. **Thalamotomy versus thalamic deep brain stimulation:** We found one systematic review (search date 2000).[65] It identified one RCT (68 people with tremor, 45 of whom had Parkinson's disease), which compared thalamotomy versus thalamic deep brain stimulation.[76] Subgroup analysis in people with Parkinson's disease found that thalamic deep brain stimulation significantly improved functional status after 6 months compared with thalamotomy (outcome assessed using Frenchay Activities Index, 0 = worst score, 60 = best score; improvement in score: 0.8 with thalamotomy *v* 5.5 with deep brain stimulation, 95% CI for between group difference 1.2 to 8.0).

Harms: **Thalamotomy versus medical treatment:** Case series included in the second systematic review found that thalamotomy was associated with reversible complications (lasting < 3 months) in 36–61% of people and permanent complications, including speech disturbance, apraxia, and death, in 14–23%.[72] Bilateral thalamotomy carries a high risk of speech disturbance.[72] **Thalamotomy versus thalamic deep brain stimulation:** The RCT found that adverse effects were significantly less common with deep brain stimulation than with thalamotomy after 6 months (AR 47% with thalamotomy *v* 18% with deep brain stimulation; P = 0.02; CI not reported).[76]

Comment: The reviews found limited evidence from case series that thalamic surgery may not be as useful as pallidal or subthalamic surgery thalamotomy for parkinsonian features other than tremor.[61,72] The second systematic review did not describe fully the case series it identified, focusing on results from "key studies".[72] See comment under pallidal surgery, p 1747.

OPTION SUBTHALAMIC SURGERY

One systematic review found no RCTs comparing subthalamic surgery versus medical treatment. One small RCT comparing subthalamic deep brain stimulation versus pallidal deep brain stimulation found no significant difference in motor scores.

Benefits: **Subthalamic deep brain stimulation versus medical treatment:** We found one systematic review (search date 2000) that identified no RCTs comparing subthalamic deep brain stimulation (see glossary, p 1750) versus medical treatment.[65] We found no subsequent RCTs. **Subthalamic deep brain stimulation versus pallidal deep brain stimulation:** See benefits of pallidal surgery, p 1746.

Harms: See comment under pallidal surgery, p 1747.

Comment: Larger and longer term RCTs are needed to compare the effects of pallidal versus subthalamic stimulation. A large RCT comparing quality of life and costs of subthalamic or pallidal lesioning and deep brain stimulation surgery versus best medical treatment is currently under way in the UK (Clarke C, personal communication, 2002).

QUESTION What are the effects of rehabilitation treatments in people with later Parkinson's disease?

OPTION PHYSIOTHERAPY

Two systematic reviews found insufficient evidence of the effects of physiotherapy in later Parkinson's disease.

Benefits: We found two systematic reviews.[77,78] The first review (search date 2000, 11 RCTs, 280 people with early stage or late stage Parkinson's disease) compared physiotherapy versus no treatment or versus inactive physiotherapy.[77] The review was unable to draw conclusions on the effects of physiotherapy in Parkinson's disease because of the small numbers of people, methodological flaws, different types of physiotherapy used, and the wide variety of outcome measures in the RCTs. The second systematic review (search date 1999, 8 RCTs included in the first review, 4 quasi-randomised studies) compared physiotherapy versus no treatment or versus other treatment (occupational therapy, regular exercises, non-specified psychological treatment).[78] It also found that methodological flaws of trials and trial heterogeneity made it difficult to draw conclusions on the effects of physiotherapy.

Harms: The systematic reviews gave no information on adverse effects.[77,78]

Comment: Further, larger, well designed RCTs are required. A large UK RCT is in preparation (Clarke C, personal communication, 2003).

OPTION OCCUPATIONAL THERAPY

One systematic review found insufficient evidence of the effects of occupational therapy in later Parkinson's disease.

Benefits: We found one systematic review (search date 2000, 2 RCTs, 84 people with early stage or late stage Parkinson's disease).[79] One RCT in the review compared occupational therapy versus no treatment, and the other RCT compared occupational therapy plus

physiotherapy versus physiotherapy alone. The review was unable to draw conclusions on the effects of occupational therapy because of the small number of people in the RCTs, methodological flaws, trial heterogeneity, and the variety of outcome measures used.[79]

Harms: The RCTs in the review gave no information on adverse effects.[79]

Comment: Further, larger, well designed RCTs are required. A UK RCT of occupational therapy in Parkinson's disease is in preparation (Clarke C, personal communication, 2003).

OPTION SPEECH AND LANGUAGE THERAPY FOR SPEECH DISTURBANCE

One systematic review found insufficient evidence of the effects of speech and language therapy for speech disturbance in later Parkinson's disease.

Benefits: We found one systematic review (search date 2000, 3 RCTs, 63 people) that compared speech and language therapy versus no treatment for speech disturbance.[80] It was unable to draw conclusions on the effects of speech and language therapy because of the small number of people, methodological flaws, and the variety of outcome measures used in the RCTs.

Harms: The RCTs in the review gave no information on adverse effects.[80]

Comment: Further, larger, well designed RCTs are required.

OPTION SWALLOWING THERAPY FOR DYSPHAGIA

One systematic review found no RCTs of swallowing therapy for dysphagia.

Benefits: We found one systematic review (search date 2000) of swallowing therapy for dysphagia, which did not identify any RCTs.[81]

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Axial effects Changes affecting axial body sections, such as head and trunk, rather than the limbs.

Deep brain stimulation Prolonged focal electrical brain stimulation through a stereotactically implanted wire.

Dopaminergic adverse effects Include dyskinesia, hallucinations, and psychosis.

Dyskinesia Abnormal or involuntary writhing or jerky movements distinct from tremor.

Motor fluctuations Fluctuations in motor symptoms, such as bradykinesia, rigidity, and tremor, during a day.

Response fluctuations Fluctuations in a person's overall response to treatment during a day.

"Off" time Periods when treatment is not working. "On" time is the period when treatment is working.

Pallidotomy Making a permanent surgical lesion, usually thermally or electrically, in the globus pallidum.

Unified Parkinson's Disease Rating Scale (UPDRS) A scale used to measure severity of Parkinson's Disease. It has six parts: mentation, behaviour, and mood (UPDRS 1); activities of daily living (UPDRS 2); motor examination (UPDRS 3); complications of treatment (UPDRS 4); a global disability staging score (UPDRS 5); and a global activities of daily living score (UPDRS 6). A higher score denotes greater disability.

Substantive changes

Pallidal surgery One RCT added;[63] categorisation unchanged.

QUESTIONS

INTERVENTIONS

See glossary, p 1764

Key Messages

- **Carbamazepine** One systematic review of three crossover RCTs found that carbamazepine increased pain relief compared with placebo. The review found that carbamazepine increased adverse effects (drowsiness, dizziness, constipation, and ataxia) compared with placebo. One small RCT provided insufficient evidence to compare tizanidine versus carbamazepine. One RCT found that pimozide reduced pain over 8 weeks compared with carbamazepine, but increased adverse effects (including hand tremors, memory impairment, and involuntary movements). One systematic review found one RCT of tocainide versus carbamazepine that was of insufficient quality.
- **Pimozide** One RCT found that pimozide reduced pain over 8 weeks compared with carbamazepine, but increased adverse effects (including hand tremors, memory impairment, and involuntary movements). Cardiac toxicity and sudden death have been reported with pimozide.
- **Baclofen** We found insufficient evidence on the effects of baclofen versus placebo or versus other active drugs.
- **Combined streptomycin and lidocaine nerve block** Small RCTs provided insufficient evidence about the effects of nerve block with streptomycin plus lidocaine compared with nerve block with lidocaine alone.
- **Lamotrigine** One systematic review provided insufficient evidence to compare lamotrigine versus placebo in people with trigeminal neuralgia.

Trigeminal neuralgia

- **Other drugs (phenytoin, clonazepam, sodium valproate, gabapentin, mexiletine, oxcarbazepine, topiramate)** We found insufficient evidence about the effects of these drugs in people with trigeminal neuralgia.
- **Peripheral laser treatment** We found insufficient evidence on the effects of peripheral laser treatment in people with trigeminal neuralgia.
- **Stereotactic radiosurgery** We found insufficient evidence about the effects of stereotactic radiosurgery in people with trigeminal neuralgia.
- **Tizanidine** One small RCT provided insufficient evidence to compare tizanidine versus carbamazepine.
- **Proparacaine eye drops** One RCT found no significant difference in pain at 30 days between placebo and a single application of proparacaine hydrochloride eye drops to the eye on the same side as the pain.
- **Tocainide** One systematic review found one RCT of tocainide versus carbamazepine which was of insufficient quality. The use of tocainide is limited by considerable harms (including serious haematological effects).
- **Cryotherapy of peripheral nerves; peripheral acupuncture; peripheral alcohol injection; peripheral injection of phenol; peripheral neurectomy; peripheral radiofrequency thermocoagulation** We found no RCTs about the effects of these interventions.

DEFINITION Trigeminal neuralgia is a characteristic pain in the distribution of one or more branches of the fifth cranial nerve. The diagnosis is made on the history alone, based on characteristic features of the pain. It occurs in paroxysms that last a few seconds to 2 minutes. The frequency of paroxysms is highly variable: from hundreds of attacks a day to long periods of remission that can last years. The pain is severe and described as intense, sharp, superficial, stabbing, burning, or like an electric shock. In any individual, the pain has the same character in different attacks. It is often triggered by touch in a specific area or by eating, talking, washing the face, or cleaning the teeth. Between paroxysms, the person is asymptomatic. Other causes of facial pain may need to be excluded.[1] In trigeminal neuralgia the neurological examination is usually normal.[2,3]

INCIDENCE/ PREVALENCE Most evidence about the incidence and prevalence of trigeminal neuralgia is from the USA.[4] The annual incidence (when age adjusted to 1980 age distribution of the USA) is 5.9/100 000 women and 3.4/100 000 men. The incidence tends to be slightly higher in women at all ages. The incidence increases with age. In men aged over 80 years the incidence is 45.2/100 000.[5] Other published surveys are small. One questionnaire survey of neurological disease in a single French village found one person with trigeminal neuralgia among 993 people.[6]

AETIOLOGY/ RISK FACTORS The cause of trigeminal neuralgia remains unclear.[7] It is more common in people with multiple sclerosis (RR 20.0, 95% CI 4.1 to 59.0).[5] Hypertension is a risk factor in women (RR 2.1, 95% CI 1.2 to 3.4) but the evidence is less clear for men (RR 1.53, 95% CI 0.30 to 4.50).[5] A study in the USA found that people with trigeminal neuralgia smoked less, consumed less alcohol, had fewer tonsillectomies, and were less likely than matched controls to be Jewish or an immigrant.[8]

PROGNOSIS One study found no reduction of 10 year survival with trigeminal neuralgia.[9] We found no evidence about the natural history of trigeminal neuralgia. The illness is characterised by recurrences and remissions. Many people have periods of remission with no pain for months or years.[3] Anecdotal reports suggest that in many people it becomes more severe and less responsive to treatment with time.[10] Most people with trigeminal neuralgia are initially managed medically, and a proportion eventually have a surgical procedure.[5] We found no good evidence about the proportion of people who require surgical treatment for pain control.

AIMS OF INTERVENTION To relieve pain with minimal adverse effects.

OUTCOMES Pain frequency and severity scores; measures of psychological distress; ability to perform normal activities; adverse effects.

METHODS *Clinical Evidence* search and appraisal March 2003. Author performed an additional hand search of her own bibliography.

QUESTION What are the effects of treatments on trigeminal neuralgia?

OPTION CARBAMAZEPINE

One systematic review of three crossover RCTs found that carbamazepine increased the proportion of people who had pain relief compared with placebo. The review found that carbamazepine increased adverse effects (drowsiness, dizziness, constipation, and ataxia) compared with placebo. One small RCT provided insufficient evidence to compare tizanidine versus carbamazepine. One RCT found that pimozide reduced pain over 8 weeks compared with carbamazepine, but increased adverse effects (including hand tremors, memory impairment, and involuntary movements). One systematic review found one RCT of tocainide versus carbamazepine that was of insufficient quality.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 3 crossover RCTs, 161 people with trigeminal neuralgia), which found that carbamazepine (for 5 days to 2 weeks) significantly increased the proportion of people having a "good" or "excellent" response compared with placebo (57% with carbamazepine *v* 18% with placebo; OR 4.8, 95% CI 3.4 to 6.9; NNT 3, 95% CI 2 to 4).[11] **Versus tizanidine:** See benefits of tizanidine, p 1758. **Versus pimozide:** See benefits of pimozide, p 1758. **Versus tocainide:** See benefits of tocainide, p 1759.

Harms: The review found that carbamazepine significantly increased adverse effects (drowsiness, dizziness, constipation, and ataxia) compared with placebo (NNH 3, 95% CI 2 to 7).[11] In the RCTs, significantly more people withdrew from the RCTs because of adverse effects with carbamazepine compared with placebo (NNH for withdrawal 24, 95 % CI 14 to 112).[12] Adverse effects described in observational studies include rashes, leucopenia, and abnormal liver function tests.[13]

Comment: The RCTs used a crossover design, and one RCT[14] used multiple crossovers so that each individual was counted more than once when calculating the estimates of effectiveness in the systematic review.[11,12] The RCTs included in the systematic review were small and short term. All of the RCTs used simple measures for pain outcomes and no quality of life measures. Diagnostic criteria were not clearly stated. Previous treatment and duration of pain varied considerably. Long term effects of carbamazepine have been assessed only in open trials. We found one report (143 people with trigeminal neuralgia followed for up to 16 years) on the long term benefits of carbamazepine.[15] Initially carbamazepine was successful in 69% of participants, but by 5–16 years only 31 participants (22%) were still finding carbamazepine effective and 44% required additional or alternative treatment.

OPTION TIZANIDINE

One small RCT provided insufficient evidence to compare tizanidine versus carbamazepine.

Benefits: **Versus placebo:** We found no RCTs. **Versus carbamazepine:** We found one systematic review (search date 1999, 1 double blind RCT, 12 people).[11] It found that similar proportions of people rated tizanidine (≤ 18 mg/day) and carbamazepine (≤ 900 mg/day) as having "very good" efficacy (analysis not by intention to treat; 1/5 people with tizanidine *v* 4/6 with carbamazepine; P value not reported).

Harms: No adverse effects were reported but two people withdrew because of inadequate pain control.[11]

Comment: The RCT was too small to establish or exclude clinically important effects.

OPTION PIMOZIDE

One RCT found that pimozide reduced pain over 8 weeks compared with carbamazepine but increased adverse effects (including hand tremors, memory impairment, and involuntary movements). Cardiac toxicity and sudden death have been reported with pimozide.

Benefits: **Versus placebo:** We found no RCTs. **Versus carbamazepine:** We found one systematic review (search date 1999)[11] that identified one double blind crossover RCT[16] comparing pimozide versus carbamazepine in 48 people with trigeminal neuralgia who were refractory to other medical treatment. Precrossover results found that significantly more people achieved a large reduction in pain severity with 8 weeks of pimozide treatment compared with carbamazepine (total pain score reduction: results presented graphically, $P < 0.001$).[16]

Harms: The RCT found that pimozide significantly increased adverse effects compared with carbamazepine (40/48 [83%] with pimozide *v* 22/48 [46%] with carbamazepine; OR 7.8, 95% CI 3.7 to 20.0).[11] Adverse effects included hand tremors, memory impairment, and involuntary movements. The use of pimozide is restricted by its cardiac toxicity and by reports of sudden death.[13,17]

Comment: This was a well conducted multicentre trial using a variety of outcome measures. The crossover design limits interpretation of the results because untested assumptions are required to perform the statistical analyses.

OPTION TOCAINIDE

One systematic review found one RCT of tocainide versus carbamazepine that was of insufficient quality. The use of tocainide is limited by considerable harms (including serious haematological effects).

Benefits: **Versus placebo:** We found no RCTs. **Versus carbamazepine:** We found one systematic review (search date 1999, 1 RCT,[18] 12 people with trigeminal neuralgia).[11] The double blind, crossover RCT had weak methods and did not report precrossover results (see comment below).

Harms: The RCT reported that one person withdrew because of a skin rash and three people had other adverse effects.[18] The use of tocainide is limited by considerable harms (including severe haematological effects).[13,19]

Comment: In the RCT, combined analysis of precrossover and postcrossover results found that tocainide versus carbamazepine had no significant effect on the number of people who improved after treatment (figures not reported).[18] The available evidence is poor, but provides no support for the use of tocainide in trigeminal neuralgia.

OPTION LAMOTRIGINE

One systematic review provided insufficient evidence to compare lamotrigine versus placebo in people with trigeminal neuralgia.

Benefits: **Versus placebo:** We found one systematic review (search date 1999)[11] that identified one small crossover RCT (14 people)[20] comparing lamotrigine versus placebo. However, the RCT did not report precrossover results for global improvement (see comment below).

Harms: In the RCT, adverse effects with lamotrigine included dizziness, constipation, nausea, and drowsiness. It may also cause serious skin rash and allergic reactions. The total number of people reporting adverse effects was the same as with placebo (7/14 [50%] with lamotrigine *v* 7/14 [50%] with placebo).[20]

Comment: The RCT (double blind crossover, 14 people with refractory trigeminal neuralgia using either carbamazepine or phenytoin) found that lamotrigine versus placebo in addition to the current medication increased the proportion of people who improved after 2 weeks of treatment (postcrossover results: 10/13 [77%] with lamotrigine *v* 8/14 [57%] with placebo; ARI +20%, 95% CI −16% to +55%).[20] This RCT was a small study and lamotrigine was used in addition to existing treatment. The crossover design and short period of treatment limits interpretation.

OPTION BACLOFEN

We found insufficient evidence on the effects of baclofen versus placebo or versus other active drugs.

Benefits: **Versus placebo:** We found no RCTs of sufficient quality (see comment below). **Versus other active drugs:** We found no RCTs of sufficient quality (see comment below).

Harms: Baclofen is associated with transient sedation and loss of muscle tone. Abrupt discontinuation may cause seizures and hallucinations. One small, poor quality trial comparing racemic baclofen versus L-baclofen reported dizziness, confusion, or lethargy (6/15 [40%] *v* 1/15 [7%]; ARI 33%, 95% CI 3% to 64%; see comment below).[21]

Comment: **Versus placebo:** We found one controlled trial (double blind, crossover, 10 people, 4 using carbamazepine or phenytoin, not clearly randomised).[22] Postcrossover analysis found that baclofen compared with placebo in addition to pre-existing treatment increased the proportion of people with relief of pain after treatment for 2 weeks (7/10 [70%] with baclofen *v* 1/10 [10%] with placebo).[22] **Racemic versus L-baclofen:** We found one trial (double blind crossover, 15 people, not clearly randomised) that compared racemic (standard) baclofen versus L-baclofen over 2 weeks.[21] It found no significant difference in response (9/15 [60%] with L-baclofen *v* 6/15 [40%] with racemic baclofen; ARI +20%, 95% CI −16% to +56%). Some people included in the study were also taking other treatments, making interpretation difficult.

OPTION PROPARACAINE HYDROCHLORIDE EYE DROPS

One RCT found no significant difference in pain at 30 days between placebo and a single application of proparacaine hydrochloride eye drops to the eye on the same side as the pain.

Benefits: **Versus placebo:** We found no systematic review but found one double blind RCT (47 people with trigeminal neuralgia) of proparacaine hydrochloride versus placebo instilled for 20 minutes on the same side as the trigeminal neuralgia on one occasion only.[23] It found no significant reduction of pain after 3, 10, and 30 days (at 30 days: 6/25 [24%] improved with proparacaine *v* 5/22 [23%] with placebo; ARI +1.3%, 95% CI −23% to +26%).

Harms: None reported.

Comment: None.

OPTION OTHER DRUGS

We found insufficient evidence about effects of phenytoin, clonazepam, sodium valproate, gabapentin, mexiletine, oxcarbazepine, or topiramate in people with trigeminal neuralgia.

Benefits: We found no systematic review and no RCTs of sufficient quality examining the effects of phenytoin, clonazepam, sodium valproate, gabapentin, mexiletine, oxcarbazepine, or topiramate in people with trigeminal neuralgia (see comment below).

Harms: See harms of antiepileptic drugs under epilepsy, p 1655. Harms of mexiletine include dizziness, nausea, vomiting, confusion, and tremor.[24] The crossover RCT (see comment below) reported adverse effects with topiramate included irritability and diarrhoea (in 2 people) and fatigue/sedation, hyperactivity, nausea, abdominal cramps, lightheadedness, and cognitive impairment (in 1 person each).[25]

Comment: We found one double blind crossover RCT (3 people with trigeminal neuralgia) that compared 12 weeks of topiramate (25 mg/day titrated up to 600 mg/day) versus placebo.[25] Titration was by weekly telephone assessment of symptoms. Washout period between crossover was 2 weeks. The trial found that topiramate reduced pain (on a 10 point scale) compared with placebo in all three people ($P = 0.04$).[25] However, the trial was at high risk of detecting effects by chance. An extended confirmatory study in which two people continued to take medication for three 8 week segments (4 weeks of placebo and 4 weeks of topiramate assigned in random order) found no significant pain reduction with topiramate compared with placebo.[25] Concurrent medications continued during the study included carbamazepine and baclofen in one person, clonazepam and tricyclic antidepressants in one person, and carbamazepine and gabapentin in one person.[25]

OPTION CRYOTHERAPY OF PERIPHERAL NERVES

We found no RCTs on the effects of cryotherapy (see glossary, p 1764) in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: We found many articles that reported studies of limited reliability, duplicated data, or included people with different types of pain.

OPTION NERVE BLOCK

We found no RCTs comparing nerve block versus placebo or no treatment. Small RCTs provided insufficient evidence about the effects of nerve block with streptomycin plus lidocaine compared with nerve block with lidocaine alone.

Benefits: **Nerve block versus placebo or no treatment:** We found no systematic review and no RCTs. **Local anaesthetic versus streptomycin plus local anaesthetic:** We found two RCTs comparing injections of streptomycin 1 g plus lidocaine (2 mL of 2% solution) versus lidocaine injections alone (1 injection weekly for 5 weeks).[26,27] The first RCT included 18 people with trigeminal neuralgia who had previously responded poorly to lidocaine injection alone (≤ 24 hours' pain relief from lidocaine alone). One person who did not gain pain relief from allocated treatment was excluded (see comment below). One week after the final injection, combined streptomycin plus lidocaine improved the chance of being pain free compared with lidocaine alone (AR for being pain free: 89% with combined injection *v* 38% with lidocaine alone; ARR 51%; CI not

provided; P = 0.04). After 30 months the RCT found no significant difference between treatments (AR for being pain free: 33% with combined injection *v* 25% with lidocaine alone; ARR 8%; CI not provided; P = 0.38).[26] The second RCT compared weekly injections of streptomycin 1 g plus lidocaine (3 mL of 2% solution) versus lidocaine alone for 5 weeks in a randomised crossover design involving 20 people with idiopathic or traumatic trigeminal neuralgia. It found no significant short term differences between the groups in severity or frequency of pain as assessed clinically and from pain diaries.[27]

Harms: People found the injections painful and some refused to have further injections.[27] No sensory changes or other adverse effects were reported.

Comment: Neither trial reported the method of randomisation. One trial had short follow up and reliability of results may have been limited by selection bias (see benefits above).[27] Streptomycin was used on the assumption that it causes a long term peripheral nerve block.

OPTION PERIPHERAL ALCOHOL INJECTIONS

We found no RCTs on the effects of injecting peripheral nerves with alcohol in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PERIPHERAL NEURECTOMY

We found no RCTs on the effects of peripheral neurectomy in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PERIPHERAL RADIOFREQUENCY THERMOCOAGULATION

We found no RCTs on the effects of peripheral radiofrequency thermocoagulation in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION STEREOTACTIC RADIOSURGERY

We found insufficient evidence about the effects of stereotactic radiosurgery in people with trigeminal neuralgia.

Benefits: We found no RCTs comparing stereotactic radiosurgery versus placebo or versus other treatments. We found one RCT comparing different radiosurgery regimens (see comment below).[28]

Harms: One RCT comparing two different radiosurgery regimens reported numbness (8/43 [19%] with two isocentres *v* 3/44 [7%] with one isocentre), mild paraesthesia (5/43 [12%] with two isocentres *v* 4/44 [9%] with one isocentre), and severe paraesthesia (1/43 [2%] with two isocentres *v* 0/44 [0%] with one isocentre; see comment below).[28]

Comment: One RCT (87 people with trigeminal neuralgia) compared radiosurgery using either one isocentre or two isocentres, the latter regimen to treat a longer length of the trigeminal nerve.[28] It found similar rates of maximal pain control (no pain with or without drugs: 29/44 [66%] with one isocentre *v* 28/43 [65%] with two isocentres) and pain control at final follow up (no pain with or without drugs: 20/44 [45%] with one isocentre *v* 23/43 [53%] with two isocentres).[28] The median follow up was 26 months (range 1–36 months).[28] People in the RCT took additional pain medication which was not specified. It reported more complications in the two isocentre group (see harms above), but pain outcomes were similar in both groups.[28] Typically, pain relief with radiosurgery is not immediate.

OPTION PERIPHERAL INJECTION OF PHENOL

We found no RCTs on the effects of peripheral nerve injection with phenol in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PERIPHERAL ACUPUNCTURE

We found no RCTs on the effects of peripheral acupuncture in people with trigeminal neuralgia.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PERIPHERAL LASER TREATMENT

We found insufficient evidence on the effects of peripheral laser treatment (see glossary, p 1764) in people with trigeminal neuralgia.

Benefits: We found no RCTs of sufficient quality.

Harms: We found no RCTs of sufficient quality.

Comment: We found one RCT (35 people with trigeminal neuralgia) comparing helium neon laser (3 treatments/week for 10 weeks, 1 mW, 632.5 nm, 20 Hz applied for 20 seconds on skin overlying the trigger nerve and 30 seconds on painful areas of the face) versus

sham treatment with apparatus that emitted no light.[29] The trial did not compare the two groups directly. However, it found that mean pain score significantly improved from baseline at weeks 6 and 7 with laser, but did not change significantly from baseline for any week with sham treatment. This reanalysis has limited reliability.

GLOSSARY

Cryotherapy After surgical exposure of the trigger nerve, three freeze–thaw cycles are applied under local anaesthesia and sedation as necessary.
Peripheral laser treatment Laser irradiation of skin overlying the trigger nerve.

Aphthous ulcers (recurrent)

Search date August 2003

Stephen Porter and Crispian Scully CBE

QUESTIONS

INTERVENTIONS

Key Messages

- **Chlorhexidine** RCTs found that chlorhexidine gluconate mouth rinses reduced the severity of each episode of ulceration, but did not effect the incidence of ulceration. Limited evidence from one RCT suggests that 0.2% chlorhexidine gel may reduce the incidence and duration of ulceration compared with control preparation. RCTs found that chlorhexidine reduced the mean severity of pain compared with an inert preparation.
- **Topical corticosteroids** Small RCTs found that topical corticosteroids reduced the number of ulcer days compared with control. RCTs found no consistent effect of topical corticosteroids on the incidence of new ulcers compared with control preparations. They found weak evidence that topical corticosteroids may reduce the duration and pain of ulcers and hasten pain relief without causing notable local or systemic adverse effects.
- **Hexitidine** Limited evidence from single RCTs found no significant difference in any of the reported outcomes between hexitidine mouthwash or a proprietary antibacterial mouthwash and control mouthwashes.

DEFINITION Recurrent aphthous ulcers are superficial and rounded, with painful mouth ulcers usually occurring in recurrent bouts at intervals of a few days to a few months.[1]

INCIDENCE/ PREVALENCE The point prevalence of recurrent aphthous ulcers in Swedish adults has been reported as 2%.[1] Prevalence may be 5–10% in some groups of children. Up to 66% of young adults give a history consistent with recurrent aphthous ulceration.

AETIOLOGY/ RISK FACTORS The causes of aphthous ulcers remain unknown. Associations with haematinic deficiency, infections, gluten sensitive enteropathy, food sensitivities, and psychological stress have rarely been confirmed. Similar ulcers are seen in Behçet's syndrome. Local physical trauma may initiate ulcers in susceptible people. Recurrent aphthous ulcers are uncommon on keratinised oral mucosal surfaces, and the frequency of recurrent aphthous ulcers may fall if patients cease any tobacco smoking habit.

PROGNOSIS About 80% of people with recurrent aphthous ulcers develop a few ulcers smaller than 1 cm in diameter that heal within 5–14 days without scarring (the pattern known as minor aphthous ulceration). The episodes recur typically after an interval of 1–4 months. One in 10 people with recurrent ulceration may have multiple minute ulcers (herpetiform ulceration). Likewise, one in 10 sufferers has a more severe form (major aphthous ulceration), with lesions larger than 1 cm that may recur after a shorter interval and can cause scarring. The majority of trials in this review have focused upon the treatment of minor aphthous ulceration.

AIMS OF INTERVENTION To reduce the severity of the episode and the incidence, duration, and pain of ulceration with minimal adverse effects.

OUTCOMES **Ulcer day index:** The sum of the number of ulcers each day over a period, usually 4–8 weeks, which indicates the severity of the episode and reflects the mean prevalence and duration of ulcers; number of ulcer free days during a specified period; **Incidence of new ulcers:** Number of new ulcers appearing within a specified period, usually 4–8 weeks; **Duration of ulceration:** mean duration of individual ulcers (difficult to determine because of uncertainty in detecting the point of complete resolution); **Severity of pain:** symptom score based on subjective pain severity recorded in categories on a questionnaire (e.g. from 0–3, ranging from no pain to severe pain) or on a 10 cm visual analogue scale; **User preference:** preference of people for one treatment over another. The diameter of lesions is a proxy measure of these clinical outcomes.

METHODS *Clinical Evidence* search and appraisal August 2003.

QUESTION What are the effects of treatments for recurrent aphthous ulcers?

OPTION TOPICAL CORTICOSTEROIDS

Small RCTs found that topical corticosteroids reduced the number of ulcer days compared with control. RCTs found no consistent effect of topical corticosteroids on the incidence of new ulcers compared with

control preparations. They found weak evidence that topical corticosteroids may reduce the duration and pain of ulcers and hasten pain relief without causing notable local or systemic adverse effects.

Benefits: We found no systematic review but found nine RCTs of corticosteroids versus placebo that reported clinical outcomes in people with recurrent aphthous ulcers (see table 1, p 1771).[2–9] Overall, one RCT found larger effect sizes than the others.[2] **Ulcer days index:** We found four RCTs reporting data on the number of ulcer days.[2,4,5,7] They found that topical corticosteroids reduced the number of ulcer days compared with control, although the reduction was significant in only two of the RCTs. **Incidence of new ulcers:** Five crossover RCTs (102 people) reported inconsistent effects on the incidence of new ulcers.[2,4,5] One RCT found no effect on reducing frequency of ulcer recurrence during follow-up in either treatment or control groups.[8] **Duration of ulceration:** We found six RCTs reporting data on ulcer duration three of which had a crossover design, but the data were not comparable.[3,4,6–9] RCTs reported the mean duration of ulcers with topical corticosteroids compared with control preparations but found no consistent effect.[3,6,8,9] One RCT found that topical corticosteroids significantly increased the proportion of people who had mean ulcer duration ≤ 6 days compared with control preparations.[6] One RCT found that topical corticosteroids significantly reduced the total number of ulcer days compared with control preparations.[8] Two RCTs found no difference between treatment and control groups.[3,9] **Severity of pain:** Four RCTs, three of which had a crossover design, reported on severity of pain with topical corticosteroids versus control, but all presented their results in different ways.[6–9] One RCT found that topical corticosteroids significantly increased the proportion of people with pain relief compared with a control preparation.[6] The first crossover RCT found that topical corticosteroids reduced symptom scores compared with a control preparation, but the difference was not significant.[7] The second crossover RCT found that topical corticosteroids significantly increased the proportion of people with reduced pain severity compared with a control preparation.[8] The third crossover RCT found that the pain score fell with time in both treatment and control groups (see comment below), but the rate of fall was significantly faster when using topical corticosteroids ($P < 0.0001$).[9] **User preference:** Two crossover RCTs found that more users preferred topical corticosteroids than control preparations.[4,6]

Harms: In five of the nine RCTs, no adverse effects were found.[2,3,6–8] One RCT reported adrenal suppression in one man using betamethasone disodium phosphate.[5] However, limited studies of adrenal function found no evidence that 0.05% fluocinonide in adhesive paste and betamethasone-17-valerate mouth rinse caused adrenal suppression.[8,15] Two RCTs gave no information on adverse effects.[4,9]

Comment: The trials differed in many ways: selection of people, type of topical corticosteroid and formulation used, control preparation used (although this was usually a base without topical steroid), duration of treatment, reported outcomes, and design (double or single

blind, parallel group or crossover, use of washout period or not). In one crossover RCT, the pain score fell during the course of the trial irrespective of the treatment received.[9] The study did not make clear if the effect of such sequencing had been allowed for. Withdrawal rates were high. Most people in the trials had more severe ulceration than the average person with recurrent aphthous ulceration.

OPTION CHLORHEXIDINE AND SIMILAR AGENTS

RCTs found that chlorhexidine gluconate mouth rinses reduced the severity of each episode of ulceration, but did not effect the incidence of ulceration. Limited evidence from one RCT suggests that 0.2% chlorhexidine gel may reduce the incidence and duration of ulceration compared with control preparation. RCTs found that chlorhexidine reduced the mean severity of pain compared with an inert preparation. Limited evidence from single RCTs found no significant difference in any of the reported outcomes between hexitidine mouthwash or a proprietary antibacterial mouthwash and control mouthwashes.

Benefits: We found no systematic review but found five RCTs (203 people with recurrent aphthous ulceration) comparing chlorhexidine gluconate or similar preparations versus inactive control preparations (see table 1, p 1771).[10–14] Four of the RCTs used a crossover design with a randomised sequence comparing a control preparation versus 1% chlorhexidine gel,[10] 0.2% chlorhexidine gel,[11] 0.2% chlorhexidine mouthwash,[12] or 0.1% hexetidine mouthwash.[13] One RCT compared a proprietary antibacterial rinse with a hydroalcoholic control.[14] **Ulcer days index:** Three RCTs reported the ulcer days index.[11–13] Two RCTs found that chlorhexidine significantly reduced the ulcer day index compared with a control preparation.[11,12] One of these RCTs found that chlorhexidine significantly increased the number of ulcer free days per 6 weeks of treatment compared with an inert preparation.[12] A third RCT found that hexitidine had no significant effect on the ulcer day index compared with a control preparation.[13] **Incidence of ulceration:** All five RCTs reported the number of ulcers, defined as either the total number of ulcers or the number of new ulcers with each treatment per week.[10–14] Only one RCT, using 0.2% chlorhexidine gel, found that active treatment significantly reduced the number of new ulcers (see comment below).[11] **Duration of ulceration:** The mean duration of individual ulcers was reported in four of the RCTs.[10,12–14] The mean duration of individual ulcers was reduced by active treatment in all four RCTs, but the difference was significant in only one RCT, using 1% chlorhexidine gel,[10] and the mean difference was less than 1 day in the others. Three RCTs found that the number of ulcers fell during the course of the study, irrespective of the treatment received (see comment below).[12–14] **Severity of pain:** All five RCTs reported on pain severity scores.[10–14] Two RCTs found that chlorhexidine significantly reduced the mean severity of pain compared with an inert preparation.[10,11] One RCT of a proprietary antibacterial mouthwash versus the alcohol-containing control preparation found no significant difference in pain severity between the treatment groups, but found a large improvement in clinical outcomes in both groups

compared with baseline levels (see comment below).[14] **User preference:** One RCT found no significant difference in user preference between treatments, but found that many more people preferred the second treatment rather than the first treatment.[13]

Harms: One RCT found that chlorhexidine had a bitter taste and was associated with brown staining of teeth and tongue and with nausea.[11] In one RCT, one person reported a severe inflammation of the gums during the treatment with 0.1% hexitidine mouthwash.[13] Three RCTs gave no information on adverse events.[10,12,14]

Comment: Four of the RCTs used a crossover design and reported high withdrawal rates. A consistent observation was that outcomes improved during the course of the trials irrespective of the treatment received. One of the studies did not make clear if the effect of sequencing had been allowed for.[11] However, data were available from only 12/26 people who were recruited, and it is not clear if there was a balanced sequencing of active and placebo treatments among these people. The parallel group trial had fewer withdrawals: 106 people with recurrent aphthous ulceration were recruited and 96 completed the study.[14] Analysis was not by intention to treat and the method of randomisation was not specified. People recruited to the trials might not be typical of the average person with recurrent aphthous ulceration.

QUESTIONS

INTERVENTIONS

Key Messages

- **Cognitive behavioural therapy** One small RCT found that cognitive behavioural therapy reduced symptom intensity in people with resistant burning mouth syndrome after 6 months compared with placebo treatment.
- **Dietary supplements** We found insufficient evidence from three small methodologically flawed RCTs to draw reliable conclusions about the effects of alphalipoic acid in people with burning mouth syndrome. We found no RCTs evaluating other vitamin or coenzyme supplements.
- **Hormone replacement therapy in postmenopausal women** We found limited evidence from one small methodologically flawed RCT that tibolone improved symptoms compared with oryzanol plus vitamin E at 6 months.
- **Antidepressants; benzydamine hydrochloride** We found insufficient evidence on the effects of these interventions.

DEFINITION Burning mouth syndrome is a psychogenic or idiopathic burning discomfort or pain affecting people with clinically normal oral mucosa in whom a medical or dental cause has been excluded.[1–3] Terms previously used to describe what is now called burning mouth syndrome include glossodynia, glossopyrosis, stomatodynia, stomatopyrosis, sore tongue, and oral dysaesthesia.[4] A survey of 669 men and 758 women randomly selected from 48 500 people aged between 20 and 69 years found that people with burning mouth also have subjective dryness (66%), take some form of medication (64%), report other systemic illnesses (57%), and have altered taste (11%).[5] Many studies of people with symptoms of burning mouth do not distinguish those with burning mouth syndrome (i.e. idiopathic disease) from those with other conditions (such as vitamin B deficiency), making results unreliable. Local and systemic factors (such as infections, allergies, ill fitting dentures,[6] hypersensitivity reactions,[7] and hormone and vitamin deficiencies[8–10]) may cause the symptom of burning mouth and should be excluded before diagnosing burning mouth syndrome.

INCIDENCE/ PREVALENCE Burning mouth syndrome mainly affects women,[11–13] particularly after the menopause when its prevalence may be 18–33%.[14] One recent study in Sweden found a prevalence of 4% for the symptom of burning mouth without clinical abnormality of the oral mucosa (11/669 [2%] men, mean age 59 years; 42/758 [6%] women, mean age 57 years), with the highest prevalence (12%) in women aged 60–69 years.[5] Reported prevalence in general populations varies from 1%[15] to 15%.[11] Incidence and prevalence vary according to diagnostic criteria,[4] and many studies included people with the symptom of burning mouth rather than with burning mouth syndrome as defined above.

AETIOLOGY/ RISK FACTORS The cause is unknown, and we found no good aetiological studies. Possible causal factors include hormonal disturbances associated with the menopause,[12–14] psychogenic factors (including anxiety, depression, stress, life events, personality disorders, and phobia of cancer),[6,16,17] and neuropathy in so-called supertasters (see glossary, p 1779).[18]

PROGNOSIS We found no prospective cohort studies or other reliable evidence describing the natural history of burning mouth syndrome.[19] We found anecdotal reports of at least partial spontaneous remission in about half of people with burning mouth syndrome within 6–7 years.[16]

AIMS OF INTERVENTION To alleviate symptoms, with minimal adverse effects.

OUTCOMES Self reported relief of symptoms (burning mouth, altered taste, dry mouth); incidence and severity of anxiety and depression; quality of life using a validated ordinal scale.

METHODS *Clinical Evidence* search and appraisal June 2003.

Burning mouth syndrome

QUESTION What are the effects of treatments?

OPTION COGNITIVE BEHAVIOURAL THERAPY

One small RCT found that cognitive behavioural therapy reduced symptom intensity in people with resistant burning mouth syndrome after 6 months compared with placebo treatment.

Benefits: We found one systematic review (search date 2000, 1 RCT, 30 people).[20] The small RCT identified by the review (30 people with resistant burning mouth syndrome) compared cognitive behavioural therapy (12–15 sessions of 1 hour/week) versus a control group who received similar attention but without the cognitive behavioural therapy sessions. It found that cognitive behavioural therapy significantly reduced the intensity of symptoms at 6 months (measured on a visual analogue scale ranging from 1 = endurable to 7 = unendurable; mean pretreatment score: 5.0 with cognitive behavioural therapy *v* 4.3 with placebo; mean score change at 6 months: –3.6 with cognitive behavioural therapy *v* +0.4 with placebo; $P < 0.001$; AR for being symptom free at 6 months: 4/15 [27%] with cognitive behavioural therapy *v* 0/15 [0%] with placebo; significance not reported).[20]

Harms: The RCT provided no information on adverse effects.[20]

Comment: The trial was small and individual characteristics of the two groups were not described; therefore, the groups may not have been comparable. The visual analogue scale for assessing oral burning was not validated.[20]

OPTION HORMONE REPLACEMENT THERAPY IN POSTMENOPAUSAL WOMEN

We found limited evidence from one small methodologically flawed RCT that tibolone improved symptoms compared with oryzanol plus vitamin E at 6 months.

Benefits: We found one systematic review (search date 2000), which identified no RCTs of sufficient quality.[20] We found one subsequent RCT (56 postmenopausal women), which compared oral tibolone (2.5 mg daily) versus oryzanol (30 mg three times daily) plus vitamin E (100 mg three times daily). The study had several methodological flaws (see comment below).[21] It found that tibolone significantly improved symptoms compared with oryzanol plus vitamin E at 3 and 6 months (AR for improvement at 3 months: 84.6% with tibolone *v* 13.3 % with oryzanol plus vitamin E; $P < 0.005$; AR for improvement at 6 months: 88.5% with tibolone *v* 16.7% with oryzanol plus vitamin E; $P < 0.005$).

Harms: Adverse effects of hormone replacement therapy are well documented (see oestrogens under menopausal symptoms, p 2459).

Comment: We found three non-randomised intervention studies with no clear diagnostic criteria or outcome measures.[22–24] The subsequent RCT (which was reported in Chinese) has a number of design weaknesses, which suggest that the results need to be interpreted with

caution.[21] It gives no clear definition of burning mouth syndrome; it does not specify the method of randomisation; the study was not blinded; the scale used for assessing improvement of symptoms was not validated, and there were important differences between the groups at baseline.

OPTION DIETARY SUPPLEMENTS

We found insufficient evidence from three small methodologically flawed RCTs to draw reliable conclusions about the effects of alphalipoic acid in people with burning mouth syndrome. We found no RCTs evaluating other vitamin or coenzyme supplements.

Benefits: We found one systematic review (search date 2000, 1 RCT, 42 people)[20] and two subsequent RCTs.[25,26] All three RCTs evaluated outcomes on a five point scale (symptoms "worsening", "unchanged", "slight improvement", "decided improvement", or "resolution"). The RCT included in the review compared alphalipoic acid (600 mg/day for 20 days, followed by 200 mg/day for 10 days) with placebo. It found that alphalipoic acid significantly improved symptoms compared with placebo (AR for "slight improvement" or "decided improvement": 16/21 [76%] with alphalipoic acid *v* 3/14 [21%] with placebo; RR 3.6, 95% CI 1.6 to 7.7; NNT 2, 95% CI 1 to 3; follow up period unclear).[20] The first subsequent RCT (60 people) found that alphalipoic acid (200 mg 3 times daily) significantly improved symptoms after 2 months compared with placebo (AR for "slight improvement", "decided improvement", or "resolution": 29/30 [97%] with alphalipoic acid *v* 12/30 [40%] with placebo; $P < 0.0001$).[25] The second subsequent RCT (80 people) compared alphalipoic acid (200 mg three times/day), lactoperoxidase mouth rinse (5–6 times/day), bethanecol (5 mg three times/day), and placebo.[26] It found that alphalipoic acid increased the proportion of people reporting improvement on the symptom scale at 60 days compared with the three other treatment options (18/20 [90%] with alphalipoic acid *v* 2/20 [10%] with bethanecol *v* 0/20 [0%] with lactoperoxidase *v* 0/20 [0%] with placebo; it is unclear to what comparison the P value of < 0.0001 refers).

