Subscription prices for *Clinical Evidence*

Clinical Evidence and *Clinical Evidence Concise* (with companion CD-ROM) are both published six monthly (June/December) by the BMJ Publishing Group. The annual subscription rates (for June, Issue 11 and December, Issue 12) are:

Concise edition

Personal: £90 • €145 • US$145 • Can$200
Institutional: £190 • €305 • US$305 • Can$420
Student/nurse: £40 • €65 • US$65 • Can$90

Full edition

Personal: £100 • €160 • US$160 • Can$220
Institutional: £210 • €335 • US$335 • Can$460
Student/nurse: £45 • €70 • US$70 • Can$100

All individual subscriptions (personal, student, nurse) include online access at no additional cost. Institutional subscriptions are for print editions only. Institutions may purchase online site licences separately. For information on site licences and individual electronic subscriptions please visit the subscription pages of our website www.clinicalevidence.com or email us at CEsubscriptions@bmjgroup.com (UK and ROW) or clinevid@pmds.com (Americas). You may also telephone us or fax us on the following numbers:

UK and ROW Tel: +44 (0)20 7383 6270 • Fax: +44 (0)20 7383 6402
Americas Tel: +1 800 373 2897/240 646 7000 • Fax: +1 240 646 7005

Bulk subscriptions for societies and organisations

The Publishers offer discounts for any society or organisation buying bulk quantities for their members/specific groups. Please contact Miranda Lonsdale, Sales Manager (UK) at mlonsdale@bmjgroup.com or Maureen Rooney, Sales Manager (USA) at mrooney@bmjgroup.com.

Rights and permission to reproduce

For information on translation rights, please contact Daniel Raymond-Barker at draymond-barker@bmjgroup.com. To request permission to reprint all or part of any contribution in *Clinical Evidence* contact Alan Thomas at athomas@bmjgroup.com.

Legal Disclaimer

The information contained in this publication, is intended for medical professionals. Categories presented in *Clinical Evidence* indicate a judgement about the strength of the evidence available to our authors prior to publication and the relative importance of benefits and harms.

We rely on our authors to confirm the accuracy of the information presented, and to describe generally accepted practices, and therefore we as the publisher, and our editors, cannot warrant its accuracy. Readers should be aware that professionals in the field may have different opinions. Because of this fact and also because of regular advances in medical research, we strongly recommend that readers independently verify specified treatments and drugs, including manufacturers' guidance. Also, the categories do not indicate whether a particular treatment is generally appropriate or whether it is suitable for a particular individual. Ultimately it is the readers' responsibility to make their own professional judgements, so to appropriately advise and treat their patients.

Description or reference to a product or publication does not imply endorsement of that product or publication, unless it is owned by the BMJ Publishing Group Limited.

To the fullest extent permitted by law, BMJ Publishing Group Limited and its editors, are not responsible for any losses, injury or damage caused to any person or property, (including under contract, by negligence, products liability or otherwise), whether they be direct or indirect, special, incidental or consequential, resulting from the application of the information in this publication

Acknowledgements

The BMJ Publishing Group thanks the following people and organisations for their advice and support: The Cochrane Collaboration, and especially Iain Chalmers, Mike Clarke, Phil Alderson, Peter Langhorne, and Carol Lefebvre; the National Health Service (NHS) Centre for Reviews and Dissemination, and especially Jos Kleijnen and Julie Glanville; the NHS, and especially Tom Mann, Sir John Patteson, Ron Stamp, Ben Toth, Veronica Fraser, Muir Gray, and Nick Rosen; the *British National Formulary*, and especially Dinesh Mehta, Eric Connor, and John Martin; *Martindale: The Complete Drug Reference*, and especially Sean Sweetman; the Health Information Research Unit at McMaster University, and especially Brian Haynes and Ann McKibbon; the United Health Foundation (UHF), and especially Reed Tuckson and Yvette Krantz; Bazian Ltd, and especially Anna Donald and Vivek Muthu; Paul Dieppe, Tonya Fancher, and Richard Kravitz who are working with *Clinical Evidence* to explore ways of presenting evidence on the usefulness of diagnostic test; previous staff who have contributed to this issue; the clinicians, epidemiologists, and members of patient groups who have acted as contributors, advisors, and peer reviewers; and members of our user panels: Lis Hawthorne and colleagues at Didcot Health Centre, Murray Lough and colleagues at Airdrie Health Centre, Alex Potter and colleagues at Clydebank Health Centre, Aimee Brame, Chris Clark, Gloria Daly, Hilary Durrant, Sarah Gwynne, James Harper, Diane Hickford, Sarosh Irani, Alison Kedward, Denise Knight, Sarah Lourenco, Vina Mayor, Michael Murphy, Ross Overshott, Deborah Rigby, and Catherine Tighe.

The BMJ Publishing Group values the ongoing support it has received from the global medical community for *Clinical Evidence*. In addition to others, we wish to acknowledge the efforts of the UHF and NHS who have provided educational funding to support wide dissemination to health professionals in the USA (UHF) and UK (NHS). We are grateful to the clinicians and patients who have taken part in focus groups, which are crucial to the development of *Clinical Evidence*. Finally, we would like to acknowledge the readers who have taken the time to send us their comments and suggestions.

Welcome to Issue 11

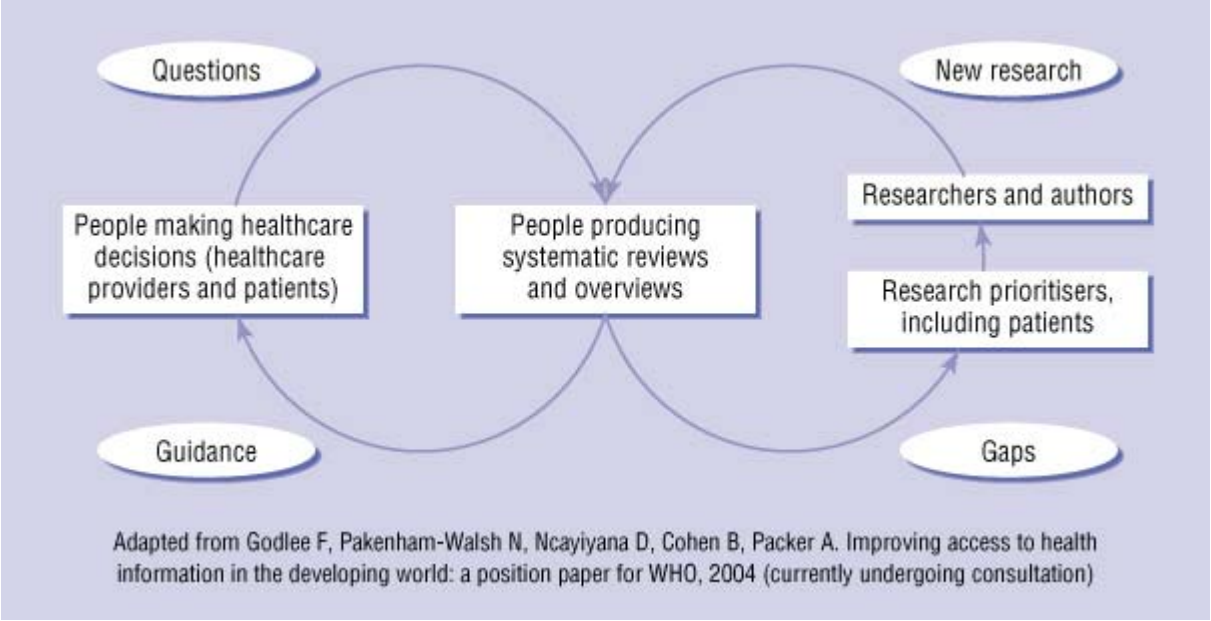
Welcome to Issue 11 of *Clinical Evidence*, the international source of the best available evidence on the effects of common clinical interventions. *Clinical Evidence* summarises the current state of knowledge and uncertainty about the prevention and treatment of clinical conditions, based on thorough searches and appraisal of the literature. It is neither a text book of medicine, nor a set of guidelines. It describes the best available evidence from systematic reviews, RCTs, and observational studies where appropriate, and if there is no good evidence it says so.

Supporting evidence based decisions

Clinical Evidence is intended as a tool for clinicians, and thereby patients, to help them make evidence based healthcare decisions. Our task is to provide information that is as accessible as possible without undue simplification. We aim to support the partnership between clinicians and patients that lies at the heart of good health care. We are working towards a future in which the information in *Clinical Evidence* can be personalised and synchronised with the electronic patient record, acknowledging that most interactions between patients and clinicians are complex and that 'evidence' is only one part of the equation.

In a truly knowledge based health system, the flow of knowledge would form a virtuous circle or (as characterised in figure 1) a figure of eight. Healthcare providers and patients generate questions during consultations. If there aren't ready answers in evidence based guidelines or handbooks, questions should be assessed by systematic review of the literature. Systematic reviews may identify good evidence to support clinical decisions, in which case this can be fed into practice. If a systematic review finds insufficient evidence to support a clinical decision, this represents a gap in our knowledge base, which should be fed into the research agenda. Ultimately, new research should be incorporated into further systematic reviews and the results of these used to guide practice. And so the cycle continues. The quality of information available at each stage depends on the quality of the information provided by the stage before.

Figure 1



Adapted from Godlee F, Pakenham-Walsh N, Ncayiyana D, Cohen B, Packer A. Improving access to health information in the developing world: a position paper for WHO, 2004 (currently undergoing consultation)

What is presented in the figure as a unidirectional flow is in reality much more complex. Information flows within and between groups in ways that are now being characterised as local information cycles. A completely inclusive information cycle exists within the world of academic research, where

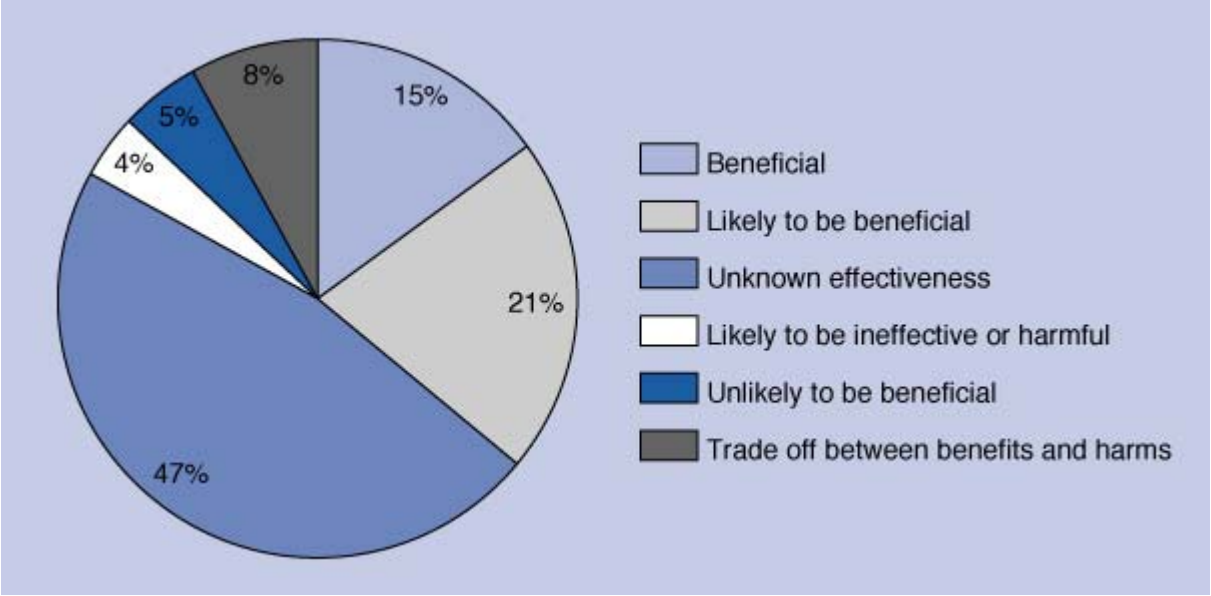
all authors are readers and all readers potential authors. But information cycles also exist, or can be established, between researchers, systematic reviewers, funders of research, healthcare providers, and patients. These information cycles have the potential to greatly increase the relevance and reliability of information about health care, and to build skills, understanding, and 'buy in' that will encourage the use of that information.

Clincial Evidence aims to establish and strengthen such information cycles. It works closely with users to identify clinical questions, and it is now working with the UK National Coordinating Centre for Health Technology Assessment to feed the gaps it identifies in the evidence back into the UK research agenda.

How much do we know?

So what can *Clinical Evidence* tell us about the state of our current knowledge? What proportion of commonly used treatments are supported by good evidence, what proportion should not be used or used only with caution, and how big are the gaps in our knowledge? A quick scan of the 2148 treatments covered in Issue 11 shows that 329 (15%) are rated as beneficial, 457 (21%) likely to be beneficial, 164 (8%) as trade off between benefits and harms, 106 (5%) unlikely to be beneficial, 94 (4%) likely to be ineffective or harmful, and 998 (47%, the largest proportion) as unknown effectiveness (see figure 2). Dividing treatments into categories is never easy. It always involves a degree of subjective judgement and is sometimes controversial. We do it because users tell us it is helpful. The figures above suggest that the research community has a large task ahead and that most decisions about treatments still rest on the individual judgements of clinicians and patients.

Figure 2



Accessibility

Clinical Evidence is currently available in five formats: the full text and Concise books; the CD-ROM, which is supplied with Concise; a version for PDA; and the website (www.clinicalevidence.com). Our website has just been redesigned and improved in response to user feedback, and further enhancements are planned throughout this year.

Whichever the format, we recognise that accessing the sort of information contained in *Clinical Evidence* can be challenging, even for experienced users. We are therefore working on making the text as readable as possible. Future issues of *Clinical Evidence* will see more of the numbers presented in data tables rather than in the text, and more use of expert commentary to highlight the

main clinical messages. We would welcome your views on other ways in which we can make the information as accessible as possible.

Update cycle

We update the *Clinical Evidence* website monthly, and produce twice yearly paper versions: full text and Concise. Each chapter is now updated every 12 months, and we will shortly be adding clinical alerts to the website to let users know about important studies that are published between updates. With each update we increase the coverage and include stronger information about the adverse effects of treatments.

The content of *Clinical Evidence* Issue 11 is a snapshot of all content that was ready for publication in February 2004. Fourteen new chapters have been added since Issue 10: acute cholecystitis, altitude sickness, athlete's foot, cataract, constipation in adults, dengue fever, ectopic pregnancy, irritable bowel syndrome, jet lag, neonatal jaundice, *Pneumocystis carinii* pneumonia in people with HIV, postnatal depression, stress incontinence, and varicocele. In addition, 109 chapters have been updated, and by the time this reaches you more new and updated chapters will have been posted on the website (www.clinicalevidence.com).

International Reach

Clinical Evidence has an international circulation. The UK NHS distributes 50 000 copies of the Concise edition to clinicians in England. This is accompanied by free online access to everyone in England and Wales. *Clinical Evidence* is now complemented by free access to *Best Treatments* through NHS Direct Online (www.besttreatments.co.uk). *Best Treatments* contains 60 chronic conditions comprehensively rewritten from the patient perspective and also provides information on operations and tests.

Thanks to the BMA, 14 000 UK medical students receive a copy of the full text edition. In the USA 500 000 copies of Concise are circulated by United Health Foundation. And thanks to the Italian Ministry of Health and the work of the Italian Cochrane Centre, 300 000 Italian doctors receive a copy of *Clinical Evidence Conciso* and CD-ROM,[1] both translated into Italian.

Clinical Evidence is also available in other non-English language editions. The Spanish translation (thanks to the Iberoamerican Cochrane Centre and MediLegis) now comes in all formats — full, concise, CD-ROM, and online.[2] The full text is available in Japanese,[3] and Russian (seven broad specialty editions).[4] The Concise edition is available in German,[5] and French (both with CD-ROM in English).[6]

Finally, *Clinical Evidence* online continues to be available free to people in developing countries as part of the HINARI initiative spearheaded by the World Health Organization and the BMJ Publishing Group. Details of those countries that qualify are available from the *Clinical Evidence* website (www.clinicalevidence.com).

Feedback

Our newly enhanced website aims to encourage feedback, all of which we welcome. If you have any comments on any of the material in *Clinical Evidence*, think that any important evidence has been missed, or have suggestions for new topics or questions please let us know. You can contact us at CEfeedback@bmjgroup.com or contact the deputy editor, David Tovey, on +44 (0)20 7383 6043. Many thanks to all of you who have already sent in your comments. Readers who would like to contribute either as authors or peer reviewers are invited to send their CV to Claire Folkes at cfolkes@bmjgroup.com

About Clinical Evidence

The inspiration for *Clinical Evidence* came in a phone call in 1995. Tom Mann and his colleagues at the NHS Executive asked the BMJ Publishing Group to explore the possibility of developing an evidence "formulary" along the lines of the *British National Formulary*. They recognised that clinicians were under increasing pressure to keep up to date and to base their practice more firmly on evidence, but that few had the necessary time or skills to do this. Their idea was to provide a pocketbook containing concise and regularly updated summaries of the best available evidence on clinical interventions. However, they didn't think that the NHS could develop such a formulary itself. "It would be marvellous", said Tom Mann, "if somebody would just do it." A small team at the BMJ set to work to produce a pilot version of what was then called the *Clinical Effectiveness Directory*.

Since that pilot, a great deal has changed. In collaboration with the American College of Physicians–American Society of Internal Medicine, we convened an international advisory board, held focus groups of clinicians, talked to patient support groups, and adopted countless good ideas from early drafts by our contributors. Throughout we have kept in mind an equation set out by Slawson et al.[1] This states that the usefulness of any source of information is equal to its relevance, multiplied by its validity, divided by the work required to extract the information. In order to be as useful as possible, we aimed for high relevance, high validity, and low work in terms of the reader's time and effort. We also kept in mind principles of transparency and explicitness. Readers needed to understand where our information came from and how it was assembled.

A UNIQUE RESOURCE

Clinical Evidence is one of growing number of sources of evidence-based information for clinicians. But it has several features that make it unique.

- Its contents are driven by questions rather than by the availability of research evidence. Rather than start with the evidence and summarise what is there, we identify important clinical questions, and then search for and summarise the best available evidence to answer them.
- It identifies but does not try to fill important gaps in the evidence. In a phrase used by Jerry Osheroff, who has led much of the research on clinicians' information needs,[2] *Clinical Evidence* presents the dark as well as the light side of the moon. We feel that it is helpful for clinicians to know when their uncertainty stems from gaps in the evidence rather than gaps in their own knowledge.
- It is continuously updated, with full literature searches in each topic every eight months. Print copies containing the latest version of each topic are published every six months and the website is refreshed with new and updated content every month.
- It specifically aims not to make recommendations. The experience of the clinical practice guideline movement has shown that it is nearly impossible to make recommendations that are appropriate in every situation. Differences in individual patients' baseline risks and preferences, and in the local availability of interventions, will always mean that the evidence must be individually interpreted rather than applied across the board. *Clinical Evidence* provides the raw material for developing locally applicable clinical practice guidelines, and for clinicians and patients to make up their own minds on the best course of action. We supply the evidence, you make the decisions.

COMPLEMENTARY BUT DIFFERENT

We are often asked how *Clinical Evidence* differs from two other high quality sources of evidence-based information: The *Cochrane Library*; and the evidence-based journals *ACP Journal Club, Evidence-Based Medicine, Evidence-Based Mental Health,* and *Evidence-Based Nursing*.

Clinical Evidence is complementary to but different from the work of the Cochrane Collaboration (www.cochrane.org), which produces and publishes high quality systematic reviews of controlled trials. *Clinical Evidence* has been called the friendly front end of the *Cochrane Library*, because it

takes this and other high quality information and pulls it together in one place in a concise format. Many of our advisors and contributors are active members of the Cochrane Collaboration, and we are exploring closer ties between *Clinical Evidence* and the Collaboration in the way the evidence is searched for, summarised, and accessed by users.

Clinical Evidence is also complementary to but different from the evidence-based journals, which select and abstract the best and most clinically relevant articles as they appear in the world's medical literature. Together these journals form a growing archive of high quality abstracts of individual articles. *Clinical Evidence* takes a different approach. It begins not with the journals but with clinical questions. It is able to answer some. For others it simply reports that no good evidence was found.

A WORK IN PROGRESS

Clinical Evidence continues to evolve. We knew when we started that we were undertaking an enormous task, and the more we work on it, the more we realise its enormity. Although we have made every effort to ensure that the searches are thorough and that the appraisals of studies are objective (see Searching and appraising the literature), we will inevitably have missed some important studies. In order not to make unjustified claims about the accuracy of the information, we use phrases such as “we found no systematic review” rather than “there is no systematic review”. In order to be as explicit as possible about the methods used for each contribution, we have asked each set of contributors to provide a brief methods section, describing the searches that were performed and how individual studies were selected.

Clinical Evidence is now a family of products, appearing in different formats and languages for different audiences. Our expectation is that *Clinical Evidence* will evolve further over the next few years, in response to the needs of clinicians and patients.

A guide to the text

SUMMARY PAGE

The summary page for each topic presents the questions addressed, some key messages, and a list of the interventions covered (in alphabetical order), categorised according to whether they have been found to be effective or not. We have developed the categories of effectiveness from one of the Cochrane Collaboration's first and most popular products, *A guide to effective care in pregnancy and childbirth*.[1] The categories we now use are explained in the table below:

Beneficial	Interventions for which effectiveness has been demonstrated by clear evidence from RCTs, and for which expectation of harms is small compared with the benefits.
Likely to be beneficial	Interventions for which effectiveness is less well established than for those listed under “beneficial”.
Trade off between benefits and harms	Interventions for which clinicians and patients should weigh up the beneficial and harmful effects according to individual circumstances and priorities.
Unknown effectiveness	Interventions for which there are currently insufficient data or data of inadequate quality.
Unlikely to be beneficial	Interventions for which lack of effectiveness is less well established than for those listed under “likely to be ineffective or harmful”.
Likely to be ineffective or harmful	Interventions for which ineffectiveness or harmfulness has been demonstrated by clear evidence.

Fitting interventions into these categories is not always straightforward. For one thing, the categories represent a mix of several hierarchies: the size of benefit (or harm), the strength of evidence (RCT or observational data), and the degree of certainty around the finding (represented by the confidence interval). Another problem is that much of the evidence that is most relevant to clinical decisions relates to comparisons between different interventions rather than to comparison with placebo or no intervention. Where necessary, we have indicated the comparisons. A third problem is that interventions may have been tested, or found to be effective, in only one group of people, such as those at high risk of an outcome. Again, we have indicated this where possible. But perhaps most difficult of all has been trying to maintain consistency across different topics. We continue to work on refining the criteria for putting interventions under each category.

Interventions that cannot be tested in an RCT for ethical or practical reasons are sometimes included in the categorisation table and are identified with an asterisk.

NEGATIVE FINDINGS

A surprisingly hard aspect to get right is the reporting of negative findings. Saying that there is no good evidence that a treatment works is not, of course, the same as saying that the treatment doesn't work. In trying to get this right, we may have erred too much on the side of caution; when in doubt, instead of saying, for example, that “the review found no difference”, we say that “the review found no evidence of a difference”. We recognise that to get this right, we need a better handle on the power of

individual systematic reviews and trials to demonstrate statistically significant differences between groups, and better information on what constitutes clinically important differences in the major outcomes for each intervention. In the meantime, we hope that the text makes a clear distinction between lack of benefit and lack of evidence of benefit.

OUTCOMES

Clinical Evidence focuses on outcomes that matter to patients, meaning those that patients themselves are aware of, such as symptom severity, quality of life, survival, disability, walking distance, and live birth rate. We are less interested in proxy outcomes such as blood lipid concentrations, blood pressure, or ovulation rates. Each topic includes a list of the main patient oriented outcomes, and where possible describes how these are measured. We have for the moment decided not to address the vexed question of what constitutes a clinically important change in an outcome, but we would welcome suggestions on how to do this.

EFFECTS, NOT EFFECTIVENESS

A key aim of *Clinical Evidence* is to emphasise the important trade offs between advantages and disadvantages of different treatment options. We therefore talk about the effects of interventions, both positive and negative, rather than the effectiveness, and for each question or intervention option we present data on benefits and harms under separate headings.

HARMS

Information about harms is often more difficult to synthesize than information about benefits.[2] Most controlled trials are designed to investigate benefits. Many either fail to document harms or present the information in a form that is difficult to analyse or interpret. When drugs are licensed they may have been used clinically in only a few thousand people; the absence of documented harms is not strong evidence that harms will not be discovered in the years after licensing.

Clinical Evidence recognises that the evidence about harms is often weaker than that about benefits. In an attempt to correct for this bias, *Clinical Evidence* has lowered the threshold for evidence to be included in the harms section. Much of the evidence for harms comes from observational studies ranging from prospective controlled cohort studies to case reports, and these are included when the harm is serious or when there is good corroborating evidence that the harm can be attributed to the treatment.

DRUG names

Clinical Evidence has an international audience. Difficulties can arise when different names for the same drug are used in different parts of the world. We state the recommended or proposed International Name where possible and give only the generic or non-proprietary names of drugs rather than the brand names. Where an international name for a drug is not available we use the most common name (e.g. aspirin). A regularly updated table of equivalent drug names, put together by *Martindale: The Complete Drug Reference,*[3] is available on the *Clinical Evidence* website (www.clinicalevidence.com).

INFORMATION ON COST

We have decided not to include information on the cost or cost effectiveness of interventions. This is not because we believe cost to be unimportant, but because the question of what constitutes good evidence on cost is much disputed and because costs vary greatly both within and between countries. However, we believe that it will become increasingly untenable for clinicians to act without paying attention to the cost of treatments. Future companion publications of *Clinical Evidence* may provide relevant information on costs.

NUMERICAL DATA

Whenever possible, data are presented in the same form as in the original studies.
However, sometimes we have changed the units or type of information in an attempt to present the results in a systematic and easily interpretable form.

AN INTERNATIONAL APPROACH

Clinical Evidence takes an international approach to the evidence. This means including drugs that are not licensed in some countries. It also means keeping in mind the practicalities of treating people in poorer countries, by covering some interventions even if they have been superseded (for example, single drug treatment for HIV infection as opposed to three drug treatment).

COMPETING INTERESTS

In line with the *BMJ*'s policy,[4] our aim is not to try to eliminate conflicts of interest but to make them explicit so that readers can judge for themselves what influence, if any, these may have had on the contributors' interpretation of the evidence. We therefore ask all contributors (and peer reviewers) to let us know about any potential competing interests, and we append any that are declared to the end of the contribution. Where the contributor gives no competing interests, we record “none declared”.

CHANGES SINCE THE LAST UPDATE

Substantive changes since the last update are listed at the end of each topic. These are defined as:

- Presentation of additional evidence that either confirms or alters the conclusions
- Re-evaluation of the evidence
- Correction of an important error

WEB ONLY TOPICS AND WEB ARCHIVE

Some topics appear only on the website and not in the paper edition. These include topics whose search date is more than 13 months before an editorial deadline for the paper edition (February for the June edition and August for the December edition each year). The “web only” topics are listed on the contents page. We also have a web archive for topics that we are no longer updating.

REFERENCE LINKS TO FULL TEXT

Clinical Evidence references link to the full text on PubMed or the Cochrane Library, as appropriate.

EMAIL ALERTING SERVICE

If you wish to be notified by email about new topics, updates, or corrections, you can register for our alerting service on our website.

HOW TO USE THE INFORMATION IN CLINICAL EVIDENCE

The type of information contained in *Clinical Evidence* is necessary but not sufficient for the provision of effective, high quality health care. It is intended as an aid to clinical decision making, to be used in conjunction with other important sources of information. These other sources include estimates of people’s baseline risk of a condition or outcome based on history, physical examination and clinical investigations; individual preferences; economic arguments; availability of treatments; and local expertise.

Some guidance on how to apply research evidence in practice is available on our website (www.clinicalevidence.com) and in appendix 3.

How Clinical Evidence is put together

The summaries in *Clinical Evidence* result from a rigorous process aimed at ensuring that they are both reliable and relevant to clinical practice.

SELECTING TOPICS

Clinical Evidence aims to cover common or important clinical conditions seen in primary and hospital care. To decide which conditions to cover we review national data on consultation rates, morbidity and mortality, we take account of national priorities for health care such as those outlined in the UK National Service Frameworks and in the US Institute of Medicine reports, and we take advice from generalist clinicians and patient groups. Our website (www.clinicalevidence.com) provides a list of conditions that we are planning to cover in future issues. Further suggestions are welcome.

SELECTING THE QUESTIONS

The questions in *Clinical Evidence* concern the benefits and harms of preventative and therapeutic interventions, with emphasis on outcomes that matter to patients. Questions are selected for their relevance to clinical practice by section advisors and contributors, in collaboration with primary care clinicians and patient groups. Each new issue of *Clinical Evidence* includes new questions as well as updates of existing questions. Readers can suggest new clinical questions using the feedback slips to be found at the back of the book and on the *Clinical Evidence* website (www.clinicalevidence.com), or by writing directly to *Clinical Evidence*.

SEARCHING AND APPRAISING THE LITERATURE

For each question, the literature is searched using the Cochrane Library, Medline, Embase and, occasionally, other electronic databases, looking first for good systematic reviews of RCTs; then for good RCTs published since the search date of the review. Where we find no good recent systematic reviews, we search for individual RCTs back to 1966. The date of the search is recorded in the methods section for each topic. Of the studies that are identified in the search, we select and summarise only a small proportion. The selection is done by critically appraising the abstracts of the studies identified in the search, a task performed independently by information scientists using validated criteria similar to those of Sackett et al[1] and Jadad.[2] [3] Where the search identifies more than one or two good reviews or trials, we select those we judge to be the most robust or relevant. Where we identify few or no good reviews or trials, we include other studies but highlight their limitations. Contributors, chosen for their clinical expertise in the field and their skills in epidemiology, are asked to review our selection of studies and to justify any additions or exclusions they wish to make.

Our search strategy and critical appraisal criteria are available on our website (www.clinicalevidence.com).

SUMMARISING THE EVIDENCE, PEER REVIEW, AND EDITING

The contributors summarise the evidence relating to each question. Each topic is then peer reviewed by the section advisors, by at least two external expert clinicians, and by an editorial committee, including external expert clinicians and epidemiologists. The revised text is then extensively edited by editors with clinical and epidemiological training, and data are checked against the original study reports. Bazian Ltd has authored several topics, as acknowledged in each, and has provided content and support.

FEEDBACK AND ERROR CORRECTIONS

Despite the extensive peer review and quality checks, we expect that the text will contain some errors and inconsistencies. Please let us know if you find any, either by using the comment card at the back of the book or by emailing us at CEfeedback@bmjgroup.com.

Glossary

The *Clinical Evidence* glossary provides a definition and some explanation of the evidence-based medicine terms that are used within *Clinical Evidence*. To make this more useful, we also include guidance notes about how the terms are used within *Clinical Evidence*. These follow the glossary definition under the heading CE guidance. Occasionally, when a term is not used in the text but represents an important concept in how *Clinical Evidence* is put together, we provide the guidance note without a definition.

Absolute risk (AR) The probability that an individual will experience the specified outcome during a specified period. It lies in the range 0 to 1, or is expressed as a percentage. In contrast to common usage, the word "risk" may refer to adverse events (such as myocardial infarction) or desirable events (such as cure).

Absolute risk increase (ARI) The absolute difference in risk between the experimental and control groups in a trial. It is used when the risk in the experimental group exceeds the risk in the control group, and is calculated by subtracting the AR in the control group from the AR in the experimental group. This figure does not give any idea of the proportional increase between the two groups: for this, relative risk (RR) is needed (see below).

Absolute risk reduction (ARR) The absolute difference in risk between the experimental and control groups in a trial. It is used when the risk in the control group exceeds the risk in the experimental group, and is calculated by subtracting the AR in the experimental group from the AR in the control group. This figure does not give any idea of the proportional reduction between the two groups: for this, relative risk (RR) is needed (see below).

Allocation concealment A method used to prevent selection bias by concealing the allocation sequence from those assigning participants to intervention groups. Allocation concealment prevents researchers from (unconsciously or otherwise) influencing which intervention group each participant is assigned to.

Applicability The application of the results from clinical trials to individual people. A randomised trial only provides direct evidence of causality within that specific trial. It takes an additional logical step to apply this result to a specific individual. Individual characteristics will affect the outcome for this person. **CE guidance** People involved in making decisions on health care must take relevant individual factors into consideration. To aid informed decision-making about applicability, we provide information on the characteristics of people recruited to trials.

Baseline risk The risk of the event occurring without the active treatment. Estimated by the baseline risk in the control group. **CE guidance** The base line risk is important for assessing the potential beneficial effects of treatment. People with a higher baseline risk can have a greater potential benefit.

Best evidence Systematic reviews of RCTs are the best method for revealing the effects of a therapeutic intervention. **CE guidance** Usually only systematic reviews of randomised controlled trials (RCTs) and RCTs will be accepted in the *Benefits* section. However, sometimes other evidence is sufficient to assign causality and in this case an RCT would not be ethical. In other cases RCTs are not practical. In these instances it is legitimate to include other forms of evidence within the *Benefits* section. RCTs are unlikely to adequately answer clinical questions in the following cases: (1) where there are good reasons to think the intervention is not likely to be beneficial or is likely to be harmful; (2) where the outcome is very rare (e.g. a 1/10000 fatal adverse reaction); (3) where the condition is very rare; (4) where very long follow up is required (e.g. does drinking milk in adolescence prevent fractures in old age?); (5) where the evidence of benefit from observational studies is overwhelming (e.g. oxygen for acute asthma attacks); (6) when applying the evidence to real clinical situations (external validity); (7) where current practice is very resistant to change and/or patients would not be willing to take the control or active treatment; (8) where the unit of randomisation would have to be too large (e.g. a nationwide public health campaign); and (9) where the condition is acute and requires immediate treatment. Of these, only the first case is categorical. For the rest the cut off point

when an RCT is not appropriate is not precisely defined. If RCTs would not be appropriate we search and include the best appropriate form of evidence.