Harms: In the second subsequent RCT, four people in the alphalipoic acid arm reported heartburn, which settled with ranitidine. Four people taking bethanecol experienced adverse events, including nausea, dizziness, cold perspiration, or abdominal pain.[26]

Comment: The three RCTs of alphalipoic acid were performed by the same group at overlapping time periods.[20,25,26] Therefore, we could not exclude the possibility that duplicate data may have been reported. Two of the trials were not clearly reported as being blinded. Unblinded assessment of subjective outcomes should be interpreted with caution.

OPTION ANTIDEPRESSANTS

We found insufficient evidence on the effects of antidepressants in people with burning mouth syndrome.

Burning mouth syndrome

Benefits: We found one systematic review[20] (search date 2000, 2 RCTs, 290 people of whom 114 had burning mouth syndrome) and one small subsequent RCT.[27] **Clomipramine and mianserin:** The review identified one short term RCT (253 people with chronic idiopathic pain syndrome, including 77 people with burning mouth syndrome) comparing clomipramine, mianserin, and placebo (see comment below).[20] The study had a number of significant methodological flaws (see comment below). It found no significant difference in improvement in pain between the three treatments over 6 weeks (analysis not by intention to treat; improvement defined as a 50% reduction in pain scores on a visual analogue scale and the Clinical Global Impression Scale; results displayed graphically; P = 0.11). **Trazodone:** The review identified one double blind RCT (37 women with burning mouth syndrome) comparing trazodone (200 mg/day) versus placebo.[20] It found no significant difference in pain or related symptoms between groups measured on a visual analogue scale (0 mm = best score and 100 mm = worst score) at 8 weeks (mean score reduction: 14 with trazodone *v* 13 with placebo; P = 0.01). **Selective serotonin reuptake inhibitors versus amisulpride:** We found one small RCT (76 people), which found similar reduction in pain score (pain assessed by 10 point visual analogue scale, higher scores indicating more severe pain) with sertraline (50 mg/day), paroxetine (20 mg/day), and amisulpride (50 mg/day) at 8 weeks (mean score reduction: 4.4 with sertraline *v* 3.7 with paroxetine *v* 4 with amisulpride; P value not reported).[27] However, the study may have lacked power to detect clinically important differences among treatments and lacked a placebo comparison.

Harms: **Clomipramine and mianserin:** Adverse effects of clomipramine, mianserin, and other antidepressants are documented elsewhere (see depressive disorders, p 1278). **Trazodone:** The RCT found that adverse effects caused 7/18 (39%) people taking trazodone to withdraw from the trial compared with 2/19 (10%) taking placebo.[20] Significantly more people given trazodone experienced dizziness and drowsiness compared with placebo (dizziness: 11/18 with trazodone *v* 1/19 with placebo, P < 0.001; drowsiness: 9/18 with trazodone *v* 2/19 with placebo, P < 0.05). **Selective serotonin reuptake inhibitors versus amisulpride:** The RCT reported no serious adverse effects in any treatment group.[27]

Comment: The trial of clomipramine and mianserin versus placebo included in the systematic review was too small to exclude an effect of treatment, did not use adequate diagnostic criteria, was of short duration, and had limited follow up.[20] In addition, the review was not able to identify how many people with burning mouth syndrome were allocated to each treatment group. Therefore, this study does not provide sufficient evidence to determine the role of antidepressants in treating burning mouth syndrome. Although the trial of trazodone versus placebo was well conducted and used several pertinent outcome measures, including psychological ones, it was too small and brief to detect clinically important effects.[20] In the

RCT comparing selective serotonin reuptake inhibitors versus amisulpride, 34 people had a concurrent psychiatric diagnosis.[27] The widespread use of antidepressants in burning mouth syndrome may be because of their effects on neuropathic pain,[28] and the association of burning mouth syndrome with generalised anxiety disorder, depression, and adverse life events.[29]

OPTION BENZYDAMINE HYDROCHLORIDE

We found insufficient evidence on the effects of benzydamine hydrochloride in burning mouth syndrome.

Benefits: We found one systematic review (search date 2000).[20] It found one small RCT (30 people with burning mouth syndrome) comparing benzydamine hydrochloride oral rinse (15 mL of 0.15% for 1 minute 3 times daily for 4 weeks), placebo, and no treatment. It found no significant difference in improvement in symptoms between groups at 4 weeks (AR for improvement: 10% with benzydamine hydrochloride *v* 20% with placebo *v* 10% with no therapy; P value not reported). However, the trial was too small to exclude a clinically important difference.[20]

Harms: No adverse effects were reported.

Comment: Inclusion criteria were well defined. The trial was incompletely blinded because the third group received no treatment.

GLOSSARY

Supertaster Persons who have the highest density of fungiform papillae, which are responsible for taste, on the anterior tongue and taste 6–n–propylthiouracil as intensely bitter.

Substantive changes

Hormone replacement therapy in postmenopausal women One RCT added;[21] conclusions unchanged.
Dietary supplements One RCT added;[26] conclusions unchanged.

Prevention and treatment in neonates
Treatment of systemic candidiasis

Key Messages

Prevention

- **Antifungal prophylaxis in people undergoing cancer treatments** One systematic review in people undergoing treatment for cancer found that antifungal drugs reduced the risk of oropharyngeal candidiasis compared with placebo or no treatment. One review found that drugs that were absorbed or partially absorbed via the gastrointestinal tract were more effective than non-absorbed drugs in preventing oral candidiasis.

Candidiasis (oropharyngeal)

- **Antifungal prophylaxis in people with advanced HIV disease** RCTs in people with HIV infection have found that daily or weekly antifungal prophylaxis with fluconazole, itraconazole, or nystatin reduces incidence and relapse of oropharyngeal candidiasis compared with placebo.
- **Antifungal prophylaxis in immunocompromised infants and children** One large RCT in immunocompromised infants and children found that fluconazole reduced the incidence of oropharyngeal candidiasis compared with oral nystatin or amphotericin B.
- **Antifungal prophylaxis in people receiving tissue transplants** Two small RCTs in people with liver transplant found no significant difference in the risk of oropharyngeal candidiasis between nystatin and fluconazole or clotrimazole. However, the trials may have lacked power to exclude clinically important differences. We found insufficient evidence from two RCTs about the effects of prophylactic chlorhexidine mouth rinse with or without nystatin compared with placebo in people receiving bone marrow transplant.
- **Continuous prophylaxis versus intermittent treatment in people with HIV infection and acute episodes of oropharyngeal candidiasis (in preventing antifungal resistance)** One RCT in people with HIV infection and acute episodes of oropharyngeal candidiasis found no significant difference in emergence of antifungal resistance between continuous antifungal prophylaxis with fluconazole and intermittent antifungal treatment with fluconazole.
- **Preventive interventions in people with diabetes** We found no systematic review or RCTs.

Treatments

- **Antifungal treatment in immunocompetent and immunocompromised infants and children** RCTs found that miconazole and fluconazole increased clinical cure of oropharyngeal candidiasis compared with nystatin in immunocompetent and immunocompromised infants and children.
- **Oral suspension of systemically absorbed azoles in people with HIV infection** RCTs have found that topical preparations of itraconazole, fluconazole, and clotrimazole effectively treat oropharyngeal candidiasis in people with HIV infection. One RCT found that fluconazole significantly reduced symptoms and signs of oropharyngeal candidiasis compared with topical nystatin.
- **Antifungal treatment for denture stomatitis** We found insufficient evidence from small RCTs to compare effects of antifungals versus placebo or versus each other for treating oropharyngeal candidiasis in people who wear dentures.
- **Antifungal treatment in people undergoing chemotherapy, radiotherapy, or both treatments for cancer** One systematic review found insufficient evidence from RCTs about the clinical effects of antifungals compared with placebo for treating oropharyngeal candidiasis in people undergoing chemotherapy or radiotherapy. It also found insufficient evidence about the effects of different antifungal agents or doses in people with oropharyngeal candidiasis who are receiving radiotherapy or chemotherapy.
- **Denture hygiene** We found insufficient evidence from RCTs to assess clinical effects on oropharyngeal candidiasis of mouth rinses, disinfectants, denture soaks, denture scrubbing, and microwave irradiation of dentures. Microwave treatment is not suitable for all dentures.
- **Treatments in people with diabetes mellitus** We found no RCTs assessing treatments for oral candidiasis in people with diabetes mellitus.

DEFINITION Oropharyngeal candidiasis is an opportunistic mucosal infection caused, in most cases, by *Candida albicans*. The four main types of oropharyngeal candidiasis are: (1) pseudomembranous (thrush), consisting of white discrete plaques on an erythematous background, located on the buccal mucosa, throat, tongue, or gingivae; (2) erythematous, consisting of smooth red patches on the hard or soft palate, dorsum of tongue, or buccal mucosa; (3) hyperplastic, consisting of white, firmly adherent patches or plaques, usually bilateral on the buccal mucosa; and (4) denture induced stomatitis, presenting as either a smooth or granular erythema confined to the denture bearing area of the hard palate and often associated with an angular cheilitis.[1] Symptoms vary, ranging from none to a sore and painful mouth with a burning tongue and altered taste. Oropharyngeal candidiasis can impair speech, nutritional intake, and quality of life.

INCIDENCE/ PREVALENCE Candida species are commensals in the gastrointestinal tract. Transmission occurs directly between infected people or on fomites (objects that can harbour pathogenic organisms). Candida is found in the mouth of 31–60% of healthy people.[2] Denture stomatitis associated with Candida is prevalent in 65% of denture wearers.[2] Oropharyngeal candidiasis affects 15–60% of people with haematological or oncological malignancies during periods of immunosuppression.[3] Oropharyngeal candidiasis occurs in 7–48% of people with HIV infection and in over 90% of those with advanced disease. In severely immunosuppressed people, relapse rates are high (30–50%) and usually occur within 14 days of stopping treatment.[4]

AETIOLOGY/ RISK FACTORS Risk factors associated with symptomatic oropharyngeal candidiasis include local or systemic immunosuppression, haematological disorders, broad spectrum antibiotic use, inhaled or systemic steroids, xerostomia, diabetes, and wearing dentures, obturators, or orthodontic appliances.[1,5] The same strain may persist for months or years in the absence of infection. In people with HIV infection, there is no direct correlation between the number of organisms and the presence of clinical disease. Symptomatic oropharyngeal candidiasis associated with *in vitro* resistance to fluconazole occurs in 5% of people with advanced HIV disease.[6] Resistance to azole antifungals is associated with severe immunosuppression (≤ 50 CD4 cells/mm^3), more episodes treated with antifungal drugs, and longer median duration of systemic azole treatment.[7]

PROGNOSIS Untreated candidiasis persists for months or years unless associated risk factors are treated or eliminated. In neonates, spontaneous cure of oropharyngeal candidiasis usually occurs after 3–8 weeks.

AIMS OF INTERVENTION To resolve signs and symptoms of oropharyngeal candidiasis; to prevent or delay relapse in immunocompromised people; and to minimise drug induced resistance, with minimum adverse effects.

OUTCOMES Resolution of signs and symptoms; clinical cure; rate of recurrence on the basis of scoring of signs and symptoms. Many RCTs report the results of mycological culture but, whenever possible, this review has not used these intermediate outcomes because the relation between the clinical and mycological culture findings is uncertain.

Candidiasis (oropharyngeal)

METHODS *Clinical Evidence* search and appraisal February 2003 including a search for observational studies on dental hygiene. This was supplemented by a search of the author's library, selecting publications in English from 1975–2003. We included only systematic reviews and RCTs that specified oropharyngeal candidiasis in the protocol design and outcome measurements. RCTs dealing with oesophagitis and invasive, systemic candidal infections were excluded.

QUESTION **What are the effects of interventions to prevent and treat oropharyngeal candidiasis in adults receiving treatment causing immunosuppression?**

OPTION ANTIFUNGAL PROPHYLAXIS IN PEOPLE RECEIVING CANCER TREATMENTS

One systematic review found that absorbed antifungal drugs reduce the risk of oropharyngeal candidiasis compared with placebo or unabsorbed antifungals. It found that partially absorbed antifungal drugs reduce the risk of oropharyngeal candidiasis compared with placebo; however, there was significant heterogeneity among studies. The systematic review found no significant difference in adverse events between absorbed antifungal drugs and placebo or no treatment.

Benefits: We found one systematic review (search date 2001, 27 RCTS, 4137 people receiving chemotherapy or radiotherapy for cancer) that compared oral and topical antifungal prophylaxis versus placebo, no treatment, or another active intervention.[8] The drugs were categorised by absorption from the gastrointestinal tract. **Absorbed antifungals versus placebo:** The review found that absorbed antifungal drugs (ketoconazole, itraconazole, fluconazole) significantly reduced the risk of oral candidiasis compared with placebo or no drug treatment (7 RCTs; 1153 people; RR 0.45, 95% CI 0.32 to 0.64).[8] **Partially absorbed antifungals versus placebo:** The review found that partially absorbed antifungal drugs (miconazole, clotrimazole) significantly reduced the risk of oral candidiasis compared with placebo or no drug treatment (4 RCTs; 292 people; RR 0.13, 95% CI 0.06 to 0.27).[8] **Unabsorbed antifungals versus placebo:** The review found that there was no significant difference in the risk of oral candidiasis between unabsorbed drugs (nystatin alone, nystatin plus chlorhexidine, amphotericin B alone, or amphotericin B combined with nystatin, norfloxacin, natamycin, thymostimulin, or chlorhexidine) and placebo (8 RCTs; 382 people; RR 0.68, 95% CI 0.46 to 1.02).[8] However, the review found significant heterogeneity in the included studies ($P < 0.001$). **Absorbed versus unabsorbed antifungals:** The review found that absorbed antifungal drugs reduced the risk of oral candidiasis compared with unabsorbed antifungal drugs (7 RCTs; 2014 people; RR 0.40, 95% CI 0.21 to 0.76).[8]

Harms: The systematic review found no significant difference in adverse events between absorbed antifungal drugs and placebo (62/437 [14%] with absorbed antifungals *v* 52/434 [12%] with placebo; RR 1.18, 95% CI 0.84 to 1.66). The most common adverse events were abdominal pain, nausea, vomiting, and rash.[8]

Comment: None.

OPTION ANTIFUNGAL PROPHYLAXIS IN ADULTS WHO HAVE RECEIVED TISSUE TRANSPLANTS

Two small RCTs in people with liver transplant found no significant difference in the risk of oropharyngeal candidiasis between nystatin and fluconazole or clotrimazole. However, the trials may have lacked power to exclude clinically important differences. We found insufficient evidence from two RCTs about effects of prophylactic chlorhexidine mouth rinse with or without nystatin compared with placebo in people receiving bone marrow transplant.

Benefits: We found no systematic review. **In people receiving liver transplant:** We found two small RCTs in people with liver transplant comparing different antifungal agents for preventing oropharyngeal candidiasis.[9,10] The first RCT (143 people) found no significant difference in the risk of oropharyngeal candidiasis between fluconazole and nystatin at 28 days (rate of oropharyngeal candidiasis: 8/76 [11%] with fluconazole *v* 14/67 [21%] with nystatin; significance not stated).[9] The second RCT (34 people) found no significant difference in the risk of oropharyngeal candidiasis between clotrimazole and nystatin during hospital stay after transplantation (rate of oropharyngeal candidiasis: 1/17 [6%] with clotrimazole *v* 1/17 [6%] with nystatin; significance not stated).[10] However, the RCTs may have lacked power to exclude clinically important differences. **In people receiving bone marrow transplant:** We found two RCTs in people with neutropenia who had received bone marrow transplants.[11,12] The first RCT (51 people) found that chlorhexidine significantly reduced the risk of oropharyngeal candidiasis compared with placebo at 60 days (2/24 [8%] with chlorhexidine *v* 15/27 [56%] with placebo; ARR 47%, 95% CI 24% to 54%; RR 0.15, 95% CI 0.03 to 0.57; NNT 2, 95% CI 2 to 4).[11] The second RCT (86 adults with leukaemia and bone marrow transplant) found no significant difference in the development of oropharyngeal candidiasis between rinses containing saline alone, chlorhexidine alone, nystatin alone, or nystatin plus chlorhexidine (no statistical analysis available).[12]

Harms: There was no increased hepatotoxicity, cyclosporin interaction, or emergence of clinically relevant resistant strains reported in people receiving antifungal prophylaxis after liver transplantation.[9]

Comment: The RCTs of chlorhexidine found conflicting results about its effect on oropharyngeal candidiasis and mucositis,[11,12] but the second RCT had four parallel arms and was not powered to detect a clinically important difference.[12]

OPTION ANTIFUNGAL TREATMENT IN PEOPLE RECEIVING CHEMOTHERAPY AND RADIOTHERAPY

One systematic review found insufficient evidence from RCTs about clinical effects of antifungals compared with placebo for treating oropharyngeal candidiasis in people undergoing chemotherapy or radiotherapy, or about effects of different antifungal agents or doses in people with oropharyngeal candidiasis who are receiving radiotherapy or chemotherapy.

Candidiasis (oropharyngeal)

Benefits: We found one systematic review (search date 2001, 8 RCTs, 418 people with cancer receiving chemotherapy, radiotherapy, or both) that compared antifungal treatment of oral candidiasis versus placebo or another active intervention.[13] **Antifungals versus placebo:** The systematic review included two placebo controlled RCTs. The first small RCT (56 people) found that ketoconazole significantly decreased oral candidiasis compared with placebo at 14 days (persistence of oral candidiasis: 10/36 [28%] people with ketoconazole *v* 16/20 [80%] people with placebo; RR 0.35, 95% CI 0.20 to 0.61).[13] The second small RCT (13 people) included in the review found no significant difference in the proportion of people with oral candidiasis between clotrimazole and placebo.[13] The timing to outcome measurement was unclear.[13] This RCT may have lacked statistical power to detect a clinically important effect. **Versus different dosages:** One RCT (52 people) included in the review found no significant difference in clinically assessed cure of oral candidiasis between a 50 mg troche of clotrimazole and 10 mg of clotrimazole (persistence of oral candidiasis: 1/26 [4%] with clotrimazole 50 mg *v* 1/26 [4%] with clotrimazole 10 mg; RR 1.00, 95% CI 0.07 to 15.15).[13] The timing of outcome measurement was unclear.[13] **Absorbed drugs versus each other:** The systematic review found no significant difference in clinically assessed cure rates between different absorbed drugs (2 RCTs; persistence of oral candidiasis: 6/46 [13%] with fluconazole *v* 8/44 [18%] with ketoconazole/itraconazole; RR 0.72, 95% CI 0.27 to 1.88).[13] **Absorbed versus non-absorbed:** The review found three RCTs comparing absorbed and non-absorbed drugs. There was significant heterogeneity among the RCTs ($P = 0.01$).[13] One RCT found fluconazole significantly improved clinical cure rates compared with nystatin. One RCT found no significant difference between ketoconazole and nystatin in clinical or mycological cure rates. One RCT found fluconazole significantly improved cure rates when assessed clinically compared with amphotericin B.[13] Pooling the results of the three RCTs, the review found no significant difference between absorbed and non-absorbed drugs in clinical cure rates (3 RCTs; persistence of oral candidiasis: 16/105 [15%] with fluconazole/ketoconazole *v* 35/102 [34%] with amphotericin/nystatin; RR 0.50, 95% CI 0.11 to 2.27; random effects model). However, given the heterogeneity of the included studies, these results may not be robust. We found one subsequent RCT (268 people with head and neck cancer, 243 evaluated) which compared fluconazole oral suspension 50 mg once daily with amphotericin B oral suspension 0.5 mg three times daily for 7–14 days.[14] It found no significant difference in rates of clinical cure of oral candidiasis between fluconazole and amphotericin (clinical cure: 26/123 [21%] with fluconazole *v* 17/120 [14%] with amphotericin B).

Harms: The systematic review did not report on harms.[13]

Comment: In assessing outcomes, the review noted that few RCTs described the clinical criteria used.[13] The review concluded that there were insufficient trials to make strong recommendations for patient care, and that there was a need for further well designed, placebo controlled trials to assess the effectiveness of old and new interventions for treating oral candidiasis.[13]

QUESTION **What are the effects of interventions to prevent and treat oropharyngeal candidiasis in infants and children?**

OPTION ANTIFUNGAL PREVENTION IN IMMUNOCOMPROMISED INFANTS AND CHILDREN

One large RCT in immunocompromised infants and children has found that fluconazole significantly reduced the incidence of oropharyngeal candidiasis compared with oral nystatin, amphotericin B, or both. More people in the fluconazole group withdrew because of adverse events, though these numbers were small.

Benefits: We found no systematic review. We found one large, unblinded, multicentre RCT in 502 immunocompromised infants and children (aged 6 months to 17 years) about to undergo initial or repeat courses of chemotherapy or radiotherapy for haematological or oncological malignancies.[3] It found that fluconazole significantly reduced the incidence of oropharyngeal candidiasis compared with oral polyenes (nystatin, oral amphotericin B, or both) (3/236 [1%] with fluconazole *v* 15/249 [6%] with oral polyenes; RR 0.21, 95% CI 0.06 to 0.72; NNT 21, 95% CI 18 to 58).[3] Eighteen of the children from the multicentre RCT[3] were enrolled in a second, small RCT (50 children in total), which compared fluconazole versus oral nystatin for preventing oropharyngeal candidiasis.[15] The RCT found no significant difference in the incidence of oral candidiasis (2/25 [8%] with fluconazole *v* 3/25 [12%] with nystatin; $P = 0.63$). However, inclusion of pre-treated children may have biased results, and the study may have lacked power to exclude clinically important differences.

Harms: In the first RCT, adverse events caused 8/245 (3%) children on fluconazole to withdraw compared with 3/257 (1%) on oral polyenes.[3] In the second RCT, no children were withdrawn from the study, but three children treated with fluconazole reported nausea and abdominal discomfort and one reported pruritus.[15]

Comment: None.

OPTION ANTIFUNGAL TREATMENT IN CHILDREN

RCTs found that miconazole and fluconazole increased clinical cure of oropharyngeal candidiasis compared with nystatin in immunocompetent and immunocompromised infants and children.

Benefits: We found no systematic review. **Immunocompetent infants and children:** We found no placebo controlled RCTs. We found two RCTs in immunocompetent infants with oropharyngeal candidiasis, which compared miconazole gel and nystatin suspension and nystatin gel and one RCT which compared fluconazole and nystatin.[16–18] Both RCTs comparing miconazole and nystatin found that miconazole significantly increased the rate of clinical cure. The larger RCT (183 infants age < 1 year with signs of oropharyngeal candidiasis) found that miconazole gel had a significantly increased cure rate compared with nystatin (at day 5: cure rate 83/98 [85%] with miconazole gel 25 mg 4 times daily *v* 18/85 [21%] with nystatin suspension 100 000 U 4 times daily; $P < 0.0001$; at day 12:

97/98 [99%] with miconazole *v* 46/85 [54%] with nystatin; P < 0.0001).[16] The smaller RCT (95 infants, mean age 5 months, range 2–17 months with clinical oral thrush) found that miconazole gel significantly increased clinical cure at 14 days compared with two brands of nystatin gel preparation (P = 0.0032 and P = 0.00068).[17] One RCT (47 infants aged 1–12 months with clinical signs of oral candidiasis and culture positive for Candida species) compared nystatin oral suspension 100 000 IU/mL four times daily for 10 days versus fluconazole suspension 3 mg/kg once daily for 7 days.[18] It found that fluconazole significantly increased clinical cure compared with nystatin (36 infants evaluated; clinical cure: 15/15 [100%] with fluconazole *v* 6/19 [32%] with nystatin, P < 0.0001).[18] **Immunocompromised infants and children:** We found no placebo controlled RCTs. We found one multicentre RCT (32 centres, 182 immunocompromised infants and children aged 5 months to 14 years), which compared fluconazole suspension 3 mg/kg versus nystatin 400 000 U four times daily for 14 days.[19] It found that fluconazole significantly increased clinical cure rate compared with nystatin (78/86 [91%] with fluconazole *v* 37/73 [51%] with nystatin; RR 1.8, 95% CI 1.6 to 1.9; NNT 2, 95% CI 2 to 3).[19] In subgroup analyses of children with HIV infection, nystatin significantly increased clinical cure compared with fluconazole (clinical cure: 28/35 [80%] with fluconazole *v* 6/29 [21%] with nystatin), and for people with malignancy (clinical cure: 49/50 [98%] with fluconazole *v* 30/42 [71%] with nystatin). Clinical relapse rates after 2 weeks were similar (18% with fluconazole *v* 24% with nystatin).

Harms: **Immunocompetent infants and children:** The most common adverse events with both miconazole and nystatin were vomiting and, more rarely, diarrhoea, affecting less than 4.5% of infants.[16,17] **Immunocompromised infants and children:** Adverse events caused 2/94 (2%) children on fluconazole to withdraw versus 0/88 (0%) children on nystatin (P = 0.04).[19]

Comment: **Immunocompetent infants and children:** The RCTs were not blinded nor placebo controlled.[16–18] There is potential for observer bias, but the clinical results were corroborated by mycological findings, which were blinded.[16] The larger RCT was carried out in 26 general practices,[16] so it is representative of the context in which most otherwise healthy infants with oropharyngeal candidiasis would be treated, especially regarding adherence and cure rate. **Immunocompromised infants and children:** Participants included in the RCT were immunocompromised for different reasons: 64 had HIV infection, 92 had a malignancy, and 26 were receiving immunosuppressive treatment.[19]

QUESTION What are the effects of interventions to prevent and treat oropharyngeal candidiasis in people with diabetes?

OPTION ANTIFUNGAL DRUGS

We found insufficient evidence about prevention or treatment of oropharyngeal candidiasis in people with diabetes.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION **What are the effects of interventions for oropharyngeal candidiasis in people with dentures?**

OPTION **ANTIFUNGAL DRUGS**

We found insufficient evidence from small RCTs to compare effects of antifungal agents versus placebo or versus each other for treating oropharyngeal candidiasis in people who wear dentures.

Benefits: We found no systematic review, but found several RCTs. **Versus placebo:** Five small RCTs compared topical oral antifungals versus placebo for the treatment of denture stomatitis.[20–24] The first small RCT (46 people) found that topical oral polyenes (nystatin, amphotericin B) significantly improved clinical cure of denture stomatitis after 4 weeks of treatment compared with placebo (nystatin *v* placebo, $P \leq 0.05$; amphotericin B *v* placebo, $P \leq 0.01$).[21] The second small RCT (22 people) found no significant difference between polyenes and placebo in the clinical appearance of denture stomatitis after 2 weeks of treatment, or 10 days after stopping treatment.[22] The third small RCT (49 people) found no significant difference between amphotericin B (with or without a hydrogen peroxide denture cleanser) and placebo in clinical cure.[20] The fourth small RCT (36 people) found no significant difference in the resolution of palatal symptoms between miconazole dental lacquer (applied to the fit surface of an upper denture as a single application) and a placebo lacquer at 14 days (symptom resolution: 54% with lacquer *v* 23% with placebo; RR 2.40, 95% CI 0.89 to 3.80).[23] The fifth small RCT (38 people) found that fluconazole significantly increased clinical improvement or cure rates compared with placebo at 2 and 4 weeks (at 2 weeks: 10/19 [53%] with fluconazole *v* 0/18 [0%] with placebo; $P < 0.001$; at 4 weeks: 5/19 [26%] with fluconazole *v* 0/19 [0%] with placebo; $P < 0.02$).[24] **Different antifungal treatments:** We found two RCTs.[25,26] The first small RCT (29 people) found no significant difference in clinical cure rate between fluconazole 50 mg daily for 14 days and amphotericin B lozenges plus denture cream for 28 days (84% with fluconazole *v* 90% with amphotericin B).[25] Clinical relapse was common in both groups at 12 weeks. The second RCT (multicentre; 305 elderly people, 176 with dentures) found no significant difference in clinical cure between fluconazole 50 mg and amphotericin B 0.5 g. Wearing dentures did not affect the response to antifungal treatment (clinical cure rate: 151/176 [86%] of denture wearers *v* 102/124 [82%] of non-denture wearers).[26] **Different modes of administration:** Two RCTs (41 people[27] and 33 people[28]) compared a single application of miconazole dental lacquer versus miconazole gel 2% applied to the denture four times daily. Neither RCT found a significant difference in palatal erythema (largest RCT, 14 days after treatment: 13/20 [65%] with lacquer *v* 16/21 [76%] with gel; RR of erythema with lacquer *v* gel: 0.85, 95% CI 0.42 to 1.20).[27,28]

Candidiasis (oropharyngeal)

Harms: None of the trials exclusively enrolling people with dentures were large enough to report reliably on adverse effects. In the large RCT of elderly people, 6/150 (4%) in the fluconazole arm and 0/155 (0%) in the amphotericin arm experienced adverse events, including diarrhoea, buccal bitterness, aggravation of pre-existing renal dysfunction (1 person, withdrawn from RCT), and increased liver transaminases (1 person, not withdrawn).[26]

Comment: Co-interventions included professional cleaning of the dentures at the start of the study, combined with advice on denture hygiene and advice not to wear the dentures while asleep at night. Because the fit surface of the denture may act as a reservoir of primary and recurrent infection, this cleaning and advice may explain the high clinical cure rate in the placebo groups. The RCTs comparing different antifungals were not sufficiently powered to detect clinically important differences.

OPTION DENTURE HYGIENE

We found insufficient evidence from RCTs to assess clinical effects on oropharyngeal candidiasis of mouth rinses, disinfectants, denture soaks, denture scrubbing, and microwave irradiation of dentures. Microwave treatment is not suitable for all dentures.

Benefits: We found no systematic review, but found four RCTs.[29–32] The first small crossover RCT (43 people aged 35–73 years) compared daily soaking of dentures in disinfectant (potassium persulphate 1%) versus placebo (water, peppermint, dye) for 4 weeks.[29] The results provided for the outcome of stomatitis were difficult to interpret and therefore no firm conclusions can be drawn. The second RCT (78 people with mild to moderate denture stomatitis) compared three treatments: mouth rinsing three times daily plus denture soaking once daily, using an antimicrobial mouth rinse; the same procedure, using a control mouth rinse, and weekly relining of the fit surface of the denture (to improve retention and reduce denture trauma) for 4 weeks.[30] It found that the antimicrobial mouth rinse significantly reduced symptoms of denture stomatitis compared with control mouth rinse ($P < 0.01$; absolute numbers not provided). The third, small RCT (34 people in long term care with acrylic dentures and a positive test for *C albicans*) compared microwave treatment (dentures scrubbed with antibacterial soap and water and then microwaved individually for 1 minute at 850 watts on days 1, 5, and 10) versus control treatment (dentures soaked in 0.2% chlorhexidine solution overnight for 14 days and scrubbed with antibacterial soap and water on days 1, 5, and 10).[31] Both groups also received the same course of topical antifungal medication (nystatin lozenges daily for 14 days). The RCT found no significant difference between treatments in the rates of dentures recolonised with *C albicans* after 3 months, although it may have lacked power to excluded a clinically important difference (RR 0.64, 95% CI 0.38 to 1.06). It found microwave treatment significantly decreased the proportion of people with infection of the oral mucosa on cytological smear after 3 months compared with control dental soak (RR 0.25, 95%

CI 0.06 to 0.59).[31] The fourth small RCT (19 elderly, chronically ill, institutionalised people receiving nystatin pastilles 3 times daily) found no additional advantage from nystatin denture soaking solution (10 000 U/mL) compared with tap water as a soaking solution (all participants clinically cured at 7 days).[32]

Harms: The first two RCTs did not report on adverse effects.[29,30] In the microwave RCT, exposure time was decided arbitrarily.[31] In the RCT, exposure to microwave at 850 watts for 90 seconds seemed to damage the denture material.[31] The RCT noted microwave treatment may damage complete dentures that have been relined, repaired, or both by producing a bubble (pocketing) in the acrylic material, and porcelain teeth with metal retaining pins may cause the microwave to spark and scorch the denture material.[31] It noted microwave treatment was not suitable for all dentures and should be used with caution.[31] Microwave treatment cannot be used for chrome dentures or dentures with metal clasps.

Comment: We found no RCT evaluating the effect of removing dentures at night on preventing denture stomatitis. Two observational studies found a correlation between the prevalence of denture stomatitis and an unhealthy lifestyle (a global measure including dietary habits, physical activity, alcohol consumption, and smoking), wearing dentures at night, and poor oral hygiene.[33,34]

QUESTION **What are the effects of interventions to prevent and treat oropharyngeal candidiasis in people with HIV infection?**

OPTION CONTINUOUS ANTIFUNGAL PROPHYLAXIS

RCTs in people with HIV infection have found that daily or weekly antifungal prophylaxis with fluconazole, itraconazole, or nystatin significantly reduces incidence and relapse of oropharyngeal candidiasis compared with placebo.

Benefits: We found one systematic review (search date 2000).[35] The review was narrative in character and no data were pooled. We found 10 RCTs using different prophylaxis protocols with follow up of 3–29 months.[36–45] All RCTs enrolled people with AIDS, AIDS related complex, or CD4 cell counts less than or equal to 300 cells/mm^3. **Fluconazole versus placebo:** We found six RCTs that used daily or weekly regimens.[36,37,39–41,46] All six RCTs found that fluconazole significantly reduced oropharyngeal candidiasis compared with placebo. The first RCT (24 people) found that fluconazole 150 mg weekly reduced clinical relapse compared with placebo during 6 months of prophylaxis (relapse: 4/9 [44%] with fluconazole *v* 5/5 [100%] with placebo; P value not provided).[36] The second RCT (323 women with HIV infection) compared fluconazole 200 mg weekly and placebo and found similar results; fluconazole reduced the risk of recurrent oropharyngeal candidiasis over 29 months (RR 0.50, 95% CI 0.33 to 0.74).[37] The third RCT (84 people) found that fluconazole significantly reduced relapse compared with placebo (73 people; median time to relapse: 168 days with fluconazole *v* 37 days with placebo; $P < 0.0001$; relapse rate: 13/31

[42%] with fluconazole *v* 25/26 [96%] with placebo).[39] The fourth RCT (60 people) found that fluconazole 50 or 100 mg reduced relapse compared with no treatment at 137–215 days (58 people evaluated; rate of relapse: 11% with fluconazole 50 mg *v* 21% with fluconazole 100 mg *v* 95% with no treatment; significance not stated).[40] The fifth small RCT (25 people with 1–4 previous episodes of thrush, but none at baseline) found that fluconazole significantly reduced oral candidiasis compared with placebo at 12 weeks (0/12 [0%] with fluconazole *v* 8/13 [62%] with placebo; P = 0.002).[41] The sixth RCT (143 people) found that fluconazole reduced relapse compared with placebo (median time to relapse: 175 days with fluconazole *v* 35 days with placebo; P < 0.00001; freedom from relapse at 37 months: 26/67 [39%] with fluconazole *v* 7/71 [10%] with placebo).[46] **Itraconazole versus placebo:** We found three RCTs.[43–45] The first RCT (70 people) found that daily prophylaxis with itraconazole 200 mg for 24 weeks significantly reduced relapse rate (5/24 [21%] with itraconazole *v* 14/20 [70%] with placebo; ARR 49%, 95% CI 19% to 64%; NNT 2, 95% CI 2 to 5) and increased the time to relapse (median time to relapse: 10.4 weeks with itraconazole *v* 8.0 weeks with placebo; P = 0.001).[43] The second RCT (374 people) compared itraconazole 200 mg daily versus placebo.[44] The primary study end point was time to development of deep fungal infections. The study was terminated because of inadequate power (see comment below). The mean duration of study treatment was 448 days with itraconazole and 386 days with placebo. The RCT found that itraconazole significantly reduced the incidence of oral candidiasis and significantly prolonged the time to development of oral candidiasis compared with placebo (oral candidiasis: RR 0.33, CI not provided; P < 0.001, logistic regression; time to development of oral candidiasis: 508 days with itraconazole *v* 413 days with placebo; P < 0.001, log rank test; see comment below).[44] The third RCT (129 people) compared itraconazole 200 mg daily versus placebo.[45] The duration of follow up was 6–104 weeks in the itraconazole group and 5–104 weeks in the placebo group. The RCT found that itraconazole significantly reduced the proportion of people with two or more episodes of oral candidiasis compared with placebo (6/63 [10%] with itraconazole *v* 15/66 [23%] with placebo; P = 0.04).[45] **Nystatin versus placebo:** One RCT found that prophylaxis with one or two nystatin 200 000 U pastilles once daily over 20 weeks significantly delayed the onset of oropharyngeal candidiasis compared with placebo (HR 0.59, 95% CI 0.40 to 0.82; P < 0.001).[38] **Fluconazole versus clotrimazole:** One large RCT (428 people from 29 sites) that compared fluconazole 200 mg daily and clotrimazole 10 mg five times daily over 35 months found that fluconazole significantly reduced the recurrence of oropharyngeal candidiasis (5.7 episodes/100 person years with fluconazole *v* 38.1 episodes/100 person years with clotrimazole; P ≤ 0.001).[42]

Harms: In one RCT comparing two different daily doses of fluconazole versus no treatment, one person stopped fluconazole because of an allergic rash.[40] One RCT found no significant difference in adverse events between fluconazole and placebo (10/12 [83%] with fluconazole *v* 9/13 [69%] with placebo; P = 0.6).[41] One RCT comparing itraconazole and placebo found that 95% (177/187) of people with

itraconazole and 95% (178/187) with placebo reported adverse events, the most frequent being gastrointestinal.[44] Most were classified as mild or moderate. Severe adverse events were reported by 38% of people with itraconazole and 36% of people with placebo. However, most adverse events were not considered to be related to study medication but, rather, related to HIV disease.[44] Study medication was withdrawn in 20% of people with itraconazole and 23% of people with placebo predominantly because of nausea and abdominal pain.[44] One RCT comparing itraconazole and placebo reported the most frequent adverse events were skin rashes (16/63 [25%] with itraconazole *v* 15/66 [23%] with placebo), mild anaemia (4/63 [6%] with itraconazole *v* 5/66 [8%] with placebo), and diarrhoea (3/63 [5%] with itraconazole *v* 5/66 [8%] with placebo).[45] One person discontinued treatment with itraconazole because of a skin rash, and concerns about hepatotoxicity resulted in treatment being discontinued in two people (1 with itraconazole and 1 with placebo). There was one case of Stevens–Johnson syndrome in a person also taking trimethoprim–sulfamethoxazole.[45] One RCT found no significant difference in rate of microbial resistance between fluconazole and placebo over 37 months (8/67 [12%] with fluconazole *v* 4/71 [6%] with placebo group, P = 0.20).[46] In the other RCTs, the most commonly reported adverse events were gastrointestinal symptoms, rash, and headache, but data on adverse effects were not presented in all the RCTs. Concomitant medication and severe underlying disease may have confounded attribution of adverse events.

Comment: Many of the RCTs were small and not blinded, and most did not adjust for confounding factors such as antiretroviral treatment and other established risk factors for oropharyngeal candidiasis. No RCTs used quality of life scores. The optimal dosage schedule and frequency of administration of preventive treatment have not been established. We found no RCTs comparing weekly and daily regimens of antifungal drugs. We found one RCT that compared two different doses of fluconazole.[40] It found no significant difference between 50 and 100 mg daily doses of fluconazole (oropharyngeal candidiasis: 2/18 [11%] with 50 mg *v* 4/19 [21%] with 100 mg; RR 0.53, 95% CI 0.09 to 2.09).[40] Subgroup analysis in the RCT comparing fluconazole to placebo, found that people with a history of oropharyngeal candidiasis had an absolute benefit of treatment with weekly fluconazole that was higher than in those with no history of infection (ARR 25.6/100 person years for those with previous infection *v* ARR 11.2/100 person years for those with no history of infection).[37] In the RCT comparing itraconazole versus placebo, too few deep fungal infections occurred to assess accurately the impact of itraconazole prophylaxis, and on the basis of statistical advice, the study was terminated.[44] Discontinuation rates were high and 145/187 (78%) of people with itraconazole versus 154/187 (82%) with placebo did not complete 2 years of medication.[44] Reasons for discontinuation were: withdrew consent (33 people with itraconazole *v* 46 with placebo); adverse event (31 with itraconazole *v* 29 with placebo); lost to follow up (17 with itraconazole *v* 11 with placebo); use of disallowed medication (15 with itraconazole *v* 3 with placebo); reached a study end point (5 with itraconazole *v* 11 with placebo); death (5 with itraconazole *v* 8 with placebo); elevated

liver function test (2 with itraconazole *v* 3 with placebo); pregnancy (0 with itraconazole *v* 1 with placebo); and other (37 with itraconazole *v* 42 with placebo).[44] The extended time interval to relapse with itraconazole may reflect the introduction of highly active antiretroviral treatment.[44]

OPTION TOPICAL ANTIFUNGAL TREATMENT

RCTs have found that topical preparations of itraconazole, fluconazole, and clotrimazole effectively treat oropharyngeal candidiasis in people with HIV infection. One RCT found that fluconazole significantly reduced symptoms and signs of oropharyngeal candidiasis compared with topical nystatin.

Benefits: We found one systematic review (search date 2000).[35] The review was narrative in character and no data were pooled. We found five RCTs comparing topical (suspensions or pastilles) versus orally absorbed antifungals for treatment of oropharyngeal candidiasis in people with HIV infection, which included four RCTs identified by the review and one subsequent RCT.[47–51] Four RCTs found that itraconazole oral solution 100 or 200 mg used in a swish and swallow mode was as effective as topical fluconazole 100 mg once daily for 14 days or topical clotrimazole 10 mg five times daily.[47–49,51] Three of these RCTs achieved clinical response rates of over 90%.[47–49] The fifth RCT comparing fluconazole 100 mg daily and nystatin liquid for 14 days found that fluconazole significantly increased complete resolution of signs and symptoms of oropharyngeal candidiasis (60/69 [87%] with fluconazole *v* 36/69 [52%] with nystatin liquid; ARI 35%, 95% CI 22% to 42%; RR 1.67, 95% CI 1.42 to 1.80; NNT 3, 95% CI 2 to 5).[50]

Harms: The most frequently reported adverse effects were gastrointestinal symptoms (nausea, diarrhoea, and vomiting). Altered taste, dry mouth, headache, and rashes were also recorded.[47–50] In the other RCT, there were no withdrawals because of adverse effects.[51] On the basis of data from five RCTs (861 people), in which adverse events were considered to be drug induced and resulted in withdrawal from the study, adverse events were reported with fluconazole (4 people), itraconazole (14 people), clotrimazole (12 people), and nystatin (1 person).[42,47–50]

Comment: Once daily dosing is likely to increase adherence to treatment. Non-adherence was reported with clotrimazole because of the inconvenience of taking multiple doses.

QUESTION Which treatments reduce the risk of acquiring resistance to antifungal drugs?

OPTION CONTINUOUS ANTIFUNGAL PROPHYLAXIS VERSUS INTERMITTENT ANTIFUNGAL TREATMENT

One RCT in people with HIV infection and acute episodes of oropharyngeal candidiasis found no significant difference between continuous antifungal prophylaxis with fluconazole and intermittent antifungal treatment with fluconazole in terms of the emergence of antifungal resistance.

Benefits: We found no systematic review. We found one RCT comparing the effects of continuous prophylaxis with fluconazole versus intermittent treatment with fluconazole 200 mg daily on the development of acquired resistance in people with HIV infection and evidence of active oropharyngeal candidiasis over a mean follow up of 11 months.[52] Antifungal sensitivity testing followed the National Committee for Clinical Laboratory Standards guidelines.[53] The RCT found that continuous prophylaxis with fluconazole reduced median annual relapse rates compared with intermittent treatment (0 episodes/year with continuous prophylaxis *v* 4.1 episodes/year with intermittent treatment; $P \leq 0.001$). It also found that antifungal resistance developed in more people on continuous prophylaxis than on intermittent treatment, but the difference was not significant (9/16 [56%] with continuous *v* 13/28 [46%] with intermittent; $P = 0.75$).[52]

Harms: No adverse reactions were reported.

Comment: Optimal treatment regimens to reduce the risk of acquiring resistance have not been evaluated adequately. In a prospective observational study of protease inhibitor treatment, 93 people with HIV and with a history of recurrent oropharyngeal candidiasis were followed up for 1 year. Oropharyngeal candidiasis was diagnosed in 2/30 (7%) people given protease inhibitors and 23/63 (37%) given other treatment ($P \leq 0.001$; CI not provided).[54] Immunomodulating antiretroviral treatments (e.g. highly active antiretroviral treatment), by reducing the number of recurrences of oropharyngeal candidiasis, are acting indirectly as antifungal sparing agents, thereby reducing exposure to antifungals and the potential risk of resistance.