Bias Systematic deviation of study results from the true results, because of the way(s) in which the study is conducted. **CE guidance** In the *Comment* section we aim to include any likely sources of bias within a trial/review.

Blinding/blinded A trial is fully blinded if all the people involved are unaware of the treatment group to which trial participants are allocated until after the interpretation of results. This includes trial participants and everyone involved in administering treatment or recording trial results. **CE guidance** Ideally, a trial should test whether people are aware of which group they have been allocated to. This is particularly important if, for example, one of the treatments has a distinctive taste or adverse effects. Unfortunately such testing is rare. The terms single and double blind are common in the literature but are not used consistently. Therefore, we attempt to report specifically who is unaware of treatment allocation.

Block randomisation Randomisation by a pattern to produce the required number of people in each group.

Case control study A study design that examines a group of people who have experienced an event (usually an adverse event) and a group of people who have not experienced the same event, and looks at how exposure to suspect (usually noxious) agents differed between the two groups. This type of study design is most useful for trying to ascertain the cause of rare events, such as rare cancers. **CE guidance** Case control studies can only generate odds ratios (OR) and not relative risk (RR). Case control studies provide weaker evidence than cohort studies but are more reliable than case series. We do not include case control studies within the *Benefits* section, unless it is not reasonable to expect higher levels of evidence.

Case series Analysis of series of people with the disease (there is no comparison group in case series). **CE guidance** Case series provide weaker evidence than case control studies. We try not to include case series within the *Benefits* section.

Cluster randomisation A cluster randomised study is one in which a group of participants are randomised to the same intervention together. Examples of cluster randomisation include allocating together people in the same village, hospital, or school. If the results are then analysed by individuals rather than the group as a whole bias can occur. **CE guidance** The unit of randomisation should be the same as the unit of analysis. Often a cluster randomised trial answers a different question from one randomised by individuals. An intervention at the level of the village or primary care practice may well have a different effect from one at the level of an individual patient. Therefore, trying to compensate by allowing for intra class correlation coefficients or some other method may not be appropriate. *Clinical Evidence* style is to include only results analysed according to the unit of randomisation; otherwise the trial is included only in the *Comment*.

Cohort study A non-experimental study design that follows a group of people (a cohort), and then looks at how events differ among people within the group. A study that examines a cohort, which differs in respect to exposure to some suspected risk factor (e.g. smoking), is useful for trying to ascertain whether exposure is likely to cause specified events (e.g. lung cancer). Prospective cohort studies (which track participants forward in time) are more reliable than retrospective cohort studies. **CE guidance** Cohort studies should not be included within the *Benefits* section, unless it is not reasonable to expect higher levels of evidence.

Completer analysis Analysis of data from only those participants who remained at the end of the study. Compare with intention to treat analysis, which uses data from all participants who enrolled (see below).

CE guidance Conference proceedings See unpublished evidence.

Confidence interval (CI) The 95% confidence interval (or 95% confidence limits) would include 95% of results from studies of the same size and design in the same population. This is close but not identical to saying that the true size of the effect (never exactly known) has a 95% chance of falling within the confidence interval. If the 95% confidence interval for a relative risk (RR) or an odds ratio (OR) crosses 1, then this is taken as no evidence of an effect. The practical advantages of a confidence interval (rather than a P value) is that they present the range of likely effects. **CE guidance** We always try to provide 95% confidence intervals for results.

CE guidance Consistency If two sections in *Clinical Evidence* address the same question then we attempt to avoid repetition of the evidence, but aim instead to provide a cross reference.

CE guidance Controlled clinical trial (CCT) A trial in which participants are assigned to two or more different treatment groups. In *Clinical Evidence*, we use the term to refer to controlled trials in which treatment is assigned by a method other than random allocation. When the method of allocation is by random selection, the study is referred to as a randomised controlled trial (RCT; see below). Non-randomised controlled trials are more likely to suffer from bias than RCTs.

Controls In a randomised controlled trial (RCT), controls refer to the participants in its comparison group. They are allocated either to placebo, no treatment, or a standard treatment.

Correlation coefficient A measure of association that indicates the degree to which two variables change together in a linear relationship. It is represented by *r*, and varies between –1 and +1. When *r* is +1, there is a prefect positive relationship (when one variable increases, so does the other, and the proportionate difference remains constant). When *r* is –1 there is a perfect negative relationship (when one variable increases the other decreases, or vice versa, and the proportionate difference remains constant). This, however, does not rule out a relationship — it just excludes a linear relationship.

Crossover randomised trial A trial in which participants receive one treatment and have outcomes measured, and then receive an alternative treatment and have outcomes measured again. The order of treatments is randomly assigned. Sometimes a period of no treatment is used before the trial starts and in between the treatments (washout periods) to minimise interference between the treatments (carry over effects). Interpretation of the results from crossover randomised controlled trials (RCTs) can be complex. **CE guidance** Crossover studies have the risk that the intervention may have an effect after it has been withdrawn, either because the washout period is not long enough or because of path dependency. A test for evidence of statistically significant heterogeneity is not sufficient to exclude clinically important heterogeneity. An effect may be important enough to affect the outcome but not large enough to be significant. Therefore, we try to only include results from crossover studies before the cross over.

Cross sectional study A study design that involves surveying a population about an exposure, or condition, or both, at one point in time. It can be used for assessing prevalence of a condition in the population. **CE guidance** Cross sectional studies should never be used for assessing causality of a treatment.

CE guidance Data pooling Crude summation of the raw data with no weighting, to be distinguished from meta-analysis (see meta-analysis).

CE guidance Decimal places We always precede decimal points with an integer. Numbers needing treatment to obtain one additional beneficial outcome (NNTs) are rounded up to whole numbers e.g. an NNT of 2.6 would become 3. Numbers needing treatment to obtain one additional harmful outcome (NNHs) are rounded down to whole numbers e.g an NNH of 2.3 would become 2. For P values, we use a maximum of three noughts after the decimal: $P < 0.0001$. We try to report the number of decimal places up to the number of noughts in the trial population e.g 247 people, with RR 4.837 would be rounded up to 4.84. We avoid use of more than three significant figures.

CE guidance Disability Adjusted Life Year (DALY) A method for measuring disease burden, which aims to quantify in a single figure both the quantity and quality of life lost or gained by a disease, risk

factor, or treatment. The DALYs lost or gained are a function of the expected number of years spent in a particular state of health, multiplied by a coefficient determined by the disability experienced in that state (ranging from 0 [optimal health] to 1 [deaths]). Later years are discounted at a rate of 3% per year, and childhood and old age are weighted to count for less.

CE guidance Drillability Refers to the ability to trace a statement from its most condensed form through to the original evidence that supports it. This requires not only the data but also all the methods used in the generation of the condensed form to be explicit and reproducible. We see it as an important component of the quality of evidence-based publications.

CE guidance Eclipsing In *Clinical Evidence* a systematic review should be excluded (eclipsed) if, and only if, there is a review with a later search date with either identical methods, clearly superior methods, or similar methods including the same primary sources.

Effect size (standardised mean differences) In the medical literature, effect size is used to refer to a variety of measures of treatment effect. In *Clinical Evidence* it refers to a standardised mean difference: a statistic for combining continuous variables (such as pain scores or height), from different scales, by dividing the difference between two means by an estimate of the within group standard deviation. **CE guidance** We avoid if possible. Standardised mean differences are very difficult for non-statisticians to interpret and combining heterogenous scales provides statistical accuracy at the expense of clinical intelligibility. We prefer results reported qualitatively to reliance on effect sizes.

CE guidance English language papers See language.

Event The occurrence of a dichotomous outcome that is being sought in the study (such as myocardial infarction, death, or a four-point improvement in pain score).

CE guidance Event rates In determining the power of a trial the event rate is more important than the number of participants. Therefore, we provide the number of events as well as the number of participants when this is available.

Experimental study A study in which the investigator studies the effect of intentionally altering one or more factors under controlled conditions.

CE guidance External validity (generalisabilty) The validity of the results of a trial beyond that trial. **CE guidance** A randomised controlled trial (RCT) only provides direct evidence of causality within that trial. It takes an additional logical step to apply this result more generally. However, practically it is necessary to assume that results are generalisable unless there is evidence to the contrary. If evidence is consistent across different settings and in different populations (e.g. across ages and countries) then there is evidence in favour of external validity. If there is only evidence from atypical setting (e.g. teaching hospital when most cases are seen in primary care) then one should be more sceptical about generalising the results. The *Comment* section should address questions of generalisability. Generalisability is not just a consequence of the entry requirements for the trial, but also depends on the population from which the trial population was drawn (see applicability).

Factorial design A factorial design attempts to evaluate more than one intervention compared with control in a single trial, by means of multiple randomisations.

False negative A person with the target condition (defined by the gold standard) who has a negative test result.

False positive A person without the target condition (defined by the gold standard) who has a positive test result.

Fixed effects The “fixed effects” model of meta-analysis assumes, often unreasonably, that the variability between the studies is exclusively because of a random sampling variation around a fixed effect (see random effects below).

CE guidance Foreign language papers See language.

CE guidance Harms Evidence-based healthcare resources often have great difficulty in providing good quality evidence on harms. Most RCTs are not designed to assess harms adequately: the sample size is too small, the trial too short, and often information on harms is not systematically collected. Often a lot of the harms data are in the form of uncontrolled case reports. Comparing data from these series is fraught with difficulties because of different numbers receiving the intervention, different baseline risks and differential reporting. We aim to search systematically for evidence on what are considered the most important harms of an intervention. The best evidence is from a systematic review of harms data that attempts to integrate data from different sources. However, because of these difficulties and following the maxim "first one must not do harm" we accept weaker evidence in the *Harms* than in the *Benefits* section. This can include information on whether the intervention has been either banned or withdrawn because of the risk of harms.

Hazard ratio (HR) Broadly equivalent to relative risk (RR); useful when the risk is not constant with respect to time. It uses information collected at different times. The term is typically used in the context of survival over time. If the HR is 0.5 then the relative risk of dying in one group is half the risk of dying in the other group. **CE guidance** If HRs are recorded in the original paper then we report these rather than calculating RR, because HRs take account of more data.

Heterogeneity In the context of meta-analysis, heterogeneity means dissimilarity between studies. It can be because of the use of different statistical methods (statistical heterogeneity), or evaluation of people with different characteristics, treatments or outcomes (clinical heterogeneity). Heterogeneity may render pooling of data in meta-analysis unreliable or inappropriate. **CE guidance** Finding no significant evidence of heterogeneity is not the same as finding evidence of no heterogeneity. If there are a small number of studies, heterogeneity may affect results but not be statistically significant.

Homogeneity Similarity (see heterogeneity above).

Incidence The number of new cases of a condition occurring in a population over a specified period of time.

CE guidance Inclusion/ exclusions We use validated search and appraisal criteria to exclude unsuitable papers. Authors are then sent exclusion forms to provide reasons why further papers are excluded (see Literature searches).

Intention to treat (ITT) analysis Analysis of data for all participants based on the group to which they were randomised and not based on the actual treatment they received. **CE guidance** Where possible we report ITT results. However, different methods go under the name ITT. Therefore, it is important to state how withdrawals were handled and any potential biases, e.g. the implication of carrying last result recorded forward will depend on the natural history of the condition.

CE guidance Language We aim to include all identified relevant papers irrespective of language If we have not been able to translate a paper in time for publication of the topic then we state this in the *Comment* section.

Likelihood ratio The ratio of the probability that an individual with the target condition has a specified test result to the probability that an individual without the target condition has the same specified test result.

CE guidance Jadad scale See Literature searches, Jadad.

Meta-analysis A statistical technique that summarises the results of several studies in a single weighted estimate, in which more weight is given to results of studies with more events and sometimes to studies of higher quality. **CE guidance** We use meta-analysis to refer to the quantitative methods (usually involving weighting) used to integrate data from trials. This is logically distinct from a systematic review, which is defined by an explicitly systematic search and appraisal of the literature. It is also distinct from data pooling, which is based purely on the raw data. If an

unpublished meta-analysis is included in *Clinical Evidence* then the methods should be made explicit, which we do through publication on the *Clinical Evidence* website. It should be noted that the statistical package RevMan assumes that all outcomes are adverse and therefore if RevMan states that the results for a beneficial outcome favour control this means the beneficial outcome is more likely with the experimental intervention.

Morbidity Rate of illness but not death.

Mortality Rate of death.

Negative likelihood ratio (NLR) The ratio of the probability that an individual with the target condition has a negative test result to the probability that an individual without the target condition has a negative test result. This is the same as the ratio (1–sensitivity/specificity).

Negative predictive value (NPV) The chance of not having a disease given a negative test result (not to be confused with specificity, which is the other way round; see below).

CE guidance Negative statements At what stage does no evidence of an effect become evidence of no effect? If confidence intervals are available then we should aim to indicate in words the potential size of effect they encompass. If a result is not significant we try and state if the confidence intervals include the possibility of a large effect (e.g. “The RCT found no significant effect but included the possibility of a large harm/ benefit/ harm or benefit”). The exact wording depends on the mean result and the width of the confidence intervals.

Non-systematic review A review or meta-analysis that either did not perform a comprehensive search of the literature and contains only a selection of studies on a clinical question, or did not state its methods for searching and appraising the studies it contains.

Not significant/non-significant (NS) In *Clinical Evidence*, not significant means that the observed difference, or a larger difference, could have arisen by chance with a probability of more than 1/20 (i.e. 5%), assuming that there is no underlying difference. This is not the same as saying there is no effect, just that this experiment does not provide convincing evidence of an effect. This could be because the trial was not powered to detect an effect that does exist, because there was no effect, or because of the play of chance. If there is a potentially clinically important difference that is not statistically significant then do not say there was a non-significant trend. Alternative phrases to describe this type of uncertainty include, “Fewer people died after taking treatment x but the difference was not significant” or “The difference was not significant but the confidence intervals covered the possibility of a large beneficial effect” or even, “The difference did not quite reach significance.”

Number needed to harm (NNH) One measure of treatment harm. It is the average number of people from a defined population you would need to treat with a specific intervention for a given period of time to cause one additional adverse outcome. NNH can be calculated as 1/ARI. In *Clinical Evidence*, these are usually rounded downwards.

Number needed to treat (NNT) One measure of treatment effectiveness. It is the average number of people who need to be treated with a specific intervention for a given period of time to prevent one additional adverse outcome or achieve one additional beneficial outcome. NNT can be calculated as 1/ARR (see appendix 2). In *Clinical Evidence*, NNTs are usually rounded upwards. **CE guidance** (1) NNTs are easy to interpret, but they can only be applied at a given level of baseline risk. (2) How do we calculate NNTs from meta-analysis data? The odds ratio (OR) (and 95% CI) with the AR in the control group can be used to generate absolute risk (AR) in the intervention group and from there to the NNT. This is a better measure than using the pooled data, which only uses trial size (not variance) and does not weight results (e.g. by trial quality). As people can not be treated as fractions, we round NNTs up and numbers needed to harm (NNHs) down to the largest absolute figure. This provides a conservative estimate of effect (it is most inaccurate for small numbers). (3) NNTs should only be provided for significant effects because of the difficulty of interpreting the confidence intervals

for non-significant results. Non-significant confidence intervals go from an NNT to an NNH by crossing infinity rather than zero.

CE guidance Observational studies We do not include observational studies in the *Benefits* section unless good RCTs are unavailable. Observational studies may be included in the *Harms* section or in the *Comment*. Observational studies are the most appropriate form of evidence for the Prognosis, Aetiology, and Incidence/Prevalence sections. The minimum data set and methods requirements for observational studies have not been finalised. However, we always indicate what kind of observational study, whether case series, case control, prospective or retrospective cohort study (see case control and cohort studies).

NNT for a meta-analysis Absolute measures are useful at describing the effort required to obtain a benefit, but are limited because they are influenced by both the treatment and also by the baseline risk of the individual. If a meta-analysis includes individuals with a range of baseline risks, then no single NNT will be applicable to the people in that meta-analysis, but a single relative measure (odds ratio or relative risk) may be applicable if there is no heterogeneity. In *Clinical Evidence*, an NNT is provided for meta-analysis, based on a combination of the summary odds ratio (OR) and the mean baseline risk observed in average of the control groups.

Odds The odds of an event happening is defined as the probability that an event will occur, expressed as a proportion of the probability that the event will not occur.

Odds ratio (OR) One measure of treatment effectiveness. It is the odds of an event happening in the experimental group expressed as a proportion of the odds of an event happening in the control group. The closer the OR is to one, the smaller the difference in effect between the experimental intervention and the control intervention. If the OR is greater (or less) than one, then the effects of the treatment are more (or less) than those of the control treatment. Note that the effects being measured may be adverse (e.g. death or disability) or desirable (e.g. survival). When events are rare the OR is analagous to the relative risk (RR), but as event rates increase the OR and RR diverge. **CE guidance:** The ratio of events to non-events in the intervention group over the ratio of events to non-events in the control group. In *Clinical Evidence* we try to provide relative risks in preference to odds ratios.

Odds reduction The complement of odds ratio (1–OR), similar to the relative risk reduction (RRR) when events are rare.

Open label trial A trial in which both participant and assessor are aware of the intervention allocated.

CE guidance Outcomes In *Clinical Evidence* we always aim to use outcomes that matter to patients and their carers. This generally means mortality, morbidity, quality of life, ability to work, pain, etc. Laboratory outcomes are avoided if possible. Even if there is a strong relationship between a laboratory outcome marker and a clinical outcome it is not automatic that it will hold under new conditions. Outcomes that are markers for clinically important patient centred outcomes are often called surrogate outcomes (e.g. ALT concentrations are a proxy for liver damage following paracetamol overdose). We only use surrogate outcomes in *Clinical Evidence* if patient centred outcomes are not available and a strong and consistent relationship between the surrogate outcome and patient centred outcomes has been established.

CE guidance Personal communication In the *Comments* section of *Clinical Evidence* we include evidence from personal communication if it is sufficiently important. In the *Benefits* section, we aim to include only the evidence that has been published in peer reviewed journals.

CE guidance PICOt Population, intervention, comparison, and outcome, all with a time element (PICOt). The current reporting requirements of systematic reviews are: how many RCTs, how many participants in each, comparing what with what, in what type of people, with what results. Each variable needs a temporal element, (how old are the participants, how long is the treatment given for, when is the outcome measured). In the future, we hoping to have a brief description in the text with full details accessible from the website.

Placebo A substance given in the control group of a clinical trial, which is ideally identical in appearance and taste or feel to the experimental treatment and believed to lack any disease specific effects. In the context of non-pharmacological interventions, placebo is usually referred to as sham treatments (see sham treatment below). **CE guidance** Placebo is not the same as giving no treatment and can induce real physiological changes. Whether it is appropriate to compare the experimental with placebo or no treatment depends on the question being asked. Where possible we report on the specific intervention given as a placebo. We include, if available, information is available on whether participants or clinicians could distinguish between placebo and the intervention.

Positive likelihood ratio (LR+) The ratio of the probability that an individual with the target condition has a positive test result to the probability that an individual without the target condition has a positive test result. This is the same as the ratio (sensitivity/1–specificity).

Positive predictive value (PPV) The chance of having a disease given a positive test result (not to be confused with sensitivity, which is the other way round; see below).

Power A study has adequate power if it can reliably detect a clinically important difference (i.e. between two treatments) if one actually exists. The power of a study is increased when it includes more events or when its measurement of outcomes is more precise. **CE guidance** We do not generally include power calculations, but prefer to provide confidence intervals (CIs) and leave it to readers to say if this covers a clinically significant difference. If no CIs are available a power calculation can be included assuming it is adequately explained.

Pragmatic RCT An RCT designed to provide results that are directly applicable to normal practice (compared with explanatory RCTs that are intended to clarify efficacy under ideal conditions). Pragmatic RCTs recruit a population that is representative of those who are normally treated, allow normal compliance with instructions (by avoiding incentives and by using oral instructions with advice to follow manufacturers' instructions), and analyse results by “intention to treat” rather than by “on treatment” methods.

Prevalence The proportion of people with a finding or disease in a given population at a given time.

CE guidance Protocols If there is no recent systematic review (search date within the last 3 years) we report recent protocols (last 2 years) identified by our search. The information specialists send to *Clinical Evidence* authors all York and Cochrane protocols identified by our search.

CE guidance Proxy outcomes See surrogate outcomes.

Publication bias Occurs when the likelihood of a study being published varies with the results it finds. Usually, this occurs when studies that find a significant effect are more likely to be published than studies that do not find a significant effect, so making it appear from surveys of the published literature that treatments are more effective than is truly the case. **CE guidance** Can occur through both preference for significant (positive) results by journals and selective releasing of results by interested parties. A systematic review can try and detect publication bias by a forest plot of size of trial against results. This assumes that larger trials are more likely to be published irrespective of the result. If a systematic review finds evidence of publication bias this should be reported. Often publication bias takes the form of slower or less prominent publication of trials with less interesting results.

P value The probability that an observed or greater difference occurred by chance, if it is assumed that there is in fact no real difference between the effects of the interventions. If this probability is less than 1/20 (which is when the P value is less than 0.05), then the result is conventionally regarded as being “statistically significant”.

CE guidance Quality Adjusted Life Year (QALY) A method for comparing health outcomes, which assigns to each year of life a weight from 1 (perfect health) to 0 (state judged equivalent to death) dependent on the individual’s health related quality of life during that year. A total score of years

multiplied by weight can then be compared across different interventions. There is disagreement about the best methods for measuring health-related quality of life.

CE guidance Quality Control At *Clinical Evidence* we aim to have explicit and transparent methods to formulate the most clinically relevant questions, selecting the most relevant outcomes, and searching, appraising and synthesising the medical literature.

CE guidance Quality of evidence See best evidence..

Quasi randomised A trial using a method of allocating participants to different forms of care that is not truly random; for example, allocation by date of birth, day of the week, medical record number, month of the year, or the order in which participants are included in the study (e.g. alternation).

CE guidance Randomised we aim to provide an explanation of how a trial is quasi-randomised in the *Comment* section.

Random effects The "random effects" model assumes a different underlying effect for each study and takes this into consideration as an additional source of variation, which leads to somewhat wider confidence intervals than the fixed effects model. Effects are assumed to be randomly distributed, and the central point of this distribution is the focus of the combined effect estimate (see fixed effects above). **CE guidance** We prefer the random effects model because the fixed effects model is appropriate only when there is no heterogeneity—in which case results will be very similar. A random effects model does not remove the effects of heterogeneity, which should be explained by differences in trial methods and populations.

Randomised controlled trial (RCT) A trial in which participants are randomly assigned to two or more groups: at least one (the experimental group) receiving an intervention that is being tested and an other (the comparison or control group) receiving an alternative treatment or placebo. This design allows assessment of the relative effects of interventions. **CE guidance:** Clinical evidence is built upon RCTs and systematic reviews of RCTs.

Regression analysis Given data on a dependent variable and one or more independent variables, regression analysis involves finding the "best" mathematical model to describe or predict the dependent variable as a function of the independent variable(s). There are several regression models that suit different needs. Common forms are linear, logistic, and proportional hazards.

Relative risk (RR) The number of times more likely (RR > 1) or less likely (RR < 1) an event is to happen in one group compared with another. It is the ratio of the absolute risk (AR) for each group. It is analogous to the odds ratio (OR) when events are rare. **CE guidance** We define relative risk as the absolute risk (AR) in the intervention group divided by the AR in the control group. It is to be distinguished from odds ratio (OR) which is the ratio of events over non-events in the intervention group over the ratio of events over non-events in the control group. In the USA, odds ratios are sometimes known us rate ratios or relative risks.

Relative risk increase (RRI) The proportional increase in risk between experimental and control participants in a trial.

Relative risk reduction (RRR) The proportional reduction in risk between experimental and control participants in a trial. It is the complement of the relative risk (1–RR).

CE guidance Searches See Literature searches.

Sensitivity The chance of having a positive test result given that you have a disease (not to be confused with positive predictive value [PPV], which is the other way around; see above).

Sensitivity analysis Analysis to test if results from meta-analysis are sensitive to restrictions on the data included. Common examples are large trials only, higher quality trials only, and more recent trials only. If results are consistent this provides stronger evidence of an effect and of generalisability.

Sham treatment An intervention given in the control group of a clinical trial, which is ideally identical in appearance and feel to the experimental treatment and believed to lack any disease specific effects (e.g. detuned ultrasound or random biofeedback). **CE guidance** Placebo is used for pills, whereas sham treatment is used for devices, psychological, and physical treatments (see placebo). We always try and provide information on the specific sham treatment regimen.

Significant By convention, taken to mean statistically significant at the 5% level (see statistically significant below). This is the same as a 95% confidence interval not including the value corresponding to no effect.

Specificity The chance of having a negative test result given that you do not have a disease (not to be confused with negative predictive value [NPV], which is the other way around; see above).

Standardised mean difference (SMD) A measure of effect size used when outcomes are continuous (such as height, weight, or symptom scores) rather than dichotomous (such as death or myocardial infarction). The mean differences in outcome between the groups being studied are standardised to account for differences in scoring methods (such as pain scores). The measure is a ratio; therefore, it has no units. **CE guidance** We avoid using SMDs if possible. SMD are very difficult for non-statisticians to interpret and combining heterogenous scales provides statistical accuracy at the expense of clinical intelligibility. We prefer results reported qualitatively to reliance on effect sizes, although we recognise that this may not always be practical.

Statistically significant Means that the findings of a study are unlikely to have arisen because of chance. Significance at the commonly cited 5% level ($P < 0.05$) means that the observed difference or greater difference would occur by chance in only 1/20 similar cases. Where the word “significant” or “significance” is used without qualification in the text, it is being used in this statistical sense.

Subgroup analysis Analysis of a part of the trial/meta-analysis population in which it is thought the effect may differ from the mean effect. **CE guidance:** Subgroup analysis should always be listed as such and generally only prespecified subgroup analysis should be included. Otherwise, they provide weak evidence and are more suited for hypothesis generation. If many tests are done on the same data this increases the chance of spurious correlation and some kind of correction is needed (e.g. Bonforroni). Given independent data, and no underlying effect, 1 time in 20 a significant result would be expected by chance.

CE guidance Surrogate outcomes Outcomes not directly of importance to patients and their carers but predictive of patient centred outcomes (see outcomes).

Systematic review A review in which specified and appropriate methods have been used to identify, appraise, and summarise studies addressing a defined question. It can, but need not, involve meta-analysis (see meta-analysis). In *Clinical Evidence*, the term systematic review refers to a systematic review of RCTs unless specified otherwise. **CE guidance** The present requirements for reporting systematic reviews are search date, number of trials of the relevant option, number of trials that perform the appropriate comparisons, comparisons, details on the type of people, follow up period, and quantified results if available.

CE guidance Trend In Clinical Evidence, we aim to avoid saying there was a non-significant trend. Alternatives include, “fewer people died after taking treatment x but the difference was not significant” or “The difference was not significant but the confidence intervals covered the possibility of a large beneficial effect” or even, “The difference did not quite reach significance.”

True negative A person without the target condition (defined by a gold standard) who has a negative test result.

True positive A person with the target condition (defined by a gold standard) who also has a positive test result.

CE guidance Unpublished evidence *Clinical Evidence* is based on published peer reviewed evidence. Unpublished conference proceedings will not be included in the *Benefits* section (except as part of a published systematic review), but may be included in the *Comment* section. Sometimes *Clinical Evidence* includes unpublished meta-analysis or, more often, data pooling performed by *Clinical Evidence* authors or editors. We clearly indicate as such and full details of workings will be available on the website. Results from unpublished meta-analysis will always be taken as subsequent to revision by proper published analysis.

Validity The soundness or rigour of a study. A study is internally valid if the way it is designed and carried out means that the results are unbiased and it gives you an accurate estimate of the effect that is being measured. A study is externally valid if its results are applicable to people encountered in regular clinical practice.

Weighted mean difference (WMD) A measure of effect size used when outcomes are continuous (such as symptom scores or height) rather than dichotomous (such as death or myocardial infarction). The mean differences in outcome between the groups being studied are weighted to account for different sample sizes and differing precision between studies. The WMD is an absolute figure and so takes the units of the original outcome measure. **CE guidance** A continuous outcome measure, similar to standardised mean differences but based on one scale so in the real units of that scale. Ideally should be replaced by a discrete outcome and a relative risk; however, we use WMD if this is not possible.

Literature Searching

We use validated search strategies to search Medline and Embase, and use the same principles when searching other databases. Our search strategies are heavily based on strategies developed by Brian Haynes and Anne McKibbon at McMaster University in Canada,[1] and strategies developed by Carol Levebvre et al at the UK Cochrane Centre[2].

If you have any comments on our processes, please contact CEfeedback@bmjgroup.com - we would love to hear from you.

Once all the searching has been performed, the results are appraised in-house by four critical appraisers, and the selected results sent to the authors. Appraisal criteria are outlined here.

SEARCH PROTOCOL

- Systematic reviews
- Randomised controlled trials
- If necessary, Cohort studies
- Internet - just a few sites are listed here. Check the ScHARR Netting the Evidence site for a comprehensive list of EBM Resources
- CRD
- Dare
- HTA
- HEBW
- DEC
- Arif
- Bandolier
- Trip

SYSTEMATIC REVIEWS - SOURCES OF EVIDENCE

Step 1 - Cochrane Library CD

Cochrane Systematic Reviews - widely recognised as some of the best, being based on rigorous searches including grey and non-English language literature together with electronic and hand searching of medical journals.

Protocols for Cochrane reviews in progress are also included on the disc together with contact details for the principal investigator.

DARE - the Database of Abstracts of Reviews of Effectiveness - on the Cochrane Library CD. This database contains abstracts of quality assessed systematic reviews located by Medline and Embase searches from 1994 onwards. There is coverage of earlier reviews but this is not complete. It also contains abstracts of all the systematic reviews included in ACP Journal Club and gives bibliographic details of other reviews identified in searches but not meeting the quality criteria for inclusion in the main database.

Step 2 - Medline and Embase

We use validated search strategies to search for systematic reviews. The strategy we use was developed by Anne McKibbon and Brian Haynes at McMaster University.[1]

- Medline is searched back to 1966 and Embase back to 1988 (click here for search strategies) to find systematic reviews not captured on the Cochrane Library. Other databases are searched as necessary.

RCTS - SOURCES OF EVIDENCE

If a high quality systematic review answering our question is found, the search for RCTs is confined to studies published after the date of the search conducted for the review (or 3 years before its publication if search date not stated).

If no relevant systematic reviews are found, Cochrane, Best Evidence, Medline, and Embase are searched to their origin.

Step 1 - Cochrane Controlled Clinical Trials Register

This contains a comprehensive collection of trials - more than on Medline.

Step 2 - Best Evidence CD

Includes abstracts of RCTs that have been quality filtered and come with a commentary

Step 3 - Medline and Embase looking back at least 3 years, or to their origin if there are no systematic reviews

These searches capture recent RCTs not yet included on Cochrane/Best Evidence.

IF SEARCHING FOR ADDITIONAL EVIDENCE ON HARM

- The Cochrane Library and Best Evidence both contain studies of adverse effects. When searching Medline for evidence on harm of an intervention (search using the MeSH subheading "adverse effects (/ae.)
- The Medline search term ae.fs. (adverse effects - floating subheading) identifies all articles with an adverse effect subheading. This can be combined (AND) with any set of references (e.g. systematic reviews on hypertension, cohort studies on asthma) to yield the subset of such articles with an adverse effects subheading.

Searching Medline for systematic reviews

NOTES ON THE SEARCH STRINGS

These search strings are written for use with OVID software. Adaptation will be necessary for different software packages. All examples show 2-3 final lines for illustration showing the results when used to inform a search for articles on asthma. Once loaded and saved on a Medline computer these searches can be easily re- run. The longer search strings may take 5-15 minutes to run.

Having run these search strings for study methodology, combine them with sensitive subject searches initially, tightening the focus of the subject search as appropriate in order to yield a manageable set of references for browsing.

Line 24 gives a set of systematic reviews.
Line 29 gives a set of systematic reviews about therapy.
Line 30 gives an unfiltered set of review articles.
Lines 31-34 are for illustration only, using “asthma” as search term

This strategy is adapted from one designed by Ann McKibbon and others at McMaster University, Canada.[1] It limits the very broad set of review articles by using terms indicating literature searches, meta-analysis or systematic reviews. If there are particular databases relevant to your area of interest (e.g. AIDSLINE, Cancer- CD) then these could be included after line 5 as textword searches, adjusting the numbering of later lines accordingly.

Line 24 gives a set of systematic reviews. Line 29 gives a set of systematic reviews about therapy. Line 30 gives an unfiltered set of review articles. Lines 31-34 are for illustration only, using "asthma" as search term.

Critical Appraisal Criteria

APPRAISING THE QUALITY OF CITED STUDIES

The aim of *Clinical Evidence* is to summarise evidence on medical interventions from high quality systematic reviews and large well-designed randomised controlled trials. Evidence on prognosis or baseline risk may also come from such studies or from well-designed cohort studies.

There are numerous checklists for assessing study quality, some of which are summarised below. No study - or checklist - is perfect, and it is not possible to lay down hard and fast criteria for inclusion.

For practical purposes it is best to think of three categories of study:

- Methodology sound; INCLUDE
- Methodology suboptimal; INCLUDE if necessary but cite reservations
- Methodology unsound; DO NOT INCLUDE

QUALITY CRITERIA FOR INCLUDED STUDIES

The following criteria are taken primarily from *Clinical Epidemiology: a basic science for clinical medicine*, Second Edition. Sackett DL, Haynes RB, Guyatt GH, Tugwell P.