Key Messages

- **Single-use mouthwash (short term benefit only)** Three small RCTs in people with confirmed halitosis found limited evidence that single-use mouthwash reduced odour unpleasantness and odour intensity between 1–8 hours after use compared with distilled water, saline rinse, or no treatment. One of these RCTs found no significant difference between single-use mouthwash and distilled water in odour unpleasantness or odour intensity after 24 hours.
- **Regular-use mouthwash** We found no RCTs on the effects of the regular use of mouthwash.
- **Artificial saliva; sugar free chewing gums; tongue cleaning, brushing, or scraping; zinc toothpastes** We found no RCTs on the effects of these interventions.

DEFINITION Halitosis is an unpleasant odour emitted from the mouth. It can be because of oral conditions including poor oral hygiene and periodontal disease or extraoral conditions such as chronic sinusitis and bronchiectasis.[1,2] In this topic, we deal only with physiological halitosis, that is, confirmed persistent bad breath in the absence of systemic, periodontal, or gum disease. We have excluded halitosis due to underlying disease, which would require disease specific treatment, pseudo-halitosis (in people who believe they have bad breath but whose breath is not considered malodourous by others), and artificially induced halitosis (e.g. in studies requiring people to stop brushing their teeth). This topic is only applicable, therefore, to people in whom underlying causes have been ruled out, and in whom pseudo-halitosis has been excluded. There is no consensus regarding duration of bad breath for diagnosis of halitosis, although the standard organoleptic test (see glossary, p 1801) for bad breath involves smelling the breath on at least two or three different days.[1]

INCIDENCE/ PREVALENCE We found no reliable estimate of prevalence, although several studies report population prevalence of halitosis (physiological or because of underlying disease) to be about 50%.[1,3–5] One cross-sectional study of 491 people found that about 5% of people with halitosis have pseudo-halitosis and about 40% of people with halitosis have physiological bad breath not due to underlying disease.[6] We found no reliable data about age or sex distribution of physiological halitosis.

AETIOLOGY/ RISK FACTORS We found no reliable data about risk factors for physiological bad breath. Mass spectrometric and gas chromatographic analysis of expelled air from the mouth of people with any type of halitosis have shown that the main malodourants are volatile sulphur compounds including hydrogen sulphide, methyl mercaptan, and dimethyl suphide.[7,8]

PROGNOSIS We found no evidence on the prognosis of halitosis.

AIMS OF INTERVENTION To improve social functioning; to reduce embarrassment; to reduce odour with minimum adverse effects.

OUTCOMES Organoleptic test scores, other odour scales, quality of life scores, embarrassment scores, and social functioning scores. We excluded non-clinical outcomes such as gas chromatography and spectroscopy results and concentrations of compounds in exhaled air.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments in people with physiological halitosis?

OPTION TONGUE CLEANING, BRUSHING, OR SCRAPING

We found no RCTs on the effects of tongue cleaning, brushing, or scraping.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION MOUTHWASHES (CONTAINING ZINC, CHLORHEXIDINE, HYDROGEN PEROXIDE, OR OTHER ANTIMICROBIAL AGENTS)

We found no RCTs on the effects of the regular use of mouthwash. Three small RCTs in people with confirmed halitosis found limited evidence that single-use mouthwash reduced odour unpleasantness and odour intensity between 1–8 hours after use compared with distilled water, saline rinse, or no treatment. One of these RCTs found no significant difference between single-use mouthwash and distilled water in odour unpleasantness or odour intensity after 24 hours.

Benefits: **Regular-use mouthwash:** We found no systematic review and no RCTs on the regular use of mouthwash. **Single-use mouthwash:** We found three small RCTs that compared single-use mouthwash versus control or no treatment.[2,9,10] The first two RCTs compared single-use 0.1% chlorine dioxide mouthwash versus distilled water in healthy adults with confirmed oral malodour.[2,9] In both RCTs, three examiners scored unpleasant breath odour on a scale from +3 (very pleasant/fresh) to –3 (very unpleasant/stale) and odour intensity from 0 (no odour) to 4 (very strong odour). The first RCT (31 people) found that chlorine dioxide containing mouthwash significantly reduced odour unpleasantness score and odour intensity score at 2, 4, and 8 hours after treatment compared with distilled water (odour unpleasantness: –1.25 at baseline to –0.63 at 8 hours with chlorine dioxide mouthwash *v* –1.40 at baseline to –1.29 at 8 hours with distilled water, $P < 0.01$; odour intensity: 1.27 at baseline to 0.63 at 8 hours with chlorine dioxide mouthwash *v* 1.42 at baseline to 1.29 at 8 hours with distilled water, $P < 0.01$).[2] It found no significant difference in odour unpleasantness or intensity between groups at 24, 48, 72, and 96 hours. The second RCT (12 people, crossover design, 96 hour washout period) found that chlorine dioxide containing mouthwash significantly reduced odour unpleasantness score at 0.5, 1, 2, and 4 hours after treatment and odour intensity score at 2 and 4 hours after treatment compared with distilled water (odour unpleasantness: –1.25 at baseline to –0.61 at 4 hours with chlorine dioxide mouthwash *v* –1.06 at baseline to –1.08 at 4 hours with distilled water, $P < 0.01$; odour intensity: 1.14 at baseline to 0.81 at 4 hours with chlorine dioxide mouthwash *v* 1.11 at baseline to 1.19 at 4 hours with distilled water, $P = 0.03$).[9] The third RCT (62 people with confirmed halitosis) compared three treatments: test mouthwash (see comment below), saline rinse, and no treatment.[10] Three trained examiners rated breath odour from 0 (low odour) to 3 (high odour). It found that the test mouthwash significantly reduced odour compared with saline rinse and no treatment at 1, 2, and 3 hours (baseline to 3 hours: 1.63 to 1.03 with test mouthwash *v* 1.51 to 1.72 with saline rinse *v* 1.63 to 1.88 with no treatment, $P < 0.05$ for test mouthwash *v* saline rinse or no treatment).

Harms: The RCTs did not report harms.[2,9,10]

Comment: The third RCT did not report details of the composition of the mouthwash used.[10] Both RCTs of chlorine dioxide containing mouthwash were conducted by the same research group.[2,9]

OPTION SUGAR FREE CHEWING GUMS

We found no RCTs on the effects of sugar free chewing gum.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ZINC TOOTHPASTES

We found no RCTs on the effects of zinc toothpaste.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ARTIFICIAL SALIVA

We found no RCTs on the effects of artificial saliva.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

GLOSSARY

Organoleptic test scores These are assigned by one or more examiners who sniff the person's exhaled breath on two or three different days. People having this examination should not have had antibiotics in the previous 3 weeks and should have refrained from eating garlic or onions and spicy foods for 48 hours and refrained from usual oral hygiene and smoking for the previous 12 hours.[1] Scoring systems vary among studies.

QUESTIONS

INTERVENTIONS

Likely to be ineffective or harmful

To be covered in future updates

Extraction of symptomatic impacted wisdom teeth

Key Messages

- **Extraction of asymptomatic impacted wisdom teeth** We found limited evidence suggesting that the harms of removing asymptomatic impacted wisdom teeth outweigh the benefits.

DEFINITION Wisdom teeth are third molars that develop in almost all adults and generally erupt between the ages of 18 and 24 years, although there is a wide variation in the age of eruption. In some people, the teeth become partially or completely impacted below the gum line because of lack of space, obstruction, or abnormal position. Impacted wisdom teeth may be diagnosed because of pain and swelling or incidentally by routine dental radiography.

INCIDENCE/ PREVALENCE Third molar impaction is common. Over 72% of Swedish people aged 20–30 years have at least one impacted lower third molar.[1] The surgical removal of impacted third molars (symptomatic and asymptomatic) is the most common procedure performed by oral and maxillofacial surgeons. It is performed on about 4/1000 people per year in England and Wales, making it one of the top 10 inpatient and day case procedures.[2–4] Up to 90% of people on oral and maxillofacial surgery hospital waiting lists are awaiting removal of wisdom teeth.[3]

AETIOLOGY/ RISK FACTORS Impacted wisdom teeth might be caused by changes in diet. A softer diet in childhood might increase the likelihood of retaining wisdom teeth in adult life.[5]

PROGNOSIS Impacted wisdom teeth can cause pain, swelling, and infection, as well as destroying adjacent teeth and bone. The removal of diseased and symptomatic wisdom teeth alleviates pain and suffering and improves oral health and function. We found no good evidence on what happens without treatment in people with asymptomatic impacted wisdom teeth.

AIMS OF INTERVENTION To prevent harms and maximise benefits of wisdom teeth removal.

OUTCOMES Pain; rates of infection; oral health and function; serious complications of intervention, including permanent or prolonged paraesthesia or anaesthesia of the lingual or inferior alveolar nerves, fracture of the mandible or the maxillary tuberosity, and oro-antral communication.

METHODS *Clinical Evidence* search and appraisal October 2003.

QUESTION Should asymptomatic and disease-free impacted wisdom teeth be removed prophylactically?

OPTION EXTRACTION OF ASYMPTOMATIC IMPACTED WISDOM TEETH

One systematic review of two RCTs found no evidence that prophylactic extraction improves outcomes compared with no extraction. Removal of lower wisdom teeth causes permanent numbness of the lower lip or tongue in about 1/200 people.

Benefits: We found one systematic review evaluating people with unerupted or impacted third molars (search date 1999, 2 RCTs).[6] It addressed both clinical preventative and cost effectiveness issues. The first RCT in the review (164 people) investigated the effects of early third molar extraction on late crowding of the lower incisors and randomised people to extraction or to no extraction of third molars.[7] It

found no clinically significant difference between the groups. However, the RCT had a low follow up rate (77 people [47%] at an average of 66 months). The second RCT in the review is still in progress, but preliminary results also suggest that no extraction could be the better option in terms of benefits such as functional health status and harms. However, more participants and longer follow up times are needed to establish this preliminary conclusion (see comment below).

Harms: Pain and swelling are almost universal after removal of impacted wisdom teeth.[8,9] The removal of the lower wisdom teeth carries the risk of damage to the inferior alveolar nerve (injured in 1–8% of people[10,11] with permanent damage in up to 1% of people[12]) and to the lingual nerve (permanently injured in up to 1% of people).[13] The risks seem to be greater with greater depth of impaction. The risks are the same whether the wisdom tooth is symptomatic or asymptomatic. Observational studies found limited evidence that complications associated with the removal of wisdom teeth are more frequent when operators are less experienced, and in older people with deeply impacted teeth.[14–19]

Comment: Implementing RCTs to answer this question is difficult. Thousands of participants, and decades of follow up, would be required to provide enough power, because disease events are rare in previously normal wisdom teeth. Evidence is, therefore, largely of inferior quality. We found one treatment guideline based on available non-RCT evidence (search date 2000; 8 clinical studies of different designs; number of participants not reported), which evaluated management of unerupted and impacted wisdom teeth.[20] It suggested that extraction is not advisable in people with deeply impacted wisdom teeth who have no history of pertinent local or systemic pathology. However, the guidelines suggested that removal of disease-free wisdom teeth in people without symptoms may be beneficial in the presence of caries in the adjacent second molar, which cannot be properly treated without the removal of the wisdom teeth. Extraction may also be beneficial in the presence of periodontal pockets distally to the second molar; and in case of resorption of the distal root of the second molar if it seems to be caused by the wisdom tooth.

Postoperative pulmonary infections

Search date July 2003

Andrew Smith

QUESTIONS

INTERVENTIONS

See glossary, p 1812

Key Messages

- **Epidural anaesthesia** Two systematic reviews have found that epidural anaesthesia with or without postoperative epidural or spinal analgesia reduces postoperative pulmonary infections compared with general anaesthesia with or without postoperative systemic analgesia. Neither review sought data on adverse effects. Subsequent and additional RCTs found inconsistent results.
- **Postoperative chest physiotherapy (deep breathing exercises)** One systematic review and one subsequent RCT have found that deep breathing exercises reduce postoperative pulmonary infections compared with control.
- **Postoperative chest physiotherapy (incentive spirometry and intermittent positive pressure breathing)** Two RCTs found that incentive spirometry reduced pulmonary complications compared with control. One RCT found that intermittent positive pressure breathing reduced postoperative pulmonary complications compared with control.
- **Advice to stop smoking preoperatively** We found no RCTs about the effects of preoperative advice to stop cigarette smoking on postoperative pulmonary infections. Two observational studies found that people who smoked were more likely to develop postoperative pulmonary complications of all kinds than those who did not. One study suggested that people who had stopped smoking for at least 2 months in the 6 months prior to surgery reverted to the risk of those who had never smoked.

DEFINITION A working diagnosis of postoperative pulmonary infection may be based on three or more new findings from: cough, phlegm, shortness of breath, chest pain, temperature above 38 °C, and pulse rate above 100 a minute.[1] In this chapter, the diagnosis of pneumonia implies consolidation observed on a chest x ray.[2]

INCIDENCE/ PREVALENCE Reported morbidity for chest complications depends on how carefully they are investigated. One study found blood gas and chest radiograph abnormalities in about 50% of people after open cholecystectomy.[3] However, less than 20% of these had abnormal clinical signs and only 10% had a clinically significant chest infection. Another study estimated the incidence of pneumonia as 20%.[4] Another used a similarly strict definition and found the incidence was 23%.[5]

AETIOLOGY/ RISK FACTORS Risk factors include increasing age (> 50 years), cigarette smoking, obesity, thoracic or upper abdominal operations, and pre-existing lung disease.[6] One multivariate analysis did not confirm the association with cigarette smoking, but suggested that longer preoperative hospital stay and higher grading on the American Society of Anesthesiologists' physical status scale (> 2) increased the risk of postoperative pulmonary complications.[5] Depression of the immune system may also contribute.[7]

PROGNOSIS In one large systematic review (search date 1997, 141 RCTs, 9559 people), 10% of people with postoperative pneumonia died.[8] If systemic sepsis ensues, mortality is likely to be substantial.[9] Pneumonia delays recovery from surgery and poor tissue oxygenation may contribute to delayed wound healing.

AIMS OF INTERVENTION To prevent the development of postoperative pulmonary infection; to minimise postoperative pain; to reduce mortality; to minimise adverse effects of treatment.

OUTCOMES Rates of clinically diagnosed postoperative pulmonary infection (as in the definition above); pain, measured using a variety of pain scales. Postoperative pulmonary complications are a commonly used outcome, but this combines pulmonary infections with other adverse outcomes. Where possible, we have reported on postoperative pulmonary infections in favour of pulmonary complications.

METHODS *Clinical Evidence* search and appraisal July 2003 including a search for observational studies on preoperative advice to stop smoking.

QUESTION What are the effects of preventive interventions?

OPTION ADVICE TO STOP SMOKING PREOPERATIVELY

We found no RCTs about the effects of preoperative advice to stop cigarette smoking on postoperative pulmonary infections. Two observational studies found that people who smoked were more likely to develop pulmonary complications of all kinds than those who did not. One study suggested that people who had stopped smoking for at least 2 months in the 6 months prior to surgery reverted to the risk of those who had never smoked.

Postoperative pulmonary infections

Benefits: We found one systematic review (search date 2001), which identified no RCTs.[10] We found no subsequent RCTs.

Harms: We found no RCTs.

Comment: One prospective observational study (200 people having coronary artery bypass surgery) found that smokers were more likely than non-smokers to develop postoperative pulmonary complications of all types.[11] People who had stopped smoking 6 months preoperatively reverted to the risk of those who had never smoked. A benefit was seen only in people who had stopped smoking for 2 months or more. A later prospective cohort study (410 people having a variety of elective procedures) found that current smokers were more likely to have postoperative pneumonia than those who had never smoked, but the differences were not tested statistically.[12] For all postoperative pulmonary complications, the odds ratio for developing complications for current smokers compared with those who had never smoked was 5.5 (95% CI 1.2 to 14.8). One multivariate analysis of postoperative pulmonary infections did not confirm the association with cigarette smoking.[5]

OPTION DIFFERENT ANAESTHETIC/ANALGESIC TECHNIQUES

Two systematic reviews have found that epidural anaesthesia with or without postoperative epidural analgesia reduces postoperative pulmonary infections compared with general anaesthesia with or without postoperative systemic analgesia. Neither review sought data on adverse effects. Subsequent and additional RCTs found inconsistent results.

Benefits: We found two systematic reviews (search dates 1997[8] and 1996[13]), one additional RCT,[14] and four subsequent RCTs.[15–18] Both reviews found that regional anaesthesia/analgesia reduced the incidence of pulmonary infections compared with systemic anaesthesia/analgesia.[8,13] The first review compared intraoperative neuraxial blockade (see glossary, p 1812) versus no neuraxial blockade (primarily general anaesthesia plus systemic analgesia).[8] The second systematic review compared three different postoperative epidural regimes with non-epidural anaesthesia/analgesia.[13]
Intraoperative regional versus general anaesthesia: The first review found that neuraxial blockade significantly reduced postoperative pneumonia compared with general anaesthesia (28 RCTs; 149/4871 [3%] with neuraxial blockade *v* 238/4688 [5%] with general anaesthesia; ARR 2%; RR 0.60, 95% CI 0.49 to 0.74; NNT 50, 95% CI 36 to 82).[8] The review found some evidence that the risk of developing pneumonia may be lower after thoracic epidural anaesthesia than after lumbar epidural or spinal anaesthesia. **Postoperative epidural local anaesthetic versus systemic opioid analgesia:** The second review identified five RCTs (215 people; 3 RCTs in people having cholecystectomy, 1 in people having upper abdominal or hip surgery, and 1 in people having upper abdominal surgery).[13] It found that postoperative epidural local anaesthesia significantly reduced the incidence of pulmonary infections compared with systemic opioids (RR 0.36, 95% CI 0.21 to 0.65; absolute figures not reported). Sensitivity analysis found that exclusion of low quality trials did not alter these results.

Postoperative epidural opioid analgesia versus systemic opioid analgesia: The second review (5 RCTs, 547 people; 2 RCTs of thoracotomies, 2 of abdominal operations, 1 of upper abdominal surgery) found no significant difference in pulmonary infections between postoperative epidural and systemic opioids (RR 0.53, 95% CI 0.18 to 1.53; absolute figures not reported; see comment below).[13] **Postoperative epidural local anaesthetic plus epidural opioid analgesia versus systemic opioid analgesia:** The second review[13] identified two RCTs[19,20] and we found one additional[14] and one subsequent RCT[15] comparing postoperative epidural local anaesthetic plus opioids versus postoperative systemic opioids. The first RCT identified by the review (153 people receiving general anaesthesia while having abdominal surgery for cancer) compared postoperative epidural bupivacaine plus morphine with postoperative intravenous fentanyl plus subcutaneous morphine.[19] It found no significant difference in the rate of postoperative pulmonary infections between epidural local anaesthesia plus analgesia and systemic analgesia (21/78 [31%] with epidural anaesthesia/analgesia *v* 23/75 [27%] with systemic analgesia; RR 0.88, 95% CI 0.53 to 1.45; analysis not intention to treat; see comment below). The second RCT identified by the review (53 people having pulmonary resection) compared five different postoperative treatment strategies: epidural morphine plus epidural bupivacaine, epidural morphine alone, epidural bupivacaine alone, epidural saline, and systemic morphine.[20] It found no significant difference in rates of pneumonia between groups (2/11 [18%] with epidural morphine plus epidural bupivacaine *v* 3/12 [25%] with epidural morphine alone *v* 1/10 [10%] with epidural bupivacaine alone *v* 2/10 [20%] with epidural saline *v* 1/10 [10%] with systemic morphine; overall $P = 0.86$; see comment below). The additional RCT (46 elderly non-smokers having major pancreatic and biliary surgery) found that postoperative epidural local anaesthetic plus opioid significantly reduced the incidence of pneumonia compared with systemic opioid (2/22 [9%] with epidural local anaesthetic plus opioid *v* 8/24 [33%] with systemic opioid; $P = 0.049$).[14] The subsequent RCT (50 people having thoracotomy) found no significant difference in postoperative pulmonary complications between epidural local anaesthetic plus opioids and intravenous patient controlled opioid (1/25 [4%] with epidural analgesia *v* 0/25 [0%] with patient controlled analgesia; see comment below).[15] Pneumonia was not separated out of pulmonary complications as a whole. **Other intraoperative/postoperative anaesthesia/analgesia combinations:** We found three subsequent RCTs.[16–18] The first RCT (24 people with chronic obstructive pulmonary disease having upper abdominal or thoracic surgery) compared intraoperative general anaesthesia followed by postoperative systemic morphine versus intraoperative general plus epidural anaesthesia followed by postoperative epidural bupivacaine plus morphine.[16] It found no significant difference in the incidence of postoperative pulmonary infection between groups (reported as non-significant; no further data available; see comment below). The second RCT (168 people having elective abdominal aortic surgery) compared intraoperative general anaesthesia followed by either postoperative epidural or intravenous analgesia versus intraoperative thoracic epidural

anaesthesia plus light general anaesthesia followed by either postoperative epidural or systemic analgesia (4 treatment groups).[17] It found no significant difference between groups in the incidence of postoperative pneumonia (see comment below). The third subsequent RCT (1021 people having abdominal operations) compared intraoperative epidural plus "light" general anaesthesia followed by epidural opioid analgesia versus general anaesthesia followed by postoperative parenteral opioid analgesia (see comment below).[18] All people received prophylactic antibiotics immediately before surgery and for 24 hours after surgery. It found no significant difference between regimens in pneumonia within 30 days after surgery (pneumonia: 40/507 [7.9%] with general anaesthesia plus postoperative parenteral opioid analgesia *v* 28/514 [5.4%] with intraoperative epidural plus "light" general anaesthesia plus epidural opioid analgesia; P = 0.15).

Harms: The RCTs were not designed to look for information about harms of epidural anaesthesia.[8,13,16–18] However, one RCT found "mild reddening" of the epidural site in 16/25 [64%] people after an average of 5.6 days.[15] We found one large prospective French cohort study (30 413 epidural anaesthetics) of the incidence of harms from epidural analgesia.[21] This study estimated the frequency of cardiac arrest (usually owing to inadvertent intravascular injection of local anaesthetic) as 1/10 000; seizures (usually the same cause) as 1.3/10 000; neurological injury as 2/10 000; radiculopathy as 1.6/10 000; and paraplegia as 0.3/10 000.[21] There were no deaths attributable to epidural analgesia. In a large US prospective uncontrolled cohort study (1297 people receiving epidurals), 0.4% of people were judged to need naloxone to reverse the adverse effects of epidural opioids on breathing.[22] One case series reported three cases in which epidural analgesia was thought to contribute to the development of postoperative pressure sores.[23] Inadvertent dural puncture with the epidural needle can cause headache (frequency increases with gauge of needle).[24] Effective pain relief can delay recognition of surgical complications, such as anastomotic breakdown, peritonitis, or compartment compression syndrome of the legs.

Comment: Most of the individual RCTs lacked power to detect a significant difference in postoperative pulmonary infections between treatments. Only when RCTs were combined by meta-analysis was benefit apparent. The two systematic reviews differ in their approach. The first review sought aggregated benefit for all types of intraoperative neuraxial blockade compared with no neuraxial blockade and had more power.[8] The second review compared different kinds of postoperative epidural anaesthesia/analgesia; the smaller numbers of RCTs and people in each subgroup probably explain the lack of a significant effect for some of the regimens.[13] Although both reviews examined the effect of epidural anaesthesia on pulmonary infection after all types of surgery, sensitivity analyses were performed only in the later review.[8] One sensitivity analysis suggested that the overall benefits of regional anaesthesia in reducing all types of postoperative complications held for all types of surgery studied. The overall benefit of regional anaesthesia seemed independent of whether it was combined with general anaesthesia.

OPTION POSTOPERATIVE CHEST PHYSIOTHERAPY

One systematic review has found that postoperative chest physiotherapy reduces postoperative pulmonary complications compared with control. The review found most evidence for deep breathing exercises, but RCTs also found evidence of benefit with incentive spirometry and intermittent positive pressure breathing. One large subsequent RCT has also found that deep breathing exercises reduce postoperative pneumonia compared with control.

Benefits: We found two systematic reviews (search date 1992, 7 RCTs, 764 people;[25] and search date 2000, 2 RCTs, 212 people[26]) and two subsequent RCTs comparing physiotherapy versus control or no treatment.[27,28] The RCTs compared three methods of physiotherapy (incentive spirometry, deep breathing exercises, and intermittent positive pressure breathing [see glossary, p 1812]) on postoperative pulmonary complications. Only people having any type of upper abdominal surgery were included. Not all of the included RCTs used pneumonia as an outcome. **Incentive spirometry:** Both reviews identified the same two RCTs comparing incentive spirometry versus control (details of control not stated in the reviews), but only the first review performed a meta-analysis.[25] It found that incentive spirometry significantly reduced the risk of postoperative pulmonary complications compared with control (212 people; OR 0.44, 95% CI 0.18 to 0.99; absolute numbers not reported). **Deep breathing/coughing exercises:** The first review[25] identified four RCTs (564 people) comparing deep breathing exercises versus control (details of control not reported in the review) and we found two subsequent RCTs comparing deep breathing exercises versus no treatment.[27,28] The review found that deep breathing exercises significantly reduced pulmonary complications compared with control but there was significant heterogeneity between trials (OR 0.43, 95% CI 0.27 to 0.63; absolute number not reported). One of the four RCTs (60 people) used an outcome measure that could not in itself diagnose pulmonary infection. The first subsequent RCT (368 people having major abdominal surgery) compared instruction to perform deep breathing exercises versus no physiotherapy instruction.[27] Additional resistance training was given to people in the treatment group at high risk (defined as aged > 50 years or with 1 of the following: smoker or ex-smoker for < 12 months, body mass index > 30, pulmonary disease needing daily medication, or other coexisting medical condition). The RCT found that, in all people having surgery, deep breathing exercises significantly reduced the risk of developing pneumonia compared with control (1/172 [0.6%] with deep breathing *v* 13/192 [6.8%] with control; RR 0.09, 95% CI 0.01 to 0.65; NNT 16, 95% CI 10 to 39). The relative risk of developing pneumonia in people at high risk was not given. The second subsequent RCT (120 people having coronary artery surgery) compared two physiotherapy groups with no treatment.[28] The RCT found low rates of chest infections in all groups (1/40 [2.5%] with no physiotherapy *v* 4/40 [10%] with instruction to perform deep breathing and coughing exercises *v* 1/40 [2.5%] with instruction to perform deep breathing and coughing exercises and more intensive attention from the physiotherapist). The RCT did not report formal statistical analysis because of

the small number of complications. **Intermittent positive pressure breathing:** The first systematic review[25] identified one RCT[1] (172 people) comparing four interventions: intermittent positive pressure breathing; incentive spirometry; deep breathing exercises; and no treatment. It found that intermittent positive pressure breathing significantly reduced pulmonary complications compared with no treatment (10/45 [22%] with intermittent positive pressure breathing *v* 21/44 [48%] with no treatment; RR 0.5, 95% CI 0.2 to 0.9; NNT 4, 95% CI 3 to 18).[1]

Harms: The reviews gave no information on adverse effects.[25,26]

Comment: Some RCTs in the first review distinguished between people at low and high risk of pulmonary complications.[25] Individual RCTs in low risk people often did not find the benefits of physiotherapy that were seen when all RCTs were pooled. The two subsequent RCTs were conducted in people at lower risk of pulmonary infection.[27,28] The first review assessed study validity by two independent assessors using the following criteria: reproducibility of patient population and surgical procedure; comparability of groups; clear description of experimental manoeuvre; presence of control group; clear description of outcome measures; random allocation with blinding; withdrawals listed; prior estimate of study power; and some measure of test of compliance with treatment.[25]

GLOSSARY

The following three modalities of physiotherapy all count as methods to increase lung volume. Increasing lung volume is thought to cause a reduction in airways resistance and an improvement in ventilation:[29]

Deep breathing The person is instructed to breathe in deeply, comfortably, and slowly through the nose, and then sigh out through the mouth. Optimum conditions to ensure that deep breaths reach poorly ventilated dependent regions include accurate positioning, ensuring the person is comfortable and relaxed, avoiding distractions, and allowing the person to get their breath back after turning to avoid breathlessness.

Incentive spirometry The flow and volume achieved by a controlled and sustained deep breath can be encouraged by an incentive spirometer, which gives the person visual feedback on their performance. The same effect can theoretically be obtained without the device, but the incentive of using a tangible object may increase inhaled volume and produce more controlled flow.

Intermittent positive pressure breathing Assisted breathing with a pressure cycled ventilator triggered into inspiration by the user and allowing passive expiration. The user begins to inhale through the machine, which senses the breath and augments it by delivering gas to the user. When a preset pressure is reached, the machine stops delivering gas and allows the user to breathe out. In most devices, the inspiratory sensitivity, flow rate, and pressure can be varied to suit the user's needs, but some devices adjust the sensitivity and flow automatically.

Neuraxial blockade Involves spinal or epidural anaesthesia.

Substantive changes

Anaesthetic/analgesia One RCT added;[18] conclusions unchanged.

Acute organophosphorus poisoning

Search date March 2003

Michael Eddleston, Surjit Singh, and Nick Buckley

QUESTIONS

INTERVENTIONS

*Based on consensus, RCTs would be considered unethical

See glossary, p 1823

Key Messages

- **Atropine** Consensus supports atropine treatment. Many case series have found that it reverses the early muscarinic effects of acute organophosphorus poisoning. We found no RCTs comparing atropine versus placebo, but such an RCT would now be considered unethical.
- **Benzodiazepines to control organophosphorus induced seizures** Consensus supports benzodiazepines for organophosphorus induced seizures. We found no RCTs comparing a benzodiazepine versus placebo or another anticonvulsant. It would now be unethical to conduct an RCT comparing benzodiazepines versus placebo.
- **Glycopyrronium bromide (glycopyrrolate)** One small RCT found no significant difference in death or ventilation rates between glycopyrronium bromide and atropine, but it may have lacked power to detect clinically important differences. Glycopyrronium bromide (glycopyrrolate) has been used instead of atropine because it is thought to have fewer adverse effects on the central nervous system.
- **Washing the poisoned person and removing contaminated clothes** Washing the poisoned person with warm water and soap and removing contaminated clothes after dermal and mucocutaneous exposure appears important and widely recommended, but this intervention has not been assessed in RCTs.

- **Gastric lavage** We found no RCTs assessing the role of gastric lavage in acute organophosphorus poisoning. If the procedure cannot be performed in sedated and intubated patients, the risk of harm due to aspiration is likely to surpass its potential benefits.
- **Milk or other home remedy immediately after ingestion** We found no RCTs on the effect of giving a "home remedy" soon after the ingestion.
- **Oximes** One systematic review found insufficient evidence about the effects of oximes in acute organophosphorus poisoning.
- **Ipecacuanha (ipecac)** We found no RCTs on the effects of ipecacuanha in acute organophosphorus poisoning. The significant risk of harm, although not quantified, probably outweighs any potential benefits.
- **Activated charcoal (single or multiple dose); α_2 adrenergic receptor agonists (clonidine); N-methyl-D-aspartate receptor antagonists; organophosphorus hydrolases; sodium bicarbonate** We found insufficient evidence about the effects of these interventions.

DEFINITION

Acute organophosphorus poisoning occurs after dermal, respiratory, or oral exposure to either low volatility pesticides (e.g. chlorpyrifos, dimethoate) or high volatility nerve gases (e.g. sarin, tabun). Acetylcholinesterase (see glossary, p 1823) inhibition at synapses results in accumulation of acetylcholine and over-activation of acetylcholine receptors at the neuromuscular junction and in the autonomic and central nervous systems.[1] Early clinical features mainly involve the parasympathetic system: bradycardia, bronchorrhoea, miosis, salivation, lachrymation, defecation, urination, and hypotension. Features of neuromuscular junction (muscle weakness and fasciculations) and central nervous system (seizures, coma) involvement are also common at this stage. An intermediate syndrome has been described (cranial nerve palsies and proximal muscle weakness with preserved distal muscle power after resolution of early cholinergic symptoms), but its definition, pathophysiology, and incidence are still unclear. A late motor or motor/sensory peripheral neuropathy may also develop after recovery from acute poisoning with some organophosphorus compounds.[1]

INCIDENCE/ PREVALENCE

Most cases occur in the developing world following occupational or deliberate exposure to organophosphorus pesticides.[2] Although data are sparse, organophosphates appear to be the most important cause of death from deliberate self poisoning worldwide.[3] In Sri Lanka, at least 17 000 cases of organophosphorus or carbamate poisoning occurred in 1999, resulting in 1700 deaths. More than 80% were intentional.[4] Case fatality rates across the developing world are commonly greater than 20%.[3] In Central America, occupational poisoning is more common than intentional poisoning and deaths are fewer.[5] Extrapolating from limited data, the World Health Organization has estimated that each year more than 200 000 people worldwide die from pesticide poisoning,[6] but these figures are old and widely contested.[2] Most deaths occur in Asia and organophosphorus pesticides probably cause at least 50% of cases.[3] Deaths from organophosphorus nerve gases occurred in Iran during the Iran–Iraq war.[7] Military or terrorist action with these chemical weapons remains possible. Twelve people died in a terrorist attack in Tokyo and thousands probably died in Iran after military or terrorist exposure.

Acute organophosphorus poisoning

AETIOLOGY/ RISK FACTORS The widespread accessibility of pesticides in rural parts of the developing world makes them easy options for acts of self harm.[3] Occupational exposure is due to insufficient or inappropriate protective equipment in the use of toxic compounds.[2]

PROGNOSIS There are no validated scoring systems for categorising severity or predicting outcome, although many have been proposed. The highly variable natural history and difficulty in determining ingested dose make predicting outcome for an individual inaccurate and potentially hazardous, because people admitted in good condition can deteriorate rapidly and require intubation and mechanical ventilation. Prognosis in acute self poisoning is likely to depend on dose and toxicity of the ingested organophosphorus (e.g. neurotoxicity potential, half life, rate of ageing [see glossary, p 1824], whether activation to the toxic compound is required [pro-poison — see glossary, p 1824], and whether dimethylated or diethylated [see comment under oximes, p 1821]).[8,9] Prognosis in occupational exposure is better because the dose is normally smaller and the route is dermal.

AIMS OF INTERVENTION To prevent death; to reduce consciousness or respiratory arrest requiring intubation with or without ventilation, pneumonia, the intermediate syndrome (see definition above), and delayed polyneuropathy; and to reduce the period of ventilation and intensive care.

OUTCOMES Rates of death, intubation, pneumonia; the intermediate syndrome; delayed polyneuropathy; and period of time requiring ventilation or intensive care.

METHODS *Clinical Evidence* search and appraisal March 2003. The authors also searched Medline, Embase, and Cochrane databases; hand searched toxicological and Indian journals (search date November 2001); and contacted experts in the field to identify unpublished studies.

QUESTION **What are the effects of treatments for acute organophosphorus poisoning?**

OPTION **DRINKING MILK OR OTHER HOME REMEDY SOON AFTER ORAL ORGANOPHOSPHORUS EXPOSURE**

We found no RCTs on the effect of giving a "home remedy" soon after the ingestion.

Benefits: We found no systematic review, RCT, or cohort study for any form of home remedy.

Harms: We found no systematic review, RCT, or cohort study of complications.

Comment: The lay practice of giving a "home remedy" soon after the ingestion, before bringing the poisoned person to hospital, is common in many parts of the world. Problems may occur when large volumes of fluid are given "to dilute the poison". Gastric emptying of a fluid is proportional to volume. It is therefore believed that increasing the volume of fluid in the stomach increases the rate of emptying into

the small bowel where the pesticide is absorbed. Giving fluids therefore risks speeding the onset of poisoning and causing respiratory arrest before the patient arrives at a healthcare facility. In contrast, a small volume highly lipid home remedy (such as unboiled eggs) may slow gastric emptying and may delay the onset of poisoning and respiratory failure until the patient has reached a healthcare facility.

OPTION WASHING THE POISONED PERSON AND REMOVING CONTAMINATED CLOTHES

We found no RCTs of washing the poisoned person and removing contaminated clothes. However, this appears to be an obvious way to reduce further dermal and mucocutaneous exposure and is widely recommended. Care should be taken to protect healthcare workers through gloves, aprons, and eye protection, with careful disposal of contaminated equipment and clothes.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study of complications in poisoned people or healthcare workers removing contaminated clothing from poisoned people. However, severe poisoning requiring intubation and mechanical ventilation has been reported in healthcare workers treating poisoned people.[10] No significant complications from the procedure for the initially poisoned person are envisaged, unless washing the poisoned person distracts caregivers from other priorities, such as resuscitation and careful observation for deterioration.

Comment: Absorbing organophosphorus compounds through the skin varies greatly, according to the volatility of the organophosphorus, its solvent, and the temperature and hydration of the skin.[11] Absorption of pesticides seems to be low, with studies of malathion, chlorpyrifos, and diazinon suggesting that less than 5% is absorbed and excreted in the urine.[12–14]

OPTION IPECACUANHA (IPECAC)

We found no RCTs on the effects of ipecacuanha (ipecac) in acute organophosphorus poisoning. The significant risk of harm, although not quantified, probably outweighs any potential benefits.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study of complications of ipecacuanha in people with acute organophosphorus poisoning, and no large, high quality RCT comparing ipecacuanha versus placebo in any form of poisoning that might have allowed calculation of complication rates. Complications of ipecacuanha may include aspiration, diarrhoea, ileus, dysrhythmias during vomiting, dystonia from treatment of vomiting, and haematemesis from vomiting.[15] Use of ipecacuanha in acute organophosphorus poisoning may be particularly hazardous because most organophosphorus compounds are dissolved in aromatic hydrocarbons, which cause serious harm if aspirated.[15]

Comment: One non-systematic review identified no human studies of ipecacuanha in people with organophosphorus poisoning.[15] One non-systematic review of ipecacuanha in all forms of poisoning found no evidence that it improved outcomes in poisoned people.[15] Administration of ipecacuanha may delay administration of activated charcoal and specific treatment for organophosphorus poisoning, in addition to increasing the risk of aspiration.

OPTION GASTRIC LAVAGE

We found no systematic review, RCT, or cohort study on the effects of gastric lavage in acute organophosphorus poisoning. If the procedure cannot be performed in sedated and intubated patients, the risk of harm due to aspiration is likely to surpass its potential benefits.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study assessing complications of gastric lavage in people with acute organophosphorus poisoning, and no large, high quality RCTs comparing gastric lavage versus placebo in any form of poisoning that allowed calculation of complication rates. Complications of gastric lavage may include aspiration, hypoxia, laryngeal spasm, and oesophageal perforation.[16] Complications are common when gastric lavage is performed in physically restrained, non-consenting patients as a routine procedure without careful control of the airway.

Comment: One non-systematic review identified no human studies of gastric lavage in people with organophosphorus poisoning.[16] One non-systematic review of gastric lavage in people with all forms of poisoning found no evidence that it improved outcome in poisoned people.[16] Gastric lavage may delay administering activated charcoal and specific treatment for organophosphorus poisoning. Anecdotal reports suggest that organophosphorus pesticides may remain in the gut for lengthy periods.[17] If studies indicate that a substantial proportion of organophosphorus remains in the stomach on admission to hospital, it may be appropriate to conduct an RCT to assess gastric lavage after protection of the airway.

OPTION ACTIVATED CHARCOAL (SINGLE OR MULTIPLE DOSE)

We found no systematic review, RCT, or cohort study on the effects of activated charcoal, in either single or multiple dose regimens, in acute organophosphorus poisoning.

Benefits: We found no systematic review, RCT, or cohort study.

Harms: We found no systematic review, RCT, or cohort study of complications in people with acute organophosphorus poisoning receiving activated charcoal and no large, high quality RCT comparing activated charcoal versus placebo in any form of poisoning that allowed calculation of complication rates. Complications of activated charcoal may include aspiration pneumonia, vomiting, diarrhoea, constipation, ileus, and reduced absorption of oral medication.[18–20] A

large retrospective case series (878 people treated with multiple dose activated charcoal) suggests that rates of adverse events with multiple dose regimens (> 2 doses) are likely to be low (significant pulmonary aspiration in 6/878 [0.6%], 95% CI 0.1% to 1.1%).[21]

Comment: **Single dose regimens:** We found no human simulated overdose studies of single dose activated charcoal in organophosphorus poisoning.[18] Animal studies indicate that activated charcoal can bind to organophosphorus pesticides.[22] One non-systematic review of single dose activated charcoal in all forms of poisoning found no evidence that it improved outcomes in poisoned people.[18] **Multiple dose regimens:** We found no human studies of multiple dose activated charcoal in organophosphorus poisoning.[19] One non-systematic review of multiple dose activated charcoal in all forms of poisoning found no evidence that it improved outcomes in poisoned people.[19] Activated charcoal may reduce the efficacy of treatments given by mouth. A large RCT comparing single or multiple dose activated charcoal versus placebo in acute organophosphorus pesticide poisoning started in Sri Lanka in 2002, and the findings are expected to be reported in 2007.[23]

OPTION ATROPINE

Atropine is the mainstay of treatment, and many case series have found that it reverses the early muscarinic effects of acute organophosphorus poisoning. We found no RCTs comparing atropine versus placebo. It would now be considered unethical to perform such an RCT.

Benefits: We found no systematic review, RCT, or cohort study. Many case series have found that atropine reverses the early muscarinic effects of acute organophosphorus poisoning.[24]

Harms: We found no systematic review, RCT, or cohort study of complication rates in people with acute organophosphorus poisoning receiving atropine. Excessive treatment with atropine results in toxicity that is characterised by confusion and tachycardia.[24] In hypoxic people, supplemental oxygen may reduce toxicity caused by tachycardia with increased myocardial oxygen demand.

Comment: Atropine competes with excess acetylcholine at muscarinic acetylcholine receptors. We found no RCTs, but its effectiveness is now considered to be beyond question, so it would be unethical to perform an RCT comparing atropine versus placebo. The optimum dose of atropine has not been determined, but may vary among poisoned people because of variation in the dose taken and possibly because of co-administration of an oxime (oximes have been proposed to have anticholinergic action at high dose).[8] The first doses are given as boluses to reverse the muscarinic signs. Current recommendations are then to set up an atropine infusion.[8] Recent RCTs from India on the use of oximes have used an infusion of atropine sufficient to keep the pupils at mid-point, heart rate greater than 100 beats a minute, normal bowel sounds, clear lungs, and no bronchorrhoea.[25–28] The atropine dose regimen has not been compared with other regimens with different end points of atropinisation (see glossary, p 1824).

OPTION GLYCOPYRRONIUM BROMIDE (GLYCOPYRROLATE)

One small RCT found no significant difference in death or ventilation rates between glycopyrronium bromide and atropine, but it may have lacked power to detect clinically important differences. Glycopyrronium bromide (glycopyrrolate) has been used instead of atropine because it is thought to have fewer adverse effects on the central nervous system.

Benefits: We found no systematic review or RCT comparing glycopyrronium bromide versus placebo. It is unlikely that such a trial would be considered ethical unless glycopyrronium bromide and placebo were administered in addition to atropine. We found one small RCT (39 people) comparing glycopyrronium bromide versus atropine.[29] It found no significant difference between atropine and glycopyrronium bromide in death rates, need for ventilation, or respiratory infection (death rates: AR 1/22 [5%] with atropine *v* 2/17 [12%] with glycopyrronium; RR 0.39, 95% CI 0.04 to 3.91; need for ventilation: AR 8/22 [36%] with atropine *v* 6/17 [35%] with glycopyrronium; RR 1.03, 95% CI 0.44 to 2.41; respiratory infection: AR 12/22 [55%] with atropine *v* 5/17 [29%] with glycopyrronium; RR 1.86, 95% CI 0.81 to 4.25). The study may have lacked power to rule out clinically important differences in mortality rates, ventilation, or intermediate syndrome.

Harms: We found no systematic review, RCT, or cohort study of complication rates in people with acute organophosphorus poisoning receiving glycopyrronium bromide. Treatment with glycopyrronium bromide may result in peripheral anticholinergic effects such as tachycardia, dry mouth, and ileus.[30] When these symptoms arise, treatment is defined as excessive.

Comment: Glycopyrronium bromide has similar effects to atropine in humans, but is more selective for peripheral cholinergic synapses, resulting in less tachycardia and confusion than occur with atropine.[30] Animal studies have found that glycopyrronium bromide is less effective at controlling bradycardia and central nervous system complications of organophosphorus poisoning. It is not widely used. We found no large RCT comparing atropine versus glycopyrronium bromide. In some regions, glycopyrronium bromide is combined with atropine to limit the central stimulation produced by atropine.