QUALITY CRITERIA FOR SYSTEMATIC STUDIES

- Questions and methods clearly stated.
- Comprehensive search methods described.
- Explicit methods used to determine which studies were included in the review.
- Methodological quality of primary studies was assessed.
- Selection and assessment of primary studies reproducible and free from bias.
- Differences in individual study results adequately explained.
- Results of primary studies combined appropriately.
- Reviewers' conclusions supported by data cited.

QUALITY CRITERIA FOR RANDOMISED CONTROLLED TRIALS

- Were the setting and study patients clearly described?
- Was assignment randomised and similarity between groups documented?
- Was allocation to study groups adequately concealed from patients and investigators, including blind assessment of outcome?
- Were all clinically relevant outcomes reported?
- Were > 80% of patients who entered the study accounted for at its conclusion?
- Were they analysed in the groups to which they were randomised (intention to treat)?
- Were both statistical and clinical significance considered?

QUALITY CRITERIA FOR COHORT STUDIES ON PROGNOSIS OR BASELINE RISK

- Was an inception cohort assembled?
- Recruitment setting, diagnostic criteria, disease severity, co-morbidity and demographic details should be documented
- Was the referral pattern described?
- Referral or diagnostics access bias avoided?
- Was an adequate follow up rate achieved?
- > 80% patients entered accounted for in results and clinical status known?
- Were objective outcome criteria developed and used?

- Was outcome assessment blind?
- Was adjustment for extraneous prognostic factors carried out?
- Quality criteria for evidence on harm

The rules of evidence on harm are the same as the rules of evidence on the beneficial effects of treatment. The best evidence on the harmfulness or otherwise of treatments comes from large randomised controlled trials (or reviews thereof). However group sizes have to be large and follow up prolonged for rare side effects to be detected and evidence on harm from RCTs may not be available. Bias due to non-comparability of groups is more likely in cohort studies and more likely still in case control studies. Case series or case reports are the weakest forms of evidence, though associations in case reports have often been subsequently confirmed

WHEN CONSIDERING EVIDENCE ON HARM:

- Was the study the strongest that could have been performed under the circumstances?
- Were study groups sufficiently comparable in respects other than exposure?
- Was determination of exposure free from bias?
- Was the determination of outcomes (in cohort studies) or the distinction between cases and controls (in case control studies) free from bias?
- Were both clinical and statistical significance considered in reporting the strength of the association?
- Is the association consistent in different studies?
- Is the temporal sequence of exposure and outcome in the right direction?
- Is there a dose response gradient?
- Does the association make sense?

Non-Hodgkin's lymphoma

Search date October 2002

Graham Mead, James Woodcock, and Charles Young

QUESTIONS

INTERVENTIONS

See glossary, p 15

Key Messages

Early stage disease

- **ACVBP versus m-BACOD** One RCT, mostly in people with early stage disease, found no significant difference in 5 year survival between ACVBP and m-BACOD.
- **Chemotherapy versus radiotherapy** We found no systematic review or RCTs of chemotherapy compared with radiotherapy.
- **CVP versus BACOP** One RCT found no significant difference in 5 year survivial between CVP and BACOP. Subgroup analysis in people with aggressive disease found no significant difference in complete remission between CVP and BACOP.

Non-Hodgkin's lymphoma

- **Short schedule CHOP plus radiotherapy versus longer schedule CHOP alone** One RCT found that short schedule CHOP plus radiotherapy significantly improved 5 year survival with the addition of radiotherapy compared with longer schedule CHOP alone. It included many older people. Longer schedule CHOP increased the risk of congestive heart failure and possibly the risk of myelosuppression.

Advanced stage disease

- **CHOP versus BCOP** One RCT compared CHOP with BCOP. Subgroup analysis of people with advanced stage disease found significantly higher complete response with CHOP. Subgroup analysis in people under 60 years of age found similar results but the difference was not significant. However, 20% of people were excluded for poorly defined reasons.
- **CHOP versus CHOP-B** One RCT in a population of mixed ages found no significant difference in 5 year mortality between CHOP and CHOP-B.
- **CHOP versus CHOP-M** One poorly reported RCT in a population of mixed ages and disease stages found similar mortality at 36 months with CHOP and CHOP-M.
- **CHOP versus CHOP plus interferon** We found no systematic review or RCTs of CHOP versus CHOP plus interferon.
- **CHOP versus CHOP plus monoclonal antibodies** We found one systematic review, which found no RCTs of CHOP versus CHOP plus monoclonal antibodies.
- **CHOP versus CHOP/VIA** One RCT, including people with stage II disease, found no significant difference in 3 year survival between CHOP and CHOP/VIA.
- **CHOP versus CIOP** One RCT of people with Kiel classification intermediate grade lymphoma, including some people with stage II disease and some people over 65 years of age, found similar overall survival at 42 months with CHOP and CIOP.
- **CHOP versus HOP** One poorly reported RCT, including people with all grades of non-Hodgkin's lymphoma, found significantly higher complete response with CHOP with HOP. However, 20% of people were excluded for a variety of reasons.
- **CHOP versus MACOP-B** One RCT, including some people aged over 65 years, found no significant difference in 3 year survival between four chemotherapy regimens: CHOP, MACOP-B, m-BACOD, and ProMACE-CytaBOM. It found limited evidence of greater toxicity with MACOP-B and m-BACOD compared with CHOP and ProMACE-CytaBOM. A second RCT, including some people with early stage disease and some older people, found no significant difference in complete response. Subgroup analysis in younger people found significantly improved 5 year survival with MACOP-B. A third RCT, including people with stage II disease, found no significant difference in complete response. Subgroup analysis from one centre found better quality of life and physical function with CHOP compared with MACOP-B. These two RCTs found a different range of adverse events with CHOP compared with MACOP-B.
- **CHOP versus m-BACOD** We found one RCT comparing four different chemotherapy regimens (see CHOP *v* MACOP-B above). A second RCT comparing CHOP with m-BACOD, including older adults and with a high withdrawal rate, found no significant difference in mortality at 4 or 5.3 years.
- **CHOP versus MEV** One RCT, including some older people and people who relapsed after treatment for early stage disease, found weak evidence of a survival benefit with CHOP compared with MEV. Subgroup analysis in people with advanced disease found that more people achieved complete response with CHOP.

- **CHOP versus PACEBOM** One RCT of people with intermediate grade lymphoma, including some people with stage II disease, found no difference in 5 or 8 year mortality in the total population. Subgroup analysis found mortality was lower with PACEBOM than CHOP in people with stage IV disease at 8 years' follow up, but the difference was not significant.
- **CHOP versus ProMACE-CytaBOM** We found one RCT comparing four different chemotherapy regimens (see CHOP *v* MACOP-B above). A second RCT, including some people with stage II disease and some people over 65 years of age, found longer median survival with CHOP compared with ProMACE-CytaBOM, but significance was not assessed.

DEFINITION

Non-Hodgkin's lymphoma (NHL) consists of a complex group of cancers arising mainly from B lymphocytes and occasionally from T lymphocytes (15% of cases). NHL usually develops in lymph nodes but can arise in other tissues almost anywhere in the body. NHL is divided according to histology and stage (spread). **Histology:** Historically histology was divided into aggressive (see glossary, p 15) and low grade disease. This chapter focuses on the most common aggressive lymphoma — diffuse large B cell lymphoma in the WHO (see table 1, p 18)[1] and REAL classification systems (see glossary, p 16). Interpretation of older studies is complicated by changes in classification systems and diagnostic techniques. We have included studies using older systems if they are primarily in people with the following types of aggressive lymphoma: Working Formulation classification — primarily intermediate grades (grades E–H [see table 2, p 18]);[2] Kiel classification — centroblastic, immunoblastic, and anaplastic (see table 3, p 19);[3] Rappaport classification — diffuse histiocytic, diffuse lymphocytic poorly differentiated, and diffuse mixed (lymphocytic and histiocytic [see table 4, p 19]).[4] There is no direct correspondence between the terms used in the different classification systems and attempts to generalise results must be treated with caution.[1–4] **Stage:** Historically, NHL has been staged according to disease spread using the Ann Arbor (see glossary, p 15) system (see table 5, p 20).[5] Ann Arbor stages I and II correspond to early disease, whereas stages III and IV are advanced disease (see glossary, p 15). However, people with bulky disease will usually be treated as having advanced disease even if the stage is only I or II. There is also substantial variation in prognosis within each stage. More recent studies assess stage using a prognostic indicator. We excluded RCTs that were primarily in children (< 16 years old), older people (> 65 years old), people with HIV infection, and people who had received prior treatment other than local radiotherapy. We also excluded RCTs of maintenance treatment and RCTs with fewer than 50 people in each arm. In RCTs of mixed populations we have reported subgroup analysis in the population of interest, if available.

INCIDENCE/ PREVALENCE

NHL occurs more commonly in males than females, and is increasing in incidence in the Western world at about 4% a year. It is the seventh most common cancer in the UK consisting of 8680 new cases in 1998 (3% of cancers) and causing 4500 deaths in 2000.[6]

AETIOLOGY/ RISK FACTORS

Unknown for most people. Surveys have implicated pesticides and hair dyes. Incidence is higher in people who are immunosuppressed.

PROGNOSIS Relates to histological type, stage, age, performance status, and lactate dehydrogenase levels. High grade lymphomas, particularly diffuse large B cell lymphoma and Burkitt's lymphoma, have a high cure rate, with both initial and salvage (high dose) chemotherapy.[7] CHOP (see glossary, p 15) is the standard treatment for aggressive NHL (but not Burkitt's lymphoma) and placebo controlled trials would be considered unethical.

AIMS OF INTERVENTION To achieve cure if possible, to palliate by achieving remission and prolonging survival, to minimise adverse effects of treatment, to maximise quality of life.

OUTCOMES Mortality at 5 or 10 years, median survival, duration of remission, quality of life, treatment mortality, other adverse effects of treatment. Only one RCT reported any quality of life results. The main secondary outcome is complete response, variously defined in different studies but usually measured at 1 or 2 months.

METHODS *Clinical Evidence* search and appraisal October 2002.

QUESTION **What are the effects of treatments for early stage aggressive non-Hodgkin's lymphoma in younger adults?**

OPTION **CHEMOTHERAPY (VERSUS CHEMOTHERAPY)**

One RCT found no significant difference in 5 year survival between CVP and BACOP. Subgroup analysis in people with aggressive disease found no significant difference in complete response between CVP and BACOP. One RCT, mostly in people with early stage disease, found no significant difference in 5 year survival between ACVBP and m-BACOD.

Benefits: We found one systematic review (search date 1998, no RCTs)[8] and two additional RCTs.[9,10] The first RCT compared CVP versus BACOP (see glossary, p 15).[9] It included 177 people with Rappaport system diffuse histiocytic, diffuse lymphocytic, diffuse mixed, lymphoblastic, and Burkitt's lymphoma, with stage I and II disease (including people with involvement of extranodal sites). About 80% were younger than 60 years. It found no significant difference in 5 year survival (73% with CVP *v* 85% with BACOP; P = 0.07). The RCT did not provide absolute data for the subgroup of people with aggressive (see glossary, p 15) lymphoma (see comment below) for mortality, survival, or disease free survival. *Clinical Evidence* subgroup analysis in people with aggressive lymphoma (including Burkitt's) found no significant difference in complete response rates at the end of the treatment (59/63 [94%] with CVP *v* 63/65 [97%] with BACOP; RR 1.00, 95% CI 0.89 to 1.04).[9] The second RCT compared ACVBP versus m-BACOD (see glossary, p 15).[10] It included 673 people aged 16–69 years with Working Formulation E, F, G, and H lymphomas and Kiel classification anaplastic large cell. About two thirds of people had stages I and II disease. It excluded people with high tumour burden (≥ 10 cm) or two or more extranodal sites. People who responded to ACVBP either partially (50–75% regression of tumour size) or completely received consolidation treatment of two courses each of methotrexate, etoposide, asparaginase, and cytarabine. The RCT did not provide absolute

data for the subgroup of people with stages I and II disease. Overall, the RCT found no significant difference in 5 year survival (75% with ACVBP *v* 73% with m-BACOD; P = 0.44) or 5 year failure free survival (65% with ACVBP *v* 61% with m-BACOD; P = 0.016).

Harms: The RCT comparing CVP versus BACOP did not report comparative harms.[9] The RCT comparing ACVBP versus m-BACOD found no significant difference in the risk of treatment related deaths (12/332 [4%] with ACVBP *v* 16/341 [5%] with m-BACOD; RR 0.80, 95% CI 0.37 to 1.60), but found that ACVBP significantly increased the risk of severe or life threatening reactions (P < 0.0001), whereas m-BACOD significantly increased pulmonary toxicity (> 1% with ACVBP *v* 19% with m-BACOD; P < 0.001).[10] Other adverse effects included cardiac, hepatic, and neurological toxicity and the development of second cancers.

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The RCT of CVP versus BACOP enrolled people according to the Rappaport system but provided subgroup analysis according to the Working Formulation.

OPTION CHEMOTHERAPY VERSUS RADIOTHERAPY

We found no systematic review or RCTs of chemotherapy versus radiotherapy.

Benefits: We found no systematic review or RCTs.

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION CHEMOTHERAPY PLUS RADIOTHERAPY VERSUS CHEMOTHERAPY ALONE

One RCT comparing longer schedule CHOP with short schedule CHOP plus radiotherapy alone found significantly improved 5 year survival with combined treatment. It included many older people. Longer schedule CHOP increased the risk of congestive heart failure and possibly the risk of myelosuppression.

Benefits: We found one systematic review (search date 1998, no RCTs).[8] We found one RCT of chemotherapy versus chemotherapy plus radiotherapy.[11] It compared eight cycles of CHOP (see glossary, p 15) versus three cycles of CHOP plus radiotherapy (total dose 4000–5500 cGy). It included 401 people with Working Formulation intermediate or high grade lymphomas D, E, F, G, H, I, and J, with stages I and II disease. Just over half were younger than 60 years. It did not report subgroup analysis by age or grade. It found that radiotherapy significantly improved progression free survival (estimated 77% with CHOP plus radiotherapy *v* 64% with CHOP; HR 1.5, 95% CI 1.0 to 2.2) and overall 5 year survival (estimated survival 82% with CHOP plus radiotherapy *v* 72% with CHOP; estimated HR 1.7, 95% CI 1.1 to 2.7; median follow up 4.4 years).

Non-Hodgkin's lymphoma

Harms: The RCT found that two people died as a result of treatment.[11] One person treated with CHOP alone died of sepsis associated with neutropenia and one person treated with CHOP plus radiotherapy died of liver failure, consistent with radiation induced hepatitis. Life threatening toxic events were more common in people treated with CHOP alone but the difference was not significant (80/201 [40%] with CHOP *v* 61/200 [31%] with CHOP plus radiotherapy; P = 0.06). The most common life threatening adverse event was myelosuppression, which caused grade 4 neutropenia (absolute neutrophil count < 500 mm) in 71/201 (35%) with CHOP alone compared with 54/200 (27%) with CHOP plus radiotherapy (P = 0.09). The RCT also found symptoms or signs of congestive heart failure or more than a 20% decrease from baseline in the left ventricular ejection fraction in significantly more people with CHOP alone (7 with CHOP alone *v* 0 with CHOP plus radiotherapy, P = 0.02). It did not describe other life threatening events.

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic review reported only some results of interest and has been used solely as a source of references.[8]

QUESTION What are the effects of treatments for advanced stage aggressive non-Hodgkin's lymphoma in younger adults?

OPTION CHOP VERSUS MACOP-B

One RCT, including some people aged over 65 years, found no significant difference in 3 year survival between four chemotherapy regimens: CHOP, MACOP-B, m-BACOD, and ProMACE-CytaBOM. It found limited evidence of greater toxicity with MACOP-B and m-BACOD versus CHOP and ProMACE-CytaBOM. A second RCT, including some people with early stage disease and some older people, found no significant difference in complete response. Subgroup analysis in younger people found significantly improved 5 year survival with MACOP-B. A third RCT, including people with stage II disease, found no significant difference in complete response. Subgroup analysis from one centre found better quality of life and physical function with CHOP compared with MACOP-B. The RCTs found a different range of adverse events with CHOP versus MACOP-B.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found three RCTs comparing CHOP and MACOP-B (see glossary, p 15).[14–18] The first RCT compared four treatment groups (CHOP [225 people] *v* m-BACOD [223 people] *v* ProMACE-CytaBOM [233 people] *v* MACOP-B [218 people]).[14,15] It included people with Working Formulation intermediate or high grade lymphomas D, E, F, G, H, and J (about 15% of people had grade group D or E lymphoma). Participants had bulky stage II, stage III, and IV disease and were aged 15–81 years, with about 75% aged under 65 years. The RCT did not report results at 5 years or more by age or grade. It found no significant difference in estimated 3 year survival (43% with CHOP *v* 43% with m-BACOD *v* 44% with ProMACE-CytaBOM *v* 40% with MACOP-B; overall P = 0.90) or 3 year disease free survival (43%

with CHOP *v* 43% with m-BACOD *v* 44% with PMCB *v* 40% with MACOP-B; overall P = 0.40; absolute numbers not reported). The RCT reported no significant difference in complete response (44% with CHOP *v* 48% with m-BACOD, *v* 56% with PMCB, *v* 51% with MACOP-B) although P values or CIs were not reported.[14,15] The second RCT compared MACOP-B versus CHOP.[16,17] It included 304 people with Working Formulation intermediate grade or high grade D, E, F, G, or H lymphoma; 15/236 (6.4%) had Working Formulation grade D lymphoma. Participants had bulky stage I–IV disease and were aged 16–72 years. About two thirds had stages III or IV disease, and about two thirds were aged under 60 years. Overall, it found no significant difference in complete response (64/125 [51%] with MACOP-B *v* 65/111 [59%] with CHOP; RR 0.87, 95% CI 0.69 to 1.10). Subgroup results by stage or grade were not reported at 5 years. Subgroup analysis in people aged 60 years or less (159 people) found MACOP-B significantly improved 5 year survival (58% with MACOP-B *v* 43% with CHOP; P = 0.03).[16,17] The third RCT compared CHOP versus MACOP-B.[18] It included 405 people with the Kiel classification aggressive (see glossary, p 15) lymphomas — centroblastic, immunoblastic, anaplastic large cell, and peripheral T cell. Participants were aged 18–67 years. Just over half of people had stage III or IV disease (51.6%). More people treated with CHOP had stage I disease (27/193 [14%] with CHOP *v* 6/181 [3%] with MACOP-B). Overall, it found no significant difference in complete response (72/193 [37%] with CHOP *v* 74/181 [41%] with MACOP-B; RR 0.91, 95% CI 0.71 to 1.18). It did not report subgroup analysis for people by stage. One centre investigated quality of life (92/106 [87%] people participated). It found significantly lower quality of life with MACOP-B at 12 weeks (P = 0.04; European Organisation for Research into Treatment of Cancer 30, modified Q of L score) and worse physical function (P = 0.01). However, at 56 weeks the difference was no longer significant (quantified results not reported). Subgroup analyses in people aged 60 years or less were presented graphically. It found no significant difference in estimated 5 year survival (59% with CHOP *v* 60% with MACOP-B; absolute numbers not presented), or estimated 5 year failure free survival (44% with CHOP *v* 47% with MACOP-B; absolute numbers not presented).[18]

Harms: The first RCT[14,15] found fatal toxicity in 1% of people treated with CHOP, 3% with ProMACE-CytaBOM, 5% with m-BACOD, and 6% with MACOP-B. It found life threatening toxicity in 31% with CHOP, 54% with m-BACOD, 29% with ProMACE-CytaBOM, and 43% with MACOP-B. Combining these two outcomes found significantly lower toxicity for CHOP and Pro-MACE-CytaBOM than m-BACOD and MACOP-B (P = 0.001). The second RCT found CHOP compared with MACOP-B significantly reduced grade 3 or 4 haematologic toxicity (P = 0.04), stomatitis (9% *v* 45%; P ≤ 0.0001), cutaneous toxicity (0% with CHOP *v* 11% with MACOP-B; P = 0.0001), and gastrointestinal ulceration (4% with CHOP *v* 12% with MACOP-B; P = 0.03), although CHOP significantly increased alopecia (71% with CHOP *v* 48% with MACOP-B; P = 0.0006).[16,17] It found no significant difference in nausea and vomiting, infection, constipation, diarrhoea, peripheral neuropathy, cardiovascular events, or myopathy. The RCT reported that people aged over 60 years

tolerated MACOP-B poorly (46% of older people completed treatment *v* 83% of younger people; P = 0.0001), with significantly more taken off treatment because of toxicity (37% of older people *v* 10% of younger people; P = 0.01). The third RCT found no significant difference in treatment related mortality (1.9% with CHOP *v* 1.7% with MACOP-B).[18] It reported on other adverse events for the people enrolled in the quality of life study. It found less appetite loss with MACOP-B but more fatigue. Beyond 12 weeks (at which time treatment with CHOP was still ongoing but MACOP-B had finished), it found more constipation and diarrhoea, nausea and vomiting, dizziness, hair loss, headache, fatigue, dryness of mouth, and heart burn with CHOP. At 56 weeks, it found more neuropathic symptoms and mucositis with MACOP-B. Absolute numbers and significance were not reported and some results were presented graphically.

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] In the first RCT of the initial 1138 people, 239 were excluded after randomisation when histology was reassessed to low grade lymphoma.[14,15] The second RCT excluded 65 people on histological or other grounds.[16,17] In the third RCT, 31 people were excluded for non-lymphoid tumours, non-eligible lymphoma categories, insufficient biopsy, or central nervous system involvement.[18]

OPTION CHOP VERSUS PACEBOM

One RCT of people with intermediate grade lymphoma, including some people with stage II disease, found no difference in 5 or 8 year mortality. Subgroup analysis found mortality was lower with PACEBOM than CHOP in people with stage IV disease at 8 years' follow up, but the difference was not significant.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found one RCT comparing CHOP versus PACEBOM (see glossary, p 16).[19,20] It included 459 people aged 16–69 years with Working Formulation F and G grade lymphoma. About two thirds had stage III or IV disease. It found no significant difference in complete response (57% with CHOP *v* 64% with PACEBOM; P = 0.14; absolute numbers not reported; see comment below). It found no significant difference in overall estimated relapse free survival at 5 years (59% with CHOP *v* 67% with PACEBOM; P > 0.05; absolute numbers not reported; results presented graphically), or at 8 years (60% with CHOP *v* 65% with PACEBOM, P = 0.65), or overall estimated survival at 5 years (50% with CHOP *v* 60% with PACEBOM; P = 0.18; results presented graphically) or at 8 years (41% with CHOP *v* 51% with PACEBOM; P = 0.11). Subgroup analysis found lower actuarial mortality with PACEBOM than with CHOP for people with stage IV disease at 8 years' follow up but the difference was not significant (42% with PACEBOM *v* 25% with CHOP; P = 0.06; absolute and relative risks not reported). Other subgroup analysis by stage was not reported.

Harms: The RCT reported three treatment related deaths with CHOP and four treatment related deaths with PACEBOM. It found PACEBOM significantly increased severe haematological toxicity (WHO 3 or 4 haematological toxicity 34% with CHOP *v* 50% with PACEBOM; P = 0.02).[19,20]

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] Criteria for complete response were stricter than for most RCTs (required normal results at 3 months after the completion of treatment).[19,20]

OPTION CHOP VERSUS PROMACE-CYTABOM

One RCT, including some people aged over 65 years, found no significant difference in 3 year survival between four chemotherapy regimens: CHOP, MACOP-B, m-BACOD, and ProMACE-CytaBOM. It found limited evidence of greater toxicity with MACOP-B and m-BACOD versus CHOP and ProMACE-CytaBOM. One RCT, including some people with stage II disease and some people aged over 65 years, found longer median survival with CHOP versus ProMACE-CytaBOM, but significance was not assessed.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below) and two RCTs.[14,15,21] The first RCT compared CHOP versus m-BACOD versus ProMACE-cytaBOM versus MACOP-B (see glossary, p 15) (see benefits of CHOP *v* MACOP-B, p 6).[14,15] The second RCT compared CHOP versus ProMACE-cytaBOM.[21] It included people with Working Formulation intermediate or high grades E, F, G, and H lymphoma and a few people with group D lymphoma (11/148 [7%]). About three quarters had stage III or IV disease. Just under half of participants were younger than 60 years (70/148 [47%]). It found no significant difference in complete response (42/73 [57.5%] with CHOP *v* 38/61 [62.3%] with ProMACE-CytaBOM, see comment below). It found longer median survival with CHOP versus ProMACE-CytaBOM (45 months with CHOP *v* 27 months with ProMACE-CytaBOM; P value not reported). The RCT did not report sufficient data on disease free survival. The RCT did not report results by stage, age, or grade.

Harms: The first RCT compared CHOP versus m-BACOD versus ProMACE-CytaBOM versus MACOP-B (see benefits of CHOP *v* MACOP-B, p 7).[14,15] The second RCT found no significant difference in toxicity between CHOP and ProMACE-CytaBOM.[21] More people died from treatment toxicity with ProMACE-CytaBOM compared with CHOP but the difference was not significant (6/72 [8%] with CHOP *v* 1/76 [1%] with ProMACE-CytaBOM; P = 0.126).

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some

results of interest and have been used solely as a source of references.[8,12,13] In the RCT comparing CHOP versus ProMACE-cytaBOM, 28 people were excluded after randomisation for unclear reasons and 14 people who died before evaluation or refused treatment were excluded from the analysis.[21]

OPTION CHOP VERSUS M-BACOD

One RCT, including some people aged over 65 years, found no significant difference in 3 year survival between four chemotherapy regimens: CHOP, MACOP-B, m-BACOD, and ProMACE-CytaBOM. It found limited evidence of greater toxicity with MACOP-B and m-BACOD versus CHOP and ProMACE-CytaBOM. A second RCT comparing CHOP with m-BACOD, including older adults and with a high withdrawal rate, found no significant difference in mortality at 4 or 5.3 years. It reported similar results in younger people.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below) and two RCTs.[14,15,22] The first RCT compared CHOP versus m-BACOD versus ProMACE-CytaBOM versus MACOP-B (see glossary, p 15) (see benefits of CHOP *v* MACOP-B, p 6).[14,15] The second RCT compared CHOP versus m-BACOD.[22] It included 392 people with Working Formulation (see table 2, p 18) groups F–H lymphoma and stages III and IV disease. Just over half of participants were over 60 years old (167/325 [51%] aged ≥ 60 years). It found no significant difference in mortality at median follow up of 4 years (91/174 [52.3%] with CHOP *v* 71/151 [47.0%] with m-BACOD; RR 1.1, 95% CI 0.9 to 1.4) or at 5.3 years (results presented graphically; 286 people available for analysis). It found no significant difference in complete response rates (88/174 [51%] with CHOP *v* 85/151 [56%] with m-BACOD; $P = 0.32$). It found no significant difference in the duration of complete response at median follow up of 4 years (numbers not reported). In the subgroups of people aged 50–60 years and aged 50 years or less, results for complete response were reported as similar (aged < 50 years, 47% with CHOP *v* 40% with m-BACOD; aged 50–59 years, 58% with CHOP *v* 61% with m-BACOD; absolute numbers and significance not reported).

Harms: The first RCT compared CHOP versus m-BACOD versus ProMACE-cytaBOM versus MACOP-B (see benefits of CHOP *v* MACOP-B, p 7).[17,18] The second RCT[22] found significantly more toxic reactions with m-BACOD versus CHOP. This included grades 2–4 of the following conditions: anaemia, leukopenia, infection, pulmonary toxicity, and thrombocytopenia. Most notably for grades 2–4 pulmonary toxicity (3% with CHOP *v* 23% with m-BACOD; $P < 0.001$), infection grades 3 and 4 (13% with CHOP *v* 35% with m-BACOD; $P < 0.001$), grades 3 and 4 thrombocytopenia (2% with CHOP *v* 13% with m-BACOD; $P = 0.003$), and stomatitis grades 3 and 4 (2% with CHOP *v* 37% with m-BACOD; $P < 0.001$). It found no significant difference in treatment related deaths (8 with CHOP *v* 9 with m-BACOD; percentages not clear).

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution.[8,12,13] The systematic reviews reported only some results of interest and have been used solely as a source of references. The second RCT excluded 67 people from analysis after randomisation, primarily for incorrect pathological assessment.[22]

OPTION CHOP VERSUS HOP

One poorly reported RCT, including people with all grades of non-Hodgkin's lymphoma, found significantly higher complete response with CHOP versus HOP. However, 20% of participants were excluded from analysis.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found one old RCT that compared CHOP versus HOP (see glossary, p 15).[23] It included 506 people with stage III or IV lymphoma. It included people with all kinds of non-Hodgkin's lymphoma, according to the Rappaport system. About two thirds had no prior treatment; a quarter had previous radiation treatment and 8% had previous chemotherapy. Ages were not reported. People who achieved complete response were rerandomised to different consolidation regimens. The RCT found no significant difference in expected survival at 1 year (81% with CHOP *v* 76% with HOP; see comment below). It found CHOP significantly increased complete response (144/204 [70%] with CHOP *v* 132/216 [61%] with HOP; RR 1.15, 95% CI 1.01 to 1.35). The RCT did not report longer term results.

Harms: The RCT reported that the most common adverse event was myelosuppression but there was no significant difference between groups (numbers not reported).[23] It found more cardiac arrhythmia with HOP (12 with HOP *v* 8 with CHOP; percentages not calculable). Drug related congestive heart failure occurred in two people in both groups but improved following discontinuation of doxorubicin.

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] The RCT excluded nearly 20% of participants after randomisation for a variety of reasons, including early death and loss to follow up.[23]

OPTION CHOP VERSUS BCOP

One RCT compared CHOP with BCOP. Subgroup analysis of people with advanced stage disease found significantly higher complete response with CHOP. Subgroup analysis in people younger than 60 years found similar results but the difference was not significant. However, 20% of participants were excluded for poorly defined reasons.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found one RCT that compared CHOP versus BCOP (see glossary, p 15).[24] It included 368 people with Rappaport nodular histiocytic, diffuse lymphocytic

poorly differentiated, diffuse mixed, diffuse histiocytic, diffuse lymphoblastic, and diffuse undifferentiated non-Hodgkin's lymphoma. Some people had prior minimal local radiotherapy. Most people had stage III or IV disease (251/283 [89%]). More than half of participants were aged 60 years or older (57%). The RCT allowed crossover in people not responding. It found no significant difference in overall survival (follow up length apparently ≥ 5 years; P = 0.09). The median duration of complete response was not reached. It found significantly more people achieved complete response with CHOP (67/153 [44%] with CHOP *v* 44/142 [31%] with BCOP; RR 1.41, 95% CI 1.04 to 1.92; see comment below). Subgroup analysis in people with stages III or IV disease found significantly more people achieved complete response with CHOP (recalculation by *Clinical Evidence* 54/132 [41%] with CHOP *v* 32/119 [27%] with BCOP; RR 1.52, 95% CI 1.06 to 2.18). Subgroup analysis in people younger than 60 years old (recalculation by *Clinical Evidence*) found a higher proportion of people had complete response with CHOP but the difference was not significant (33/73 [45%] with CHOP *v* 19/64 [30%] with BCOP; RR 1.52, 95% CI 0.97 to 2.40).

Harms: The RCT found similar rates of adverse events considered life threatening for both groups (including granulocytes 5% with CHOP *v* 9% with BCOP; platelets 3% with CHOP *v* 2% with BCOP).[24]

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] The RCT excluded 72 people (20%) after randomisation (23 people for being ineligible, 21 for major protocol variations, 28 for not receiving adequate treatment; details of these criteria were not explained).[24]

OPTION CHOP VERSUS MEV

One RCT, including some older people and people who relapsed after treatment for early stage disease, found weak evidence of a survival benefit with CHOP versus MEV. Subgroup analysis in people with advanced disease found that more people achieved complete response with CHOP.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found one RCT of CHOP versus MEV (see glossary, p 16).[25] It included 153 adults with Rappaport system diffuse histiocytic, nodular histiocytic, or diffuse mixed lymphoma. The median age of participants was 65 years for CHOP and 63 years for MEV. Inclusion criteria were stages III or IV or systemic relapse after local radiotherapy for stage I or II disease. People with progressive disease and who relapsed were taken off protocol but included in intention to treat results. Overall results found that at follow up (duration not stated) significantly more people were still alive and in first complete remission with CHOP (23/67 [34%] with CHOP *v* 7/74 [9%] with MEV; P < 0.001). However, it found no significant difference in actuarial survival at 36

months (results presented graphically). Subgroup analysis in people with stage III or IV disease found significantly higher complete response with CHOP versus MEV (38/57 [66%] with CHOP *v* 16/65 [25%] with MEV; $P < 0.001$; see comment below). Results by grade were not reported.

Harms: The RCT of CHOP versus MEV did not report on adverse events.[25]

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] Eight people were excluded after randomisation as the diagnosis was changed.[25]

OPTION CHOP VERSUS CIOP

One RCT, including some people with stage II disease and some people over 65 years, found similar overall survival at 42 months with CHOP versus CIOP.

Benefits: We found three systematic reviews (search dates 1998,[8] 2000,[12] and not stated;[13] see comment below). We found one RCT that compared CHOP versus CIOP (see glossary, p 15).[26] It included 103 people with stage II–IV (84% stage III or IV) Kiel classification intermediate grade non-Hodgkin's lymphoma (see comment below). Participants were aged 26–69 years. It found no significant difference in complete response (33/52 [63%] with CHOP *v* 30/51 [59%] with CIOP, RR 1.1, 95% CI 0.8 to 1.5). It found similar overall survival at 42 months (85% with CHOP *v* 90% with CIOP; absolute numbers and significance not reported). The RCT did not report results by stage or grade.