OPTION OXIMES

One systematic review of two small RCTs found insufficient evidence on the effects of oximes in acute poisoning.

Benefits: We found one systematic review of oximes (search date 2002; 2 RCTs, 182 people; the inclusion criterion was any RCT of oximes in organophosphorus poisoned people).[9] Both RCTs focused on pralidoxime in pesticide poisoned people.[27,28] Neither of the two RCTs found any benefit of pralidoxime. The second RCT found that an infusion of 12 g pralidoxime over 3 days increased risks of death, intermediate syndrome, and requirement for ventilation compared with placebo (death: AR 16/55 [29%] with pralidoxime *v* 3/55 [5%]

with placebo; RR 5.3, 95% CI 1.7 to 17.3; intermediate syndrome: 36/55 [65%] with pralidoxime *v* 19/55 [35%] with placebo; RR 1.9, 95% CI 1.3 to 2.9; requirement for ventilation: 36/55 [67%] with pralidoxime *v* 22/55 [40%] with placebo; RR 1.7, 95% CI 1.1 to 2.4).

Harms: Neither RCT reported the incidence of complications in people with acute organophosphorus poisoning receiving oximes.[25–28] Complications of oximes include hypertension, cardiac dysrhythmias (including cardiac arrest with rapid administration), headache, blurred vision, dizziness, and epigastric discomfort.[31] Such adverse effects with pralidoxime have been reported only with either rapid administration or doses greater than 30 mg/kg bolus. It may be difficult to distinguish these adverse effects from the effects of organophosphorus. In one observational clinical study of a different oxime (obidoxime), a high dose regimen (8 mg/kg bolus, then 2 mg/kg/hour infusion) produced hepatitis in 3/12 people.[7] Two of six deaths were because of liver failure. The use of pralidoxime in eight people in the same study (dose 30 mg/kg bolus, and then 8 mg/kg/hour infusion) did not produce hepatitis. A more recently developed oxime (HI-6) has also been used in humans with no reported adverse effects.[32] We found no human studies that assessed the harms of giving oximes for carbamate poisoning (which presents with a similar cholinergic crisis but has a better prognosis).[1]

Comment: Oximes (such as pralidoxime, obidoxime, and HI-6) reactivate acetylcholinesterases (see glossary, p 1823) inhibited by organophosphorus poisoning.[8,9] Reactivation is limited by ageing (see glossary, p 1823) of the acetylcholinesterases and high concentrations of pesticides. Ageing of the acetylcholinesterases takes longer with diethyl organophosphorus compounds than with dimethyl organophosphorus compounds (120 hours *v* 12 hours). Oximes may therefore be effective for people presenting after about 12 hours if they have been exposed to a diethyl organophosphorus. Treatment may be beneficial if continued for as long as the person is symptomatic because it may take several days for the pesticide concentration to drop below the point at which the rate of reactivation surpasses reinhibition.[8,9] Both RCTs used doses of pralidoxime that are different from the regimen currently recommended by the World Health Organization (at least 30 mg/kg bolus, then 8 mg/kg/hour iv infusion).[27,28] The reporting of the methods was poor, and baseline differences in the second RCT suggested that more severely poisoned people might have been randomised to the intervention arm.[9] Post hoc analysis of the first RCT suggested that people receiving pralidoxime 1 g in the first 12 hours may be less likely to develop the intermediate syndrome than those receiving less than 1 g in the first 12 hours (29% *v* 51%; RR 0.58, 95% CI 0.27 to 1.26).[25] Studies in poisoned people indicate that oximes can reactivate acetylcholinesterase but have not been able to prove clinical benefit.[33] In vitro studies have also revealed mechanisms whereby oximes may be detrimental.[34] A large RCT will start in Sri Lanka in 2003–2004 and the findings are expected to be reported in 2007.[35]

Acute organophosphorus poisoning

OPTION ORGANOPHOSPHORUS HYDROLASES

We found no RCTs on the effects of organophosphorus hydrolases.

Benefits: We found no systematic reviews and no RCTs.

Harms: We found no systematic review, RCT, or cohort study.

Comment: Oxime efficacy is normally limited by the presence of high pesticide concentrations, which reinhibit acetylcholinesterases (see glossary, p 1823) that have been reactivated by the oximes.[9] A method of rapidly reducing pesticide concentrations could potentially allow oximes to be more effective. Animal studies have found that organophosphorus hydrolases (such as mammalian paraoxanase or the bacterial hydrolase isolated from *Pseudomonas* species) cleave organophosphorus compounds, lowering blood and tissue concentrations of organophosphorus.[36,37] These may prove beneficial for managing people with both pesticide and nerve gas organophosphorus poisoning.

OPTION SODIUM BICARBONATE

We found no RCTs on the effects of sodium bicarbonate in acute organophosphorus poisoning.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study of complications in people with acute organophosphorus poisoning receiving sodium bicarbonate. Dose dependent complications of sodium bicarbonate may include sodium and fluid overload and decreased oxygen delivery.[38]

Comment: Animal studies suggest that increasing the pH with sodium bicarbonate reduces mortality rates.[39,40] This effect is independent of correction of acidosis because it is seen in animals that are not acidotic. Studies conducted in Brazil[40] and Iran[7] have claimed good results in uncontrolled studies. The mechanism of action of sodium bicarbonate in organophosphorus poisoning is unknown. However, it is unclear whether the limited increase in pH that is possible in vivo is sufficient to make a significant difference in organophosphorus hydrolysis rates.

OPTION BENZODIAZEPINES

Diazepam is standard treatment for organophosphorus induced seizures. We found no RCTs comparing diazepam or other benzodiazepines versus placebo or another anticonvulsant. It would now be considered unethical to perform an RCT comparing benzodiazepines versus placebo in people with seizures.

Benefits: Many case series have reported that diazepam controls seizures in acute organophosphorus poisoning.[41]

Harms: We found no systematic review, RCT, or cohort study of complication rates in people with acute organophosphorus poisoning receiving diazepam. Excessive treatment with diazepam may result in respiratory depression requiring intubation and ventilation. However, this is also a direct complication of organophosphorus poisoning and it is difficult to distinguish between the two.[41]

Comment: Benzodiazepines such as diazepam, lorazepam, and midazolam are widely used for treating organophosphorus induced seizures. However, the seizures are believed to be started by excess acetylcholine in the brain following acetylcholinesterase (see glossary, p 1823) inhibition, with subsequent disruption of other neurotransmitter systems such as glutamate and catecholamine. Benziodiazepines work at γ-aminobutyric acid receptors. Other treatments may therefore be beneficial. Sufficient atropinisation (see glossary, p 1824) may help to manage organophosphorus induced seizures. Routine benzodiazepines before any seizure occurs has support from animal models, but we found no studies in humans.[42]

OPTION CLONIDINE

We found no RCTs on the effects of clonidine in acute organophosphorus poisoning.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study of complications in people with acute organophosphorus poisoning receiving clonidine. Complications of clonidine may include sedation, hypotension, bradycardia, and (with prolonged use) rebound hypertension.[43]

Comment: Clonidine inhibits the release of acetylcholine from cholinergic neurones and has α_2 adrenergic agonist effects. Animal studies have found that clonidine pretreatment improves survival after organophosphorus poisoning; combination with atropine was more than additive.[44] This treatment has not yet been studied in organophosphorus poisoning in humans.

OPTION N-METHYL-D-ASPARTATE RECEPTOR ANTAGONISTS

We found no RCTs on the effects of N-methyl-D-aspartate receptor antagonists in acute organophosphorus poisoning.

Benefits: We found no systematic review and no RCTs.

Harms: We found no systematic review, RCT, or cohort study of complications in people with acute organophosphorus poisoning receiving N-methyl-D-aspartate (NMDA) receptor antagonists. A dose ranging clinical study found that complications of NMDA receptor antagonists include dizziness, vomiting, nausea, stupor, agitation, and hallucinations.[45]

Comment: Primate studies have found that treating with NMDA receptor antagonists, such as gacyclidine, improves clinical recovery, reduces neural death, and improves electroencephalogram activity following organophosphorus poisoning.[46]

GLOSSARY

Acetylcholinesterase An enzyme that cleaves acetylcholine.

Ageing Esterases (such as acetylcholinesterase and neurotoxic target esterase) are inhibited by organophosphorus through phosphorylation. Inhibited acetylcholinesterase reactivates spontaneously at very slow rates; oximes speed up this reaction. However, phosphorylated acetylcholinesterase may lose an alkyl side

chain non-enzymatically, leaving a hydroxyl group in its place ("ageing"). Regeneration is then no longer possible.

Atropinisation Administering atropine until it reaches sufficiently high blood levels to suppress cholinergic signs clinically.

Pro-poisons Some organophosphorus pesticides require activation in vivo to become toxic.

Rates of ageing The rate depends on the identity of the alkyl side chains on each organophosphorus. Those with two methyl groups will age faster than those with two ethyl groups and thus become unresponsive to oximes at an earlier time point.

QUESTIONS

INTERVENTIONS

Key Messages

- **Acetylcysteine** One systematic review found one RCT in people with established paracetamol induced liver failure. It found that acetylcysteine reduced mortality after 21 days compared with placebo. One observational study found that people given early treatment with acetylcysteine were less likely to develop liver damage than untreated historical controls.
- **Methionine** One systematic review found insufficient evidence on the effects of methionine on mortality. It found limited evidence that methionine reduced hepatotoxicity compared with supportive care.
- **Activated charcoal (single or multiple dose)** One systematic review found no evidence on the effects of activated charcoal, whether in single or multiple dose regimens, in people poisoning by paracetamol. One large case series found that clinically significant complications of multiple dose activated charcoal are rare.
- **Gastric lavage** One systematic review found no evidence of the effects of gastric lavage in paracetamol poisoning.
- **Ipecacuanha** One systematic review found no evidence on the clinical effects of ipecacuanha in paracetamol poisoning.

Paracetamol (acetaminophen) poisoning

DEFINITION Paracetamol poisoning occurs as a result of either accidental or intentional overdose with paracetamol (acetaminophen).

INCIDENCE/ PREVALENCE Paracetamol is the most common drug used for self poisoning in the UK.[1] It is also a common means of self poisoning in the rest of Europe, North America, and Australasia. An estimated 41 200 cases of poisoning with products containing paracetamol occurred in 1989–1990 in England and Wales, with a mortality of 0.40% (95% CI 0.38% to 0.46%). Overdoses owing to paracetamol alone result in an estimated 150–200 deaths and 15–20 liver transplants each year in England and Wales.

AETIOLOGY/ RISK FACTORS Most cases in the UK are impulsive acts of self harm in young people.[1,2] In one study of 80 people who had overdosed with paracetamol, 42 had obtained the tablets for the specific purpose of taking an overdose and 33 had obtained them less than 1 hour before the act.[2]

PROGNOSIS People with blood paracetamol concentrations above the standard treatment line (defined in the UK as a line joining 200 mg/L at 4 hours and 30 mg/L at 15 hours on a semilogarithmic plot) have a poor prognosis without treatment (see figure 1, p 1832).[3–5] In one study of 57 untreated people with blood concentrations above this line, 33 developed severe liver damage and three died.[4] People with a history of chronic alcohol misuse, use of enzyme inducing drugs, eating disorders, or multiple paracetamol overdoses may be at risk of liver damage with blood concentrations below this line.[6] In the USA, a lower line is used as an indication for treatment, but we found no data relating this line to prognostic outcomes.[7] **Dose effect:** The dose ingested also indicates the risk of hepatotoxicity. People ingesting less than 125 mg/kg had no significant hepatotoxicity with a sharp dose dependent rise for higher doses.[8] The threshold for toxicity after acute ingestion may be higher in children, where a single dose of less than 200 mg/kg has not been reported to lead to death and rarely causes hepatotoxicity.[9] For people who present later than 24 hours or an unknown time after ingestion, several other prognostic indicators have been proposed, including prothrombin time and abnormal liver function tests.[10,11] These have not been validated prospectively.

AIMS OF INTERVENTION To prevent liver failure, liver transplantation, or death, with minimal adverse effects.

OUTCOMES Mortality, hepatotoxicity (most commonly defined by the objective criterion of blood aspartate aminotransferase > 1000 U/L), liver failure, or liver transplantation.

METHODS *Clinical Evidence* search and appraisal July 2003, including a search for observational studies. The authors also searched Current Awareness in Clinical Toxicology (http://www.npis.org/cact/cact.htm) and contacted experts in the field to identify unpublished studies.

Paracetamol (acetaminophen) poisoning

QUESTION **What are the effects of treatments for acute paracetamol poisoning?**

OPTION ACETYLCYSTEINE

One systematic review found one RCT in people with established paracetamol induced liver failure. It found that acetylcysteine reduced mortality after 21 days compared with placebo. One observational study found that people given early treatment with acetylcysteine were less likely to develop liver damage than untreated historical controls.

Benefits: We found one systematic review (search date 2001, 1 RCT, 50 people with established paracetamol induced liver failure), which compared intravenous acetylcysteine (150 mg/kg over 15 minutes, 50 mg/kg over 4 hours, and then 100 mg/kg diluted in 5% dextrose over 16 hours, continued until death or recovery) versus a placebo infusion of 5% dextrose.[12] It found that after 21 days, acetylcysteine significantly reduced mortality compared with placebo (mortality: 13/25 [52%] with acetylcysteine *v* 20/25 [80%] with placebo; RR 0.65, 95% CI 0.43 to 0.99; NNT 4, 95% CI 2 to 16).

Harms: The systematic review found no evidence that quantified harms from acetylcysteine,[12] and the included RCT did not specifically assess adverse outcomes and none were noted.[13] Five case series found that the incidence of adverse effects from intravenous acetylcysteine was 5–23%.[14–18] These were predominantly rash, urticaria, and occasionally more serious anaphylactoid reactions occurring with the initial "loading" dose. In most or all cases, adverse effects responded to temporary stopping of infusions and symptomatic treatment, and did not recur when treatment recommenced. Three deaths have been reported, two followed a 10-fold miscalculation of the dose of acetylcysteine and the other occurred in a person with severe asthma.[19,20] Adverse reactions seem to be more common in people with asthma and those who have non-toxic paracetamol concentrations.[16] Vomiting is common after oral acetylcysteine and occurred in 63% of people in one series despite previous administration of metoclopramide.[17] Oral acetylcysteine can also cause hypersensitivity and anaphylactoid reactions.[21]

Comment: In the RCT, allocation was concealed but treatment was not blinded.[13] There were differences between the groups in prognostic variables (prothrombin time, coma grade) and other treatments, but a possible confounding effect could not be assessed adequately because of the small size of the study. One observational study evaluated the effects of intravenous acetylcysteine in people presenting early to hospital.[4] It found that people treated within 10 hours of ingestion were less likely to develop liver damage than untreated historical controls (1/62 [2%] with treated people *v* 33/57 [58%] with untreated people). As a result, subsequent RCTs were considered unethical. A systematic review of numerous case series found evidence that acetylcysteine is beneficial in paracetamol poisoning.[14] For both oral and intravenous acetylcysteine, overall hepatotoxicity was worse if treatment was delayed beyond 8–10 hours (1% in those treated within 8 hours *v* 46% in those treated after 16 hours).[4,14] We found no RCTs of different regimens

and no evidence of a difference between oral and intravenous routes of administration.[14] The optimal dose, route, and duration of treatment is unknown. Two recent observational studies comparing different protocols for intravenous[22] and oral[23] acetylcysteine did not find marked differences in outcomes.

OPTION ACTIVATED CHARCOAL (SINGLE OR MULTIPLE DOSE)

One systematic review found no evidence on the effects of activated charcoal, whether in single or multiple dose regimens, in people poisoned by paracetamol. One large case series found that clinically significant complications of multiple dose activated charcoal are rare.

Benefits: We found one systematic review (search date 2001), which found no RCTs that examined clinical outcomes after paracetamol poisoning.[12]

Harms: The systematic review found no large study of complications in people poisoned by paracetamol who received single doses of activated charcoal.[12] Reported harms may include aspiration pneumonia, vomiting, diarrhoea, constipation, ileus, and interference with regular medications.[24] One large retrospective case series (878 people treated with multiple dose activated charcoal) suggested that rates of clinically significant adverse events with multiple dose regimens are likely to be low (significant pulmonary aspiration in 6/878 [0.6%], 95% CI 0.1% to 1.1%).[25]

Comment: **Single dose regimens:** The systematic review included simulated overdose studies in volunteers, which found that activated charcoal given within 2 hours of paracetamol ingestion decreased absorption by a variable amount and that this amount diminished with time.[12] One cohort study in 450 consecutive people who had taken ≥10 g of paracetamol found that those who had been given activated charcoal were significantly less likely to have high risk blood paracetamol concentrations (OR 0.36, 95% CI 0.23 to 0.58).[3] The effect was seen only in those treated within 2 hours, and the study was not large enough to assess the effect of many potential confounders.[3] One non-systematic review of activated charcoal in all forms of poisoning found no evidence that activated charcoal improved outcome in poisoned people.[26] **Multiple dose regimens:** The review found no studies of simulated overdose that evaluated multiple dose regimens in paracetamol poisoning.[12] One non-systematic review of case series and reports of multiple dose regimens in all forms of poisoning found no evidence that multiple dose regimens improved outcomes in poisoned people.[27] The rapid absorption and short half life of paracetamol suggest that a beneficial effect is unlikely.

OPTION GASTRIC LAVAGE

One systematic review found no evidence of the effects of gastric lavage in paracetamol poisoning.

Benefits: We found one systematic review (search date 2001), which found no RCTs or cohort studies that reported clinical outcomes.[12]

Harms: The systematic review found no large study of complications in people poisoned by paracetamol who received gastric lavage.[12] Harms may include aspiration of stomach contents, hypoxia, and oesophageal perforation.[28]

Comment: The systematic review included studies of simulated overdose in human volunteers, which found that gastric lavage carried out within 1 hour removed a variable number of paracetamol tablets and that the number diminished with time.[12] One cohort study (described previously) (see comment under acitvated charcoal, p 1829) found that those given activated charcoal were significantly less likely to have high risk blood paracetamol concentrations (OR 0.36, 95% CI 0.23 to 0.58).[3] The addition of gastric lavage to activated charcoal regimens did not decrease the risk further (OR 1.12, 95% CI 0.57 to 2.20).[3] One non-systematic review of gastric lavage in all forms of poisoning found no evidence that gastric lavage improved outcome in poisoned people.[29]

OPTION IPECACUANHA

One systematic review found no evidence on the clinical effects of ipecacuanha in paracetamol poisoning.

Benefits: We found one systematic review (search date 2001), which found no evidence of clinical effects of ipecacuanha in paracetamol poisoning.[12]

Harms: The systematic review found no studies that quantified harms from ipecacuanha in paracetamol poisoning.[12] Specific complications of ipecacuanha may include aspiration, diarrhoea, ileus, arrhythmia during vomiting, dystonia from treatment for vomiting, and haematemesis from vomiting.[28]

Comment: Human simulated overdose studies suggest that ipecacuanha given within 1 hour could reduce paracetamol absorption but no studies have shown a change in clinical outcome.[24] One non-systematic review of ipecacuanha in all forms of poisoning found no evidence that ipecacuanha improved outcome in poisoned people.[24] Administration of ipecacuanha may delay the administration of activated charcoal and oral antidotes.

OPTION METHIONINE

One systematic review found insufficient evidence on the effects of methionine on mortality. It found limited evidence that methionine reduced hepatotoxicity compared with supportive care.

Benefits: One systematic review (search date 2001, 1 RCT, 40 people with blood concentrations of paracetamol above the UK standard treatment line [see figure 1, p 1832]) compared oral methionine (2.5 g 4 hourly for 4 doses), intravenous mercaptamine (formerly named cysteamine, 3.6 g over 20 hours), and supportive care.[12] It found no significant effect on mortality (0 deaths with methionine *v* 0 deaths with mercaptamine *v* 1 with supportive care). Only 27 people had a liver biopsy. Fewer people suffered grade III hepatic necrosis with methionine than with supportive care (0/9 [0%] with methionine *v* 6/10 [60%] with supportive care) or had peak aspartate aminotransferase greater than 1000 U (1/13 [8%] with methionine *v* 8/13 [62%] with supportive care; RR 0.13, 95% CI 0.02 to 0.86; NNT 2, 95% CI 2 to 6).

Harms: The systematic review did not address harms from methionine.[12] No serious adverse effects associated with treatment were reported in the included RCT, but vomiting after administration of methionine occurred in 8/13 people (62%).[30] The incidence of adverse effects in the control group was not reported.

Comment: Interpretation of liver biopsy results from the RCT was difficult as not all people were tested and an intention to treat analysis was not possible. We found one case series in people treated with methionine in early and late paracetamol poisoning, but there was no untreated group for comparison.[31]

Substantive changes

Acetylcysteine One new case series added under harms section;[18] conclusions unchanged but harms data broadened.

Activated charcoal One retrospective case series on multiple doses of charcoal added to harms section;[25] conclusions unchanged but harms data improved.

Ectopic pregnancy

Search date April 2003

Bazian Ltd

QUESTIONS

INTERVENTIONS

See glossary, p 1838

Key Messages

- **Choice between open and laparoscopic salpingostomy** One systematic review found that, compared with laparoscopic salpingostomy, open salpingostomy increased rates of elimination of tubal pregnancy. It found no significant difference in rates of subsequent intrauterine pregnancy or repeat ectopic pregnancy, but perioperative blood loss was higher with open salpingostomy.
- **Methotrexate (oral)** One small RCT identified by a systematic review found no significant difference between oral methotrexate 2.5 mg daily for 5 days and expectant management in the need for laparoscopy for persistent adnexal mass within 3 months.
- **Methotrexate (intramuscular, multiple or single dose)** One RCT identified by a systematic review found no significant difference in rates of elimination of tubal pregnancy, tubal preservation, spontaneous intrauterine pregnancy, or repeat ectopic pregnancy at 18 months between multiple dose intramuscular methotrexate (1 mg/kg on days 1, 2, 4, and 6) plus folic acid compared with laparoscopic salpingostomy. The same RCT found that multiple dose methotrexate decreased health related quality of life compared with laparoscopic salpingostomy. One systematic review found higher rates of persistent ectopic pregnancy and lower rates of elimination of tubal pregnancy with single dose intramuscular methotrexate 1 mg/kg or 50 mg/m^2 compared with laparoscopic salpingostomy.
- **Salpingostomy** We found no RCTs comparing salpingostomy with expectant management. One RCT identified by a systematic review found no significant difference in rates of elimination of tubal pregnancy, tubal preservation, spontaneous intrauterine pregnancy, or repeat ectopic pregnancy at 18 months between multiple dose intramuscular methotrexate (1 mg/kg on days 1, 2, 4, and 6) plus folic acid compared with laparoscopic salpingostomy. The

same RCT found that multiple dose methotrexate decreased health related quality of life compared with laparoscopic salpingostomy. One systematic review found higher rates of persistent ectopic pregnancy and lower rates of elimination of tubal pregnancy with single dose intramuscular methotrexate 1 mg/kg or 50 mg/m^2 compared with laparoscopic salpingostomy.

- **Fimbrial expression, salpingectomy, salpingo-oophorectomy** We found no systematic review or RCTs that evaluated these interventions.

DEFINITION

In ectopic pregnancy, the fertilised ovum implants on a surface other than the uterine endometrium. Almost all ectopic pregnancies implant in the fallopian tubes. Ectopic pregnancies are detected by clinical suspicion and serial measurement of serum human chorionic gonadotrophin (hCG) or ultrasound.[1] Spontaneous resolution occurs only in selected cases: in women with a small adnexal mass on transvaginal sonography, decreasing hCG levels, and only minor symptoms.[2,3] **Population:** This chapter covers management in women with non-ruptured, tubal ectopic pregnancy only. Typically, this group would consist of women with small tubal pregnancies confirmed ultrasonographically or based on serial hCG levels. We have excluded women with an acute presentation of ectopic pregnancy (such as peritonism, or with evidence of rupture or bleeding).

INCIDENCE/ PREVALENCE

Small studies suggest that 1–2% of reported pregnancies are ectopic.[4,5] A recent large study attempted to estimate the proportion of ectopic pregnancies in the USA using national data sets, but found that data were too flawed to provide an accurate estimate of the incidence.[6]

AETIOLOGY/ RISK FACTORS

A recent large case-control study suggested that the main risk factors for ectopic pregnancy were history of pelvic infection (OR 3.4, 95% CI 2.4 to 5.0) and smoking (OR 3.9, 95% CI 2.6 to 5.9).[7] Other risk factors were age, previous spontaneous abortion, history of infertility, and previous use of an intrauterine contraceptive device.[7] Earlier studies have found that previous ectopic pregnancy, previous tubal surgery including tubal sterilisation, documented tubal pathology, intrauterine contraceptive device, previous genital infections, smoking and *in utero* diethylstilbestrol exposure were associated with ectopic pregnancy.[8–10] The risk of ectopic pregnancy varies with method of tubal sterilisation. Women sterilised by bipolar tubal coagulation before the age of 30 years were found to have a risk of ectopic pregnancy 27 times greater than women who had postpartum partial salpingectomy (see glossary, p 1838).[9]

PROGNOSIS

Risks of ectopic pregnancy include tubal rupture, life-threatening bleeding, and subsequent infertility. The combination of transvaginal ultrasound and hCG measurements allow the condition to be diagnosed earlier now than previously. Consequently, mortality has fallen over time in the developed world from 35.5 deaths per 10 000 cases to 3.8 deaths per 10 000 cases between 1970 and 1989 in the USA and from 16 deaths per 10 000 cases to three deaths per 10 000 pregnancies between 1973 and 1993 in the UK.[3] However, mortality remains high in poorer countries: 100–300 deaths per 10 000 cases in one African survey.[11] Evaluating expectant management (see glossary, p 1838) to assess prognosis is difficult because of ethical concerns about exposing women to

undue risk of acute complications, which may also have medico-legal implications.[12] However, expectant management has been suggested as a feasible option in women at low risk of acute complications (such as asymptomatic women and women with small adnexal masses and decreasing hCG levels), and in the presence of close monitoring. A recent non-systematic review found rates of spontaneous resolution with expectant management to range from 46–65%.[3] One prospective cohort study (118 women) found that rates of spontaneous resolution varied with hCG level from 98% where hCG concentrations were less than 200 mIU/mL to 25% for hCG concentration greater than 2000 mIU/mL.[2] However, no factors have yet been found that reliably predict tubal rupture or bleeding.[3]

AIMS OF INTERVENTION To prevent tubal rupture; reduce maternal death; increase chances of future intrauterine pregnancy; and minimise adverse effects of treatments.

OUTCOMES Maternal mortality, tubal rupture, persistence or elimination of ectopic pregnancy (measured by ultrasound or by serial hCG levels); recurrence rate; long term spontaneous live birth rate (i.e. without subsequent intervention for infertility); quality of life; acute clinical complications of treatment (e.g. haemorrhage, infection); long term fertility; and complications of surgery, such as bleeding, hysterectomy, and transfusion.

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments for non-ruptured tubal pregnancy? New

OPTION FIMBRIAL EXPRESSION

We found no systematic review or RCTs that evaluated fimbrial expression.

Benefits: We found no systematic review or RCTs that compared fimbrial expression (see glossary, p 1838) with either expectant management (see glossary, p 1838) or other treatment.

Harms: We found no systematic review or RCTs.

Comment: It may not be ethically feasible to compares surgical management versus expectant management in an RCT (see prognosis, p 1834).

OPTION SALPINGECTOMY

We found no systematic review or RCTs that evaluated salpingectomy.

Benefits: We found no systematic review or RCTs that compared salpingectomy (see glossary, p 1838) with either expectant management (see glossary, p 1838) or other treatment.

Harms: We found no systematic review or RCTs.

Comment: It may not be ethically feasible to compare surgical management versus expectant management in an RCT (see prognosis, p 1834).

OPTION SALPINGO-OOPHORECTOMY

We found no systematic review or RCTs that evaluated salpingo-oophorectomy.

Benefits: We found no systematic review or RCTs that compared salpingo-oophorectomy (see glossary, p 1838) with either expectant management (see glossary, p 1838) or other treatment.

Harms: We found no systematic review or RCTs.

Comment: It may not be ethically feasible to compare surgical management versus expectant management in an RCT (see prognosis, p 1834).

OPTION SALPINGOSTOMY (OPEN OR LAPAROSCOPIC)

We found no RCTs comparing salpingostomy with expectant management. One systematic review found that, compared with laparoscopic salpingostomy, open salpingostomy increased rates of elimination of tubal pregnancy. It found no significant difference in rates of subsequent intrauterine pregnancy or repeat ectopic pregnancy, but perioperative blood loss was higher with open salpingostomy. One RCT identified by the review found no significant difference between laparoscopic salpingostomy and intramuscular methotrexate (multiple dose, 1 mg/kg on days 1, 2, 4, and 6) plus folic acid in terms of rate of elimination of tubal pregnancy, tubal preservation, spontaneous intrauterine pregnancy, or repeat ectopic pregnancy at 18 months. The same RCT found that multiple dose methotrexate decreased health related quality of life compared with laparoscopic salpingostomy.

Benefits: **Versus expectant management:** See glossary, p 1838. We found no systematic review or RCTs. **Open versus laparoscopic salpingostomy:** See glossary, p 1838. We found one systematic review (search date not reported), which identified three RCTs.[1] The review found that, compared with laparoscopic salpingostomy, open salpingostomy significantly increased rates of elimination of tubal pregnancies. It found no significant difference in rates of persistent ectopic pregnancy [see glossary, p 1838]; 3 RCTs, 228 with small unruptured tubal pregnancy; elimination of tubal pregnancy: RR 1.11, 95% CI 1.03 to 1.20; persistent ectopic pregnancy: RR 0.28, 95% CI 0.05 to 1.58). The review also found no significant difference between open and laparoscopic salpingostomy in rates of subsequent intrauterine pregnancy or repeat ectopic pregnancy among 145 women trying to conceive (3 RCTs, 145 women trying to conceive; rates of subsequent intrauterine pregnancy: RR 0.83, 95% CI 0.66 to 1.14; repeat ectopic pregnancy: RR 2.33, 95% CI 0.83 to 6.70). The review did not distinguish between spontaneous pregnancy and pregnancy after *in vitro* fertilisation. **Laparoscopic salpingostomy versus systemic methotrexate:** See benefits of systemic methotrexate, p 1837.

Harms: **Versus expectant management:** We found no systematic review or RCTs. **Open versus laparoscopic salpingostomy:** The review found that laparoscopic salpingostomy reduced perioperative blood loss compared with open salpingostomy (blood loss varied among studies: 62–79 mL with laparoscopic salpingostomy *v* 115–195 mL

with open salpingostomy).[1] One RCT included in the review (60 women) found intraoperative complications in 2/30 women (both haematosalpinx) with laparoscopy compared with no complications with laparotomy.[13] Other complications in this RCT included wound infection in 2/30 with laparotomy and 1/30 with postoperative fever with each type of surgery. **Laparoscopic salpingostomy versus systemic methotrexate:** See harms of systemic methotrexate, p 1838.

Comment: It may not be ethically feasible to compare surgical management with expectant management in an RCT (see prognosis, p 1834).

OPTION SYSTEMIC METHOTREXATE

One small RCT identified by a systematic review found no significant difference between oral methotrexate 2.5 mg daily for 5 days and expectant management in the need for laparoscopy for persistent adnexal mass within 3 months. The review found higher rates of persistent ectopic pregnancy and lower rates of elimination of tubal pregnancy with single dose intramuscular methotrexate 1 mg/kg or 50 mg/m^2 compared with laparoscopic salpingostomy. One RCT identified by the review found no significant difference in rates of elimination of tubal pregnancy plus tubal preservation, spontaneous intrauterine pregnancy, or repeat ectopic pregnancy at 18 months between multiple dose intramuscular methotrexate (1 mg/kg on days 1, 2, 4, and 6) plus folic acid compared with laparoscopic salpingostomy. The same RCT found that multiple dose methotrexate decreased health related quality of life compared with laparoscopic salpingostomy.

Benefits: We found one systematic review (search date not reported).[1] **Oral methotrexate versus expectant management:** The review identified one RCT, which found no significant difference between oral methotrexate 2.5 mg daily for 5 days and expectant management (see glossary, p 1838) in the need for laparoscopy within 3 months (1 RCT, 60 women with ectopic pregnancy < 4 cm and serum human chorionic gonadotrophin concentration < 5000 IU/L, mean age 31 years; need for laparoscopy within 3 months: 77% with each treatment [absolute numbers not provided]; RR 1.00, 95% CI 0.76 to 1.30).[12] The RCT did not report results on subsequent fertility. In the RCT, laparoscopy was performed if the adnexal mass remained visible on transvaginal ultrasonography and human chorionic gonadotrophin concentration was less than 1.0 IU/L. **Single dose intramuscular methotrexate versus laparoscopic salpingostomy:** See glossary, p 1838. The review found significantly higher rates of persistent ectopic pregnancy (see glossary, p 1838) and lower rates of elimination of tubal pregnancy with single dose intramuscular methotrexate 1 mg/kg or 50 mg/m^2 compared with laparoscopic salpingostomy (3 RCTs, 207 women, haemodynamically stable with a small unruptured pregnancy, persistent ectopic pregnancy: RR 3.6, 95% CI 1.7 to 8.0; elimination of tubal pregnancy: RR 0.83, 95% CI 0.71 to 0.97).[1] The review found no significant difference between treatments in subsequent intrauterine pregnancies or repeat ectopic pregnancy (intrauterine pregnancy: RR 0.99, 95% CI 0.55 to 1.80; repeat ectopic pregnancy: RR 0.27, 95% CI 0.02 to 4.50). One RCT (62 women)

identified by the review found that single dose intramuscular methotrexate significantly increased physical function compared with laparoscopic salpingostomy ($P < 0.01$) but found no significant difference in psychological functioning.[14] **Multiple dose intramuscular methotrexate versus laparoscopic salpingostomy:** The review identified one RCT, which found no significant difference in rates of elimination of tubal pregnancy plus tubal preservation, spontaneous intrauterine pregnancy, or repeat ectopic pregnancy at 18 months between multiple dose methotrexate (1 mg/kg on days 1, 2, 4, and 6) plus folic acid compared with laparoscopic salpingostomy (1 RCT, 100 women, elimination of tubal pregnancy plus tubal preservation: RR 1.20, 95% CI 0.93 to 1.40; spontaneous intrauterine pregnancy in 74 women trying to conceive: 12/34 [35%] with methotrexate *v* 16/40 [40%] with laparoscopic salpingostomy; RR 0.89, 95% CI 0.42 to 1.90; repeat ectopic pregnancy: RR 0.77, 95% CI 0.17 to 3.40).[15]

Harms:

Oral methotrexate versus expectant management: The RCT identified by the review[1] did not report on harms.[12] **Single dose intramuscular methotrexate versus laparoscopic salpingostomy:** The review did not report on adverse events for this comparison.[1] **Multiple dose intramuscular methotrexate versus laparoscopic salpingostomy:** The RCT (100 women) identified by the review[1] found that, compared with laparoscopic salpingostomy, multiple dose methotrexate significantly decreased health related quality of life (physical functioning, role functioning, social functioning, energy, pain, physical symptoms, overall quality of life, and depression; $P < 0.05$).[1]

Comment:

Oral methotrexate versus expectant management: In the RCT, 23% of women in both treatment groups required surgical management but no details were given in the report of the RCT.[12] **Higher versus lower single dose intramuscular methotrexate:** The review identified one RCT which was published as an abstract only.[16] The RCT found no significant difference in rates of elimination of tubal pregnancy or persistent ectopic pregnancy between 25 and 50 mg/m^2 of intramuscular methotrexate (40 women, elimination of tubal pregnancy: RR 1.30, 95% CI 0.75 to 2.10; persistent ectopic pregnancy: RR 0.75, 0.27 to 2.00).[16]

GLOSSARY

Expectant management A "watch and wait" policy of observation only, involving no immediate intervention to eliminate the ectopic pregnancy. Intervention is indicated if the condition deteriorates or fails to resolve spontaneously.

Fimbrial expression In fimbrial expression (also known as tubal milking) the tubal pregnancy is milked out of the end of the fallopian tube.

Persistent ectopic pregnancy In persistent ectopic pregnancy some of the tissue from the pregnancy remains in the tube and resumes growing.

Salpingectomy In salpingectomy the fallopian tube is surgically removed.

Salpingo-oophorectomy In salpingo-oophorectomy the ovary and the fallopian tube are both surgically removed.

Salpingostomy In salpingostomy (open or laparoscopic), the surgeon makes an incision in the fallopian tube and removes the tubal pregnancy.

Nausea and vomiting in early pregnancy

Search date July 2003

Richmal Oates-Whitehead

QUESTIONS

INTERVENTIONS

See glossary, p 1851

Key Messages

Nausea and vomiting in pregnancy

- **Ginger** Three RCTs and one randomised crossover trial found that ginger reduced nausea and vomiting in early pregnancy. One further RCT found that ginger reduced nausea and dry retching, but had no effect on episodes of vomiting.
- **Acupressure** One systematic review of small RCTs found limited evidence that P6 acupressure reduced self reported morning sickness compared with sham acupressure or no intervention. Three subsequent RCTs and two randomised crossover trials found that P6 acupressure reduced the duration, but not necessarily the intensity, of nausea and vomiting.
- **Antihistamines (H1 antagonists)** Two systematic reviews found limited evidence that antihistamines reduced nausea and vomiting, with no evidence of teratogenicity.
- **Cyanocobalamin (vitamin B_{12})** One systematic review has found that cyanocobalamin reduces vomiting episodes compared with placebo.
- **Pyridoxine (vitamin B_6)** Two systematic reviews found limited evidence that pyridoxine reduced nausea but found no evidence of an effect on vomiting.

- **Acupuncture** One RCT found that acupuncture reduced nausea and retching compared with no acupuncture, with no evidence of adverse effects. However, an improvement was also found with sham acupuncture compared with no treatment. A second smaller RCT found no significant difference in nausea between acupuncture and sham acupuncture.
- **Dietary interventions (other than ginger)** We found no RCTs of dietary interventions (other than ginger).
- **Phenothiazines** One systematic review found limited evidence that phenothiazines reduced the proportion of women with nausea and vomiting. However, the results were not conclusive. The review found no evidence of teratogenicity.

Hyperemesis gravidarum

- **Acupuncture** One small randomised, crossover RCT found a faster reduction in nausea, as measured on a visual analogue scale, after active PC6 acupuncture compared with sham acupuncture. Episodes of vomiting were also reduced. However, we were unable to draw reliable conclusions from this study.
- **Corticosteroids** One small RCT found no significant improvement in persistent vomiting or readmission to hospital after 1 week of treatment with prednisolone compared with placebo. One small RCT found no significant improvement in persistence of vomiting but found that prednisolone reduced admission to hospital compared with promethazine.
- **Corticotropins** One small RCT found no significant difference in nausea and vomiting between intramuscular corticotropin (adrenocorticotrophic hormone [ACTH]) and placebo.
- **Diazepam** One RCT provided insufficient evidence to assess the effects of diazepam in women with hyperemesis gravidarum.
- **Dietary interventions (other than ginger)** One small crossover RCT found no significant difference in nausea and vomiting after 3 weeks of dietary supplementation with carob seed flour compared with placebo.
- **Ginger** One small RCT provided insufficient evidence to assess the effects of ginger in hyperemesis gravidarum.
- **Ondansetron** One small RCT provided insufficient evidence to assess the effects of ondansetron in hyperemesis gravidarum.

DEFINITION

Nausea and vomiting are both common in early pregnancy. Although often called "morning sickness", nausea and vomiting can occur at any time of the day and may be constant.[1] Symptoms usually start between 4 and 7 weeks' gestation (one study found this to be the case in 70% of affected women)[2] and stop by 16 weeks in about 90% of women.[1–3] One study found that fewer than 10% of affected women suffer nausea and/or vomiting before the first missed period.[3] Most women do not require treatment. However, persistent vomiting and severe nausea can progress to hyperemesis if the woman is unable to maintain adequate hydration, fluid and electrolyte balance, and nutrition. **Hyperemesis gravidarum** is a diagnosis of exclusion, characterised by prolonged and severe nausea and vomiting, dehydration, and weight loss.[1] Laboratory investigation may show ketosis, hyponatraemia, hypokalaemia, hypouricaemia, metabolic hypochloraemic alkalosis (see glossary, p 1851), and ketonuria.

Nausea and vomiting in early pregnancy

INCIDENCE/ PREVALENCE Nausea affects about 70% and vomiting about 60% of pregnant women.[1] The true incidence of hyperemesis gravidarum is not known. It has been documented to range from 3 to 20 per thousand pregnancies. However, most authors report an incidence of 1 in 200.[2]

AETIOLOGY/ RISK FACTORS The causes of nausea and vomiting in pregnancy are unknown. One theory, that they are caused by the rise in human chorionic gonadotrophin concentration, is compatible with the natural history of the condition, its severity in pregnancies affected by hydatidiform mole (see glossary, p 1851), and its good prognosis (see prognosis below).[4] The aetiology of hyperemesis gravidarum is also uncertain. Again, endocrine and psychological factors are suspected, but evidence is inconclusive.[4]

PROGNOSIS One systematic review (search date 1988) found that nausea and vomiting were associated with a reduced risk of miscarriage (6 studies, 14 564 women; OR 0.36, 95% CI 0.32 to 0.42) but found no association with perinatal mortality.[5] Nausea and vomiting and hyperemesis usually improve over the course of pregnancy, but in one cross sectional observational study 13% of women reported that nausea and vomiting persisted beyond 20 weeks' gestation.[6]

AIMS OF INTERVENTION To reduce the incidence and severity of nausea and vomiting in early pregnancy; to reduce the incidence and severity of hyperemesis gravidarum; to minimise adverse effects of treatment and possible teratogenic effects on the fetus.

OUTCOMES Persistence, severity, or both, of nausea and vomiting episodes as measured on validated scales; maternal mortality; rates of admission and readmission to hospital and duration of hospital stay; incidence and severity of adverse effects of treatment; and incidence of teratogenic effects of treatments on the fetus.

METHODS *Clinical Evidence* search and appraisal July 2003. The author also performed additional searches of the Cochrane Library Issue 2, 2003, Medline, Embase, and Cinahl in April 2003.

QUESTION What are the effects of treatment for nausea and vomiting in early pregnancy?

OPTION ACUPRESSURE

One systematic review of small RCTs has found limited evidence that P6 acupressure reduces self reported morning sickness compared with sham acupressure or no treatment. Three subsequent RCTs and two randomised crossover trials found that P6 acupressure reduced the duration, but not necessarily the intensity, of nausea and vomiting.

Benefits: We found one systematic review (search date 2001, 4 RCTs, 661 women),[7] three subsequent RCTs,[8–10] one additional RCT (excluded because it was small and of poor quality),[11] and two randomised crossover trials.[12,13] The review found that, compared with placebo or sham treatment, acupressure significantly reduced the proportion of women reporting morning sickness (2 RCTs, 404 women; OR 0.35, 95% CI 0.23 to 0.54; see comment below).[7] However, the authors commented that the odds ratio may be an overestimate

as the two trials that could not be included in the summary calculation[14,15] found no evidence of effect and one of these RCTs had the highest completion rate of all four trials (92%).[15] The first subsequent RCT (97 women, 8–12 weeks' gestation) found that, compared with a sham acupressure wristband, 4 day administration of acupressure wristband significantly reduced the duration of nausea and vomiting (WMD 1.89 hours/12 hour cycle, 95% CI 0.33 hours/12 hour cycle to 3.45 hours/12 hour cycle), but did not reduce the intensity (measured with a non-graded visual analogue scale ranging from zero to five; WMD +0.25 units, 95% CI –0.12 units to +0.62 units).[8] The second RCT (138 women randomised at 13 weeks of gestation, 110 women analysed) found that acupressure administered via a wristband to the P6 point reduced the frequency and severity of nausea compared with a sham acupressure wristband (data were not provided in a way that allowed further statistical calculation).[9] The third RCT (60 women, with mean gestational ages of 9.8 weeks in the P6 group, 9.6 weeks in the placebo group, and 10.8 weeks for those receiving no treatment) compared acupressure administered via a wristband to the P6 point for 14 days versus sham acupressure and no treatment.[10] On day one, a significant improvement in nausea scores was found with both acupressure and sham acupressure compared with no treatment (acupressure: WMD –2.4 average degree of nausea score, 95% CI –3.78 to –1.02; sham acupressure: WMD –2.00 average degree of nausea score, 95% CI –3.30 to –0.70). By day 6, the significant improvement with acupressure compared with no treatment remained (WMD –2.0, 95% CI –3.37 to –0.63) and there was a trend towards improvement with acupressure compared with sham acupressure (WMD –1.4, 95% CI –2.89 to +0.09; P = 0.07). By day 14, the significant improvement with both acupressure and sham acupressure compared with no treatment was still evident (acupressure: WMD –2.3 average degree of nausea score, 95% CI –3.79 to –0.81; sham acupressure: WMD –1.70 average degree of nausea score, 95% CI –3.25 to –0.15). There was no significant difference between any of the groups in episodes of vomiting at the end of the 14 day treatment. The randomised crossover RCTs (both with 23 women randomised at 16 and 14 weeks of gestation, respectively, 15 [65%] women analysed) found a significant improvement in the severity of nausea with P6 acupressure measured with a 10 cm visual analogue scale compared with sham acupuncture (first study: WMD 1.69 cm, 95% CI 0.32 cm to 3.06 cm; second study provided insufficient data).[12,13]

Harms: None reported.