Harms: The RCT found significantly more grade 3 or 4 alopecia with CHOP versus CIOP (58% with CHOP *v* 20% with CIOP).[26] It found no significant difference in other grade 3 or 4 toxicities, including neutropenia (17% with CHOP *v* 15.5% with CIOP), nausea and vomiting (8% with CHOP *v* 8% with CIOP), oral mucositis (8% with CHOP *v* 4% with CIOP), peripheral neurotoxicity (6% with CHOP *v* 6% with CIOP), and hepatic toxicity (2% with CHOP *v* 2% with CIOP). There were no treatment related deaths.

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] It is unclear exactly which histologies correspond to intermediate grade Kiel classification.[26]

OPTION CHOP VERSUS CHOP VARIATIONS

One poorly reported RCT in a population of mixed ages and disease stages found similar mortality at 36 months with CHOP and CHOP-M. One RCT in a population of mixed ages found no significant difference in 5 year mortality between CHOP and CHOP-B. One RCT, including people with stage II disease, found no significant difference in 3 year survival between CHOP and CHOP/VIA.

Non-Hodgkin's lymphoma

Benefits: We found one systematic review (search date 1998; see comment below)[8] and three RCTs.[27–29] **CHOP versus CHOP-M:** We found one RCT reported as an abstract only.[27] It included 221 people aged 17–75 years with high grade non-Hodgkin's lymphoma (classification system unclear). Most people had stage III or IV disease (165/212 [78%]). Previous treatment status was not stated. It found similar complete response (59% with CHOP *v* 61% with CHOP-M [see glossary, p 15]; absolute numbers and significance not reported). Complete response was not defined. Estimated survival at 36 months was also similar (30% with CHOP *v* 31% with CHOP-M; significance not reported). It did not report subgroup analysis. **CHOP versus CHOP-B:** We found one RCT.[28] It included 274 people with stage III and IV non-Hodgkin's lymphoma. It included people with Working Formulation group D, E, F, G, and H lymphomas. About 10% had prior radiotherapy. Under half were aged younger than 60 years. The RCT rerandomised responders to high or normal dose methotrexate. Overall results were not reported fully. The RCT found no significant difference in estimated survival at 5 years (37% with CHOP *v* 39% with CHOP-B [see glossary, p 15]; P = 0.73) in people with diffuse large cell lymphoma (177 people, group G and H). It also found no significant difference in failure free survival at 5 years for people with group E and F lymphoma (17% with CHOP *v* 15% with CHOP-B; P = 0.34). **CHOP versus CHOP/VIA:** We found one RCT.[29] It included 132 people with Working Formulation E, F, G, or H lymphoma, with mean age 55 years. It included people with disease stages II (34%), III, or IV. Radiotherapy was given to people with a tumour mass of 10 cm or more. It found no significant difference in complete remission (64% with CHOP *v* 63% with CHOP/VIA [see glossary, p 15]; P = NS, absolute numbers not reported; 114 people evaluated). It reported no difference in response between treatment groups for the different stages (numbers not reported). Actuarial survival at 36 months from diagnosis was 53.5% with CHOP *v* 48% with CHOP/VIA. The difference was reported as non-significant, but absolute numbers were not reported.

Harms: **CHOP versus CHOP-M:** The RCT did not report on harms.[27] **CHOP versus CHOP-B:** The RCT found no significant difference in treatment related deaths (4/92 [4%] with CHOP *v* 4/85 [5%] with CHOP-B); it did not report comparative results for other adverse events.[28] **CHOP versus CHOP/VIA:** In the RCT, one person with CHOP and two with CHOP/VIA died during initial treatment phase. It found rates of WHO grade 3 or 4 toxicities varied by drug (anaemia 6% with CHOP *v* 9% with CHOP/VIA; neutropenia 15.5% with CHOP *v* 22% with CHOP/VIA; thrombocytopenia 4% with CHOP *v* 11.5% with CHOP/VIA; nausea and vomiting 8% with CHOP *v* 9% with CHOP/VIA; gastrointestinal 0% with CHOP *v* 2% with CHOP/VIA; neurological 10% with CHOP *v* 4.5% with CHOP/VIA).[29]

Comment: Subgroup analysis provides a weaker method of assessing the effects of an intervention than overall analysis and should be treated with caution. The systematic reviews reported only some results of interest and have been used solely as a source of references.[8,12,13] RCTs of high dose CHOP plus granulocyte colony stimulating factor versus standard dose CHOP and those with bone

marrow transplantation will be included in future *Clinical Evidence* updates. The RCT of CHOP compared with CHOP-M excluded nine people from analysis on histology grounds. The RCT of CHOP versus CHOP/VIA excluded 11 people on histology, two for lack of data, and one for prior treatment.[29]

OPTION CHOP VERSUS CHOP PLUS INTERFERON

We found no systematic review or RCTs.

Benefits: We found no systematic review or RCTs

Harms: We found no systematic review or RCTs.

Comment: None.

OPTION CHOP VERSUS CHOP PLUS MONOCLONAL ANTIBODIES

We found one systematic review, which found no RCTs.

Benefits: We found one systematic review (search date 1999, no RCTs).[30]

Harms: We found no RCTs.

Comment: None.

GLOSSARY

ACVBP Doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisone.
Aggressive disease Diffuse large B cell lymphoma has been classified variously as diffuse histiocytic lymphoma and occasionally as diffuse mixed lymphocytic–histiocytic lymphoma (Rappaport), centroblastic lymphoma, and large cell anaplastic (B cell) lymphoma (Kiel) and diffuse large cell lymphoma, diffuse large cell lymphoma immunoblastic, and occasionally diffuse mixed small and large cell lymphoma (Working Formulation).[1,3,6]
Ann Arbor See table 5, p 20.
BACOP Bleomycin, doxorubicin, cyclophosphamide, vincristine, prednisone.
BCOP 1,3-bis(2-chloroethyl)-1-nitrosourea carmustine (now accepted more), cyclophosphamide, vincristine, prednisone.
CHOP Cyclophosphamide, doxorubicin, vincristine, prednisone.
CHOP-B Cyclophosphamide, doxorubicin, vincristine, prednisone plus low dose bleomycin.
CHOP-M Cyclophosphamide, doxorubicin, vincristine, prednisone, methotrexate.
CHOP/VIA Alternate administration of CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) with VIA (etoposide, ifosfamide, cytarabine).
CIOP Idarubicin, cyclophosphamide, vincristine, prednisone.
CVP Cyclophosphamide, vincristine, prednisone.
Early and advanced disease Staging is historically done by the Ann Arbor system (see table 5, p 20). We have treated people with stage I or stage II non-bulky disease as having early disease, whereas stage III or IV, or bulky are included as advanced disease. It is recognised that there will be substantial variation even within these groups and that in more recent trials participants stage will be assessed by use of the International Prognostic Index (IPI score).
HOP Doxorubicin, vincristine, prednisone.
MACOP-B Methotrexate, leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin.
m-BACOD Low dose methotrexate, leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin.

Non-Hodgkin's lymphoma

MEV Cyclophosphamide, vincristine, methotrexate.
PACEBOM Prednisolone, doxorubicin, cyclophosphamide, etoposide, bleomycin, vincristine, methotrexate.
ProMACE-CytaBOM Prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide, cytarabine, bleomycin, vincristine, methotrexate, with leucovorin rescue.
REAL A precursor to the present WHO classification system.
WHO The World Health Organization classify lymphomas on the basis of standard stains (e.g. H and E, and reticulin) supplemented by immunophenotyping using an increasing battery of monoclonal antibodies. Where possible fresh tissue is also obtained for cytogenetic analysis. The classification then consists of an amalgamation of the above data with clinical information, ideally in a multidisciplinary team setting (see table 1, p 18).[1]

TABLE 2 **International Working Formulation Classification (see text, p 3).[2]**

Grade	Working formulation	Classification
Low grade		
A	Small lymphocytic, consistent with chronic lymphocytic leukaemia	SL
B	Follicular, predominantly small cleaved cell	FSC
C	Follicular, mixed small cleaved and large cell	FM
Intermediate grade		
D	Follicular, predominately large cell	FL
E	Diffuse, small cleaved cell	DSC
F	Diffuse mixed, small and large cell	DM
G	Diffuse, large cell cleaved or non cleaved cell	DL
High grade		
H	Immunoblastic, large cell	BL
I	Lymphoblastic, convoluted or non-convoluted cell	LL
J	Small non-cleaved cell, Burkitt's or non-Burkitt's	SNC

TABLE 3 **Updated Kiel classification (see text, p 3).[3]**

B Cell lymphoma	T cell lymphoma
Low grade	
Lymphocytic, chronic lymphocytic, and prolymphocytic leukaemia; hairy cell leukaemia	Lymphocytic, chronic lymphocytic, and prolymphocytic leukaemia
Lymphoplasmacytic/cytoid	Small, cerebriform cell mycosis fungoides, Sezary's syndrome
Plasmacytic	Lymphoepithedloid (Lennert's syndrome)
Centroblastic/centrocytic, follicular, and diffuse	Angioimmunioblastic T zone
High grade	
Centrocytic	Pleomorphic, small cell
Immunoblastic	Immunoblastic
Large cell anaplastic	Large cell anaplastic
Burkitt's lymphoma	
Lymphoblastic	Lymphoblastic

TABLE 4 **Rappaport classification (see text, p 3).[4]**

Desciption	Classification
Diffuse lymphocytic, well differentiated	DLWD
Nodular lymphocytic poorly differentiated	NLPD
Nodular mixed, lympocytic and histiocytic	NM
Nodular histiocytic	NH
Diffuse lymphocytic poorly differentiated	DLDP
Diffuse mixed, lymphocytic and histiocytic	DM
Diffuse histiocytic	DH
Diffuse lymphoblastic	DL
Diffuse undifferentiated, Burkitt's or non-Burkitt's	DU

Sickle cell disease

QUESTIONS

INTERVENTIONS

See glossary, p 35

Key Messages

Prevention

- **Penicillin prophylaxis in children under 5 years of age** One systematic review found that penicillin prophylaxis in children younger than 5 years reduced the risk of invasive pneumococcal infections and related deaths.

Sickle cell disease

- **Hydroxyurea** Two RCTs found that hydroxyurea reduced the risk of acute chest syndrome and the need for blood transfusion in people with sickle cell disease. A non-significant reduction was also found for stroke, hepatic sequestration, and death related to sickle cell disease. Hydroxyurea has been associated with neutropenia, hair loss, skin rash, and gastrointestinal disturbances. We found no evidence on the long term effects of hydroxyurea.
- **Avoidance of cold environment; limiting physical exercise** We found no RCTs or observational studies of sufficient quality about the effects of these interventions in preventing sickle cell crisis and other life threatening complications.
- **Malaria chemoprophylaxis** We found no RCTs of malaria chemoprophylaxis in people with sickle cell disease.
- **Pneumococcal vaccine** One RCT found insufficient evidence to determine whether polysaccharide pneumococcal vaccine is effective. We found no RCTs of conjugate pneumococcal vaccine in sickle cell disease. Three RCTs found that pneumococcal vaccines caused local reaction and fever but no severe adverse events.

Treatment

- **Controlled release oral morphine given after an intravenous bolus dose of morphine** One RCT found that controlled release oral morphine was as effective as intravenous morphine after an intravenous loading dose of morphine at onset of treatment.
- **Corticosteroid as adjunct to narcotic analgesics** One RCT found that intravenous methylprednisolone improved pain relief as an adjunct to intravenous morphine, but was associated with a high rate of recurrence of crisis.
- **Patient controlled analgesia** Two small RCTs found no significant difference between patient controlled analgesia using either meperidine or morphine and intermittent parenteral treatment. The incidence of adverse effects was also equal in both regimens.
- **Acupuncture** We found no systematic reviews or RCTs on the effects of acupuncture in sickle cell disease.
- **Codeine** We found no systematic reviews or RCTs on the effects of codeine in sickle cell disease.
- **Diflunisal** One RCT found no significant difference between oral diflunisal and placebo as an adjunct to meperidine in sickle cell crisis.
- **Ketorolac** Four RCTs found insufficient and conflicting evidence on the pain relieving effect of ketorolac in sickle cell crisis.
- **Oxygen** Two RCTs found insufficient evidence on the effects of oxygen therapy as an adjunct to analgesics. The RCTs excluded patients with acute chest syndrome.
- **Rehydration** We found no systematic reviews or RCTs on the effects of rehydration in sickle cell crisis.
- **Aspirin; ibuprofen; paracetamol** We found no RCTs on the effects of these analgesics in sickle cell crisis.

DEFINITION **Sickle cell disease** refers to a group of disorders caused by inheritance of a pair of abnormal haemoglobin genes, including the sickle cell gene. It is characterised by chronic haemolytic anaemia and episodic clinical events called "crises".[1] Vaso-occlusive painful crisis is the most common and occurs when abnormal red cells clog small vessels causing tissue ischaemia. The others are hyper

haemolytic crisis (excessive haemolysis), acute chest syndrome, sequestration crisis, and aplastic crisis (see glossary, p 34). Infections such as pneumonia, septicaemia, meningitis, and osteomyelitis are common in people with sickle cell disease. A common variant of sickle cell disease, also characterised by haemolytic anaemia, occurs in people with one sickle and one thalassaemia gene. **Sickle cell trait** occurs in people with one sickle gene and one normal gene. People with sickle cell trait do not have any clinical manifestation of illness. This topic covers people with sickle cell disease with or without thalassaemia.

INCIDENCE/ PREVALENCE

Sickle cell disease is most common among people living in or originating from sub-Saharan Africa.[2] The disorder also affects people of Mediterranean, Caribbean, Middle Eastern, and Asian origin. Sickle cell trait affects about 10–30% of Africa's tropical populations.[3] Sickle cell disease affects an estimated 1–2% (120 000) of newborns in Africa. About 60 000 people in the USA[4] and 10 000 in the UK suffer from the disease.[5] The sickle cell gene is most common in areas where malaria is endemic: sickle cell trait effects about 10–30% of people in tropical Africa.[3] Sickle cell disease effects an estimated 1–2% (120 000) of newborns in Africa[3] and 250 000 newborns worldwide. About 60 000 people in the USA[4] and 10 000 in the UK[5] suffer from the disease.

AETIOLOGY/ RISK FACTORS

Factors that precipitate or modulate the occurrence of sickle cell crisis are not fully understood, but infections, hypoxia, dehydration, acidosis, stress (such as major surgery or childbirth), and cold are believed to play some role. In tropical Africa, malaria is the most common cause of anaemic and vaso-occlusive crisis.[3] High levels of fetal haemoglobin is known to ameliorate the severity and incidence of sickle cell crisis and other complications of the disease.

PROGNOSIS

People affected by sickle cell disease are predisposed to bacterial infections, especially to those caused by encapsulated organisms such as *Pneumococcus*, *Haemophilus influenzae*, *Meningococcus*, and *Salmonella* species. Severe bacterial infections such as pneumonia, meningitis, and septicaemia are common causes of morbidity and mortality, especially among young children.[6] About 10% of children with sickle cell anaemia may develop a stroke, and more than half of these may suffer recurrent strokes.[7] Abnormal features of cerebral blood vessels shown by transcranial Doppler scan predict a high risk of stroke in children with sickle cell disease.[8] Frequent episodes of crisis, infections, and organ damage reduce the quality of life of people with sickle cell disease. High rate of painful crisis is an index of clinical severity that correlates with early death. Life expectancy remains low, especially in communities with poor access to health services. In some parts of Africa, about 50% of children with sickle cell disease die before their first birthday.[3] The average life expectancy for men and women with sickle cell disease in the USA is about 42 and 48 years, respectively.[9] Frequent blood transfusions could increase the risk of immune reactions and infections, such as HIV and hepatitis B or C viruses, and Chagas' disease.

Sickle cell disease

AIMS OF INTERVENTION To reduce the incidence and severity of sickle cell crisis and other acute complications; to prevent organ damage; to improve quality of life and increase life expectancy; to achieve effective pain relief during painful crises, with minimal adverse events.

OUTCOMES Mortality; quality of life; adverse effects of treatment (e.g. gastrointestinal bleeding due to non-steroidal anti-inflammatory drugs, addiction to narcotic analgesics, immune reactions and infections due to blood transfusions such as HIV, viral hepatitis, and Chagas' disease); incidence of life threatening complications (e.g. stroke, acute chest syndrome, and sequestration crisis — see glossary, p 34); and incidence of painful crisis. Secondary outcomes include duration of painful crisis, days out of school or work, blood transfusion for severe anaemia, and infectious complications (invasive pneumococcal infection or acute osteomyelitis). Fetal and total haemoglobin levels are considered proxy outcomes and are not addressed in this chapter.

METHODS *Clinical Evidence* search and appraisal January 2003; this included a search for observational studies on limiting physical exercise and avoidance of cold environment.

QUESTION **What are the effects of interventions to prevent sickle cell crisis and other acute complications of sickle cell disease?**

OPTION ANTIBIOTIC PROPHYLAXIS

One systematic review found that penicillin prophylaxis in children younger than 5 years reduced the risk of invasive pneumococcal infections and related deaths.