Comment: Conducting high quality trials in this area is difficult because nausea and vomiting tend to resolve spontaneously and interventions are difficult to mask and to control with credible placebos. The trial with the largest sample size[16] was subsequently described in a paper that questioned the reliability of the randomisation.[17] The type of acupressure differed in the two RCTs included in the summary calculation in the systematic review.[7] In the first included RCT, P6 acupressure was applied as a band applying pressure to the P6 point. Placebo treatment comprised a similar band with the point

blunted, not exerting pressure on the P6 point. Each type of band was put on each wrist in sequence. Data for meta-analysis were taken from the third phase, when one group received active treatment to both wrists and the other placebo treatment to both wrists, for 72 hours. In the second RCT included in the review, acupressure to the P6 point was compared with pressure applied to a point close to the right elbow (sham acupressure), both for 5 minutes every 4 hours on four successive mornings. A control group without treatment was asked only to complete a record form.[7]

OPTION ACUPUNCTURE

One RCT found that acupuncture reduced nausea and retching compared with no acupuncture, with no evidence of adverse effects. However, an improvement was also found with sham acupuncture compared with no treatment. A second smaller RCT found no significant difference in nausea between acupuncture and sham acupuncture.

Benefits: We found no systematic review but found two RCTs.[18,19] The first RCT (593 women with nausea and vomiting in early pregnancy) compared weekly traditional acupuncture for 4 weeks versus PC6 acupuncture (see glossary, p 1851), sham acupuncture, or no acupuncture.[18] Rates of vomiting did not differ significantly between groups. However, significantly more women receiving traditional, PC6, or sham acupuncture reported improvement in nausea compared with women receiving no acupuncture (see comment below). The improvement compared with no acupuncture was noted after 1 week of treatment with traditional acupuncture (13/135 [10%] with acupuncture *v* 4/127 [3%] with no acupuncture; RR 0.93, 95% CI 0.88 to 0.99; NNT 15, CI not reported), after 2 weeks in women receiving PC6 acupuncture (see glossary, p 1851) ($P < 0.05$), and after 3 weeks in women receiving sham acupuncture ($P < 0.01$). Women receiving PC6 and sham acupuncture also reported significantly less dry retching compared with no acupuncture ($P < 0.001$). The second RCT (55 women, 6–10 weeks' gestation) found no significant difference in nausea between multisite acupuncture and sham acupuncture ($P = 0.9$).[19]

Harms: A follow up study of the first RCT[18] found no differences between study groups in perinatal outcome, congenital abnormalities, pregnancy complications, or other infant outcomes.[20]

Comment: In the first RCT, the significant improvement in all groups receiving an intervention (traditional acupuncture, PC6 acupuncture, and sham acupuncture) makes it difficult to establish whether the results were influenced by a placebo effect.[18]

OPTION ANTIHISTAMINES (H1 ANTAGONISTS)

Two systematic reviews found limited evidence that antihistamines reduced nausea and vomiting, with no evidence of teratogenicity.

Benefits: We found two systematic reviews.[7,21] The more recent systematic review (search date 2001, 12 RCTs, 1505 women) found that, compared with placebo, antihistamines as a group significantly reduced nausea (timeframes not specified; OR 0.17, 95% CI 0.13

to 0.21).[7] The earlier systematic review (search date 1998, 7 RCTs, 1190 women) found that H1 antagonist antihistamines significantly reduced treatment failure (RR 0.34, 95% CI 0.27 to 0.43).[21] However, the conclusions need to be interpreted with care because significant heterogeneity was found between studies.[21]

Harms: The earlier review included 24 controlled studies in > 200 000 women treated between 1960 and 1991.[21] It found no significant increase in teratogenicity with antihistamines (RR 0.76, 95% CI 0.60 to 0.94). The more recent review included three RCTs that gathered evidence on harms from 179 women.[7] It found that antihistamines significantly increased drowsiness (23/94 [24%] with antihistamines *v* 9/85 [11%] with placebo; RR 2.3, 95% CI 1.1 to 4.7; NNH 7, 95% CI 3 to 32).

Comment: The trials identified by the reviews were old and did not provide details on randomisation or concealment strategies.[7,21] The more recent review combined results from trials in which different antihistamines (e.g. buclizine, dimenhydrinate, doxylamine, hydroxyzine, meclozine) were compared with placebo.[7] The earlier review found important heterogeneity in the meta-analysis, which may be attributed to the variety of drugs included.[21] A preparation combining doxylamine plus dicycloverine plus pyridoxine assessed in the reviews was found to reduce nausea and vomiting. However, this preparation was withdrawn from the market in several countries after publication of papers suggesting teratogenicity, although such claims have subsequently been refuted.

OPTION CYANOCOBALAMIN (VITAMIN B_{12})

One systematic review has found that cyanocobalamin reduces vomiting episodes compared with placebo.

Benefits: We found one systematic review (search date 1998, 2 RCTs, 1018 women).[21] It found that cyanocobalamin (oral vitamin B_{12}) significantly reduced vomiting episodes compared with placebo (timeframes not specified; RR 0.49, 95% CI 0.28 to 0.86).[21]

Harms: The review searched for controlled trials addressing potential teratogenicity of cyanocobalamin and found no evidence of this.[21]

Comment: The conclusions of the review are mostly based on one RCT, which accounted for 1000 women and used a daily dose of a multivitamin compound that contained 4 μg cyanocobalamin in each tablet.[22] The smaller RCT used a dose of cyanocobalamin of 25 μg orally twice daily for 7 days (Jewell D, personal communication, 2001). It is believed that the combination of cyanocobalamin plus folic acid may prevent neural tube defects.

OPTION DIETARY INTERVENTIONS (OTHER THAN GINGER)

We found no RCTs of dietary interventions (other than ginger).

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION GINGER

Three RCTs and one randomised crossover trial found that ginger reduced nausea and vomiting in early pregnancy. One further RCT found that ginger reduced nausea and dry retching, but had no effect on episodes of vomiting.

Benefits: We found no systematic review. We found three RCTs[23–25] and one randomised crossover trial[26] examining the use of ginger as an antiemetic in early pregnancy. The first RCT (70 women of < 17 weeks gestation) compared 250 mg of ginger in oral capsules taken four times daily versus placebo.[23] It found that ginger significantly reduced the proportion of women with vomiting after 4 days compared with placebo (12/32 [38%] with ginger *v* 23/35 [66%] with placebo; RR 0.57, 95% CI 0.34 to 0.95; NNT 4, 95% CI 2 to 12), and significantly reduced symptoms (non-specifically described) after 7 days (28/32 [88%] with ginger *v* 10/35 [29%] with placebo; RR 0.18, 95% CI 0.07 to 0.45; NNT 2, CI not reported). The second RCT (26 women with gestational age < 13 weeks) compared 15 mL of ginger syrup containing 250 mg of ginger taken four times daily versus placebo.[24] After 6 days, significantly more women had stopped vomiting with ginger (8/12 [67%] with ginger *v* 2/10 [20%] with placebo; RR 0.42, 95% CI 0.18 to 0.98; NNT 2, CI not reported). The third RCT (120 women with gestational age ranging between 5.5 weeks and 18 weeks compared 125 mg of ginger in oral capsules taken four times daily for four days versus placebo.[25] It found that ginger significantly reduced nausea severity scores over each of the 4 treatment days (reported as significant, results presented graphically). It also significantly reduced dry retching, but only on the first 2 days of treatment (reported as significant, no further data reported). Ginger had no significant effect on episodes of vomiting (reported as non-significant, no further data reported). The randomised crossover trial (30 women) compared 250 mg of ginger in oral capsules taken four times daily for 4 days versus placebo.[26] It found that ginger significantly reduced nausea and vomiting severity scores compared with placebo ($P = 0.035$).

Harms: The first RCT found no significant difference in spontaneous abortions between ginger and placebo (1/32 [3%] with ginger *v* 3/38 [8%] with placebo; $P = 0.4$), but the sample size may have been too small to rule out a clinically important difference.[23] The third RCT found that the most serious adverse effect was heartburn and reflux (no data available to establish a comparison between groups).[25]

Comment: Ginger used for the first RCT[23] and the randomised crossover trial[26] was derived from fresh ginger roots and given in capsules. The authors of the RCT warn that different presentations of ginger may have a different magnitude of effects. The active ingredient that improves nausea and vomiting has not been isolated.[23]

OPTION PHENOTHIAZINES

One systematic review found limited evidence that phenothiazines reduced the proportion of women with nausea and vomiting. However, the results were not conclusive. The review found no evidence of teratogenicity.

Benefits: We found one systematic review (search date 1998, 3 RCTs, 398 women).[21] It found that, compared with placebo, phenothiazines significantly reduced the proportion of women with nausea or vomiting (timeframes not specified; RR 0.31, 95% CI 0.24 to 0.42). One of the RCTs recruited women after the first trimester of pregnancy. After excluding this RCT, the results favouring phenothiazines remained significant. The review found that phenothiazines significantly reduced treatment failure compared with placebo (definition not reported; 26/145 [18%] with phenothiazines *v* 89/139 [64%] with placebo; RR 0.28, 95% CI 0.19 to 0.41; NNT 3, 95% CI 2 to 3).

Harms: The review assessed harms, gathering evidence from seven controlled observational trials (78 440 women), which found no evidence of teratogenicity (RR 1.00, 95% CI 0.84 to 1.18).[21] However, harms associated with different phenothiazines vary, making it difficult to interpret a summary analysis.

Comment: The trials identified by the review were old and lacked sufficient information to appraise the quality of randomisation or allocation concealment. Only two RCTs provided support for the review's conclusions and the analysis in the review combined results for different phenothiazines. It should therefore be viewed with caution.

OPTION PYRIDOXINE (VITAMIN B_6)

Two systematic reviews of pyridoxine found limited evidence that pyridoxine reduced nausea but found no evidence of an effect on vomiting. One review found no evidence of teratogenicity.

Benefits: We found two systematic reviews.[7,21] The first review (search date 1998, 3 RCTs, 949 women) found that pyridoxine had similar "failure rates" compared with placebo (3 RCTs, 949 women; RR 0.97, 95% CI 0.78 to 1.20; see comment below).[21] However, pyridoxine significantly improved nausea scores (2 RCTs, 395 women; WMD 0.92, 95% CI 0.44 to 1.40). The second systematic review (search date 2001, 2 RCTs, 392 women) compared pyridoxine versus placebo or no treatment.[7] It found that pyridoxine did not significantly reduce vomiting (timeframes not specified; OR 0.91, 95% CI 0.60 to 1.38) but significantly reduced nausea (change in a 10 cm visual analogue scale; WMD 0.9 cm, 95% CI 0.4 cm to 1.4 cm).

Harms: The first review searched for evidence on harms (search date 1998, 1 cohort study, 1369 women).[21] It found no significant increase in major fetal malformations attributable to pyridoxine (RR 1.05, 95% CI 0.60 to 1.84).[21]

Comment: The first review[21] included one RCT in which the nature of randomisation was unclear.[7] The remaining two RCTs were included in both reviews.[7,21] "Failure rates" were defined in various subjective ways and included failure to achieve resolution or a clinically important improvement in symptoms.[21]

QUESTION What are the effects of treatments for hyperemesis gravidarum?

OPTION ACUPUNCTURE

One small randomised crossover RCT found a faster reduction in nausea, as measured on a visual analogue scale, after active PC6 acupuncture compared with sham acupuncture. Episodes of vomiting were also reduced. However, we were unable to draw reliable conclusions from this study.

Benefits: We found no systematic review or RCTs. We found one crossover RCT (50 women admitted to hospital with vomiting and gestational age range between 6 and 16 weeks, comparing PC6 acupuncture versus sham acupuncture.[27] PC6 acupuncture was applied 5 mm beneath the skin at days 1, 2, 5, and 6 and evaluated at the eighth day, while sham acupuncture was applied 1–2 mm beneath the skin on the lateral side of the forearm. Both interventions were given three times daily for 30 minutes.[27] All women were vomiting on the day of randomisation. The RCT found that women receiving acupuncture had a significantly faster resolution of nausea than women receiving sham acupuncture ($P = 0.032$). No significant differences were found between groups with regard to food intake and the need for intravenous fluids.[27]

Harms: No adverse effects were reported.

Comment: The placebo treatment (sham acupuncture) used in the RCT was superficial acupuncture on an area away from a "real" acupuncture point. Needles were inserted only 1–2 mm into the skin. The authors of the RCT state that this kind of stimulation minimises the specific effects of acupuncture.[27] However, it may not be an entirely inert placebo, as some sensory stimulation does occur.

OPTION CORTICOTROPINS

One small RCT found no significant difference in nausea and vomiting between intramuscular corticotropin (adrenocorticotrophic hormone [ACTH]) and placebo.

Benefits: We found two systematic reviews of corticotropins in hyperemesis gravidarum, which identified the same single RCT (search dates 1998[21] and 2001;[7] 1 RCT, 32 women whose gestational ages and severity of hyperemesis were not described). The RCT compared 0.5 mg of intramuscular corticotropin versus placebo.[28] It found no significant difference between intramuscular corticotropin and placebo in nausea relief scores (measured on a scale ranging from 15 denoting a lack of nausea to 20 denoting the worst possible hyperemesis; WMD +0.6 mean relief score, 95% CI –1.65 to

+2.85). There was no significant difference between groups in the time from starting treatment to stopping vomiting, and all women stopped vomiting while in hospital. Women remained at hospital for at least 10 days. There was no significant difference between groups in the number of readmissions to hospital.

Harms: The systematic reviews reported no adverse effects.[7,21]

Comment: None.

OPTION CORTICOSTEROIDS

One small RCT found no significant improvement in persistent vomiting or readmission to hospital after 1 week of treatment with prednisolone compared with placebo. One small RCT found no significant improvement in persistence of vomiting but found that prednisolone reduced admission to hospital compared with promethazine.

Benefits: We found two systematic reviews and one subsequent RCT.[7,21,29] The two reviews identified the same single RCT (search dates 1998[21] and 2001[7]; 1 RCT, 40 women). **Versus placebo:** The subsequent RCT (25 women with severe hyperemesis, mean gestational age of 10.6 weeks for prednisolone and 8.3 weeks for placebo) compared oral prednisolone 20 mg twice daily versus placebo for 1 week.[29] Oral prednisolone had no significant effect on persistent vomiting (5/12 [42%] with prednisolone *v* 7/12 [58%] with placebo; RR 1.4 95% CI 0.6 to 3.2) or on subsequent readmission to hospital (5/12 [42%] with prednisolone *v* 8/12 [67%] with placebo; RR 1.6, 95% CI 0.7 to 3.5). **Versus promethazine:** The RCT identified by the reviews compared oral methylprednisolone versus promethazine (40 women admitted to hospital at < 16 weeks' gestation).[30] It found that methylprednisolone had no significant effect on persistence of vomiting compared with promethazine (OR 1.56, 95% CI 0.25 to 9.94). However, there was a reduction in rates of subsequent admission to hospital (0/17 [0%] with methylprednisolone *v* 5/18 [28%] with promethazine; OR 0.11, 95% CI 0.02 to 0.71).

Harms: The first review also included controlled observational studies (8 studies, 109 602 women) and found no evidence of teratogenicity (RR 1.24, 95% CI 0.97 to 1.60).[21]

Comment: The rates of spontaneous resolution of symptoms in control groups were high. The possible benefit (based on a single small trial)[30] of methylprednisolone in preventing subsequent admission to hospital must be balanced against possible adverse effects of steroids given in the first trimester of pregnancy. The subsequent RCT was too small to rule out a clinically important effect.[29]

OPTION DIAZEPAM

One RCT provided insufficient evidence to assess the effects of diazepam in women with hyperemesis gravidarum.

Benefits: We found one systematic review (search date 2001, 1 RCT, 50 women admitted to hospital)[7] comparing intravenous fluids containing a multivitamin preparation with or without diazepam 20 mg

daily. After symptoms settled, women were randomised to receive oral diazepam 5 mg twice daily for 1 week or placebo. The trial found no significant difference in persistence of vomiting after 2 days of treatment (assessment not clearly specified; OR 0.64, 95% CI 0.10 to 4.19), but reported a difference in rates of readmission to hospital (4% with diazepam *v* 27% with placebo; detailed figures not reported)[7].

Harms: The trial did not report on adverse effects or acceptability of treatment.

Comment: The trial was too small to draw reliable conclusions. The rate of resolution in the control group was high and the effects of the vitamins used in the RCT are unknown.

OPTION DIETARY INTERVENTIONS (OTHER THAN GINGER)

One small crossover RCT found no significant difference in nausea and vomiting after 3 weeks of dietary supplementation with carob seed flour compared with placebo.

Benefits: We found no systematic review. We found one crossover RCT (43 women), which compared 1 g daily of a powder containing 96.5% carob seed flour plus 3.5% calcium lactate versus placebo for 3 weeks.[31] It found no significant difference in relief of vomiting (subjective improvement: 20/34 [59%] with carob seed flour *v* 18/36 [50%] with placebo; RR 1.18, 95% CI 0.82 to 1.70].[31]

Harms: The RCT found no adverse effects.[31]

Comment: The trial was conducted in 1966. It is unclear whether the composition of carob seed flour now commercially available will be the same as was used in the trial.[31]

OPTION GINGER

One small RCT provided insufficient evidence on the effects of ginger.

Benefits: We found one systematic review (search date 2001, 1 crossover RCT, 27 women), which compared ginger 250 mg in oral capsules taken four times daily versus placebo.[7] After 4 days of treatment the RCT found no improvement in a hyperemesis score that evaluated the degree of nausea, vomiting, and weight loss (WMD +3.15, 95% CI −0.92 to +7.22).

Harms: The RCT found no adverse effects.

Comment: The trial reported results before crossover but it was too small to allow reliable conclusions.

OPTION ONDANSETRON

One small RCT provided evidence to assess the effects of ondansetron in hyperemesis gravidarum.

Benefits: **Versus placebo:** We found no systematic review or RCTs. **Versus promethazine:** We found one systematic review (search date 2001, 1 RCT, 27 women admitted to hospital).[7] The RCT compared

ondansetron 10 mg versus promethazine 50 mg, both given by 50 mL solution over 30 minutes. Subsequent doses were given as needed every 8 hours until the woman was able to eat a bland diet. The RCT found no significant difference in persistence of vomiting between ondansetron and promethazine (2/15 [13%] with ondansetron *v* 3/12 [25%] with promethazine; OR 0.33, 95% CI 0.04 to 2.60).[7]

Harms: The RCT gave no information on adverse effects.[7]

Comment: The RCT was too small to draw reliable conclusions.[7]

GLOSSARY

Acupressure Pressure applied to a specific point of the body. It does not require needles and can be administered by patients themselves. Commercial products available include an elastic band to fit around the wrist with a plastic disc to apply pressure at the P6 point.

Hydatidiform mole A condition in which there is abnormal cystic development of the placenta. The uterus is often large for the duration of pregnancy and there may be vaginal bleeding, lack of fetal movement and fetal heart sounds, and severe nausea and vomiting. Rarer, but important, complications include haemorrhage, intrauterine infection, raised blood pressure, and persistent gestational trophoblastic disease, which may infiltrate local tissues or metastasise to distant sites.

Metabolic hypochloraemic alkalosis Excess base alkali in the body fluids caused by chloride loss.

P6 acupressure Pressure is applied at the P6 (Neiguan) point on the volar aspect of the wrist.

PC6 acupuncture The needle is applied at the PC6 point located near to the wrist crease.

Substantive changes

Acupressure in nausea and vomiting One RCT added;[10] categorisation unchanged.

Acupuncture in nausea and vomiting Information on harms enhanced with the addition of one follow up study;[20] categorisation unchanged.

Ginger in nausea and vomiting One RCT added;[25] categorisation unchanged.

Key Messages

- **Absorbable synthetic sutures for perineal repair of first and second degree tears and episiotomies (reduces short term pain)** One systematic review has found that absorbable synthetic sutures reduce pain at up to 10 days after birth compared with catgut sutures. One subsequent RCT, however, found no significant difference in perineal pain at 3 days, although it may have lacked power to detect a clinically important effect. The systematic review and the subsequent RCT found no significant difference between absorbable synthetic sutures and catgut sutures in pain or dyspareunia at 3 months, but one RCT with 12 months' follow up, which was included in the review, found lower rates of dyspareunia with absorbable synthetic sutures. RCTs found no significant difference between rapidly absorbed and standard synthetic sutures in overall perineal pain, pain on sitting, or dyspareunia. The RCTs found reduced perineal pain on walking with rapidly absorbed synthetic sutures.
- **Continuous subcutaneous technique of perineal skin closure of first and second degree tears and episiotomies (reduces short term pain)** One systematic review has found that continuous subcuticular sutures for perineal skin reduced short term pain compared with interrupted sutures, but there was no significant difference in perineal pain or dyspareunia at 3 months post partum. One RCT found that a loose continuous suture reduced short term perineal pain and suture removal compared with interrupted sutures for repair of all layers up to 3 months post partum.
- **Continuous support during labour (reduces operative vaginal birth)** One systematic review has found that providing continuous support for women during childbirth reduces the rate of operative vaginal birth (vacuum extraction or forceps) compared with usual care. It found no significant difference in the risk of episiotomy or perineal trauma (defined as episiotomy or laceration requiring suturing).
- **Restrictive use of episiotomy (reduces risk of posterior trauma compared with routine use)** One systematic review found that restricting episiotomy to specific fetal and maternal indications reduced the rates of posterior perineal trauma, need for suturing, and healing complications compared with routine use, but increased the rates of anterior vaginal and labial trauma, which carries minimal morbidity.
- **Non-suturing of perineal skin in first and second degree tears and episiotomies (reduces dyspareunia)** One large RCT has found no significant difference between leaving the perineal skin unsutured compared with conventional suturing in pain at 10 days after birth. A second RCT found that non-suturing reduced pain for up to 3 months following delivery. Both RCTs found that non-suturing of the perineal skin reduced dyspareunia at 3 months after birth.
- **"Hands poised" versus "hands on" method of delivery (increases pain and need for manual delivery of placenta, no significant difference in rate of perineal trauma, and reduces eposiotomy rate)** One multicentre RCT and one quasi-randomised trial found that the "hands poised" method (not touching the baby's head or supporting the mother's perineum) reduced

episiotomy rates compared with the conventional "hands on" method (applying pressure to the baby's head during delivery and supporting the mother's perineum). The RCT found no evidence of an effect on the risk of perineal trauma, but found that the "hands poised" group had an increased risk of requiring manual removal of the placenta and higher rates of short term perineal pain.

- **Upright versus supine or lateral position during delivery (fewer episiotomies but more second degree tears than supine or lateral positions)** One systematic review found that any upright position for delivery marginally reduced episiotomies compared with supine or lateral positions but this was offset by an increase in second degree tears. Rates of assisted vaginal delivery were slightly reduced in the upright group.
- **Vacuum extraction (less perineal trauma than with forceps but newborns have increased risk of cephalhaematoma)** One systematic review and subsequent RCTs have found that vacuum extraction reduces the rate of severe perineal trauma compared with forceps delivery, but increases the incidence of neonatal cephalhaematoma and retinal haemorrhage.
- **Different methods and materials for repair of third and fourth degree tears** One small RCT comparing the overlap method versus the end-to-end method for primary repair of third degree obstetric tears found no significant difference in perineal discomfort and a non-significant reduction in the rate of reported faecal urgency and anal incontinence.
- **Passive descent in the second stage of labour** One RCT comparing passive fetal descent versus immediate active pushing found no significant difference in perineal trauma.
- **Sustained breath holding (Valsalva) method of pushing** One systematic review of two poor quality controlled clinical trials found no significant difference in the extent or rate of perineal trauma between sustained breath holding (Valsalva) and spontaneous exhalatory methods of pushing during the second stage of labour.
- **Midline episiotomy incision (associated with higher risk of third or fourth degree tears compared with mediolateral incision)** We found no evidence that midline episiotomy incision improved perineal pain or wound dehiscence compared with mediolateral incision. Limited evidence from one quasi-randomised trial suggests that midline incision may increase the risk of third and fourth degree tears compared with mediolateral incision.
- **Epidural anaesthesia (increases instrumental delivery, which is associated with increased rates of perineal trauma)** One systematic review found no direct evidence about the effects of epidural compared with other forms of anaesthesia on rates of perineal trauma. However, RCTs found that epidural anaesthesia maintained beyond the first stage of labour compared with epidural restricted to the first stage of labour significantly increased the risk of instrumental delivery, which in turn is associated with an increased risk of perineal trauma.
- **Non-suturing of muscle and skin in first and second degree perineal tears (poorer wound healing than with suturing)** Two small RCTs found no significant difference in short term perineal pain between non-suturing and suturing of first and second degree tears. One of the RCTs found no significant difference in healing between groups but the second RCT found that a greater proportion of women in the non-sutured group had poorer wound healing at 6 weeks after birth.

Perineal care

DEFINITION

Perineal trauma is any damage to the genitalia during childbirth that occurs spontaneously or intentionally by surgical incision (episiotomy). Anterior perineal trauma is injury to the labia, anterior vagina, urethra, or clitoris, and is usually associated with little morbidity. Posterior perineal trauma is any injury to the posterior vaginal wall, perineal muscles, or anal sphincter. First degree spontaneous tears involve only skin; second degree tears involve perineal muscles; third degree tears partially or completely disrupt the anal sphincter; and fourth degree tears completely disrupt the external and internal anal sphincter and epithelium.[1]

INCIDENCE/ PREVALENCE

Over 85% of women having a vaginal birth sustain some form of perineal trauma,[2] and 60–70% receive stitches — equivalent to 400 000 women a year in the UK in 1997.[2,3] There are wide variations in rates of episiotomy: 8% in the Netherlands, 13% in England, 43% in the USA, and 99% in east European countries.[4–6] Sutured spontaneous tears are reported in about a third of women in the USA[4] and the UK,[7] but this is probably an underestimate because of inconsistency of reporting and classification of perineal trauma. The incidence of anal sphincter tears varies between 0.5% in the UK, 2.5% in Denmark, and 7% in Canada.[8]

AETIOLOGY/ RISK FACTORS

Perineal trauma occurs during spontaneous or assisted vaginal delivery and is usually more extensive after the first vaginal delivery.[1] Associated risk factors also include increased fetal size, mode of delivery, and malpresentation and malposition of the fetus. Other maternal factors that may increase the extent and degree of trauma are ethnicity (white people are probably at greater risk than black people), older age, abnormal collagen synthesis, and poor nutritional state.[10] Clinicians' practices or preferences in terms of intrapartum interventions may influence the severity and rate of perineal trauma (e.g. use of ventouse *v* forceps).

PROGNOSIS

Perineal trauma affects women's physical, psychological, and social wellbeing in the immediate postnatal period as well as the long term. It can also disrupt breast feeding, family life, and sexual relations. In the UK, about 23–42% of women will continue to have pain and discomfort for 10–12 days post partum, and 7–10% of women will continue to have long term pain (3–18 months after delivery);[2,3,10] 23% of women will experience superficial dyspareunia at 3 months; 3–10% will report faecal incontinence;[11,12] and up to 24% will have urinary problems.[2,3] Complications depend on the severity of perineal trauma and on the effectiveness of treatment.

AIMS OF INTERVENTION

To reduce the rate and severity of trauma; to improve the short and long term maternal morbidity associated with perineal injury and repair.

OUTCOMES

Quality of life; incidence and severity of perineal trauma; psychological trauma; short and long term perineal pain; blood loss; infection; wound dehiscence; superficial dyspareunia; stress incontinence; faecal incontinence; adverse effects of treatment.

QUESTION **What are the effects of intrapartum surgical interventions on the risk of perineal trauma?**

OPTION RESTRICTIVE VERSUS ROUTINE USE OF EPISIOTOMY

One systematic review found that restricting the use of episiotomy to specific fetal and maternal indications reduced the rates of posterior perineal trauma, need for suturing, and healing complications compared with routine use, but increased the rates of anterior vaginal and labial trauma, which carries minimal morbidity.

Benefits: We found one systematic review (updated 1999, search date not reported, 6 RCTs, 4850 women) comparing restricted versus routine episiotomy.[13] In the routine episiotomy group 1752/2409 (73%) women had an episiotomy compared with 673/2441 (28%) women in the restricted group. Restricted use of episiotomy was associated with lower risk of posterior perineal trauma, less perineal pain at discharge from hospital, less suturing, and fewer healing complications (posterior perineal trauma, 4 RCTs, 2079 women: 744/1039 [72%] with restricted *v* 849/1040 [82%] with routine; RR 0.88, 95% CI 0.84 to 0.92; NNT 10, 95% CI 8 to 16; perineal pain at discharge from hospital, 1 RCT, 2422 women: 371/1207 [31%] with restricted *v* 516/1215 [42%] with routine; RR 0.72, 95% CI 0.65 to 0.81; NNT 9, 95% CI 7 to 12; suturing, 5 RCTs, 4133 women: 1327/2080 [64%] with restricted *v* 1768/2053 [86%] with routine; RR 0.74, 95% CI 0.71 to 0.77; NNT 4, 95% CI 4 to 5; healing complications, 1 RCT, 1119 women: 114/555 [21%] with restricted *v* 168/564 [30%] with routine; RR 0.69, 95% CI 0.56 to 0.85; NNT 11, 95% CI 7 to 23). There were no significant differences in the two groups in overall rates of severe vaginal or perineal trauma, dyspareunia within 3 months or dyspareunia in the next 3 years, or urinary incontinence at 3 months (severe vaginal or perineal trauma, 3 RCTs, 4284 women: 87/2155 [4.0%] with restricted *v* 77/2129 [3.6%] with routine; RR 1.11, 95% CI 0.83 to 1.50; dyspareunia within 3 months, 1 RCT, 895 women: 96/438 [22%] with restricted *v* 82/457 [18%] with routine; RR 1.22, 95% CI 0.94 to 1.59; dyspareunia in the next 3 years, 1 RCT, 674 women: 52/329 [16%] with restricted *v* 45/345 [13%] with routine; RR 1.21, 95% CI 0.84 to 1.75; and urinary incontinence at 3 months, 2 RCTs, 1569 women: 140/775 [18%] with restricted *v* 147/794 [19%] with routine; RR 0.98, 95% CI 0.79 to 1.20).[13]

Harms: We found no reports of serious harms associated with restricted use of episiotomy apart from higher rates of anterior perineal trauma, which carries minimal morbidity (4 RCTs, 4342 women; 425/2144 [20%] with restricted *v* 243/2198 [11%] with routine; RR 1.79, 95% CI 1.55 to 2.07; NNH 11, 95% CI 9 to 16).[13]

Comment: The six RCTs included in the review varied in quality. The method of randomisation was not clear in one trial. All trials performed intention to treat analysis. The trials took place in the UK, Canada, and Argentina. The types of episiotomy performed were mediolateral in five of the trials and midline in the sixth.

OPTION MIDLINE VERSUS MEDIOLATERAL EPISIOTOMY INCISION

We found no evidence that midline episiotomy incision improved perineal pain or wound dehiscence compared with mediolateral incision. Limited evidence from one quasi-randomised trial suggests that midline incision may increase the risk of third and fourth degree tears compared with mediolateral incision.

Benefits: We found no systematic review comparing mediolateral versus midline episiotomy incisions. However, stratified analysis of data from the systematic review of routine compared with restricted episiotomy found no difference in the overall results between midline and mediolateral episiotomies.[13] We found one quasi-randomised trial (407 primigravidas, 24% withdrawals)[14] and one abstract (no detailed data)[15] comparing midline versus mediolateral episiotomies. These were of poor quality and found no evidence of a difference in perineal pain or wound dehiscence. Women who had had a midline episiotomy experienced significantly less perineal bruising and resumed sexual intercourse earlier.

Harms: The quasi-randomised trial found that midline episiotomies increased the risk of third or fourth degree tears (39/163 [24%] with midline episiotomy *v* 22/244 [9%] with mediolateral episiotomy; RR 2.7, 95% CI 1.6 to 4.3; NNH 6, 95% CI 4 to 13).[14] However, these results have to be approached with care because the study limitations compromise their validity. Two retrospective cohort studies, including 5376 primiparous and 341 multiparous women, also found that midline episiotomies were associated with a fourfold increased risk of third and fourth degree tears after allowing for multiple confounders (CI not reported).[16,17]

Comment: It is claimed that midline incision is easier to repair and that it is associated with less blood loss, better healing, less pain, and earlier resumption of sexual intercourse. We found no reliable evidence to support these claims. One of the trials had an increased risk of selection bias because of quasi-random treatment allocation and because analysis was not by intention to treat.[14] The other trial did not describe the method of treatment allocation.[15]

OPTION EPIDURAL ANAESTHESIA

One systematic review found no direct evidence about the effects of epidural compared with other forms of anaesthesia on rates of perineal trauma. However, RCTs found that epidural anaesthesia maintained beyond the first stage of labour compared with epidural restricted to the first stage of labour increased the risk of instrumental delivery, which in turn is associated with an increased risk of perineal trauma.

Benefits: We found one systematic review (updated 1999, search date not reported, 11 RCTs comparing epidural anaesthesia *v* other forms of analgesia, 3157 women).[18] The RCTs did not report the incidence of perineal trauma. Six trials (1252 women) reported rates of instrumental delivery when the epidural block was maintained beyond the first stage of labour. It found that epidurals significantly increased the risk of instrumental delivery compared with non-epidural (6 RCTs: 168/628 with epidural analgesia v 102/624 with

non-epidural analgesia; OR 2.03, 95% CI 1.51 to 2.73).[18] Two trials (131 women) reported rates of instrumental delivery when the epidural block was restricted to the first stage of labour. It found no significant difference in the risk of instrumental delivery between epidural analgesia compared with non-epidural analgesia (2 RCTs: 18/67 with epidural analgesia *v* 14/64 with non-epidural analgesia; OR 1.30, 95% CI 0.59 to 2.88).

Harms: Analysis of observational evidence found that epidural block was associated with an increased incidence of chronic backache, chronic headache, bladder problems, tingling and numbness, and "sensory confusion".[19]

Comment: The quality of the trials was variable in that the methods of randomisation in five of the trials included in the systematic review were not clearly described.

OPTION VACUUM EXTRACTION VERSUS FORCEPS

One systematic review and subsequent RCTs have found that vacuum extraction reduces the rate of severe perineal trauma compared with forceps delivery, but increases the incidence of neonatal cephalhaematoma and retinal haemorrhage.

Benefits: We found one systematic review[20] and three subsequent RCTs.[21–23] The systematic review (search date 1999, 10 RCTs comparing vacuum extraction *v* forceps, 2885 women) found that women allocated to vacuum extraction rather than forceps were significantly less likely to suffer severe perineal injury and severe perineal pain at 24 hours (severe perineal injury, 7 RCTs, 2582 women: 127/1296 [10%] with vacuum *v* 261/1286 [20%] with forceps; RR 0.46, 95% CI 0.38 to 0.56; NNT 10, 95% CI 8 to 12; severe perineal pain, 1 RCT, 495 women: 21/247 [9%] with vacuum *v* 37/248 [15%] with forceps; RR 0.57, 95% CI 0.34 to 0.94; NNT 16, 95% CI 10 to 119).[20] The subsequent RCTs found a non-significant reduction in severe perineal trauma[21,22] and third degree tears[23] with vacuum extraction compared with forceps delivery (perineal trauma: 2/70 [2.8%] with vacuum *v* 4/70 [5.7%] with forceps; RR 0.50, 95% CI 0.10 to 2.64[21] and 2/204 [1.0%] with vacuum *v* 4/238 [1.7%] with forceps; RR 0.58, 95% CI 0.19 to 3.15;[22] third degree tear: 5/69 [7%] with vacuum *v* 10/61 [16%] with forceps; RR 0.44, 95% CI 0.16 to 1.22[23]). The third subsequent RCT found that vacuum extraction significantly reduced the proportion of women complaining of altered faecal continence compared with forceps at 3 months after birth (intention to treat analysis: 23/69 [33%] with vacuum *v* 36/61 [59%] with forceps; RR 0.35, 95% CI 0.17 to 0.71).[23]

Harms: The systematic review and two of the subsequent RCTs found that babies delivered by vacuum extraction were at higher risk of cephalhaematoma (systematic review:[20] 6 RCTs, 1966 women: 98/995 [10%] with vacuum *v* 40/971 [4%] with forceps; RR 2.34, 95% CI 1.64 to 3.35; NNH 17, 95% CI 10 to 35; first subsequent RCT:[21] 6/70 [8.6%] with vacuum *v* 2/70 [2.8%] with forceps; RR 3.0, 95% CI 0.63 to 14.36; second subsequent RCT:[22] 12/204 [5.9%] with vacuum *v* 2/238 [0.8%] with forceps; RR 7.00, 95% CI 1.59 to

30.91). The systematic review also found that vacuum extraction was associated with significantly higher rates of retinal haemorrhage and failed delivery with the selected instrument than forceps (retinal haemorrhage, 5 RCTs, 445 women: 109/224 [49%] with vacuum *v* 74/221 [34%] with forceps; RR 1.46, 95% CI 1.17 to 1.83; NNH 7, 95% CI 4 to 17; failed delivery with selected instrument, 9 RCTs, 2849 women: 166/1436 [12%] with vacuum *v* 102/1413 [7%] with forceps; RR 1.60, 95% CI 1.27 to 2.02; NNH 23, 95% CI 14 to 51).[20]

Comment: The trials in the systematic review varied in quality, some using quasi-random treatment allocation.[20] None of the trials attempted to "blind" the allocated intervention during the postnatal assessments. The trials took place in different countries (UK, USA, South Africa, Denmark, Sweden, and Greece), and the procedures in the studies were comparable to everyday practice when an assisted delivery is required. Although some studies were performed in teaching hospitals, they were pragmatic, with wide inclusion criteria. The evidence is likely to be generalisable. The subsequent RCTs were carried out in teaching hospitals in Mexico,[21] Sri Lanka, [22] and Ireland.[23] One of the trials had an additional control group of 70 women undergoing spontaneous vaginal delivery.[21]. The most recent RCT failed to reach adequate power to detect a 20% difference between vacuum and forceps in morbidity.[23]

QUESTION What are the effects of intrapartum non-surgical interventions on the risk of perineal trauma?

OPTION CONTINUOUS SUPPORT DURING LABOUR

One systematic review has found that providing continuous support for women during childbirth reduces the rate of operative vaginal birth (vacuum extraction or forceps) compared with usual care. It found no significant difference in the risk of episiotomy or perineal trauma (defined as episiotomy or laceration requiring suturing).

Benefits: We found one systematic review (search date 2003, 15 RCTs, ≥ 12 791 women) comparing continuous, one to one intrapartum support from a professional nurse, midwife, or lay person with usual care.[24] It found that continuous support (see glossary, p 1869) significantly reduced operative vaginal birth compared with usual care (14 RCTs, 12757 women; 1039/6344 [16%] with continuous support *v* 1159/6413 [18%] with usual care; RR 0.89, 95% CI 0.83 to 0.96). There was no significant difference in the rate of episiotomy or perineal trauma (episiotomy, 1 RCT, 6915 women: 894/3454 [25.9%] with continuous support *v* 919/3461 [26.5%] with usual care; RR 0.97, 95% CI 0.90 to 1.05); perineal trauma, 2 RCTs, 7328 women: 1996/3663 [54%] with continuous support *v* 2026/3665 [55%] with usual care; RR 0.99, 95% CI 0.95 to 1.03).[24]

Harms: We found no evidence of harmful effects. The trials in the review examined a wide range of outcomes, but none revealed harmful effects.[24]

Comment: The trials in the systematic review were of reasonable quality, with one trial using a central computerised randomisation service, 12 using sealed opaque envelopes, and two using methods that were centrally controlled, but not concealed for treatment allocation.[24] Although the experimental intervention was always described as one to one support, the experience, relationship to the labouring woman, timing, and duration of support varied between trials. The pragmatic trials took place in a wide variety of settings (Australia, Belgium, Botswana, Canada, Finland, France, Greece, Guatemala, Mexico, South Africa, and the USA).

OPTION UPRIGHT POSITION DURING DELIVERY

One systematic review found that any upright position marginally reduced episiotomies compared with the supine or lateral positions for delivery but this was offset by an increase in second degree tears. Rates of assisted vaginal delivery were slightly reduced in the upright group.

Benefits: We found one systematic review (substantially amended March 1999, search date not reported, 18 RCTs, 5307 women) comparing any upright position for delivery (birthing chairs, stools, cushions, and squatting) with supine or lateral positions.[25] It found that the upright position significantly reduced the episiotomy rate but this was offset by an increase in second degree tears (episiotomy, 11 RCTs, 3846 women: 667/1922 [35%] in upright position *v* 782/1924 [41%] in supine or lithotomy position; RR 0.84, 95% CI 0.78 to 0.91; NNH 17, 95% CI 12 to 35; tears, 10 RCTs, 4257 women: 384/2108 [18%] in upright position *v* 339/2149 [16%] in supine or lithotomy position; RR 1.21, 95% CI 1.07 to 1.37; NNH 40, 95% CI 20 to 574). There was a marginal but significant reduction in assisted vaginal deliveries in the upright group and no significant difference in rates of third and fourth degree tears (assisted vaginal delivery, 17 RCTs, 5267 women: 261/2617 [10%] in upright position *v* 308/2650 [12%] in supine or lithotomy position; RR 0.86, 95% CI 0.73 to 1.00; third and fourth degree tears, 4 RCTs, 1478 women: 5/719 [0.7%] in upright position *v* 6/759 [0.8%] in supine or lithotomy position; RR 0.91, 95% CI 0.31 to 2.68).[25]

Harms: The review found that women delivering in the upright position were slightly more at risk of blood loss estimated to be greater than 500 mL and blood transfusion (blood loss > 500 mL, 10 RCTs, 4303 women: 139/2136 [6%] in upright position *v* 82/2167 [4%] in supine or lithotomy position; RR 1.72, 95% CI 1.32 to 2.23; NNH 36, 95% CI 21 to 82; blood transfusion, 2 RCTs, 1747 women: 14/891 [2%] in upright position *v* 8/856 [1%] in supine or lithotomy position; RR 1.66, 95% CI 0.70 to 3.94).[25]

Comment: The findings of this systematic review should be interpreted with caution because of the variable qualities of the trials and diversity of the treatment interventions (squatting, kneeling, Gardosi cushion [see glossary, p 1869], birthing chair).[25] The reviewers state that the main outcome measures may have been affected because of

participants being excluded from some of the trials after randomisation, and several women allocated to deliver in the upright position had difficulty complying. Further, well designed trials are needed, with particular attention given to methodological and clinical heterogeneity, observer bias, intention to treat analysis, and standardised objective measurements of blood loss.

OPTION ALTERNATIVE METHODS OF BEARING DOWN (PUSHING)

One systematic review of two poor quality controlled clinical trials found no significant difference in the extent or rate of perineal trauma between sustained breath holding (Valsalva) and spontaneous exhalatory methods of pushing during the second stage of labour. One additional RCT comparing passive fetal descent with immediate active pushing also found no significant difference in the rates of perineal trauma.

Benefits: We found one systematic review (search date 1993, 5 trials, of which 2 were known to be RCTs, 471 women) comparing bearing down by sustained breath holding (Valsalva) versus exhalatory or spontaneous pushing.[26] Only two of the trials provided data on perineal trauma requiring suturing, and they found no significant difference between the two interventions (2 RCTs, 338 women; 57/172 [33%] with sustained Valsalva *v* 66/166 [40%] with exhalatory bearing down; RR 0.83, 95% CI 0.61 to 1.10). One additional RCT (252 women) compared passive fetal descent (see glossary, p 1869) versus active pushing from the start of the second stage of labour.[27] It found no significant difference between bearing down methods for rates of perineal laceration or instrumental delivery (laceration rate in primiparous women 46.9% with passive descent *v* 46.2% with active pushing, P = 0.94; laceration rate in multiparous women 36.4% with passive descent *v* 33.3% with active pushing, P = 0.73; rate of instrumental delivery in primiparous women 22.6% with passive descent *v* 29.7% with active pushing, P = 0.36; rate of instrumental delivery in multiparous women 3.1% with passive descent *v* 12.7% with active pushing, P = 0.078; CI not reported).

Harms: It is unclear whether the rate of adverse perineal outcomes is affected by different types of bearing down during the second stage of labour.

Comment: The review included published and unpublished trials.[26] Three of the trials were small and of very poor quality. Two of these trials found reduced rates of perineal trauma in the spontaneous bearing down group, but this was not supported by data from the two subsequent, more robust controlled trials.

OPTION "HANDS POISED" VERSUS "HANDS ON"

One multicentre RCT and one quasi-randomised trial found that the "hands poised" method (not touching the baby's head or supporting the mother's perineum) reduced episiotomy rates compared with the conventional "hands on" method (applying pressure to the baby's head during delivery and supporting the mother's perineum). The RCT found no evidence of an effect on the risk of perineal trauma, but found that the "hands poised" group had an increased risk of requiring manual removal of the placenta and higher rates of short term perineal pain.

Benefits: We found no systematic review. We found one randomised and one quasi-randomised trial comparing the "hands poised" versus the "hands on" method of delivery. The RCT (5471 women) found that the "hands poised" method significantly reduced the episiotomy rate compared with the "hands on" method (280/2740 [10%] with "hands poised" *v* 351/2731 [13%] with "hands on"; RR 0.79, 95% CI 0.65 to 0.96; NNT 38, 95% CI 23 to 106).[2] It found no significant difference between methods in the risk of perineal trauma requiring suturing or third and fourth degree tears (suturing required: 1636/2740 [60%] with "hands poised" *v* 1605/2731 [59%] with "hands on"; RR 1.02, 95% CI 0.97 to 1.06; third and fourth degree tears: 40/2740 [1.5%] with "hands poised" *v* 31/2731 [1.2%] with "hands on"; RR 1.3, 95% CI 0.81 to 2.05). The quasi-randomised trial (1161 women) found that the "hands poised" method significantly reduced episiotomy rates and third degree tears (episiotomy: 51/502 [10%] with "hands poised" delivery *v* 103/574 [18%] with "hands on"; RR 0.57, 95% CI 0.41 to 0.78; third degree tears: 5/502 [1.0%] with "hands poised" *v* 16/574 [2.8%] with "hands on"; RR 0.36, 95% CI 0.13 to 0.97).[28] There was no significant difference in the rate of first and second degree perineal trauma (175/502 [35%] with "hands poised" *v* 171/574 [30%] with "hands on"; RR 1.17, 95% CI 0.98 to 1.39).

Harms: The RCT found that the "hands poised" method significantly increased the risk of requiring manual removal of the placenta and significantly increased perineal pain 10 days after delivery (manual removal: 71/2740 [2.6%] with "hands poised" *v* 42/2731 [1.5%] with "hands on"; RR 1.69, 95% CI 1.16 to 2.46; NNH 95, 95% CI 45 to 417; perineal pain: 910/2669 [34%] with "hands poised" *v* 823/2647 [31%] with "hands on"; RR 1.10, 95% CI 1.02 to 1.19; NNH 33, 95% CI 18 to 212).[2]

Comment: The RCT was a large robust multicentre pragmatic trial carried out in the UK and the results are likely to be generalisable.[2] The quasi-randomised trial, carried out in the University Hospital of Vienna, used alternate allocation based on the date of delivery: even days allocated to "hands on", odd days to "hands poised". Data were missing for 45 women in the "hands poised" group and 40 in the "hands on" group.[28]

QUESTION What are the effects of different methods and materials for primary repair of first and second degree tears and episiotomies?

OPTION NON-SUTURING

We found two small RCTs that compared the effects of non-suturing versus suturing of muscle and skin for first and second degree tears. The first found a non-significant increase in short term discomfort with non-suturing but no evidence of a difference in healing. The second RCT found no significant difference between methods in perineal pain but found that non-suturing reduced good wound healing compared with suturing at 6 weeks after delivery. Two RCTs that compared leaving only the perineal skin unsutured versus suturing of the skin found different results. One RCT found no significant difference in perineal pain at 10

days after birth but the second RCT found that non-suturing reduced pain up to 3 months following delivery. Both RCTs found that non-suturing of perineal skin reduced dyspareunia up to 3 months after birth.

Benefits: We found no systematic review. **Non-suturing of perineal muscle and skin:** We found two small RCTs comparing non-suturing with suturing of first and second degree tears.[29,30] Results from the first small RCT (78 primiparous women in Sweden) should be interpreted with caution (see comment below).[29] It found that women in the non-suture group reported a non-significant increase in rates of a "burning sensation" and soreness at 2–3 days after birth (burning sensation: 9/40 [23%] in non-sutured *v* 4/38 [11%] in sutured; RR 0.47, 95% CI 0.16 to 1.39; soreness: 3/40 [8%] in non-sutured *v* 1/38 [3%] in sutured; RR 0.35, 95% CI 0.04 to 3.23). There was no significant difference in healing at 2–3 days and 8 weeks after birth (see comment below).[29] The second RCT (74 primiparous women in Scotland) found no significant difference in McGill pain scores at 10 days and 6 weeks between the non-sutured and sutured groups (P = 0.8 at both 10 days and 6 weeks), but found that wound healing was significantly poorer with non-suturing up to 6 weeks following delivery (26/31 [84%] in sutured *v* 16/36 [44%] in non-sutured; RR 0.53, 95% CI 0.36 to 0.29).[30] **Non-suturing of perineal skin alone:** We found two RCTs that compared leaving the perineal skin unsutured but apposed (the vagina and perineal muscle were sutured) with a conventional repair in which all three layers were sutured.[31,32] The RCTs found different results for perineal pain. The first RCT (1780 primiparous and multiparous women with first and second degree tears or episiotomies after spontaneous or assisted vaginal delivery in a single UK centre) found no significant difference in perineal pain at 10 days after birth (221/886 [25%] with skin unsutured *v* 244/885 [28%] with skin sutured; RR 0.91, 95% CI 0.77 to 1.06).[31] The second RCT was a multicentre trial carried out in Nigeria (823 women who sustained a second degree tear or episiotomy).[32] It found that leaving the perineal skin unsutured significantly reduced the proportion of women with perineal pain at 48 hours, 14 days, 6 weeks, and 3 months following delivery (48 hours: 237/417 [57%] with skin unsutured *v* 265/406 [65%] with skin sutured; RR 0.87, 95% CI 0.78 to 0.97; 14 days: 93/417 [22%] with skin unsutured *v* 117/406 [29%] with skin sutured; RR 0.77, 95% CI 0.61 to 0.98; 6 weeks: 41/417 [10%] with skin unsutured *v* 62/406 [15%] with skin sutured; RR 0.64, 95% CI 0.44 to 0.93; 3 months: 4/417 [1%] with skin unsutured *v* 21/406 [5%] with skin sutured; RR 0.19, 95% CI 0.06 to 0.54). Both RCTs found that leaving the perineal skin unsutured significantly reduced superficial dyspareunia at 3 months after birth (first RCT:[31] 128/828 [16%] with skin unsutured *v* 162/836 [19%] with skin sutured; RR 0.80, 95% CI 0.64 to 0.99; NNT 26, 95% CI 14 to 345; second RCT:[32] 26/417 [6%] with skin unsutured *v* 49/406 [12%] with skin sutured; RR 0.52, 95% CI 0.33 to 0.81).

Harms: **Non-suturing of perineal muscle and skin:** See benefits above. No additional harms were reported in the two identified RCTs.[29,30] **Non-suturing of perineal skin alone:** See benefits above. The two RCTs found that leaving the perineal skin unsutured but apposed increased rates of wound gaping at 48 hours compared with suturing (203/885 [23%] with skin unsutured *v* 40/889 [4%] with skin

sutured; RR 5.10, 95% CI 3.68 to 7.06[31] and 107/417 [26%] with skin unsutured *v* 21/406 [5%] with skin sutured; RR 4.96, 95% CI 3.17 to 7.76[32]). One RCT found that non-suturing of the skin increased wound gaping at 10 days[31] but the second RCT found no significant differences in wound gaping at 14 days and 6 weeks after birth (day 10: 227/886 [26%] with skin unsutured *v* 145/885 [16%] with skin sutured; RR 1.56, 95% CI 1.30 to 1.88;[31] 14 days: 86/417 [21%] with skin unsutured *v* 67/406 [17%] with skin sutured; RR 1.25, 95% CI 0.94 to 1.67;[32] longer term results were not reported in the second RCT[32]). The second RCT judged wounds as gaping if the edges were more than 0.5 cm apart.[32] One RCT found no significant differences in wound breakdown at 14 days (13/417 [3%] with skin unsutured *v* 10/406 [2%] with skin sutured; RR 1.27, 95% CI 0.56 to 2.85).[32]

Comment: **Non-suturing of perineal muscle and skin:** Results from one of the small RCTs[29] comparing non-suturing versus suturing must be interpreted with caution because the study limitations compromise the validity of these results. It is unclear how healing was defined and assessed, and the study had an insufficient sample size to rule out clinically important differences. This is suggested by the broad confidence intervals in the presence of a big difference in rates between the study groups. The second small RCT evaluating non-suturing versus suturing was of reasonable methodological quality and used sealed opaque envelopes to allocate treatment. It was acknowledged that it was impossible to blind assessors to the allocated treatment and that this may have biased results.[30] **Non-suturing of perineal skin alone:** The two RCTs evaluating non-suturing of perineal skin were pragmatic studies, and the results are likely to be generalisable.[31,32] The subsequent RCT recruited 1077 women into the trial but only 823 of these responded up to 3 months after birth and were included in the analysis.[32]

OPTION ABSORBABLE SUTURES

One systematic review has found that absorbable synthetic sutures reduce pain at up to 10 days after birth compared with catgut sutures. One subsequent RCT, however, found no significant difference in perineal pain at 3 days, although it may have lacked power to detect a clinically important effect. The systematic review and the subsequent RCT found no significant difference between absorbable synthetic sutures and catgut sutures in pain or dyspareunia at 3 months, but one RCT with 12 months' follow up, which was included in the review, found lower rates of dyspareunia with absorbable synthetic sutures. RCTs found no significant difference between rapidly absorbed and standard synthetic sutures in overall perineal pain, pain on sitting, or dyspareunia. The RCTs found reduced perineal pain on walking with rapidly absorbed synthetic sutures.

Benefits: **Absorbable synthetic sutures versus catgut:** We found one systematic review (search date 1999, 8 RCTs conducted in Europe and the USA, 3681 primiparous and multiparous women)[33] and one subsequent RCT carried out in Australia (391 women who sustained a first or second degree tear or episiotomy following a spontaneous vaginal delivery)[34] that compared absorbable synthetic (standard polyglactin 910 or polyglycolic acid) versus catgut

suture material for perineal repair. The systematic review found that absorbable synthetic material reduced analgesia use within 10 days and reduced rates of suture dehiscence and resuturing (analgesic use: 5 RCTs, 2820 women; AR 262/1422 [18%] with absorbable synthetic v 338/1398 [24%] with catgut; RR 0.74, 95% CI 0.65 to 0.85; NNT 18, 95% CI 13 to 35).[33] At 3 months, there was no significant difference in perineal pain or dyspareunia (perineal pain, 2 RCTs; AR 92/1061 [9%] with absorbable synthetic v 112/1068 [11%] with chromic catgut; RR 0.86, 95% CI 0.64 to 1.08; dyspareunia, 3 RCTs: AR 171/1086 [16%] with absorbable synthetic v 180/1089 [17%] with chromic catgut; RR 0.95, 95% CI 0.79 to 1.15). At 12 months after birth (1 RCT, 793 women),[35] rates of dyspareunia were lower with absorbable synthetic sutures than with chromic catgut (AR 30/395 [8%] with absorbable synthetic v 51/398 [13%] with chromic catgut; RR 0.59, 95% CI 0.39 to 0.91; NNT 20, 95% CI 11 to 106).[36] The subsequent RCT found no significant difference in perineal pain at 3 days or at 3 months, although it may have lacked power to detect clinically important effects (perineal pain at 3 days: 112/187 [60%] with absorbable synthetic v 124/188 [66%] with chromic catgut; RR 0.91, 95% CI 0.78 to 1.06; perineal pain at 3 months: 17/167 [10%] with absorbable synthetic v 14/174 [8%] with chromic catgut; RR 1.26, 95% CI 0.64 to 2.48).[34] The RCT found that absorbable sutures increased dyspareunia at 3 and 6 months and perineal pain at 6 months, but neither difference was statistically significant (dyspareunia at 3 months: 35/132 [27%] with absorbable synthetic v 27/144 [19%] with chromic catgut; RR 1.41, 95% CI 0.91 to 2.20; perineal pain at 6 months: 9/158 [6%] with absorbable synthetic v 5/159 [3%] with chromic catgut; RR 1.81, 95% CI 0.62 to 5.28; dyspareunia at 6 months: 24/148 [16%] with absorbable synthetic v 19/147 [13%] with chromic catgut; RR 1.25, 95% CI 0.72 to 2.19).[34] **Different types of absorbable synthetic suture:** We found no systematic review. We found three RCTs comparing rapidly absorbed polyglactin 910 with standard polyglactin 910 (153 women in Northern Ireland;[37] 308 primiparous women in Demark;[38] 1542 women in the UK[39]). The first RCT did not report data in a format that was suitable for inclusion here.[37] The other two RCTs both found that rapidly absorbed sutures were associated with reduced pain on walking in the 2 weeks post partum (AR 46/138 [33.3%] with rapidly absorbed v 65/134 [48.5%] with standard; RR 0.69, 95% CI 0.51 to 0.92;[38] AR 259/769 [33.7%] with rapidly absorbed v 314/770 [40.8%] with standard; RR 0.83, 95% CI 0.73 to 0.94[39]). There was no significant difference in overall perineal pain, pain on sitting, or dyspareunia. Rapidly absorbed sutures were removed less frequently during the 3 months post partum (22/769 [2.7%] with rapidly absorbed v 98/770 [12.7%] with standard; RR 0.23, 95% CI 0.14 to 0.35).[39]

Harms:

Absorbable synthetic sutures versus catgut: The systematic review[33] found that suture removal was more common in the absorbable synthetic group than in the catgut group up to 3 months after birth (2 RCTs, 2129 women: 191/1061 [18%] with absorbable synthetic v 108/1068 [10%] with chromic catgut; RR 1.78,

95% CI 1.44 to 2.20; NNH 13, 95% CI 8 to 22).[29,36] The subsequent RCT found that more people repaired with absorbable synthetic material reported problems with their sutures at 6 weeks compared with people repaired with catgut (8/184 [4.4%] with absorbable synthetic material v 3/184 [1.6%] with catgut).[34] **Different types of absorbable synthetic suture:** Suture removal was less frequent in the rapidly absorbed polyglactin 910 group than in the standard polyglactin 910 group (22/769 [3%] with rapidly absorbed polyglactin v 98/770 [13%] with standard polyglactin; OR 0.26, 95% CI 0.18 to 0.37).[39]

Comment: **Absorbable synthetic sutures versus catgut:** The trials in the systematic review varied in quality and in operator skills and training. It was not possible to "blind" outcome assessment because of the obvious differences in method and materials used. Most of the trials used "intention to treat" as the method of analysis. The subsequent RCT used sealed opaque envelopes for treatment allocation and analysis was by intention to treat.[34] It was not possible to blind operators to allocated treatments due to obvious differences in suture materials. Follow up was by face to face interview until participants were discharged from hospital and then via telephone interview. The RCT was powered to detect a reduction in short term pain from 60% to 45%. **Different types of absorbable synthetic suture:** The RCT comparing different types of absorbable sutures also compared continuous versus interrupted sutures for all layers (see continuous sutures, p 1867).[39] Suture materials were produced by the manufactures in an identical form in order to "blind" allocated treatments from the participants, operators, and assessors. It was a large, robust trial, and its results are likely to be generalisable.[39]

OPTION CONTINUOUS SUTURES

One systematic review has found that continuous subcuticular sutures for perineal skin reduced short term pain compared with interrupted sutures, but there was no significant difference in perineal pain or dyspareunia at 3 months post partum. One RCT found that a loose continuous suture reduced short term perineal pain and suture removal up to 3 months post partum compared with interrupted sutures for repair of all layers.

Benefits: **For repair of perineal skin:** We found one systematic review that compared continuous subcuticular with interrupted sutures inserted close to the perineal skin to appose the perineal skin (search date 1999, 4 RCTs conducted in Europe and the UK, 1864 primiparous and multiparous women).[40] Meta-analysis found that continuous sutures reduced short term pain (pain up to day 10, 3 RCTs, 1588 women: 160/789 [20%] with continuous *v* 218/799 [27%] with interrupted; RR 0.75, 95% CI 0.63 to 0.89; NNT 14, 95% CI 10 to 34). There was no significant difference in pain at 3 months (1 RCT, 961 women: 58/465 [13%] with continuous *v* 51/451 [11%] with interrupted; RR 1.10, 95% CI 0.77 to 1.57). Sutures were removed less frequently up to 3 months post partum (1 RCT, 916 women: 121/465 [26%] with continuous *v* 166/451 [37%] with interrupted; RR 0.71, 95% CI 0.58 to 0.86; NNT 9, 95% CI 6 to 20).[40] **For repair of all layers:** We found no systematic

review. We found one RCT (1542 women with second degree tears or episiotomy in the UK) comparing a loose continuous suture for all layers with interrupted sutures.[39] It found that continuous sutures reduced short and long term pain (at 10 days: 204/770 [26.5%] with continuous *v* 338/769 [44.0%] with interrupted; RR 0.60, 95% CI 0.52 to 0.70; at 3 months: 70/751 [9%] with continuous *v* 95/741 [13%] with interrupted; RR 0.73, 95% CI 0.54 to 0.97; at 12 months: 31/700 [4%] with continuous *v* 47/689 [7%] with interrupted; RR 0.65, 95% CI 0.42 to 1.01). No significant differences were found in rates of local dyspareunia at 3 or 12 months (at 3 months: 98/581 [17%] with continuous *v* 102/593 [17%] with interrupted; RR 0.98, 95% CI 0.76 to 1.26; at 12 months: 94/658 [14%] with continuous *v* 91/667 [14%] with interrupted; RR 1.05, 95% CI 0.80 to 1.37). Continuous sutures were removed less frequently up to 3 months post partum (24/770 [3%] with continuous *v* 96/769 [12%] with interrupted; RR 0.25, 95% CI 0.16 to 0.39).[39]

Harms: **For repair of all layers:** Suture removal was more common up to 3 months after birth in the interrupted suture group than in the continuous group (96/769 [12%] with interrupted *v* 24/770 [3%] with continuous; RR 4.01, 95% CI 2.59 to 6.19).[39]

Comment: The RCT comparing continuous with interrupted sutures for all layers also compared different types of absorbable sutures (see absorbable sutures, p 1865). It was a large, robust trial, and its results are likely to be generalisable.[39]

QUESTION **What are the effects of different methods and materials for primary repair of third and fourth degree tears?**

OPTION **DIFFERENT METHODS AND MATERIALS FOR REPAIR OF THIRD AND FOURTH DEGREE TEARS**

One small RCT comparing the overlap with the end-to-end method for primary repair of third degree obstetric tears found no significant difference in perineal discomfort and a non-significant reduction in the rate of reported faecal urgency and anal incontinence.

Benefits: We found no systematic review. We found one small RCT (112 primiparous women in Ireland) comparing overlap with end-to-end (see glossary, p 1869) approximation for primary repair of third degree obstetric anal sphincter tears.[41] It found no significant difference in perineal discomfort, faecal urgency or faecal incontinence (perineal discomfort: 20/55 [36%] with overlap *v* 22/57 [39%] with end-to-end; RR 0.94, 95% CI 0.58 to 1.52; faecal urgency: 11/55 [20%] with overlap *v* 17/57 [30%] with end-to-end; RR 0.67, 95% CI 0.35 to 1.30; faecal incontinence: 2/55 [4%] with overlap *v* 5/57 [9%] with end-to-end; RR 0.42, 95% CI 0.08 to 2.05).

Harms: The RCT assessed the presence of residual defects of the anal sphincter with ultrasound and found no significant differences between groups. Two thirds (74/112 [66.0%]) of women had a

residual full thickness defect in the external anal sphincter ultrasound after primary repair at 3 months post partum (34/55 [62.0%] with overlap *v* 40/57 [70.0%] with end-to-end; RR 0.88, 95% CI 0.67 to 1.15). No other harms were reported and the clinical significance of this finding is unclear.

Comment: A pilot study for an RCT comparing the overlap with the end-to-end method for repair of third and fourth degree obstetric anal sphincter tears should be published later this year (Fernando R, personal communication, 2003).

GLOSSARY

Continuous support during labour The presence of a companion (lay person or health care worker) who provides continuous social support for the woman during the intrapartum period; social support may include advice, information, assistance, or emotional support.

End-to-end technique for primary repair of third degree obstetric anal sphincter tears involves the torn ends of the external anal sphincter being juxtaposed with interrupted sutures.

Gardosi cushion An obstetric aid used during the second stage of labour, which allows most of the woman's weight to rest on her thighs instead of her feet, while being in a squatting position.

Overlap technique for primary repair of third degree obstetric anal sphincter tears involves the torn ends of the external anal sphincter being overlapped and sutured with interrupted stitches.

Passive fetal descent An alternative method of bearing down, involving a period of rest to allow passive descent of the fetus before active pushing.

Substantive changes

Vacuum extraction versus forceps One RCT added;[23] categorisation unchanged.

Continuous support during labour One systematic review added, which found that continuous support during labour reduces the rate of operative vaginal birth (vacuum extraction or forceps) compared with usual care.[24] Continuous support during labour recategorised to Beneficial.

Non-suturing Two RCTs added.[30,32] Categorisation for non-suturing of muscle and skin changed to Likely to be ineffective or harmful, because of evidence of poorer wound healing.

Absorbable sutures One RCT added;[34] categorisation unchanged.

Perineal care

Chris Kettle
Dr (PhD); Clinical Midwife Specialist
University Hospital of North Staffordshire (NHS Trust), Stoke-on-Trent, UK

Competing interests: The author was the recipient of a fellowship from the Iolanthe Midwifery Research Trust, which provided funding to enable her to carry out a randomised controlled trial of perineal repair after childbirth — The Methods or Materials Study (MOMS). The Iolanthe Midwifery Research Trust and Ethicon Ltd, UK (manufacturers of suture material) provided funding for employment of a part time data management clerk for the trial. The author has received a Smith & Nephew Fellowship 2001–2002, to provide funding to allow her to complete her research (MOMS) and PhD thesis.
We would like to acknowledge the previous contributors of this chapter, including Bazian Ltd.

Postnatal depression

Unknown effectiveness

Covered elsewhere in *Clinical Evidence*

Depressive disorders, p 1278

*Limited evidence of short term benefit from one small RCT which excluded breast feeding women

See glossary, p 1884

Key Messages

- **Antidepressants (fluoxetine)** Limited evidence from one small RCT suggests that fluoxetine may improve postnatal depression at 4 and 1)2 weeks compared with placebo. The RCT had problems with recruitment and a high drop out rate, and it excluded breastfeeding women. We found no RCTs that satisfactorily compared fluoxetine versus psychological treatment.
- **Cognitive behavioural therapy (individual)** One RCT provided limited evidence that individual cognitive behavioural therapy and ideal standard care both improved depressive symptoms, but that there was no difference between the two interventions. Limited evidence from one RCT suggests that individual cognitive behavioural therapy may improve postnatal depression in the short term (immediately after treatment) compared with routine primary care. The RCT found no clear longer term benefits (9 months to 5 years post partum) from individual cognitive behavioural therapy in comparison with routine primary care, non-directive counselling, or psychodynamic therapy.
- **Interpersonal psychotherapy** One RCT found that interpersonal psychotherapy improved postnatal depression compared with waiting list controls at 12 weeks.
- **Non-directive counselling** Limited evidence from two RCTs suggests that in the short term (immediately after treatment) non-directive counselling may improve postnatal depression compared with routine primary care. The one RCT with follow up beyond 12 weeks found no clear longer term benefits (from 9 months to 5 years post partum) from non-directive counselling compared with routine primary care, individual cognitive behavioural therapy, or psychodynamic therapy.

- **Psychodynamic therapy** Limited evidence from one RCT suggests that psychodynamic therapy may improve postnatal depression in the short term (immediately after treatment) compared with routine primary care. The RCT found no clear longer term benefits (9 months to 5 years post partum) from psychodynamic therapy compared with routine primary care, non-directive counselling, or cognitive behavioural therapy.
- **Antidepressants other than fluoxetine** We found no RCTs on the effects of antidepressants in women with postnatal depression, and no RCTs that satisfactorily compared antidepressants other than fluoxetine versus psychological treatments.
- **Cognitive behavioural therapy (group)** One small RCT in women with a high level of depressive symptoms on screening found that group cognitive behavioural therapy improved symptoms at 6 months compared with routine primary care.
- **Hormones** Limited evidence from one small RCT in women with severe postnatal depression suggests that oestrogen treatment may improve postnatal depression at 3 and 6 months compared with placebo.
- **Light therapy** We found no RCTs evaluating light therapy.
- **Mother–infant interaction coaching** One small RCT found that mother–infant interaction coaching had no significant effect on maternal depression scores compared with usual treatment, but it improved maternal responsiveness to the infant within 10 weeks of starting treatment.
- **Psychoeducation with partner** One small RCT found that psychoeducation with partner reduced patients' depression scores and partners' psychiatric morbidity compared with psychoeducation without partner.
- **Telephone based peer support (mother to mother)** One small RCT found that telephone based peer support reduced depression scores after 8 weeks compared with usual treatment.

DEFINITION Postnatal depression (PND) is broadly defined as non-psychotic depression occurring during the first 6 months post partum. Puerperal mental disorders have only recently been categorised separately in psychiatric classifications, but both the International Classification of Diseases (ICD-10)[1] and the Diagnostic and Statistical Manual of mental disorders, fourth edition (DSM-IV) require certain qualifications to be met that limit their use: ICD-10 categorises mental disorders that occur post partum as puerperal but only if they cannot otherwise be classified, and DSM-IV allows "postpartum onset" to be specified for mood disorders starting within 4 weeks' post partum.[2] In clinical practice and research the broader definition above is often used, because whether or not PND is truly distinct from depression in general, depression in the postpartum period raises treatment issues for the nursing mother and has implications for the developing infant (see prognosis below). The symptoms are similar to symptoms of depression at other times of life, but in addition to low mood, sleep disturbance, change in appetite, diurnal variation in mood, poor concentration, and irritability, women with postnatal depression also experience guilt about their inability to look after their new baby. In many countries, health visitors screen for PND using the Edinburgh Postnatal Depression Scale (see glossary, p 1884),[3,4] which elicits depressive symptoms.

Postnatal depression

INCIDENCE/ PREVALENCE The prevalence of depression in women post partum is similar to that found in women generally. However, the incidence of depression in the first month after childbirth is three times the average monthly incidence in non-childbearing women.[5] Studies across different cultures have shown a consistent incidence of postnatal depression (10–15%),[6] with higher rates in teenage mothers. A meta-analysis of studies mainly based in the developed world found the incidence of postnatal depression to be 12–13%.[7]

AETIOLOGY/ RISK FACTORS Three systematic reviews have identified the following risk factors for postnatal depression: past history of any psychopathology (including history of previous postnatal depression), low social support, poor marital relationship, and recent life events.[7–9]

PROGNOSIS Most episodes of PND resolve spontaneously within 3–6 months,[10] but about one in four affected mothers are still depressed on the child's first birthday.[11] In the developed world, suicide is now the main cause of maternal deaths in the first year post partum,[12] but the suicide rate is lower at this time than in age matched non-postpartum women.[13] PND is also associated with reduced likelihood of secure attachment,[14] deficits in maternal–infant interactions,[15] and impaired cognitive and emotional development of the child, particularly in boys living in areas of socioeconomic deprivation.[15–17] These associations remain significant even after controlling for subsequent episodes of depression in the mother.

AIMS OF INTERVENTION To improve symptoms, quality of life, mother–infant interaction, with minimal adverse effects on mother and child.

OUTCOMES Symptom scores (e.g. the Edinburgh Postnatal Depression Scale[3,4]) and other scales used in studies of depression at other times in life (see depressive disorders, p 1278) quality of life, mother–infant interaction (rated using questionnaires or observer rated videos), effect on marital/family relationship (rated using questionnaires), rates of suicide.

METHODS *Clinical Evidence* search and appraisal May 2003. We searched Medline (1996 to date), Embase (1980 to date), the Cochrane Library 2003, Issue 2, and two independent critical appraisers appraised the results. We included only RCTs with a minimum of 6 weeks' follow up. We included non-blinded studies as it can be difficult to blind patients and assessors to psychological interventions.

QUESTION What are the effects of treatments? New

OPTION ANTIDEPRESSANTS

Limited evidence from one small RCT suggests that fluoxetine may improve postnatal depression at 4 and 12 weeks compared with placebo. The RCT had problems with recruitment and a high drop out rate, and it excluded breastfeeding women. We found no RCTs that satisfactorily compared fluoxetine versus psychological treatment. We found no RCTs on the effects of other antidepressants in women with postnatal depression, and no RCTs that satisfactorily compared other antidepressants versus psychological treatments.

Benefits: We found three systematic reviews (search dates 1998,[18] 1999,[19] and 2000[20]). All three reviews found the same single RCT[21] (87 women recruited from community based screening, 51 with a major and 36 with a minor depressive episode defined by research diagnostic criteria[22]). This trial conducted a four way comparison: fluoxetine 20 mg plus one session (the assessment session) of cognitive behavioural counselling (see glossary, p 1884), fluoxetine 20 mg plus six sessions of cognitive behavioural counselling, and placebo plus one session of cognitive behavioural counselling, placebo plus six sessions of cognitive behavioural counselling. Outcomes were assessed at 4 and 12 weeks using the Clinical Interview Schedule (revised),[23] the Edinburgh Postnatal Depression Scale (see glossary, p 1884),[3,4] and the Hamilton Depression Scale,[24] using an intention to treat analysis. The trial had several weaknesses (see comment below). Fluoxetine significantly reduced depression scores measured as part of the revised Clinical Interview Schedule at 4 and 12 weeks compared with placebo (percentage difference of geometric mean scores between fluoxetine and placebo at 4 weeks: 37.1%, 95% CI 5.7% to 58.0%; at 12 weeks: 40.7%, 95% CI 10.9% to 60.6%). The trial did not report on infant outcomes.

Harms: **Effects on the infant:** The RCT excluded breastfeeding mothers and did not report on adverse effects on the infant.[21] We found some evidence of short term adverse effects in infants whose mothers were using antidepressants while breastfeeding.[25] A review of 95 case reports and small case series on the use of psychotropic medications during breastfeeding found one case of respiratory depression in a nursing infant whose mother was treated with doxepin, which resolved 24 hours after discontinuation of breastfeeding.[25] The review also identified 10 cases of adverse effects in 190 nursing infants whose mothers were treated with fluoxetine. Six infants had unconfirmed and unspecified adverse effects that resolved spontaneously. Three infants were reported to have colic. One infant had an episode of transient seizure-like activity at 3 weeks of age and episodes of unresponsiveness at 4 months of age, with one episode of peripheral cyanosis at 5.5 months of age. The results of neurological monitoring were within normal limits up to 1 year of age. The review found no adverse effects in the infants of breastfeeding mothers taking other tricyclic antidepressants. A review of three controlled follow up studies of antidepressants used during breastfeeding (79 infants) found no infant developmental abnormalities with tricyclics or sertraline.[26] We found no good evidence on long term risks to the developing child from maternal use of antidepressants. **Effects on the mother:** The RCT reported no suicides in the 12 week follow up period.[21] See harms of antidepressants in the chapter on depressive disorders, p 1278.

Comment: The RCT had several weaknesses.[21] Most of the women who were approached (101/188 [54%]) refused to participate, most commonly because of reluctance to take antidepressants. A further 26/87 (30%) of the participants dropped out after randomisation.

However, the authors performed an appropriate intention to treat analysis. The design of the trial does not allow comparison between fluoxetine and cognitive behavioural counselling as all the women received one session of cognitive behavioural counselling.

OPTION HORMONES

Limited evidence from one small RCT in women with severe postnatal depression suggests that oestrogen treatment may improve postnatal depression at 3 and 6 months compared with placebo.

Benefits: We found two systematic reviews (search dates 2000[20] and 2001[27]), both of which found the same single RCT[28] (61 women with major depression beginning within 3 months post partum who, at enrolment, were < 18 months post partum, recruited from outpatient clinics, general practitioners, and self referrals). Women were excluded if they were breastfeeding, had a medical history that would contraindicate oestrogen therapy, or had changed psychotropic medication in the previous 6 weeks. The RCT compared oestrogen treatment (oestradiol skin patches for 6 months plus additional dydrogesterone tablets for 12 days each month) versus placebo (patches and tablets). After 3 and 6 months, the women taking oestrogen had significantly lower Edinburgh Postnatal Depression Scale scores (see glossary, p 1884) than those taking placebo (WMD at 3 months –3.20, 95% CI –5.97 to –0.43; at 6 months –4.38, 95% CI –1.89 to –6.87). The trial did not report on infant outcomes.

Harms: **Effects on the infant:** The RCT did not report on adverse effects on the infant.[28] **Effects on the mother:** Endometrial curettage at the end of treatment showed endometrial changes (details not reported) in three women in the treatment group, which had resolved by follow up at 9 months.[28] One woman in the oestrogen group, who had been admitted to a psychiatric ward soon after the start of the study because of her worsening mental state, committed suicide. However, her clinical consultant had stopped the oestrogen treatment soon after admission. For harms of oestrogen treatment see also menopausal symptoms, p 2459 and secondary prevention of ischaemic cardiac events, p 197.

Comment: None.

OPTION LIGHT THERAPY

We found no RCTs evaluating light therapy.

Benefits: We found one systematic review (search date 2000, no RCTs)[20] and no subsequent RCTs.

Harms: We found no good information on adverse effects of light therapy.

Comment: Case studies of two women with postnatal depression found a drop in depression scores with 4 weeks of daily light therapy.[29]

OPTION NON-DIRECTIVE COUNSELLING

Limited evidence from two RCTs suggests that in the short term (immediately after treatment) non-directive counselling may improve postnatal depression compared with routine primary care. The one RCT

with follow up beyond 12 weeks found no clear longer term benefits (from 9 months to 5 years post partum) from non-directive counselling in comparison with routine primary care, individual cognitive behavioural therapy, or psychodynamic therapy.

Benefits: We found three systematic reviews (search dates 1997,[30] 2000,[20] and 2001[31]), all of which found the same single RCT.[32] We also found one subsequent RCT.[33,34] The RCT identified by all three reviews (55 women with depression defined by research diagnostic criteria,[21] recruited from the community up to 13 weeks' post partum) compared non-directive counselling, delivered by trained health visitors for 8 weeks, versus routine primary care.[32] The subsequent larger RCT (193 women with major depression [DSM-III-R][2] recruited from the community within 8 weeks' post partum) had several methodological flaws (see comment below). It compared non-directive counselling, psychodynamic therapy, individual cognitive behavioural therapy, and routine primary care conducted in the women's homes by trained therapists on a weekly basis from 8 to 18 weeks' post partum.[33,34] Outcomes, assessed at 4.5 months, 9 months, 18 months, and 5 years post partum were: the proportion of women with a diagnosis of depression, using the Structured Clinical Interview for DSM-III-R Diagnoses (SCID) adjusted for mean baseline SCID scores; depression scores, using the Edinburgh Postnatal Depression Scale (EPDS; see glossary, p 1884); at 4.5 months: mother–infant interactions, using rated videotapes; maternal management of the infant and problems in mother and infant relationship, both using a checklist; at 18 months: infant emotional and behavioural problems using a modified Behavioural Screening Questionnaire with maternal reports, infant attachment using Ainsworth Strange Situation Procedure and infant cognitive development using the Mental Development Index of the Bayley Scales of Infant Development; at 5 years: child emotional and behavioural difficulties, using maternal reports on the Rutter A[2] Scale and teacher reports using the Preschool Behaviour Checklist; and child cognitive development, using the McCarthy Scales. **Versus routine primary care:** The first, smaller RCT found that after an average of 5 weeks' treatment, non-directive counselling significantly reduced the number of women who were categorised as depressed compared with routine primary care (69% with non-directive counselling *v* 38% with routine primary care; difference 31.7%, 95% CI 5% to 58%; P = 0.03).[32] The subsequent, larger RCT found that, immediately after treatment (at 4.5 months' post partum), non-directive counselling increased (though not significantly) the proportion of women without depression compared with routine primary care (26/48 [54%] with non-directive counselling *v* 20/50 [40%] with routine primary care; RR 1.38, 95% CI 0.82 to 1.89).[33,34] It also found that non-directive counselling significantly reduced depression scores compared with routine primary care (mean EPDS score adjusted for mean centred baseline EPDS scores: 9.9 with non-directive counselling *v* 11.3 with routine primary care; treatment effect for non-directive counselling: –2.1, 95% CI –3.8 to –0.3; P = 0.02). It also found that non-directive counselling significantly reduced the proportion of women with mother–infant relationship difficulties compared with routine primary care (proportion of women reporting problems,

adjusted for relationship problems prior to treatment: 53% [23/43] with non-directive counselling *v* 74% [26/35] with routine primary care; RR 0.63, 95% CI 0.32 to 0.97). After controlling for baseline differences between groups, there were no significant differences between non-directive counselling and routine primary care in terms of behavioural management problems (P = 0.77), nor in terms of maternal sensitivity in mother–infant interactions (P = 0.14), except for women with high social adversity, among whom non-directive counselling significantly improved maternal sensitivity (P = 0.04). In the longer term (at 9 months, 18 months, and 5 years post partum), there were no significant differences in any outcomes except for some evidence that non-directive counselling improved infant emotional and behavioural problems compared with routine primary care at 18 months post partum (P = 0.001). However, this outcome relied solely on maternal reports (see comment below). **Versus cognitive behavioural therapy (individual):** The RCT[33,34] found no significant difference between non-directive counselling and individual cognitive behavioural therapy for any outcomes immediately after treatment or in the longer term. There was some evidence that non-directive counselling improved infant emotional and behavioural problems compared with cognitive behavioural therapy at 18 months post partum. However, this outcome relied solely on maternal reports (see comment below). **Versus psychodynamic therapy:** The RCT[33,34] found no significant difference between non-directive counselling and psychodynamic therapy for any outcomes immediately after treatment or in the longer term. There was some evidence that non-directive counselling improved infant emotional and behavioural problems compared with psychodynamic therapy at 18 months post partum. However, this outcome relied solely on maternal reports (see comment below). **Versus antidepressants:** We found no RCTs comparing non-directive counselling versus antidepressants.

Harms: None reported.

Comment: The subsequent, larger RCT[33,34] had several methodological flaws. It was underpowered to detect differences between treatment groups and there was no adjustment for multiple comparisons. More women in the routine primary care group had experienced social adversity compared with the treatment groups (35% in the routine primary care group *v* 30% in the non-directive counselling group *v* 24% in the cognitive behavioural therapy group *v* 10% in psychodynamic therapy group) and this was not controlled for in some analyses. Ten per cent of the women who were randomised did not complete the trial. More women dropped out of the non-directive counselling and psychodynamic therapy groups (6 from the non-directive counselling group *v* 8 from the psychodynamic therapy group *v* 1 from the cognitive therapy group *v* 4 from the routine primary care group). Reasons for non-completion were not investigated and the authors did not perform an intention to treat analysis. Women who did not complete therapy were younger

(P = 0.004) and more likely to be single or separated (P = 0.05). The infant outcomes which showed a beneficial effect of treatment (i.e. fewer mother–infant relationship problems at 4.5 months and fewer emotional and behavioural problems at 18 months) relied solely on maternal reports.

OPTION COGNITIVE BEHAVIOURAL THERAPY (INDIVIDUAL)

One RCT provided limited evidence that individual cognitive behavioural therapy and ideal standard care both improved depressive symptoms, but that there was no difference between the two interventions. Limited evidence from one RCT suggests that individual cognitive behavioural therapy may improve postnatal depression in the short term (immediately after treatment) compared with routine primary care. The RCT found no clear longer term benefits (9 months to 5 years post partum) from individual cognitive behavioural therapy in comparison with routine primary care, non-directive counselling, or psychodynamic therapy.

Benefits: We found no systematic review. We found two RCTs.[33–35] The first RCT (37 women, 32% major depression, 68% minor, recruited from the community) compared modified cognitive behavioural therapy (CBT) delivered by specifically trained early childhood nurses once a week for 6 weeks versus ideal standard care (weekly 20–60 minute appointments for mothercraft advice and non-specific support delivered by early childhood nurses who had not received specific training).[35] For a description of the second RCT and a comment on its methodology see non-directive counselling, p 1877.[33,34] **Versus ideal standard care:** The first RCT found that individual CBT and ideal standard care were both effective in improving depressive symptoms immediately and at 6 months post-treatment but there was no significant difference between the two interventions (Edinburgh Postnatal Depression [EPDS; see glossary, p 1884] mean score: 15.9 pretreatment CBT group *v* 13.7 with ideal standard care, P = 0.03; 8.1 post intervention CBT *v* 6.5 with ideal standard care, P value not reported, reported as not significant; 6.2 at 6 months with CBT *v* 7.7 with ideal standard care, P value not reported, reported as not significant).[35] (See comment below.) **Versus routine primary care:** The second RCT found that immediately after treatment (at 4.5 months post partum), individual CBT increased (though not significantly) the proportion of women without depression compared with routine primary care (57% [24/42] with CBT *v* 40% [20/50] with routine primary care; RR 1.50, 95% CI 0.92 to 1.98).[33,34] It also found that individual CBT significantly reduced depression scores compared with routine primary care (mean EPDS score: 9.2 with CBT *v* 11.3 with routine primary care; treatment effect for CBT –2.7, 95% CI –4.5 to –0.9; P = 0.003). It also found that individual CBT significantly reduced the proportion of women with mother–infant relationship difficulties compared with routine primary care (proportion of women reporting problems, adjusted for relationship problems prior to treatment: 39% [16/41] with CBT *v* 74% [26/35] with routine primary care; RR 0.46, 95% CI 0.2 to 0.81).[33,34] After controlling for baseline differences between groups, there were no significant differences between CBT and routine primary care in terms of behavioural management problems (P = 0.60), nor in terms of mother infant interactions

(results presented graphically; P value not reported). In the medium to longer term (at 9 months, 18 months, and 5 years post partum), there were no significant differences in any outcome, except for infant emotional and behavioural problems, for which CBT achieved significant improvement at 18 months post partum compared with routine primary care (P = 0.06). However, this outcome relied solely on maternal reports (see comment under non-directive counselling, p 1878). **Versus non-directive counselling:** See benefits of non-directive counselling, p 1877. **Versus psychodynamic therapy:** The second RCT found no significant difference between CBT and psychodynamic counselling for any outcomes.[33,34] **Versus antidepressants:** We found no satisfactory RCTs comparing CBT versus antidepressants.

Harms: None reported.

Comment: The first RCT was probably underpowered to compare modified CBT versus ideal standard care effectively. There was a trend towards CBT being more effective. Adjusting for baseline EPDS (which was higher in the CBT group) in a multivariate analysis had no impact on results at any time point.[35] For a comment on the methodology of the second RCT, see comment under non-directive counselling, p 1878.[33,34]

OPTION COGNITIVE BEHAVIOURAL THERAPY (GROUP)

One small RCT in women with a high level of depressive symptoms on screening found that group cognitive behavioural therapy improved symptoms at 6 months compared with routine primary care.

Benefits: We found no systematic review but found one RCT (45 women < 1 year post partum, recruited from the community with the Edinburgh Postnatal Depression Scale [EPDS; see glossary, p 1884] > 12 but no confirmation of diagnosis of postnatal depression by diagnostic interview, block randomised).[36] The RCT compared group cognitive behavioural therapy including education and relaxation, given by two health visitors for 2 hours each week for 8 weeks, versus routine primary care. At 6 months, group cognitive therapy significantly improved depression scores (proportion of women scoring < 13 on the EPDS: 65% [15/23] with group cognitive therapy *v* 36% [8/22] with routine primary care; P = 0.05). The RCT did not report on outcomes in infants.

Harms: None reported.

Comment: The RCT's criteria for inclusion (EPDS > 12) and response to treatment (EPDS < 13) meant that a small change in EPDS would count as a response to treatment.

OPTION PSYCHOEDUCATION WITH PARTNER

One small RCT found that psychoeducation with partner reduced patients' depression scores and partners' psychiatric morbidity compared with psychoeducation without partner.

Benefits: We found one systematic review[20] (search date 2000, 1 RCT,[37] 29 women < 12 months post partum, referred to hospital with major depression of postpartum onset). All women in the RCT attended seven clinic visits for assessment of mood, adjustment of medication and psychoeducation. The women in the intervention group brought their partners to four of the visits. The RCT found significantly lower depression scores in the group attending with their partners at 10 weeks' follow up (mean Edinburgh Postnatal Depression Scale [EPDS; see glossary, p 1884] 8.6 with partner *v* 14.7 without partner; P = 0.01). It also found significantly lower psychological morbidity in partners who attended clinics (mean General Health Questionnaire score 18.4 in partners who attended *v* 43 in the control group; P = 0.01). The RCT did not report on outcomes in infants.

Harms: None reported

Comment: Women taking psychotropic medication were included and no adjustment was made for any potential confounding effect of medication.

OPTION INTERPERSONAL PSYCHOTHERAPY

One RCT found that interpersonal psychotherapy improved postnatal depression compared with waiting list controls at 12 weeks.

Benefits: We found one systematic review (search date 2000, 1 RCT).[20] The RCT[38] (120 women recruited from the community with major depression [DSM-IV criteria and > 11 on the Hamilton Depression Rating Scale; HDRS],[24] for an average duration of 7 months) found that interpersonal psychotherapy, performed by experienced psychotherapists for 1 hour once a week for 12 weeks, significantly increased the proportion of women recovering from depression compared with remaining on a waiting list (proportion of women recovering, defined as HDRS < 7: 31% [19/60] with interpersonal psychotherapy *v* 15% [9/60] with control; RR 2.11, 95% CI 1.04 to 4.28). There were also significant improvements in social adjustments (mean score on the Social Adjustment Scale — Self Report (SAS-SR[39]): 1.93 with interpersonal psychotherapy *v* 2.35 with waiting list control; P < 0.001). Subscales of the SAS-SR showed significant improvements in relationship with spouse (P < 0.001), relationship with children older than 2 years (P < 0.05), relationship with immediate family (P = 0.002), and relationship with friends (P = 0.003; absolute numbers not reported). The Postpartum Adjustment Questionnaire[40] also showed a significant effect of interpersonal psychotherapy (mean reduction 0.30 with interpersonal pyschotherapy *v* 0.12 with waiting list control; P = 0.001). There were no significant differences between groups for the Dyadic Adjustment Scale, a specific measure of adjustment in relationship with partner.[41] The RCT did not report on outcomes in infants.

Harms: No harms reported.

Comment: The RCT had problems with recruitment (132 women declined to participate) but achieved an 80% follow up (withdrawal rate 20% in the treatment group *v* 15% among controls; P = 0.47). There were no significant clinical or demographic differences between women who dropped out and women who stayed in the study.

OPTION PSYCHODYNAMIC THERAPY

Limited evidence from one RCT suggests that psychodynamic therapy may improve postnatal depression in the short term (immediately after treatment) compared with routine primary care. The RCT found no clear longer term benefits (9 months to 5 years post partum) from psychodynamic therapy compared with routine primary care, non-directive counselling, or cognitive behavioural therapy.

Benefits: We found no systematic review but found one RCT (193 women with major depression [DSM-III-R][2] recruited from the community within 8 weeks post partum).[33,34] For a description of the RCT and a comment on its methodological flaws, see non-directive counselling, p 1877. **Versus routine primary care:** The RCT found that immediately after therapy (at 4.5 months post partum), psychodynamic therapy significantly increased the proportion of women without depression compared with routine primary care (71% [32/45] with psychodynamic therapy *v* 40% [20/50] with routine primary care; RR 1.89, 95% CI 1.33 to 2.33).[33,34] It also found that psychodynamic therapy significantly reduced depression scores compared with routine primary care (mean Edinburgh Postnatal Depression Scores [EPDS; see glossary, p 1884]: 8.9 with psychodynamic therapy *v* 11.3 with routine primary care; treatment effect for psychodynamic therapy –2.6, 95% CI –4.4 to –0.9; P = 0.003). It also found that psychodynamic therapy significantly reduced the proportion of women with mother–infant relationship difficulties compared with routine primary care (proportion of women reporting problems, adjusted for relationship problems prior to treatment: 47% [20/43] with psychodynamic therapy *v* 74% [26/35] with routine primary care; RR 0.57, 95% CI 0.28 to 0.92). After controlling for baseline differences between groups, there were no significant differences between psychodynamic therapy and routine primary care in behavioural management problems or mother–infant interactions. In the longer term (at 9 months, 18 months, and 5 years post partum), there were no significant differences for any outcomes except for infant emotional and behavioural problems, for which psychodynamic therapy achieved significant improvement at 18 months post partum (P = 0.03) compared with routine primary care. However, this outcome relied solely on maternal reports (see comment under non-directive counsellingsee comment under non-directive counselling, p 0).**Versus non-directive counselling:** See benefits of non-directive counselling, p 1877. **Versus cognitive behavioural therapy:** See benefits of cognitive behavioural therapy (individual), p 1879 and cognitive behavioural therpay (group), p 1880. **Versus antidepressants:** We found no satisfactory RCTs comparing psychodynamic therapy versus antidepressants.

Harms: None reported.

Comment: For comments on the RCT's methodology see comment under non-directive counselling, p 1878.[33,34]

OPTION MOTHER–INFANT INTERACTION COACHING

One small RCT found that mother–infant interaction coaching had no significant effect on maternal depression scores compared with usual treatment, but it improved maternal responsiveness to the infant within 10 weeks of starting treatment.

Benefits: We found no systematic review but found one RCT (122 women recruited from the community with Edinburgh Postnatal Depression Scale see glossary, p 1884] > 10 at 4–8 weeks post partum).[42] This compared interaction coaching (see glossary, p 1884) using a variable number of 15 minute sessions depending on the needs of the mother and infant, versus treatment as usual. After 6 to 10 weeks there was no significant difference in depression scores between treatment and control groups. However, there was a significant difference in maternal responsiveness in Dyadic Mutuality Code scores,[43,44] based on videotaped mother–infant interactions rated by a researcher blind to randomisation status (mean score at 6 weeks: 9.73 with interaction coaching *v* 8.77 with usual treatment; P = 0.02; mean at 10 weeks: 9.55 with interaction coaching *v* 8.80 with usual treatment; P = 0.03). Baseline scores were not significantly different in the two groups. The RCT did not investigate infant outcomes.

Harms: None reported.

Comment: Additional psychiatric treatment for depression was given to women if required.

OPTION TELEPHONE BASED PEER SUPPORT (MOTHER TO MOTHER)

One small RCT found that telephone based peer support reduced depression scores after 8 weeks compared with usual treatment.

Benefits: We found no systematic review but found one RCT (42 women recruited from the community identifed as high risk for postnatal depression with Edinburgh Postnatal Depression Scale [EPDS see glossary, p 1884] > 9 at 8 weeks' post partum) comparing individually tailored mother to mother telephone based support, using trained lay volunteers with a personal history of postnatal depression, versus treatment as usual.[45] It found that telephone support significantly reduced depression scores after 8 weeks compared with usual care (proportion of women with EPDS > 12: 15% [3/20] with telephone support *v* 52% [11/21] with usual care; OR 6.23, 95% CI 1.40 to 27.8; P = 0.01). The RCT did not investigate infant outcomes.

Harms: None reported.

Comment: The acceptance rate for enrolment into the trial was 67%. Over a third of peer volunteers (38%) referred a mother to a professional health service and this was not controlled for in the analysis.

GLOSSARY

Cognitive behavioural counselling is derived from cognitive behavioural therapy and designed to be delivered by professionals such as health visitors who are not specialists in mental health. It is sometimes known as CREST because it incorporates child care advice, reassurance, enjoyment, support from others, and targets.
Interaction coaching for at-risk parents and their infants is a six key element intervention strategy designed to strengthen the early parent–infant relationship.
The Edinburgh Postnatal Depression Scale (EPDS) was designed as a screening questionnaire to identify possible depression in a clinical or research setting. The EPDS has a high sensitivity (95%) and specificity (93%) for postnatal depression[3,4] and is used by many health visitors and in many clinical research studies of postnatal depression.

Interventions in women with pre-existing hypertension

Treatment for postpartum hypertension

*Consensus opinion is that women with severe hypertension during pregnancy should have antihypertensive treatment. Placebo controlled trials would therefore be unethical.

See glossary, p 1900

Key Messages

Prevention

- **Antiplatelet drugs** One systematic review and one subsequent RCT have found that, in women considered at risk of pre-eclampsia, antiplatelet drugs (mainly aspirin) reduce the risk of pre-eclampsia, death of the baby, and delivery before 37 weeks compared with placebo or no treatment. The RCTs found no significant difference in other important outcomes. The systematic review found no evidence that aspirin increased the risk of bleeding in mother or baby compared with placebo.
- **Calcium supplementation** One systematic review has found that calcium supplementation (mainly 2 g daily) reduces the risk of pre-eclampsia and reduces the risk of having a baby with birth weight under 2500 g compared with placebo. There was no significant effect on the risk of caesarean section, preterm delivery, stillbirth, or perinatal death of the baby before discharge from hospital.
- **Magnesium supplementation** One systematic review found insufficient evidence about the effects of magnesium supplements on the risk of pre-eclampsia or its complications.
- **Other pharmacological agents (atenolol or nitrates)** We found two small RCTs; one compared atenolol versus placebo and the other compared glyceryl trinitrate patches versus placebo. Both were too small for any reliable conclusions.
- **Salt restriction** Limited evidence from one systematic review found no significant difference in the risk of pre-eclampsia with a low salt diet compared with a normal diet.
- **Vitamins C and E** One RCT in high risk women found limited evidence that vitamins C and E reduced the risk of pre-eclampsia compared with placebo.
- **Fish oil and/or evening primrose oil** We found six RCTs of fish oil and/or evening primrose oil, which were too small to draw reliable conclusions.

Treatments

- **Magnesium sulphate for eclampsia** Systematic reviews have found that magnesium sulphate reduces the risk of further fits in women with eclampsia compared with phenytoin, diazepam, or lytic cocktail. All reviews found trends towards reduced maternal mortality with magnesium sulphate, although the benefit was not significant.
- **Prophylactic magnesium sulphate in severe pre-eclampsia** One systematic review has found that prophylactic magnesium sulphate halves the risk of eclampsia compared with placebo, phenytoin, or nimodipine in women with severe pre-eclampsia. The trials found no evidence of a difference between magnesium sulphate and placebo for rate of stillbirth or perinatal mortality in babies born to women with severe pre-eclampsia. A quarter of women reported mild adverse effects (mainly flushing).
- **Antihypertensive drugs for very high blood pressure** Consensus opinion is that women with severe hypertension during pregnancy should have antihypertensive treatment. Placebo trials would therefore be unethical. One systematic review and one subsequent RCT in women with blood pressures high enough to merit immediate treatment found no evidence of a difference in the control of blood pressure by various antihypertensive drugs. The studies were too small to draw any further conclusions about the relative effects of different agents. Ketanserin and diazoxide may be associated with more adverse effects than hydralazine and labetalol.

Pre-eclampsia and hypertension

- **Aggressive management for severe early onset pre-eclampsia** One systematic review based on two small RCTs found no evidence that aggressive management reduced stillbirth or perinatal death rates compared with expectant management in babies born to mothers with severe early onset pre-eclampsia. However, it found that aggressive management increased rates of admission to neonatal intensive care and increased the risk of necrotising enterocolitis and respiratory distress in the baby compared with expectant management. We found insufficient evidence about effects of aggressive compared with expectant management in the mother.
- **Antihypertensive drugs for mild to moderate hypertension** Two systematic reviews have found that antihypertensive agents may halve the risk of severe hypertension but the effects of antihypertensive agents on other important outcomes are unclear. Systematic reviews found that angiotensin converting enzyme inhibitors used in pregnancy were associated with fetal renal failure, and found that β blockers increased the risk of the baby being small for its gestational age. It remains unclear whether treatment of mild to moderate hypertension during pregnancy is worthwhile with any antihypertensive agent compared with no treatment.
- **Antioxidants in severe pre-eclampsia** One RCT found insufficient evidence about the effects of a combination of vitamin E plus vitamin C plus allopurinol compared with placebo.
- **Bed rest/hospital admission** We found insufficient evidence about hospital admission or bed rest compared with outpatient or day care or normal activities in hospital.
- **Choice of analgesia during labour with severe pre-eclampsia** One RCT found that epidural analgesia during labour reduced mean pain scores compared with patient controlled analgesia given intravenously, but the clinical importance of the difference was unclear.
- **Plasma volume expansion in severe pre-eclampsia** One systematic review comparing plasma volume expansion with no expansion found insufficient evidence to draw reliable conclusions.
- **Prophylactic diazepam in severe pre-eclampsia** One systematic review found insufficient evidence about effects of diazepam compared with no anticonvulsants in women with severe pre-eclampsia.

DEFINITION Hypertension during pregnancy may be associated with one of several conditions. **Pregnancy induced hypertension** is a rise in blood pressure, without proteinuria, during the second half of pregnancy. **Pre-eclampsia** is a multisystem disorder, unique to pregnancy, which is usually associated with raised blood pressure and proteinuria. It rarely presents before 20 weeks' gestation. **Eclampsia** is one or more convulsions in association with the syndrome of pre-eclampsia. **Pre-existing hypertension** (not covered in this chapter) is known hypertension before pregnancy or raised blood pressure before 20 weeks' gestation. It may be essential hypertension or, less commonly, secondary to underlying disease.[1]

INCIDENCE/ PREVALENCE Pregnancy induced hypertension affects 10% of pregnancies and pre-eclampsia complicates 2–8% pregnancies.[2] Eclampsia occurs in about 1/2000 deliveries in developed countries.[3] In developing countries, estimates of the incidence of eclampsia vary from 1/100–1/1700.[4,5]

AETIOLOGY/ RISK FACTORS The cause of pre-eclampsia is unknown. It is likely to be multifactorial and may result from deficient placental implantation during the first half of pregnancy.[6] Pre-eclampsia is more common among women likely to have a large placenta, such as those with multiple pregnancy, and among women with medical conditions associated with microvascular disease, such as diabetes, hypertension, and collagen vascular disease.[7,8] Other risk factors include genetic susceptibility, increased parity, and older maternal age.[9] Cigarette smoking seems to be associated with a lower risk of pre-eclampsia, but this potential benefit is outweighed by an increase in adverse outcomes such as low birth weight, placental abruption, and perinatal death.[10]

PROGNOSIS The outcome of pregnancy in women with pregnancy induced hypertension alone is at least as good as that for normotensive pregnancies.[7,11] However, once pre-eclampsia develops, morbidity and mortality rise for both mother and child. For example, perinatal mortality for women with severe pre-eclampsia is double that for normotensive women.[7] Perinatal outcome is worse with early gestational hypertension.[7,9,11] Perinatal mortality also increases in women with severe essential hypertension.[12]

AIMS OF INTERVENTION To delay or prevent the development of pre-eclampsia and eclampsia, and to improve outcomes for women and their children. Once pre-eclampsia has occurred, to minimise morbidity and mortality for women and their children, and to ensure that health service resources are used appropriately.

OUTCOMES **For the woman:** Rates of pre-eclampsia (proteinuria and hypertension), eclampsia, death, severe morbidity (such as renal failure, coagulopathy, cardiac failure, liver failure, and stroke), placental abruption, and caesarean section; use of resources (such as dialysis, ventilation, admission to intensive care, or length of stay); adverse effects of treatment. **For the child:** Rates of death, intrauterine growth restriction, prematurity, and severe morbidity (such as intraventricular haemorrhage, respiratory distress syndrome, or asphyxia); measures of infant and child development (such as cerebral palsy or significant learning disability); use of resources (such as admission to special care nursery, ventilation, length of stay in hospital, and special needs in the community); adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal April 2003 and author search of the register of trials held by the Cochrane Pregnancy and Childbirth Group June 2002.

QUESTION What are the effects of preventive interventions in women at high risk of pre-eclampsia?

OPTION ANTIPLATELET DRUGS

One systematic review and one subsequent RCT have found that, in women considered at risk of pre-eclampsia, antiplatelet drugs (mainly aspirin) reduce the risk of pre-eclampsia, death of the baby, and delivery

before 37 weeks compared with placebo or no treatment. The RCTs found no significant difference in other important outcomes. The systematic review found no evidence that aspirin increased the risk of bleeding in mother or baby compared with placebo.

Benefits: We found one systematic review[13] of antiplatelet agents (search date 1999, 39 RCTs, 30 563 women) and one subsequent small RCT.[14] **Versus placebo/no antiplatelet drug:** The systematic review found that, in women considered at risk of pre-eclampsia, antiplatelet agents reduced pre-eclampsia (32 RCTs: 975/14 743 women [6.6%] with antiplatelet *v* 1142/14 588 women [7.8%] with no antiplatelet; RR 0.85, 95% CI 0.78 to 0.92; NNT 59, 95% CI 59 to 167), premature delivery before 37 completed weeks (23 RCTs: 2447/14 169 women [17.3%] with antiplatelet *v* 2621/14 099 [18.6%] with no antiplatelet; RR 0.92, 95% CI 0.88 to 0.97; NNT 72, 95% CI 44 to 200), and baby deaths (30 RCTs: 383/15 091 women [2.5%] with antiplatelet *v* 439/15 002 [2.9%] with no antiplatelet; RR 0.86, 95% CI 0.75 to 0.98; NNT 250, 95% CI 95 to > 10 000).[13] There were no clear effects on other important outcomes. There was no effect of starting treatment before 20 weeks, and no significant difference in the relative risk reduction between women at high and low risk for pre-eclampsia and its complications. The benefit was greatest for women given more than 75 mg aspirin daily. The subsequent small RCT (placebo controlled, 90 women at high risk based on Doppler ultrasound of uterine arteries) found that low dose aspirin 0.5 mg/kg daily versus placebo significantly reduced the incidence of pre-eclampsia (4.7% with aspirin *v* 23.3% with placebo; RR 0.20, 95% CI 0.05 to 0.86) and hypertension before 37 weeks (2.3% with aspirin *v* 20.9% with placebo; RR 0.22, 95% CI 0.05 to 0.97).[14] **Versus each other:** Trials comparing one antiplatelet agent with another were too small for reliable conclusions.[13]

Harms: The systematic review found no evidence that aspirin increased the risk of bleeding for mother or baby.[13] Two studies followed up children of mothers enrolled in trials comparing aspirin with placebo for 12–18 months.[15,16] They found no significant difference between aspirin and placebo for hospital visits for congenital malformations, motor deficit, developmental delay, respiratory problems, or bleeding problems; height or weight below the third centile; or bleeding rates in children of treated mothers.

Comment: Almost all studies used low dose aspirin 50–75 mg daily and most were placebo controlled. The RCTs included women with a variety of risk factors, including a history of previous early onset disease, diabetes, or chronic hypertension, and were conducted in different countries in the developed and developing world. The number needed to treat values cannot be applied directly to different populations of women; the values stated represent estimates for women with a risk of pre-eclampsia that is an average over all the participants in the RCTs. The absolute benefit was higher (and the NNT lower) in women at higher risk of pre-eclampsia.

OPTION CALCIUM SUPPLEMENTATION

One systematic review has found that calcium supplementation (mainly 2 g daily) reduces the risk of pre-eclampsia and reduces the risk of having a baby with birth weight under 2500 g compared with placebo. There was no significant effect on the risk of caesarean section, preterm delivery, stillbirth, or perinatal death before discharge from hospital.

Benefits: **Versus placebo:** We found one systematic review of calcium supplementation (search date 2001, 11 RCTs, 7203 women).[17] It found that calcium (mainly 2 g daily) significantly reduced the risk of pre-eclampsia compared with placebo (11 RCTs: 197/3427 [6%] with calcium supplementation *v* 294/3452 [9%] with placebo; RR 0.68, 95% CI 0.57 to 0.81; NNT 38, 95% CI 26 to 67). Subgroup analysis found that the greatest effect was in women with low dietary calcium (27/907 [3%] with calcium supplementation *v* 90/935 [10%] with placebo for low dietary calcium compared with 169/2505 [7%] with calcium supplementation *v* 197/2517 [8%] with placebo for normal dietary calcium). Calcium supplementation significantly reduced the risk of having a baby with birth weight under 2500 g (234/3230 [7.2%] with calcium supplementation *v* 283/3261 [8.7%] with placebo; RR 0.83, 95% CI 0.71 to 0.98; NNT 67, 95% CI 36 to 1000). It found no significant difference between calcium supplements and placebo on the risk of caesarean delivery, preterm delivery, or death of the baby. **Calcium and evening primrose oil versus placebo:** One small trial (48 women) did not provide sufficient evidence for reliable conclusions.[18]

Harms: After follow up of 518 children to 7 years of age, the review found no harms associated with maternal calcium supplements.[17]

Comment: Most trials in the systematic review were of good quality and included a wide range of women. They were conducted largely in the USA and South America. They included mainly women at low risk with adequate dietary calcium, so the proportion of women in the category who would benefit most from calcium supplementation was small. Several studies reported that adherence to treatment was between 60–90%.[17] The proportion of women taking 90–100% of all allocated treatment was low (20% in 1 study).[17]

OPTION OTHER DIETARY CHANGE

We found insufficient evidence from six small RCTs about effects on pre-eclampsia or preterm birth of fish oil, evening primrose oil, or both compared with either placebo or each other. Systematic reviews have found insufficient evidence from small RCTs about effects on pre-eclampsia of reduced salt intake (to 20–50 mmol daily) or magnesium supplements. One RCT in high risk women found limited evidence that vitamin C and E supplements reduced the risk of pre-eclampsia compared with placebo. One small RCT found that supplementation with protein, fish oil, and calcium, plus rest in the left lateral position, reduced the risk of pre-eclampsia compared with iron supplementation.

Benefits: **Fish and/or evening primrose oil:** We found no systematic review. We found six RCTs of fish oil and/or evening primrose oil that were too small to draw reliable conclusions.[19–24] **Protein, fish oil, and**

calcium, plus rest in left lateral position: We found one RCT (74 women with a positive roll over test (see glossary, p 1900) at 28–29 weeks).[25] It compared protein 25 mg, fish oil 300 mg, and calcium 300 mg three times a week plus 15 minutes rest in the left lateral position twice daily versus ferrous sulphate 105 mg three times a week. It found that the multiple supplements reduced pre-eclampsia compared with iron supplementation (2/37 [5%] with multiple supplements *v* 16/37 [46%] with iron suplementation; RR 0.12, 95% CI 0.03 to 0.51; NNT 3, 95% CI 2 to 6). It was too small for reliable conclusions on other outcomes. **Salt restriction:** We found one systematic review (search date 1999, 2 RCTs, 600 women) comparing reduced salt with normal dietary salt.[26] It found no significant difference for rates of pre-eclampsia, although the trials may have lacked power to detect clinically important effects (RR 1.11, 95% CI 0.46 to 2.66). **Magnesium:** We found one systematic review (search date 2001, 2 RCTs, 474 women) reporting pre-eclampsia. The RCTs were too small for reliable conclusions.[27] **Vitamins C and E:** We found one RCT (283 high risk women), which found that vitamin C 1000 mg daily plus vitamin E 400 IU daily significantly reduced pre-eclampsia compared with placebo (11/141 [8%] with vitamins *v* 24/142 [17%] with placebo; RR 0.46, 95% CI 0.24 to 0.91; NNT 11, 95% CI 8 to 61).[28] The study was too small to provide reliable evidence about effects on other important outcomes.

Harms:

Fish and/or evening primrose oil: One RCT (533 women) found no significant difference between fish oil and olive oil or no supplement for rates of post-term delivery (RR 1.19, 95% CI 0.73 to 1.93) and postpartum haemorrhage (RR 1.21, 95% CI 0.76 to 1.92).[29] These outcomes were not reported in the other smaller studies. Vomiting was more commonly reported in the oil treated groups, but numbers were not provided.[23] No other adverse events were reported. **Reduced salt:** We found no evidence of harmful effects in the trials.[26] **Magnesium:** There was no significant difference between the groups in the number of reported adverse effects (RR 0.84, 95% CI 0.65 to 1.08).[27] **Vitamins C and E:** We found little evidence about the safety of these vitamins at the high doses used in the RCT.[28]

Comment:

The fish oil RCTs may have been difficult to blind because of the distinctive taste of fish oil. One study found that olive oil provided better masking than a no oil placebo.[29] The trials of salt restriction were conducted in the Netherlands, where advice to restrict salt intake during pregnancy has been routine for many years. Such advice is no longer widespread elsewhere. An updated systematic review of fish oil for prevention of pre-eclampsia will be available soon.[30]

OPTION OTHER PHARMACOLOGICAL AGENTS

We found two small RCTs. One compared atenolol with placebo and the other compared glyceryl trinitrate patches with placebo. Both were too small for any reliable conclusions.

Benefits: **Atenolol:** We found one small RCT (68 women without hypertension selected because they had a cardiac output > 7.4 L/minute), which found no significant reduction in the risk of pre-eclampsia with atenolol 100 mg daily (1/28 [4%] with atenolol *v* 5/28 [18%] with placebo; RR 0.20, 95% CI 0.02 to 1.60).[31] **Glyceryl trinitrate:** One small RCT (40 women) found no significant difference between glyceryl trinitrate patches and placebo (RR 1.13, 95% CI 0.35 to 3.60), but the confidence interval was wide.[32]

Harms: The RCT comparing atenolol with placebo found that mean birth weight was significantly lower with atenolol for a subgroup of primiparous women (mean difference 440 g; P = 0.02).[31]

Comment: Although the possible benefits of atenolol for prevention of pre-eclampsia remain unclear, the reduction in birth weight may be real. Concerns about the possible harmful effects of atenolol on fetal growth and development have been discussed for some time (see harms of antihypertensive agents, p 1895).[33,34]

QUESTION What are the effects of interventions in women who develop hypertension during pregnancy?

OPTION BED REST/HOSPITAL ADMISSION

We found insufficient evidence about hospital admission or bed rest compared with outpatient or day care.

Benefits: **Versus no hospital admission:** We found two systematic reviews of hospital admission.[35,36] The first systematic review (search date 1993, 3 trials, 408 women) compared hospital admission with outpatient clinic assessment for non-proteinuric hypertension and found no significant difference for any major outcome.[35] The second systematic review (search date 1993, 2 RCTs, 145 women with proteinuric hypertension) compared bed rest in hospital with normal ambulation in hospital, but the trials were too small for any reliable conclusions.[36] **Versus antenatal day care units:** We found one systematic review (search date 2001, 1 RCT, 54 women).[37] The RCT was too small for reliable conclusions.

Harms: It has been suggested that hospital admission increases the risk of venous stasis, thromboembolic disease, or infection, but we found no evidence in this context. In the trial of antenatal day care, women preferred not to be admitted to hospital. We found no evidence from the other trials about the views of women and their families.

Comment: Trials of hospital admission and bed rest in hospital were conducted before widespread introduction of day care assessment units. Women with hypertension during pregnancy are now often seen in day care units, but only one small trial has compared day care assessment with assessment in an outpatient clinic. An updated systematic review of bed rest with or without hospitalisation is in preparation.[38]

OPTION ANTIHYPERTENSIVE AGENTS

Two systematic reviews have found evidence that antihypertensive agents may halve the risk of severe hypertension but the effects of antihypertensive agents on other important outcomes are unclear. Angiotensin converting enzyme inhibitors used in pregnancy are associated with fetal renal failure. β blockers may increase the risk of the baby being small for gestational age. It remains unclear whether treatment of mild to moderate hypertension during pregnancy is worthwhile with any antihypertensive agent compared with no treatment.

Benefits: We found two systematic reviews[39,40] and one subsequent RCT.[41] The first systematic review (search date 2000, 40 RCTs, > 3797 women with mild to moderate hypertension) included studies that compared any antihypertensive drug with placebo or with another antihypertensive drug.[39] The second systematic review (search date 2002, 29 RCTs, 2500 women with mild to moderate hypertension) included only studies that compared β blockers with no antihypertensive drug or with another antihypertensive drug.[40] **Versus placebo or no antihypertensive drug:** The first review found that antihypertensive drugs significantly reduced the risk of developing severe hypertension compared with no antihypertensive drugs but found no significant difference between treatment for pre-eclampsia and perinatal death (severe hypertension, 17 RCTs: RR 0.52, 95% CI 0.41 to 0.64; NNT 12, 95% CI 9 to 17; pre-eclampsia: RR 0.99, 95% CI 0.84 to 1.18; perinatal death: RR 0.71, 95% CI 0.46 to 1.09).[39] The second review found that β blockers significantly reduced the development of severe hypertension compared with no β blockers (11 RCTs, 1128 women: RR 0.37, 95% CI 0.26 to 0.53).[40] The review found insufficient evidence for other maternal outcomes. **Versus other antihypertensive agents:** Neither systematic review found any clear difference among any of these drugs for the risk of developing severe hypertension or pre-eclampsia.[39,40] The first review found that methyldopa may increase the risk of the baby dying compared with other antihypertensive agents but the RCTs were small and used weak methods, so that the difference may have arisen because of random error or bias (baby death, 14 RCTs: RR 0.49, 95% CI 0.24 to 0.99).[39] The small subsequent RCT (33 women) comparing alternative antihypertensive drugs found no significant differences in the risk of pre-eclampsia.[41]

Harms: The antihypertensive agents included in the systematic reviews[39,40] seem to be well tolerated during pregnancy, but adverse effects have not been reported in many RCTs. All antihypertensive drugs cross the placenta, but few trials reported possible adverse effects for the baby. The second review found β blockers significantly increased the baby's risk of being small for its gestational age (13 RCTs, 854 women: RR 1.34, 95% CI 1.01 to 1.79).[40] Meta regression within a systematic review suggested that lowering blood pressure for women with mild or moderate hypertension may

increase the risk of having a baby that is small for its gestational age.[42] One systematic review (search date 1999, 13 small RCTs in women with pre-existing chronic hypertension) found that angiotensin converting enzyme inhibitors used in the second or third trimester are associated with fetal renal failure.[43,44]

Comment: The RCTs were too small to exclude beneficial effects of antihypertensive agents. The trials had problems with their methods. Many were not placebo controlled, and few attempted to blind blood pressure measurement. Many important outcomes were reported by only a few studies. We found little evidence about adherence to treatment. One systematic review found that the effects of antihypertensive agents in women with pre-existing chronic hypertension were similar to those described above for women with pregnancy induced hypertension. The review did not establish or exclude benefit from treatment.[43,44]

QUESTION **What are the effects of interventions in women who develop severe pre-eclampsia or very high blood pressure during pregnancy?**

OPTION **ANTIHYPERTENSIVE DRUGS FOR VERY HIGH BLOOD PRESSURE**

Consensus opinion is that women with severe hypertension during pregnancy should have antihypertensive treatment. Placebo trials would therefore be unethical. One systematic review and one subsequent RCT in women with blood pressures high enough to merit immediate treatment found no evidence of a difference in the control of blood pressure by various antihypertensive drugs. The studies were too small to draw any further conclusions about the relative effects of different agents. Ketanserin and diazoxide may be associated with more adverse effects than hydralazine and labetalol.

Benefits: We found one systematic review (search date 2002, 14 trials, 1637 women)[45] and one small subsequent RCT.[46] There were no placebo controlled trials, which would be unethical for women with very high blood pressure. The review compared many agents (including hydralazine, labetalol, nifedipine, diazoxide, and ketanserin) mainly with hydralazine.[45] It found that all the active agents reduced blood pressure, but there was no significant evidence that one drug was better than another. The first subsequent RCT (126 women) compared nifedipine 8 mg sublingually with hydralazine (5 mg iv followed by further doses of 10 mg).[46] It found that nifedipine significantly delayed development of hypertensive crisis compared with hydralazine (median time to hypertensive crisis 3.1 hours with nifedipine *v* 2.1 hours with hydralazine; P = 0.005).

Harms: The use of ketanserin is associated with more persistent hypertension than hydralazine (RR 8.44, 95% CI 2.05 to 34.70), and labetalol is associated with less hypotension requiring treatment than diazoxide (RR 0.06, 95% CI 0 to 0.99).[45] Hypotension may compromise fetoplacental blood flow. Only four RCTs reported adverse effects, and frequency varied from 5–50%. Antihypertensive drugs cross the placenta, but we found little evidence about effects on the baby.

Comment: Women in these studies had blood pressures high enough to merit immediate treatment, and many also had proteinuria or "severe pre-eclampsia". The trials were small and reported few outcomes other than control of blood pressure. In most trials, there was no blinding after trial entry. One small RCT (60 women with severe hypertension) found no significant difference in treatment success between intravenous labetalol and nicardipine given over 1 hour (blood pressure decreased by 20%: 63% with labetalol *v* 70% with nicardipine, P = 0.58).[47]

OPTION PLASMA VOLUME EXPANSION

One systematic review comparing plasma volume expansion with no expansion found insufficient evidence to draw reliable conclusions.

Benefits: We found one systematic review (search date 2000, 3 RCTs, 61 women)[48] evaluating colloid solutions compared with placebo or no infusion. The RCTs were too small for reliable conclusions but suggest that plasma volume expansion is not beneficial.[48]

Harms: RCTs found no significant difference between plasma volume expansion and either placebo or no infusion in the risk of caesarean section or the need for additional treatment (caesarean section: RR 1.5, 95% CI 0.8 to 2.9; additional treatment: RR 1.5, 95% CI 0.7 to 3.1).[48]

Comment: These three RCTs all used a colloid rather than crystalloid solution. Two systematic reviews (search dates 1999)[49,50] of plasma volume expansion in critically ill men and non-pregnant women have found an increased mortality with albumin (a colloid) when compared with either no expansion or crystalloid.

OPTION ANTIOXIDANTS

We found insufficient evidence on the effects of antioxidants.

Benefits: We found no systematic review. We found one RCT (56 women) comparing vitamin E plus vitamin C plus allopurinol with placebo.[51] It was too small for reliable conclusions to be drawn.

Harms: We found insufficient evidence for reliable conclusions.

Comment: Women in this study had severe pre-eclampsia at 24–32 weeks' gestation.

OPTION PROPHYLACTIC ANTICONVULSANTS FOR WOMEN WITH SEVERE PRE-ECLAMPSIA

One systematic review has found that prophylactic magnesium sulphate halves the risk of eclampsia compared with placebo, phenytoin, or nimodipine in women with severe pre-eclampsia. The trials found no evidence of a difference between magnesium sulphate and placebo for rate of stillbirth or perinatal mortality in babies born to women with severe pre-eclampsia. A quarter of women reported mild adverse effects (mainly flushing). The review found insufficient evidence about effects of diazepam in women with severe pre-eclampsia.

Benefits: We found one systematic review (search date 2002, 13 RCTs, 15 756 women).[52] **Magnesium sulphate versus placebo or no anticonvulsant:** Meta-analysis of the six RCTs (11 444 women) that compared magnesium sulphate with placebo found that prophylactic magnesium sulphate significantly reduced the risk of eclampsia compared with placebo (43/5722 [0.8%] with magnesium sulphate *v* 107/5722 [1.9%] with placebo; RR 0.41, 95% CI 0.29 to 0.58; NNT 100, 95% CI 50 to 100). It also found that magnesium sulphate reduced maternal mortality compared with placebo, although the results were not significant (11/5400 [0.2%] with magnesium sulphate *v* 21/5395 [0.4%] with placebo; RR 0.54, 95% CI 0.26 to 1.10). For women randomised before delivery, there was no significant difference for rate of stillbirth or perinatal death (stillbirth: 424/5003 [8%] with magnesium sulphate *v* 426/4958 [8%] with placebo; RR 0.99, 95% CI 0.87 to 1.12; perinatal death: 538/4655 [12%] with magnesium sulphate *v* 541/4604 [12%] with placebo; RR 0.98, 95% CI 0.88 to 1.10).[52] **Magnesium sulphate versus phenytoin, nimodipine, or diazepam:** Two RCTs (2241 women) found that magnesium sulphate significantly reduced the risk of eclampsia compared with phenytoin (0/1109 [0%] with magnesium sulphate *v* 10/1132 [0.8%] with phenytoin; RR 0.05, 95% CI 0 to 0.84).[52] One trial (1650 women) found magnesium sulphate significantly reduced the risk of eclampsia compared with nimodipine (7/813 [0.8%] with magnesium sulphate *v* 21/819 [2.6%] with nimodipine; RR 0.33, 95% CI 0.14 to 0.77).[52] There was insufficient evidence for reliable conclusions about magnesium sulphate compared with diazepam (2 trials, 66 women).[52]

Harms: One large placebo controlled trial in the review reported adverse effects in detail.[53] A quarter of women experienced adverse effects (1201/4999 [24%] with magnesium sulphate *v* 228/4993 [5%] with placebo).[53] Specific effects included flushing (987/4999 [20%] with magnesium sulphate *v* 98/4993 [2%] with placebo) and respiratory depression was rare (51/4999 [1%] with magnesium sulphate *v* 26/4993 [0.5%] with placebo). Meta-analysis of the six placebo controlled RCTs found that magnesium sulphate slightly increased caesarean section rates compared with placebo (2528/5082 [50%] with magnesium sulphate *v* 2370/5026 [47%] with placebo; RR 1.05, 95% CI 1.01 to 1.10; NNH 34, 95% CI 25 to 100). Compared with phenytoin, magnesium sulphate was also associated with an increased risk of caesarean section (RR 1.21, 95% CI 1.05 to 1.41; NNH 29, 95% CI 12 to 84).[52] One small RCT evaluated magnesium sulphate for preventing and treating preterm labour in women who did not have pre-eclampsia. It found an increase in infant mortality for babies born to these women. Many of the infants had very low birth weight (< 1500 g).[54]

Comment: Most of the data in these trials refer to women with relatively severe pre-eclampsia. One small study recruited only women with mild pre-eclampsia. Long term follow up of women and children in the large RCT is continuing.[53] Weak evidence from two case control studies suggests that magnesium sulphate may be associated with a decreased risk of cerebral palsy in babies weighing less than 1500 g.[55,56]

OPTION AGGRESSIVE MANAGEMENT FOR SEVERE EARLY ONSET PRE-ECLAMPSIA

One systematic review based on two small RCTs found no evidence that aggressive management reduced stillbirth or perinatal death rates compared with expectant management in babies born to mothers with severe early onset pre-eclampsia. However, it found that aggressive management increased rates of admission to neonatal intensive care and increased the risk of necrotising enterocolitis and respiratory distress in the baby compared with expectant management. We found insufficient evidence about effects of aggressive compared with expectant management in the mother.

Benefits: We found one systematic review (search date 2002, 2 RCTs, 133 women at 28–34 weeks' gestation).[57] It found that, for the baby, there was no significant difference in rates of stillbirth or death after delivery for aggressive, interventional management versus expectant care (RR of death or stillbirth for interventional *v* expectant care 1.50, 95% CI 0.42 to 5.41). Babies of mothers in the aggressive management group were less likely to be small for gestational age than those in the expectant group (RR for aggressive *v* expectant management 0.36, 95% CI 0.14 to 0.90). The review found insufficient evidence about effects on maternal outcomes.

Harms: Aggressive management increased risks of respiratory distress syndrome, necrotising enterocolitis, and rate of admission to neonatal intensive care in babies born to mothers with severe pre-eclampsia (respiratory distress syndrome: 34/66 [52%] babies with aggressive management *v* 15/67 [22%] with expectant care; RR 2.30, 95% CI 1.39 to 3.81; necrotising colitis: RR 5.5, 95% CI 1.04 to 29.56; admission to neonatal intensive care: RR 1.32, 95% CI 1.13 to 1.55). We found insufficient evidence for reliable conclusions about effects of expectant management on maternal morbidity.

Comment: None.

OPTION CHOICE OF ANALGESIA DURING LABOUR

One RCT in women with severe pre-eclampsia found that epidural analgesia during labour reduced pain scores compared with patient controlled analgesia given intravenously, but the clinical importance of the difference was not clear.

Benefits: We found one RCT (105 women with severe pre-eclampsia) comparing patient controlled analgesia given intravenously with epidural analgesia.[58] It found that epidural analgesia significantly reduced mean pain scores but the clinical importance of the difference is unclear. The trial was too small for a reliable conclusion about other outcomes. We found no RCTs of other forms of intrapartum analgesia for this group of women.

Harms: Women allocated an epidural were more likely to have hypotension requiring intravenous ephedrine (5/56 [9%] with epidural *v* 0/60 [0%] with patient controlled analgesia).[58] Neonatal naloxone was

more likely to be given after patient controlled analgesia given intravenously (31/60 [54%] with patient controlled analgesia given intravenously *v* 5/56 [9%] with epidural analgesia; RR 5.71, 95% CI 2.39 to 13.60; NNH 3, 95% CI 2 to 4). The trial was too small for reliable conclusions about other outcomes.

Comment: The drug used for patient controlled analgesia was not reported.

QUESTION **What is the best choice of anticonvulsant for women with eclampsia?**

OPTION **ANTICONVULSANTS IN WOMEN WITH ECLAMPSIA**

Systematic reviews have found that magnesium sulphate reduces the risk of further fits in women with eclampsia compared with phenytoin, diazepam, or lytic cocktail. All reviews found trends towards reduced maternal mortality with magnesium sulphate, although the benefit was not significant.

Benefits: **Magnesium sulphate versus diazepam:** We found one systematic review (search date 1999, 5 RCTs, 1236 women).[59] It found that magnesium sulphate significantly reduced both maternal mortality and further fits compared with diazepam (maternal mortality: 21/617 [3.4%] with magnesium sulphate *v* 36/619 [5.8%] with diazepam; RR 0.59, 95% CI 0.36 to 1.00; further fits: 71/618 [11%] with magnesium sulphate *v* 160/618 [26%] with diazepam; RR 0.45, 95% CI 0.35 to 0.58). There was no evidence of any differential effects on any other reported outcome. **Magnesium sulphate versus phenytoin:** We found one systematic review (search date 1999, 4 RCTs, 823 women)[60] and one subsequent small RCT.[61] The review found that magnesium sulphate significantly reduced the risks of further fits, pneumonia, requirement for ventilation, and admission to intensive care compared with phenytoin (further fits: 23/423 [5.4%] with magnesium sulphate *v* 73/422 [17%] with phenytoin; RR 0.32, 95% CI 0.21 to 0.50; pneumonia: RR 0.44, 95% CI 0.24 to 0.79; requirement for ventilation: RR 0.66, 95% CI 0.49 to 0.90; admission to intensive care: RR 0.67, 95% CI 0.50 to 0.89).[60] It also found that magnesium sulphate significantly reduced the proportion of babies dying or staying in a special baby care unit for more than 7 days compared with phenytoin (RR 0.77, 95% CI 0.63 to 0.95). The lower maternal death rate with magnesium sulphate compared with phenytoin was not significant, but the confidence interval was wide and a clinically important effect could not be excluded (RR 0.51, 95% CI 0.25 to 1.06). The small subsequent RCT (50 women) reported results consistent with those of the review.[61] **Magnesium suplhate versus lytic cocktail:** We found one systematic review (search date 2000, 2 RCTs, 199 women).[62] Magnesium sulphate versus lytic cocktail (see glossary, p 1900) significantly reduced further fits, pneumonia, respiratory depression, and fetal or infant death (further fits: 4/96 [4%] with magnesium sulphate *v* 49/102 [48%] with lytic cocktail; RR 0.09, 95% CI 0.03 to 0.24; pneumonia: 1/51 [2%] with magnesium sulphate *v* 11/57 [19%] with lytic cocktail; RR 0.08, 95% CI 0.02 to 0.42; respiratory depression: 0/96 [0%] with magnesium sulphate *v* 8/102 [8%] with lytic cocktail; RR 0.12,

95% CI 0.02 to 0.91; fetal or infant death: 14/89 [16%] with magnesium sulphate *v* 30/88 [34%] with lytic cocktail; RR 0.45, 95% CI 0.26 to 0.79). There was a non-significant reduction in maternal deaths (1/96 [1%] with magnesium sulphate *v* 6/102 [6%] with lytic cocktail; RR 0.25, 95% CI 0.04 to 1.43).

Harms: We found no good evidence from RCTs about harms. Clinical experience suggests that magnesium sulphate is safer than phenytoin for both the woman and her baby and considerably safer than lytic cocktail.

Comment: Most information about the comparisons with diazepam and phenytoin comes from one large multicentre trial, in which adherence to treatment was 99%. The lytic cocktail trials included women with antepartum or postpartum eclampsia.

GLOSSARY

Lytic cocktail A mixture of pethidine, chlorpromazine, and promethazine.

Roll over test A test in which a woman lies on her left side for 15 minutes after which blood pressure is recorded. She then rolls into the supine position and, after 5 minutes, blood pressure is measured again. A rise in diastolic blood pressure in the supine position of more than 20 mm Hg is defined as abnormal. The value of this test has been questioned.

Substantive changes

Prophylactic anticonvulsants One systematic review updated;[52] conclusion unchanged.

Preterm birth

Key Messages

- **Antenatal corticosteroids** One systematic review found that antenatal corticosteroids significantly reduced respiratory distress syndrome, intraventricular haemorrhage, and neonatal mortality compared with placebo or no treatment.

- **Antibiotic treatment for premature rupture of the membranes (prolongs gestation and may reduce infection, but unknown effect on perinatal mortality)** One systematic review in women with premature rupture of membranes has found that antibiotics prolong pregnancy and reduce the risk of neonatal morbidity, such as neonatal infection, requirement for treatment with oxygen, and abnormal cerebral ultrasound, compared with placebo. It found that co-amoxiclav (amoxycillin plus clavulanic acid) increased the risk of neonatal necrotising enterocolitis compared with placebo.

- **Calcium channel blockers** We found no systematic review or RCTs comparing calcium channel blockers versus placebo. One systematic review has found that calcium channel blockers significantly reduce deliveries within 48 hours, neonatal morbidity, and withdrawals caused by maternal adverse effects compared with other tocolytics (mainly β agonists).

- **Prophylactic cervical cerclage for women at risk of cervical incompetence where cervical changes have not been identified** Systematic reviews identified five RCTs that found different results for women where cervical changes have not been identified. One large RCT found that cervical cerclage at 9 to 29 weeks reduced delivery before 33 weeks' gestation in women with a previous preterm delivery or previous cervical surgery, but doubled the risk of puerperal pyrexia compared with no cerclage. The other four smaller RCTs found no significant difference in preterm delivery before 34 weeks between cerclage at 10 to 30 weeks and no cerclage in women with a variety of risk factors for preterm delivery.

- **Amnioinfusion for preterm rupture of the membranes** One systematic review found insufficient evidence from one RCT about the effects of amnioinfusion compared with no amnioinfusion in improving neonatal outcomes after preterm rupture of the membranes.

- **Oxytocin receptor antagonists (atosiban)** One systematic review identified two RCTs that compared atosiban with placebo and found different results. The larger RCT found that atosiban prolonged pregnancy compared with placebo but found that atosiban appeared to increase fetal deaths below 28 weeks' gestation. The other RCT found that atosiban increased delivery within 48 hours.

- **Prophylactic cervical cerclage for women at risk of cervical incompetence where cervical changes have been identified** Two RCTs identified by a systematic review found different results for women where cervical changes were present. One RCT found no significant difference in delivery before 34 weeks. The other small RCT found that cerclage plus bed rest reduced delivery before 34 weeks compared with bed rest alone. Neither RCT found a significant difference in perinatal death between cerclage plus bed rest and bed rest alone.

- **Prostaglandin inhibitors (indometacin)** One systematic review found limited evidence that indometacin reduced delivery within 48 hours and 7 days and delivery before 37 weeks' gestation compared with placebo. However, it found no significant difference between indometacin and placebo or no treatment in perinatal mortality, respiratory distress syndrome, bronchopulmonary dysplasia, necrotising enterocolitis, neonatal sepsis, or low birth weight. The review may have lacked power to detect a clinically important effect.
- **Elective rather than selective caesarean delivery in preterm labour** One systematic review has found that elective caesarean delivery increases maternal morbidity compared with selective caesarean delivery, and found no significant difference in neonatal morbidity or mortality. The RCTs may have been underpowered to detect a clinically important neonatal benefit.
- **Enhanced antenatal care programmes for socially deprived population groups/high risk groups** RCTs carried out in a range of countries found no significant difference between enhanced antenatal care and usual care in reducing the risk of preterm delivery.
- **Magnesium sulphate** One systematic review found no significant difference between magnesium sulphate and placebo in delivery before 36 weeks; perinatal mortality or respiratory distress syndrome. A second systematic review found no significant difference between magnesium sulphate and other tocolytics (betamimetics, calcium channel blockers, prostaglandin synthetase inhibitors, nitroglycerine, alcohol and dextrose infusion) in delivery within 48 hours, although results were heterogeneous.
- **Antibiotic treatment for preterm labour with intact membranes** One systematic review found that antibiotics do not prolong pregnancy and do not reduce perinatal mortality compared with placebo, but they do reduce the incidence of maternal infection.
- **Betamimetics** One systematic review has found no significant difference between β_2 agonists and placebo or no treatment in perinatal mortality, respiratory distress syndrome or birth weight less than 2500 g. It found that β_2 agonists increased maternal adverse effects such as chest pain, palpitations, dyspnoea, tremor, nausea, vomiting, headache, hyperglycaemia, hypokalaemia compared with placebo or no treatment.
- **Thyrotropin releasing hormone plus corticorsteroids before preterm delivery** One systematic review in women at risk of preterm birth has found no significant difference between thyrotropin releasing hormone plus corticosteroids and corticosteroids alone in improving neonatal outcomes. Thyrotropin releasing hormone plus corticosteroids increased maternal and fetal adverse events compared with corticosteroids alone.

DEFINITION

Preterm or premature birth is defined by the World Health Organization as delivery of an infant before 37 completed weeks of gestation.[1] There is no set lower limit to this definition, but 23–24 weeks' gestation is widely accepted,[1] which approximates to an average fetal weight of 500 g.

INCIDENCE/ PREVALENCE

Preterm birth occurs in about 5–10% of all births in developed countries,[2–4] but in recent years the incidence seems to have increased in some countries, particularly the USA.[5] We found little reliable evidence for incidence (using the definition of premature birth given above) in less developed countries. The rate in northwestern Ethiopia has been reported to vary between 11–22% depending on the age group of mothers studied, and is highest in teenage mothers.[6]

AETIOLOGY/ RISK FACTORS About 30% of preterm births are unexplained and spontaneous.[4,7,8] The two strongest risk factors for idiopathic preterm labour (see glossary, p 1920) are low socioeconomic status and previous preterm delivery. Multiple pregnancy accounts for about another 30% of cases.[4,7] Other known risk factors include genital tract infection, preterm rupture of the membranes (see glossary, p 1920), antepartum haemorrhage, cervical incompetence, and congenital uterine abnormalities, which collectively account for about 20–25% of cases. The remaining cases (15–20%) are attributed to elective preterm delivery secondary to hypertensive disorders of pregnancy, intrauterine fetal growth restriction, congenital abnormalities, trauma and medical disorders of pregnancy.[4,5,7,8]

PROGNOSIS Preterm labour usually results in preterm birth. One systematic review (search date not stated), which compared tocolysis versus placebo, found that about 27% of preterm labours resolved spontaneously and about 70% progressed to preterm delivery.[9] Observational studies have found that one preterm birth significantly raises the risk of another in a subsequent pregnancy.[10]

AIMS OF INTERVENTION To prevent preterm birth; to prolong the interval between threatened preterm labour and delivery; to optimise the condition of the fetus in preparation for delivery in order to improve neonatal outcome; to minimise maternal morbidity.

OUTCOMES Perinatal (see glossary, p 1920) mortality, neonatal mortality, and morbidity (incidence of respiratory distress syndrome, intraventricular haemorrhage, necrotising enterocolitis, neonatal sepsis, and neonatal convulsions); maternal adverse effects. Proxy outcomes include duration of pregnancy, number of hours or days between onset of labour and delivery, and incidence of preterm delivery.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION **What are the effects of preventive interventions in women at high risk of preterm delivery?**

OPTION **ENHANCED ANTENATAL CARE FOR SOCIALLY DEPRIVED POPULATION GROUPS/HIGH RISK GROUPS**

RCTs carried out in a range of countries found no significant difference between enhanced antenatal care and usual care in reducing the risk of preterm delivery.

Benefits: We found no systematic review. We found 11 RCTs.[11–21] All of the RCTs (carried out in Europe, USA, and Latin America; number of high risk women ranging from 150–2200) found no significant difference between enhanced antenatal care (see glossary, p 1920) and usual antenatal care in reducing preterm birth (see table 1, p 1922).

Harms: The RCTs gave no information on adverse effects.[11–21]

Comment: The definition of enhanced antenatal care varied.[11–21] Examples of enhanced antenatal care include increased number of antenatal visits, a bed rest programme including rest periods three times daily, home visits by midwives, fortnightly social worker counselling sessions, nutritional education, peer group education, and counselling by a psychologist.

OPTION PROPHYLACTIC CERVICAL CERCLAGE IN WOMEN AT RISK OF CERVICAL INCOMPETENCE

Systematic reviews identified five RCTs that found different results for women where cervical changes have not been identified. One large RCT found that cerclage at 9 to 29 weeks reduced delivery before 33 weeks' gestation in women with a previous preterm delivery or previous cervical surgery, but doubled the risk of puerperal pyrexia compared with no cerclage. The other four smaller RCTs found no significant difference in preterm delivery before 34 weeks between cerclage at 10 to 30 weeks and no cerclage in women with a variety of risk factors for preterm delivery. Two RCTs identified by a systematic review found different results for women where cervical changes were present. One RCT found no significant difference in delivery before 34 weeks. The other small RCT found that cerclage plus bed rest reduced delivery before 34 weeks compared with bed rest alone. Neither RCT found a significant difference in perinatal death between cerclage plus bed rest and bed rest alone.

Benefits: **When cervical changes have not been identified:** We found one systematic review (search date 2002, 5 RCTs).[22] The review did not pool data from these RCTs. The first RCT identified by the review (1292 women, 71% with a history of preterm delivery and 11% with previous cervical surgery, obstetricians were uncertain whether to advise cervical cerclage [see glossary, p 1920]) found that cerclage at 9 to 29 weeks significantly reduced delivery before 33 weeks' gestation but found no significant difference in the rate of deliveries occurring between weeks 33 and 36 (before 33 weeks: 83/647 [13%] with cerclage *v* 110/645 [17%] with no cerclage; RR 0.75, 95% CI 0.57 to 0.98; NNT 24, 95% CI 14 to 275).[23] The second RCT identified by the review (194 women with 2 to 4 previous preterm deliveries or 1 or more second trimester losses) found no significant difference in delivery before 34 weeks' gestation between cerclage at 15 to 21 weeks and no cerlcage (12/96 [13%] with cerclage *v* 10/98 [10%] with no cerclage; OR 1.29, 95% CI 0.53 to 3.15).[24] The third RCT identified by the review (506 women judged to be at moderate risk of preterm labour due to previous live pregnancy at 29 to 36 weeks, previous preterm labour, or late miscarriage) found no significant difference in delivery before 34 weeks' gestation between cerclage at 10 to 28 weeks and no cerclage (14/268 [1.5%] with cerclage *v* 1/238 [0.4%] with no cerclage; OR 0.88, 95% CI 0.36 to 2.16).[25] The fourth RCT identified by the review (50 women with twin pregnancies after induction of ovulation, excluding women with cervical insufficiency) found no significant difference in delivery before 34 weeks' gestation between cerclage at 13 weeks and no cerclage (6/25 [24%] with cerclage *v* 5/25 [20%] with no cerclage; OR 1.26, 95% CI 0.33 to 4.84).[26] The fifth RCT identified by the review (71% of women had

previous first or second trimester miscarriage, 29% previous preterm birth, number of women not stated in review) found no significant difference in delivery before 34 weeks' gestation between cerclage at 21 to 30 weeks and no cerlcage (OR 0.70, 95% CI 0.33 to 1.48).[27] **When cervical changes are present:** We found one systematic review (search date 2002, 2 RCTs, 148 women) of cervical cerclage when cervical change has been detected by transvaginal ultrasound.[28] It found significant heterogeneity between RCTs for delivery before 34 weeks (P = 0.03).[28] The first RCT identified by the review (35 women with cervical length < 25 mm and gestational age < 27 weeks) found that cerclage plus bed rest significantly reduced delivery before 34 weeks compared with bed rest alone (0/19 [0%] with cerclage plus bed rest *v* 7/16 [44%] with bed rest alone; NNT 3, 95% CI 2 to 5; P = 0.002). It found no significant difference in neonatal survival between cerclage plus bed rest and bed rest alone (19/19 [100%] with cerclage plus bed rest *v* 13/16 [81%] with bed rest alone; ARR +0.19, 95% CI −0.02 to +0.43).[29] The second RCT identified by the review (113 women between 16 and 24 weeks of gestation and distal cervix < 2.5 cm or membrane prolapse into endocervical canal at least 25% of cervical length) found no significant difference between cerclage plus bed rest and with bed rest alone in delivery before 34 weeks, perinatal death, placental abruption, or chorioamnionitis (delivery < 34 weeks: 35% *v* 36%; P = 0.80; perinatal death:13% *v* 12%; P = 0.90; placental abruption: 11% *v* 14%; P = 0.80; chorioamnionitis: 20% *v* 10%; P = 0.20).[30]

Harms: **When cervical changes have not been identified:** The first RCT identified by the review (1292 women) addressing prophylactic use of cerclage found that insertion of cervical sutures doubled the risk of puerperal pyrexia compared with no sutures (24/415 [6%] with cerclage *v* 11/405 [3%] with no cerclage; RR 2.13, 95% CI 1.06 to 4.15; NNH 33, 95% CI 12 to 607).[23] Information about puerperal pyrexia was collected only after 360 women had already been recruited to the trial. It was defined as a temperature of greater than 38 °C but uterine infection was mentioned as a possible cause of the pyrexia in only 13/24 (54%) in the cerclage group and 6/11 (55%) in the non-cerclage groups. The second smaller RCT identified by the review (194 women) found that cervical cerclage increased puerperal pyrexia but the increase was not statistically significant (10% *v* 3%, P = 0.07).[24] **When cervical changes are present:** The systematic review (search date 2002) found no significant difference between cerclage and no cerclage in maternal infection (2 RCTs, 148 women: RR 0.78, 95% CI 0.39 to 1.56).[28] One RCT identified by the review found no significant difference between cerclage and no cerclage in chorioamnionitis (20% *v* 10.3%, P = 0.2).[30]

Comment: Both systematic reviews presented results from meta-analyses using data from all included RCTs.[22,28] The authors of the second review considered that, although no significant statistical heterogeneity was found, pooling was inappropriate in view of the difference in the characteristics and quality of the RCTs. Timing of suturing ranged from 13 to 30 weeks.[22] The RCTs included women with twin or singleton pregnancies; women with previous second trimester

miscarriage or preterm delivery; previous cervical surgery; premature rupture of membranes before 32 weeks; women with second trimester dilation of internal os on ultrasonography; and women with primary or secondary infertility after induced ovulation. The second review found that overall, cervical cerclage significantly reduced spontaneous preterm birth before 34 weeks compared with no cerclage, but found no significant difference between treatments for preterm delivery before 37 weeks (before 34 weeks, 7 RCTs: OR 0.75, 95% CI 0.59 to 0.96; before 37 weeks, 6 RCTs: OR 0.86, 95% CI 0.71 to 1.05).[22] The first review found that overall, cervical cerclage significantly reduced spontaneous preterm birth before 32 weeks compared with no cerclage but found no significant difference between treatments for preterm delivery before 37 weeks (before 32 weeks, 3 RCTs, 770 women: RR 1.29, 95% CI 0.67 to 2.49; delivery before 37 weeks: 4 RCTs, 2062 women: RR 1.04, 95% CI 0.99 to 1.10).[28] The two RCTs that examined cervical cerclage in the mid-trimester with documented cervical change differed in terms of patient selection and methodology.[29,30] Broad confidence intervals suggest that sample size may have been insufficient to rule out clinically important differences in neonatal mortality.

QUESTION What are the effects of interventions to improve outcome after preterm rupture of the membranes?

OPTION ANTIBIOTIC TREATMENT FOR PRETERM RUPTURE OF THE MEMBRANES

One systematic review in women with preterm rupture of membranes has found that antibiotics prolong pregnancy and reduce the risk of neonatal morbidity, such as neonatal infection, requirement for treatment with oxygen, and abnormal cerebral ultrasound, compared with placebo. It found that co-amoxiclav (amoxicillin [amoxycillin] plus clavulanic acid) increased the risk of neonatal necrotising enterocolitis compared with placebo.

Benefits: One systematic review (search date 2003, 19 RCTs, > 6000 women with rupture of membranes before 37 weeks' gestation) found that antibiotics (including erythromycin, co-amoxiclav, benzylpenicillin, ampicillin, piperacillin, or clindamycin) significantly reduced the proportion of babies born within 48 hours and within 7 days following preterm premature rupture of the membranes (see glossary, p 1920) compared with placebo (within 48 hours: RR 0.71, 95% CI 0.58 to 0.87; within 7 days: RR 0.80, CI 0.71 to 0.90).[31] It found that antibiotics significantly reduced neonatal infection, requirement for supplementary oxygen and abnormal cerebral ultrasound compared with placebo but found no significant difference between treatments in perinatal mortality (neonatal infection: RR 0.68, CI 0.53 to 0.87; requirement for supplementary oxygen: RR 0.88, 95% CI 0.81 to 0.96; abnormal cerebral ultrasound: RR 0.82, 95% CI 0.68 to 0.98). **Penicillins (excluding co-amoxiclav):** The review found that any penicillin (except co-amoxiclav) significantly reduced the proportion of babies born within 48 hours and within 7 days compared with placebo (< 48

hours, 3 RCTS, 220 babies: RR 0.41, 95% CI 0.25 to 0.66; < 7 days, 3 RCTs, 220 babies: RR 0.68, 95% CI 0.56 to 0.82).[31] It found that penicillin significantly reduced neonatal infection and major cerebral abnormality on ultrasound before discharge (neonatal infection, 4 RCTs, 416 babies: RR 0.33, 95% CI 0.14 to 0.81; major cerebral abnormality, 3 RCTs, 267 babies: RR 0.49, 95% CI 0.25 to 0.97). **Co-amoxiclav**: The review found that co-amoxiclav significantly reduced the proportion of babies born within 48 hours and within 7 days compared with placebo (< 48 hours, 1 RCT, 2430 babies: 0.75, 95% CI 0.67 to 0.84; < 7 days, 1 RCT, 2430 babies: RR 0.91, 95% CI 0.85 to 0.97).[31] **Erythromycin:** The review found that erythromycin significantly reduced the proportion of babies born within 48 hours (2 RCTs, 2635 babies: RR 0.84, 95% CI 0.76 to 0.93).[31]

Harms: **Co-amoxiclav**: The review (search date 2003) found that co-amoxiclav significantly increased the proportion of babies with necrotising enterocolitis compared with placebo (2 RCTs, 2492 babies: RR 4.60, 95% CI 1.98 to 10.72).[31]

Comment: Most of the RCTs in the review did not include antenatal administration of steroids but 77% of the women in one large RCT received steroids.[32] All but one of the RCTs in the review gave data on the percentage of withdrawals, which was always less than 20%.[31]

OPTION AMNIOINFUSION FOR PRETERM RUPTURE OF THE MEMBRANES

One systematic review found insufficient evidence from one RCT about the effects of amnioinfusion compared with no amnioinfusion in improving neonatal outcomes after preterm rupture of the membranes.

Benefits: We found one systematic review (search date 2001, 1 RCT, 66 women) comparing amnioinfusion (see glossary, p 1920) with no amnioinfusion.[33] It found no significant difference between amnioinfusion and no amnioinfusion in rates of caesarean section, low Apgar scores (see glossary, p 1920), neonatal mortality, or endometritis.

Harms: No adverse effects were reported in the RCT identified by the review.[33]

Comment: The RCT was too small to detect clinically important changes in some of the outcomes (rates of caesarean section, neonatal mortality, and infectious morbidity) and had shortcomings in methods used (unspecified method of random assignment of women; blinding of treatment not possible).[33]

QUESTION What are the effects of treatments to stop contractions in preterm labour?

OPTION BETAMIMETICS New

One systematic review has found no significant difference between β_2 agonists and placebo or no treatment in perinatal mortality, respiratory distress syndrome or birth weight less than 2500 g. It found that

β_2 agonists increased maternal adverse effects such as chest pain, palpitations, dyspnoea, tremor, nausea, vomiting, headache, hyperglycaemia, and hypokalaemia compared with placebo or no treatment.

Benefits: We found one systematic review (search date 1998, 8 RCTs).[34] The systematic review found no significant difference between β_2 agonists and placebo or no treatment in perinatal (see glossary, p 1920) mortality, respiratory distress syndrome or birth weight less than 2500 g (perinatal mortality; 62/682 [9%] with β_2 agonists *v* 48/604 [8%] with placebo or no treatment; OR 1.08, 95% CI 0.72 to 1.62; respiratory distress syndrome, 6 RCTs: 117/639 [18%] with β_2 agonists *v* 140/565 [25%] with placebo or no treatment; OR 0.76, 95% CI 0.57 to 1.01; birth weight less than 2500 g, 5 RCTs: 332/601 [55%] with β_2 agonists *v* 332/525 [63%] with placebo or no treatment; OR 0.79, 95% CI 0.61 to 1.01).[34] It found no significant difference between treatments in patent ductus arteriosus, necrotising enterocolitis, intraventricular haemorrhage, seizures, hypoglycaemia, or neonatal sepsis.[34]

Harms: The systematic review found that β_2 agonists significantly increased maternal adverse effects, such as chest pain, palpitations, dyspnoea, tremor, nausea, vomiting, headache, hyperglycaemia, or hypokalaemia compared with placebo or no treatment (chest pain, 2 RCTs: 39/406 [10%] with β_2 agonists *v* 3/408 [1%] with placebo or no treatment; OR 6.2, 95% CI 3.3 to 11.5), palpitations, 3 RCTs: 200/420 [48%] with β_2 agonists *v* 19/423 [4%] with placebo or no treatment; OR 10.2, 95% CI 7.4 to 13.9; dyspnoea, 2 RCTs: 55/406 [14%] with β_2 agonists *v* 4/408 [1%] with placebo or no treatment; OR 6.6, 95% CI 3.9 to 11.2; tremor, 1 RCT: 138/352 [39%] with β_2 agonists *v* 13/356 [4%] with placebo or no treatment; OR 8.3, 95% CI 5.8 to 11.9; nausea, 1 RCT: 72/352 [20%] with β_2 agonists *v* 42/356 [12%] with placebo or no treatment; OR 1.9, 95% CI 1.3 to 2.8; vomiting, 2 RCTs: 48/366 [13%] with β_2 agonists *v* 29/371 [8%] with placebo or no treatment; OR 1.8, 95% CI 1.1 to 2.9; headache, 2 RCTs: 84/366 [23%] with β_2 agonists *v* 22/371 [6%] with placebo or no treatment; OR 4.0, 95% CI 2.6 to 6.0; hyperglycaemia, 1 RCT: 106/352 [30%] with β_2 agonists *v* 37/356 [10%] with placebo or no treatment; OR 3.4, 95% CI 2.4 to 4.9; hypokalaemia, 1 RCT: 138/352 [39%] with β_2 agonists *v* 23/356 [6%] with placebo or no treatment; OR 6.4, 95% CI 4.5 to 9.1).[34] Frequently, these adverse effects necessitated discontinuation of treatment (3 RCTs: 25/88 [28%] with β_2 agonists *v* 0/86 with placebo or no treatment; OR 11.5, 95% CI 4.8 to 27.5).

Comment: None.

OPTION CALCIUM CHANNEL BLOCKERS New

We found no systematic review or RCTs comparing calcium channel blockers with placebo. One systematic review has found that calcium channel blockers significantly reduce deliveries within 48 hours, neonatal morbidity, and withdrawals caused by maternal adverse effects compared with other tocolytics (mainly β agonists).

Benefits: **Versus placebo:** We found no systematic review or RCTs comparing calcium channel blockers versus placebo. **Versus other tocolytics:** We found one systematic review (search date 2002, 12 RCTs, 1029 women) comparing calcium channel blockers (nifedipine and nicardipine in 2 RCTs) versus other tocolytics (see glossary, p 1920) (10 RCTs *v* ritodrine; 1 RCT each *v* salbutamol and magnesium sulphate) for preterm labour (between 20 and 36 weeks).[35] The review found that calcium channel blockers significantly reduced delivery within 48 hours and 7 days and reduced delivery before 34 weeks compared with other tocolytics (delivery within 48 hours, 9 RCTs, 761 women: 74/383 [19%] with calcium channel blocker *v* 87/378 [23%] with other tocolytics; RR 0.8, 95% CI 0.61 to 1.0; dielvery within 7 days, 4 RCTs, 453 women: 71/229 [31%] *v* 86/224 [38%]; RR 0.76, 95% CI 0.60 to 0.97; delivery before 34 weeks, 6 RCTs, 619 women: 107/311 [34%] *v* 122/308 [40%]; RR 0.83, 95% CI 0.69 to 0.99). It found that calcium channel blockers significantly reduced neonatal morbidity including respiratory distress syndrome, necrotising enterocolitis, and intraventricular haemorrhage (respiratory distress syndrome, 9 RCTs, 763 newborns: 48/386 [12%] with calcium channel blocker *v* 72/377 [19%] with other tocolytics; RR 0.63, 0.46 to 0.88; necrotising enterocolitis, 3 RCTs, 323 newborns: 1/166 [1%] *v* 8/157 [5%]; RR 0.21, 95% CI 0.05 to 0.96; intraventricular haemorrhage, 3 RCTs, 340 newborns: 19/173 [11%] *v* 31/167 [19%]; RR 0.59, 95% CI 0.36 to 0.98). No significant differences were found in perinatal mortality (10 RCTs, 810 newborns: 13/400 [3%] with calcium channel blocker *v* 7/410 [2%] with other tocolytics; RR 1.65, 95% CI 0.74 to 3.64).

Harms: **Versus other tocolytics:** The systematic review (search date 1998) found that calcium channel blockers significantly reduced discontinuation because of adverse effects compared with other tocolytics (10 RCTs, 833 women: 1/419 [0.2%] with calcium channel blocker *v* 29/414 [7.0%] with other tocolytics; RR 0.14, 95% CI 0.05 to 0.36).[35] The systematic review did not report specific adverse effects of calcium channel blockers.

Comment: None.

OPTION MAGNESIUM SULPHATE New

One systematic review found no significant difference between magnesium sulphate and placebo in delivery before 36 weeks; perinatal mortality, or respiratory distress syndrome. A second systematic review found no significant difference between magnesium sulphate and other tocolytics (betamimetics, calcium channel blockers, prostaglandin synthetase inhibitors, nitroglycerine, alcohol and dextrose infusion) in delivery within 48 hours, although results were heterogeneous.

Benefits: **Versus placebo:** One systematic review (search date 1998, 4 RCTs) found no significant difference between magnesium sulphate and placebo or no treatment in delivery before 36 weeks (2 RCTs, 191 women: 61/92 [66%] with magnesium sulphate *v* 74/99[75%] with control; OR 0.67, 95% CI 0.36 to 1.26).[34] It found no significant difference between magnesium sulphate and placebo or no

treatment for perinatal mortality or respiratory distress syndrome (perinatal mortality: 11/169 [6.5%] with magnesium sulphate *v* 7/182 [3.8%] with placebo or no treatment; OR 1.83, 95% CI 0.70 to 4.77; respiratory distress syndrome, 3 RCTs: 22/139 [16%] with magnesium sulphate *v* 22/153 [14%] with placebo or no treatment; OR 1.19, 95% CI 0.61 to 2.31).[34] It also found no significant difference between magnesium sulphate and placebo or no treatment in birth weight less than 2500 g, patent ductus arteriosus, necrotising enterocolitis, intraventricular haemorrhage, seizures, hypoglycaemia, or neonatal sepsis. The number of newborns assessed for these outcomes was small. **Versus other tocolytics (see glossary, p 1920):** A second systematic review (search date 2002) compared magnesium sulphate versus placebo, no treatment, and other tocolytics (betamimetics, calcium channel blockers, prostaglandin synthetase inhibitors, nitroglycerine, alcohol and dextrose infusion).[36] The studies included in the review comparing magnesium sulphate versus placebo, no treatment, or sedation were the same as those included in the initial review except for the addition of a study that compared magnesium sulphate versus barbiturate and bed rest.[37] The review found no significant difference between magnesium sulphate and other treatment in delivery within 48 hours, although significant statistical heterogeneity was found (11 RCTs, 881 women: RR 0.85, 95% CI 0.58 to 1.25).

Harms: **Versus placebo:** The systematic review found that magnesium sulphate significantly increased discontinuation of treatment compared with placebo or no treatment (3 RCTs: 10/137 [7%] with magnesium sulphate *v* 0/144 [0%] with placebo or no treatment; OR 8.36, 95% CI 2.36 to 29.61).[34] **Versus other tocolytics:** The second systematic review found that the magnesium sulphate significantly increased fetal, neonatal, and infant mortality (7 RCTs, 727 babies: 18/340 [5%] with magnesium sulphate *v* 6/387 [2%] with other tocolytics; RR 2.82, 95% CI 1.20 to 6.62).[36]

Comment: None.

OPTION OXYTOCIN RECEPTOR ANTAGONISTS (ATOSIBAN) New

One systematic review identified two RCTs that compared atosiban with placebo and found different results. The larger RCT found that atosiban prolonged pregnancy compared with placebo but found that atosiban appeared to increase fetal deaths below 28 weeks' gestation. The other RCT found that atosiban increased delivery within 48 hours.

Benefits: **Versus placebo:** We found one systematic review (search date 1998, 2 RCTs).[34] The first RCT identified by the systematic review (120 women at 20 to 36 weeks' gestation, with more than 4 contractions/hour and with no cervical changes, 114 deliveries) found that atosiban (300μg/minute for 2 hours) increased delivery within 48 hours, but the statistical significance was not reported (5/56 [8.9%] with atosiban *v* 2/56 [3.6%] with placebo, P not reported).[38] The second RCT identified by the review was identified as an abstract. The later full publication of this RCT (501 women with preterm labour diagnosed by uterine contractions and cervical changes, at 20 to 33 weeks) found that atosiban significantly

increased the proportion women undelivered without use of an alternative tocolytic at 24 and 48 hours and 7 days (24 hours: 73% with atosiban *v* 58% with placebo, OR 1.93, 95% CI 1.30 to 2.86; 48 hours: 67% with atosiban *v* 36% with placebo, OR 1.62, 95% CI 1.10 to 2.37; 7 days: 62% with atosiban *v* 49% with placebo, OR 1.70, 95% CI 1.17 to 2.46).[39] It found no significant difference between atosiban and placebo in the median time to delivery (25.6 days with atosiban *v* 21.0 days with placebo, P not reported). For pregnancies over 28 weeks' gestation (424 pregnancies), it found that atosiban significantly prolonged pregnancy for up to 24 hours, 48 hours, and up to 7 days compared with placebo (delay up to 24 hours: 150/203 [74%] with atosiban *v* 128/221 [58%] with placebo; RR 1.28, 95% CI 1.11 to 1.47; NNT 7, 95% CI 4 to 15; delay 48 hours: 140/203 [69%] with atosiban *v* 122/221 [55%] with placebo; RR 1.25, 95% CI 1.08 to 1.45; NNT 8, 95% CI 5 to 23; delay up to 7 days: 131/203 [65%] with atosiban *v* 105/220 [48%] with placebo; RR 1.35, 95% CI 1.14 to 1.60; NNT 6, 95% CI 4 to 14).[39]

Harms: The systematic review found increased nausea with atosiban compared with placebo or no treatment but found no significant difference in vomiting (nausea, 2 RCTs: 33/306 [11%] with atosiban *v* 15/307 [5%] with placebo or no treatment; OR 2.3, 95% CI 1.3 to 4.1; vomiting, 2 RCTs: 10/306 [3%] with atosiban *v* 13/307 [4%] with placebo or no treatment; OR 0.8, 95% CI 0.3 to 1.8).[34] Atosiban significantly reduced chest pain and dyspnoea (chest pain, 2 RCTs: 3/306 [1%] with atosiban *v* 13/307 [4%] with placebo or no treatment; OR 0.3, 95% CI 0.1 to 0.8; dyspnoea, 1 RCT: 1/250 [0.4%] with atosiban *v* 7/251 [3%] with placebo or no treatment; OR 0.22, 95% CI 0.05 to 0.89) compared with placebo or no treatment). The subsequent full report of one of the included RCTs found that atosiban significantly increased injection site reactions after prolonged use and significantly increased withdrawal owing to adverse effects (injection site reaction: 110/250 [44%] with atosiban *v* 58/251 [23%] with placebo; RR 1.90, 95% CI 1.46 to 2.48; NNH 4, 95% CI 3 to 7; withdrawal: 16% with atosiban *v* 4% with placebo).[39] It found that atosiban increased infant death compared with placebo (13/288 [4.5%] with atosiban *v* 5/295 [1.7%] with placebo, P not reported).[39] Analysis by gestational age at admission found that most of the mortality with atosiban occurred in pregnancies less than 26 weeks' gestation (mortality in pregnancies < 26 weeks: 10/27 [37%] with atosiban *v* 0/16 [0%] with placebo; see comment below; 26 to 28 weeks: 0/26[0%] *v* 1/26 [4%]; 28 to 32 weeks: 2/126 [2%] *v* 2/125 [2%]; ≥ 32 weeks: 1/109 [1%] *v* 2/128 [2%]).[39]

Comment: In the first RCT identified by the systematic review, infusions were halted in two people (one in each treatment group) and these people were not included in the analysis.[38] Tocolytic rescue with ritodrine was used in the second RCT comparing atosiban versus placebo.[39] In this RCT, 24/246 (10%) women randomised to receive atosiban and 13/255 (5%) women randomised to receive placebo were recruited at less than 26 weeks' gestation. This may have contributed to a higher incidence of fetal mortality at less than 26 weeks' gestation in the atosiban group.

OPTION PROSTAGLANDIN INHIBITORS (INDOMETACIN) New

One systematic review found limited evidence that indometacin reduced delivery within 48 hours and 7 days and delivery before 37 weeks' gestation compared with placebo. However, it found no significant difference between indometacin and placebo or no treatment in perinatal mortality, respiratory distress syndrome, bronchopulmonary dysplasia, necrotising enterocolitis, neonatal sepsis, or low birth weight. The review may have lacked power to detect a clinically important effect.

Benefits: We found one systematic review comparing indometacin versus placebo (search date 1998, 3 RCTs, 100 women).[34] It found that indometacin significantly reduced delivery within 48 hours, 7 days and delivery before 37 weeks compared with placebo but the number of women studied was small (within 48 hours, 2 RCTs: 4/34 [12%] with indometacin *v* 22/36 [61%] with placebo, OR 0.12, 95% CI 0.05 to 0.32; within 7 days, 1 RCT: 3/18 [17%] with indometacin *v* 15/18 [83%] with placebo, OR 0.07, 0.02 to 0.27 before 37 weeks, 1 RCT: 3/18 [17%] with indometacin *v* 14/18 [78%] with placebo, OR 0.09, 95% CI 0.03 to 0.24). It found no significant difference between indometacin and placebo or no treatment in perinatal mortality, respiratory distress syndrome, bronchopulmonary dysplasia, necrotising enterocolitis, neonatal sepsis, or low birth weight.[34] The number of newborns assessed for these outcomes may be too small to exclude a clinically important difference.

Harms: The systematic review found that indometacin significantly increased the incidence of postpartum haemorrhage compared with placebo or no treatment but found no significant difference in nausea or chorioamnionitis (haemorrhage, 1 RCT: 7/16 [44%] with indometacin *v* 2/18 [11%] with placebo or no treatment; OR 5.1, 95% CI 1.1 to 22.9; nausea, 1 RCT: 2/18 [11%] with indometacin *v* 0/18 with placebo or no treatment; OR 7.8, 95% CI 0.5 to 130.5; chorioamnionitis, 1 RCT: 2/15 [13%] with indometacin *v* 0/15 with placebo or no treatment; OR 7.9, 95% CI 0.5 to 133.3).[34] The number of women assessed for these outcomes may be too small to exclude a clinically important difference.

Comment: None.

QUESTION What are the effects of elective compared with selective caesarean delivery for women in preterm labour?

OPTION ELECTIVE VERSUS SELECTIVE CAESAREAN DELIVERY

One systematic review has found that elective caesarean delivery increases maternal morbidity compared with selective caesarean delivery, and found no significant difference in neonatal morbidity or mortality. The RCTs may have been underpowered to detect a clinically important neonatal benefit.

Benefits: We found one systematic review (search date not stated, 6 RCTs, 122 women).[40] It found no significant difference in neonatal morbidity and mortality between elective caesarean delivery and selective caesarean (see glossary, p 1920) delivery (low Apgar score [see glossary, p 1920] at 5 minutes: OR 0.68, 95% CI 0.29 to 1.60; need for neonatal intubation: OR 0.58, 95% CI 0.26 to 1.31; intracranial haemorrhage: OR 0.86, 95% CI 0.20 to 3.67; perinatal death: OR 0.32, 95% CI 0.07 to 1.36).

Harms: The review found that major maternal complications were reported in 7/84 (8%) women, all after caesarean delivery, although one of these women was allocated to expectant management.[40] Maternal complications were therefore significantly higher in women allocated to elective caesarean compared with selective caesarean delivery (4 RCTs, 84 women: AR 6/44 [14%] with elective caesarean delivery *v* 1/40 [3%] with selective caesarean delivery; OR 6.18, 95% CI 1.27 to 30.10). Elective caesarean delivery may occasionally result in unnecessary preterm delivery; two women allocated to the selective delivery group did not deliver until some weeks after entry to one trial.

Comment: The confidence intervals in the systematic review suggest that RCTs were underpowered and no meaningful conclusions can be drawn on the neonatal effects of elective caesarean section.[40] The fetus presented by the breech in three of the studies. About a sixth of each group delivered by an alternative route, but the analysis was by intention to treat. Sample size of trials was small and most of the trials were terminated because of recruitment difficulties.

QUESTION What are the effects of interventions to improve outcome in preterm delivery?

OPTION ANTENATAL CORTICOSTEROIDS BEFORE PRETERM DELIVERY

One systematic review found that antenatal corticosteroids significantly reduced respiratory distress syndrome, intraventricular haemorrhage, and neonatal mortality compared with placebo or no treatment.

Benefits: We found one systematic review (search date 1996, 18 RCTs, > 3700 babies) in women experiencing anticipated preterm delivery (elective or after spontaneous onset of preterm labour [see glossary, p 1920]) that compared corticosteroids (β methasone, dexamethasone, or hydrocortisone) versus placebo or no treatment.[41] The review found that antenatal corticosteroids significantly reduced respiratory distress syndrome compared with placebo or no treatment (18 RCTs, 3735 neonates: 292/1885 [15%] with corticosteroids *v* 439/1850 [24%] with placebo or no treatment; OR 0.52, 95% CI 0.44 to 0.62). Three RCTs (48 neonates) identified by the review found no significant difference between antenatal corticosteroids and placebo or no treatment in respiratory distress syndrome in neonates delivered before 28 weeks' gestation (7/17 [41%] with corticosteroids *v* 18/31 [58%] with placebo or no treatment; OR 0.64, 95% CI 0.16 to 2.50). Six RCTs identified by the review (349 neonates) found no significant difference between

antenatal corticosteroids and placebo or no treatment in respiratory distress syndrome in babies delivered within less than 24 hours of initial treatment (45/176 [26%] with corticosteroids *v* 57/173 [33%] with placebo or no treatment; OR 0.70, 95% CI 0.43 to 1.16). One RCT (42 neonates) identified by the review found no significant difference between antenatal corticosteroids and placebo or no treatment in respiratory distress syndrome in babies delivered within less than 48 hours of initial treatment (3/23 [13%] with corticosteroids *v* 6/19 [32%] with placebo or no treatment; OR 0.34, 95% CI 0.08 to 1.47). The review found that both β methasone and dexamethasone significantly reduced respiratory distress, but hydrocortisone did not (data not reported in the review). The small numbers of evaluable neonates from twin pregnancies did not allow a confident statement about the effects in multiple pregnancy. Antenatal corticosteroids significantly reduced neonatal mortality and intraventricular haemorrhage (neonatal mortality, 14 RCTs: 129/1770 [7%] with corticosteroids *v* 204/1747 [12%] with placebo or no treatment; OR 0.60, 95% CI 0.48 to 0.75; intraventricular haemorrhage (diagnosed at autopsy: 7/446 [1.6%] with corticosteroids *v* 23/417 [5.5%] with placebo or no treatment; OR 0.29, 95% CI 0.14 to 0.61; intraventricular haemorrhage diagnosed by ultrasound: 47/300 [16%] with corticosteroids *v* 77/296 [26%] with placebo or no treatment; OR 0.48, 95% CI 0.32 to 0.72). It found no significant difference between antenatal corticosteroids and placebo in necrotising enterocolitis or chronic lung disease (necrotising enterocolitis: 17/587 [3%] with corticosteroids *v* 27/567 [5%] with placebo or no treatment; OR 0.59, 95% CI 0.32 to 1.09; chronic lung disease: 38/204 [19%] with corticosteroids *v* 25/207 [12%] with placebo or no treatment; OR 1.57, 95% CI 0.87 to 2.84).[41]

Harms: The RCTs in the review found no strong evidence of any adverse effects of corticosteroids.[41] Subgroup analysis in one RCT in the review suggested that corticosteroids may be associated with death in hypertensive women, but no deaths in hypertensive women were observed in the other three RCTs in the review for which data were available.

Comment: The absence of a significant beneficial effect of corticosteroids on respiratory distress syndrome at less than 28 weeks' gestation may be because of the small numbers available for analysis at this gestation.[41] No RCTs in the review addressed the potentially harmful effects of repeated doses of antenatal corticosteroids, or whether one form of corticosteroid was more harmful than another, as a retrospective cohort study (883 babies delivered between 24 and 31 weeks' gestation) suggests.[42]

OPTION THYROTROPIN RELEASING HORMONE PLUS CORTICOSTEROIDS BEFORE PRETERM DELIVERY

One systematic review in women at risk of preterm birth found no difference in neonatal outcomes between thyrotropin releasing hormone plus corticosteroids and corticosteroids alone, and has found that thyrotropin releasing hormone plus corticosteroids increase maternal and fetal adverse events compared with corticosteroids alone.

Preterm birth

Benefits: We found one systematic review (search date 1999, 11 RCTs, > 4500 women at risk of preterm birth) that compared thyrotropin releasing hormone (TRH) plus steroids with steroids alone.[43] It found no significant difference between TRH plus steroids and steroids alone in gestational age at delivery, respiratory distress syndrome, periventricular or intraventricular haemorrhage, necrotising enterocolitis or death prior to hospital discharge (mean gestational age of 32 weeks in both groups; respiratory distress syndrome: 676/1832 [37%] with TRH plus steroids *v* 640/1837 [35%] with steroids alone; RR 1.06, 95% CI 0.97 to 1.16; periventricular or intraventricular haemorrhage: 282/1819 [16%] with TRH plus steroids *v* 262/1826 [14%] with steroids alone; RR 1.08, 95% CI 0.93 to 1.26; necrotising enterocolitis: 56/1555 [4%] with TRH plus steroids *v* 61/1548 [4%] with steroids alone; RR 0.91, 95% CI 0.64 to 1.30; death prior to hospital discharge: 185/1842 [10%] with TRH plus steroids *v* 177/1852 [9%] with steroids alone; RR 1.05, 95% CI 0.86 to 1.27).