Benefits: We found one systematic review (search date 2001, 3 RCTs, 857 children with sickle cell anaemia).[10] One of the RCTs (242 children in Jamaica, aged 6–36 months) had a factorial design (see main glossary) comparing monthly intramuscular penicillin injection (dose not specified) versus no injection. Half of the children receiving penicillin and half of those not receiving penicillin also received either polysaccharide pneumococcal vaccine or *H influenzae* vaccine, while half in each group received no vaccine. No details were given about the method of allocation for the vaccine. The second RCT (215 children in the USA, aged 3–36 months) compared oral penicillin (125 mg twice daily) versus placebo. All children received polysaccharide pneumococcal vaccine (see glossary, p 35) at the ages of 1 and 2 years. Meta-analysis of both RCTs showed that penicillin prophylaxis reduced the risk of pneumococcal infections regardless of vaccination status (9/248 [3.6%] with penicillin prophylaxis *v* 19/209 [9.1%] without penicillin prophylaxis; RR 0.39, 95% CI 0.17 to 0.88). There was no significant difference in risk of death between those given penicillin and those not given penicillin (0/105 [0.0%] with penicillin *v* 4/110 [3.6%] without penicillin; RR 0.12, 95% CI 0.01 to 2.14).[11] The wide confidence interval indicates low precision; small size of sample may be responsible. Penicillin prophylaxis was discontinued earlier than

planned because of a significant reduction in the risk of pneumococcal infection in the penicillin group compared with placebo (RR 0.16, 95% CI 0.04 to 0.70), which made it unethical to continue recruitment. The third RCT (400 children in the USA) identified in the systematic review was meant to assess of the effect of stopping penicillin prophylaxis after the age of 5 years. It found that stopping penicillin prophylaxis was not associated with an increase in the risk of pneumococcal infections (RR 0.99, 95% CI 0.14 to 7.08) or in the risk of dying (RR 0.99, 95% CI 0.14 to 6.96).[12]

Harms: The systematic review found no severe adverse effects. One RCT recorded minor adverse effects, including localised reactions to vaccine (2 cases) and nausea/vomiting (3 cases); the difference between the penicillin prophylaxis group (4/210) and placebo group (1/199) was not statistically significant (RR 3.84, 95% CI 0.43 to 34.70).

Comment: Antibiotic prophylaxis and pneumococcal vaccines are recommended to reduce morbidity and mortality from pneumococcal infections in vulnerable groups, including children with sickle cell disease.[13] The effectiveness of antibiotic prophylaxis could be diminished by high incidence of *S pneumoniae* resistance. Allergy to penicillin is a contraindication. Erythromycin is usually the recommended alternative to penicillin but its value in sickle cell disease has not been evaluated in an RCT.

OPTION MALARIA CHEMOPROPHYLAXIS

We found no RCTs of malaria chemoprophylaxis in people with sickle cell disease.

Benefits: We found no systematic reviews or RCTs of malaria chemoprophylaxis in people with sickle cell disease.

Harms: We found no systematic review or RCTs. Adverse effects of drugs commonly used for malaria prophylaxis (chloroquine, proguanil, doxycycline, mefloquine and atovoquone–proguanil) are described elsewhere (see malaria: prevention in travellers, p 1027).

Comment: Because falciparum malaria is known to precipitate sickle cell crisis, and increase the risk of death in children with sickle cell anaemia, regular chemoprophylaxis with antimalarial drugs is advocated.[3] See malaria: prevention in travellers, p 1027.

OPTION PNEUMOCOCCAL VACCINES

We found no systematic review or RCTs evaluating the clinical effects of pneumococcal vaccines in sickle cell disease. Three RCTs found that pneumococcal vaccines caused local reaction and fever but no severe adverse events.

Benefits: We found no systematic review. **Polysaccharide pneumococcal vaccine:** We found one RCT (123 Zambian residents with sickle cell anaemia aged > 2 years; 106 aged 2–15 years). It compared polyvalent polysaccharide pneumococcal vaccine (see glossary,

p 35) versus placebo for a period of 2 years, but reported no data on clinical effects.[14] **Pneumococcal conjugate vaccine:** We found no systematic reviews or RCTs evaluating the clinical effects of pneumococcal conjugate vaccine (see glossary, p 34) in people with sickle cell disease.

Harms: **Polyvalent polysaccharide vaccine:** The RCT of pneumococcal polysaccharide vaccine found a non-significant increase in adverse effects (sore arm, induration at the site of injection, and fever) with the vaccine (3/61 [5%] with vaccine *v* 0/62 [0%] with no vaccine; ARI +4.9%, 95% CI −3.7% to +11.6%).[14] One RCT of pneumococcal polysaccharide vaccine assessed the incidence of reactions following booster immunisation in 32 children with sickle cell disease aged < 5 years who had been immunised with the same vaccine 2 or more years before the booster.[15] Post-vaccination reactions (muscle pain, fever, headache, or rash) were found in 16 (50%) children after booster vaccine and in 7 (21.9%) after placebo (RR 2.29, 95% CI 1.09 to 4.79) **Pneumococcal conjugate vaccine:** One RCT (22 children, 11 allocated to each intervention) comparing a combined schedule of 7 valent pneumococcal conjugate vaccine followed by 23 valent polysaccharide pneumococcal vaccine versus 23 valent vaccine alone found post-vaccination fever in 27.3% and 18.1% of the groups, respectively; the relative risk is not significantly different (RR 1.50, 95% CI 0.31 to 7.30).[16]

Comment: Antibiotic prophylaxis and pneumococcal vaccines are recommended to reduce morbidity and mortality from pneumococcal infections in vulnerable groups, including children with sickle cell disease.[13] An increase in penicillin resistant strains of *Streptococcus pneumoniae* has highlighted the potential for pneumococcal vaccination as an alternative. Polyvalent polysaccharide pneumococcal vaccine offers no protective immunity to children younger than 2 years, who have the highest rates of invasive pneumococcal infections.[13] Newly developed pneumococcal conjugate vaccines show protective efficacy in children younger than 2 years and are recommended for routine use in young infants,[17] but this has not been demonstrated in infants with sickle cell disease.

OPTION HYDROXYUREA

Two RCTs found that hydroxyurea reduced the risk of acute chest syndrome and the need for blood transfusion in people with sickle cell disease. A non-significant reduction was also found for stroke, hepatic sequestration, and death related to sickle cell disease. Hydroxyurea has been associated with neutropenia, hair loss, skin rash, and gastrointestinal disturbances. We found no evidence on the long term effects of hydroxyurea.

Benefits: We found one systematic review (search date 2001, 2 RCTs).[18] Both of the included RCTs compared hydroxyurea versus placebo (25 children, crossover design;[19] 299 adults, parallel group design[20]). **Painful crisis:** Both RCTs found a significant reduction in the incidence of painful crisis. The parallel RCT found that hydroxyurea reduced the number of painful crises compared with placebo after a mean follow up of 21 months (mean number of episodes

during follow up 5.1 with hydroxyurea *v* 7.9 with placebo; WMD –2.8, 95% CI –4.74 to –0.86).[20] The crossover study reported a reduced duration of hospital stay with hydroxyurea compared with placebo by the sixth month of follow up (mean duration of hospital stay 5.3 days with hydroxyurea *v* 15.2 days with placebo); available data were insufficient to test for statistical significance.[19] **Death and life threatening complications:** The parallel RCT found that hydroxyurea significantly reduced the risk of acute chest syndrome (see glossary, p 34) (RR 0.44, 95% CI 0.28 to 0.68) and the need for blood transfusion (RR 0.67, 95% CI 0.52 to 0.87).[20] No significant reductions were found for stroke (RR 0.64, 95% CI 0.11 to 3.80), hepatic sequestration (RR 0.32, 95% CI 0.03 to 3.06), and death related to sickle cell disease (RR 0.48, 95% CI 0.09 to 2.60), although the trend favoured hydroxyurea. The study was too small to rule out clinically relevant effects. **Quality of life:** The parallel RCT reported data on quality of life collected at 6 monthly intervals using the Health Status Survey, Profile of Mood States, and the Ladder of Life.[20] Lower scores reflect lower quality of life in all scales. Scores on all the quality of life scales assessed at baseline and by the 12th month were higher with hydroxyurea compared with placebo, but the weighted mean differences were not statistically significant (general health perception: WMD +0.6, 95% CI –0.18 to +1.38; social function: WMD +0.2, 95% CI –0.36 to +0.76; pain recall: WMD +0.4, 95% CI –0.18 to +0.98; and Ladder of Life: WMD +0.4, 95% CI –0.15 to +0.95).

Harms: Neutrophil count was significantly lower with hydroxyurea compared with placebo at the end of the parallel RCT (WMD –1.9, 95% CI –2.57 to –1.29).[20] Neutropenia (neutrophil count 2500 x 109/L) was reported in 79% of the people in the hydroxyurea group compared with 37% of the people allocated to placebo, but no case of infection was related to neutropenia among participants. Some participants suffered hair loss, skin rash, and gastrointestinal disturbances, but these did not differ significantly between groups. The long term safety of hydroxyurea in sickle cell disease remains uncertain.

Comment: Data extracted from the crossover RCT were obtained during the sixth month before crossover.[19] Hydroxyurea in adults was given at 15 mg/kg daily, and the dose increased at 12 weekly intervals by 2.5 mg/kg daily until mild bone marrow suppression was detected (not stated how). Dose in children was 20 mg/kg daily and increased to a maximum of 25 mg/kg daily.

OPTION LIMITING PHYSICAL EXERCISE

We found no RCTs or observational studies of sufficient quality about the effects of limiting exercise to prevent sickle cell crisis and other life threatening complications of sickle cell disease.

Benefits: We found no systematic reviews, RCTs, or observational studies that met our inclusion criteria.

Harms: We found no RCTs or observational studies that met our inclusion criteria.

Comment: Moderate exercise is generally accepted to be beneficial, especially in reducing risk of cardiovascular disease. Moderate exercise is therefore unlikely to cause harm in people with sickle cell disease. Strenuous exercise is suspected to lead to factors that may precipitate sickle cell crisis, such as low tissue oxygen saturation, dehydration, and stress.

OPTION AVOIDANCE OF COLD ENVIRONMENT

We found no RCTs or observational studies of sufficient quality about the effects of avoiding exposure to cold environment to prevent crisis and other life threatening complications of sickle cell disease.

Benefits: We found no systematic reviews, RCTs, or observational studies that met our inclusion criteria.

Harms: We found no RCTs or observational studies that met our inclusion criteria.

Comment: A 10 year retrospective study found a close correlation between cold weather and admissions for sickle cell painful crisis.[21] One observational study in 60 men with sickle cell disease and 30 adults with normal haemoglobin genotype found that vasoconstriction induced by skin cooling was significantly more likely to occur in people with sickle cell disease than in those with normal haemoglobin genotype (83% *v* 60%; P = 0.03).[22] Among people with sickle cell disease, the frequency of painful crises was significantly greater in those prone to cooling induced vasoconstriction than those less prone (0.36 crises per year *v* 0.12 crises per year; P = 0.04).[22]

QUESTION What are the effects of interventions to treat pain in sickle cell crisis?

OPTION PARACETAMOL

We found no RCTs of paracetamol (acetaminophen) in sickle cell crisis.

Benefits: We found no systematic review or RCTs.

Harms: We found no evidence on the adverse effects of paracetamol relating to its use in treating pain in sickle cell crisis.

Comment: Paracetamol is widely used by clinicians to relieve mild pain and fever. Standard clinical dosage of paracetamol is well tolerated and unlikely to cause harm, but overdose is known to cause liver toxicity. See paracetamol (acetaminophen) poisoning, p 1826.

OPTION ASPIRIN

We found no RCTs of aspirin in sickle cell crisis.

Benefits: We found no systematic reviews or RCTs.

Harms: We found no evidence on the adverse effects of aspirin in relation to its use in treating pain in sickle cell crisis.

Comment: Aspirin is widely used by clinicians to relieve mild pain and fever, although there is concern about using it in children because it has been associated with Reye's syndrome. The adverse effects of aspirin in different populations are discussed in other *Clinical Evidence* topics. (see primary prevention, p 163; stroke prevention, p 257; and non-steroidal anti-inflammatory drugs, p 1551) Studies on long term aspirin prophylaxis address a different question to that addressed here on treating acute pain in sickle cell crisis.

OPTION IBUPROFEN

We found no RCTs of ibuprofen for treating pain in sickle cell crisis.

Benefits: We found no systematic reviews or RCTs.

Harms: Ibuprofen is widely used by clinicians to relieve mild pain and fever. The adverse affects of ibuprofen in other populations are discussed in other *Clinical Evidence* topics (see acute otitis media, p 314; carpal tunnel syndrome, p 1417; and migraine headache, p 1687).

Comment: Adverse events associated with non-steroidal anti-inflammatory drugs have been reviewed elsewhere in *Clinical Evidence* (see non-steroidal anti-inflammatory drugs, p 1551; low back pain and sciatica [acute, p 1500 and chronic, p 1516]; osteoarthritis, p 1560; tennis elbow, p 1633; and dysmenorrhoea, p 2370).

OPTION DIFLUNISAL

One RCT found that diflunisal had no narcotic sparing effect and did not enhance the pain relieving effect of intramuscular meperidine.

Benefits: We found no systematic review. We found one RCT (32 adults, 46 episodes of crisis, randomisation based on the episodes), which compared oral diflunisal (1000 mg loading dose followed by 500 mg 12 hourly for 5 days) versus placebo in people having a sickle cell painful crisis.[23] Intravenous meperidine (1.0–1.5 mg/kg) and hydroxyzine (0.5 1.0 mg/kg) were given every 3–4 hours as necessary for pain relief in all people. A categorical pain scale ranging from 0–5 was used to assess response to treatment. No significant difference was found in the mean total amount of meperidine administered (1400 mg with diflunisal *v* 1000 mg with placebo; WMD +400.0, 95% CI –28.6 to +828.6). Average pain intensity difference scores did not differ significantly between diflunisal and placebo groups.

Harms: We found no systematic reviews or RCTs assessing harms of diflunisal in people with sickle cell disease. Adverse events associated with non-steroidal anti-inflammatory drugs have been reviewed elsewhere in *Clinical Evidence* (see non-steroidal anti-inflammatory drugs, p 1551; low back pain and sciatica [acute, p 1500 and chronic, p 1516]; osteoarthritis, p 1560; tennis elbow, p 1633; and dysmenorrhoea, p 2370).

Comment: None.

OPTION KETOROLAC

Four RCTs found insufficient evidence on the effects of parenteral ketorolac in relieving pain in sickle cell crisis.

Benefits: We found no systematic review. We found four small RCTs of ketorolac compared with placebo. **Versus meperidine:** One crossover RCT (20 adolescents aged 11–19 years) compared parenteral ketorolac (1.0 mg/kg) versus parenteral meperidine (1.5 mg/kg) in sickle cell vaso-occlusive crisis in the first phase (150 minutes) before crossover.[24] Pain was measured in a visual analogue scale (VAS) ranging from 0–80 mm where 0 mm denotes "no pain" and 80 mm denotes "the worst pain I've ever had". Measurements were taken at 30 minutes and 150 minutes. It found that ketorolac significantly reduced pain compared with meperidine at 30 minutes (mean VAS 39 mm with ketorolac *v* 54 mm with meperidine; $P < 0.01$) and at 150 minutes (mean VAS 33 mm with ketorolac *v* 56 mm with meperidine; $P < 0.01$). No significant reduction was found in the number of pain free people at 150 minutes with ketorolac compared with meperidine (4/10 [40%] with ketorolac *v* 2/10 [20%] with meperidine; RR 2.0, 95% CI 0.47 to 8.56), but the study was too small to rule out clinically important differences. Data obtained after crossover were not included because it is deemed unsuitable to confirm the effect of either drug. **Ketorolac plus meperidine versus placebo plus meperidine:** One RCT (18 adults with sickle cell crisis) found no significant difference in the pain relieving effects of a single dose of intramuscular ketorolac (60 mg) compared with placebo given as a supplement to repeated doses of intravenous meperidine.[25] Another RCT (21 people with sickle cell crisis, aged > 14 years) found intravenous infusion of ketorolac (150 mg first day, 120 mg subsequent days for total of 5 days) to be more effective than placebo as a supplement to intermittent intramuscular meperidine (100 mg every 3 hours if pain level is moderate or severe).[26] The intravenous ketorolac group required a significantly lower amount of meperidine to control pain compared with placebo (WMD –937.8 mg of meperidine, 95% CI –1803.2 mg to –72.4 mg). **Ketorolac plus morphine sulphate versus placebo plus morphine sulphate:** One RCT (29 people, 41 episodes of sickle cell crisis, age 5–17 years; basis for randomisation episodes of crisis) compared intravenous ketorolac (0.9 mg/kg) versus placebo as supplements to simultaneous treatment with parenteral morphine sulphate (0.1 mg/kg).[27] Morphine was repeated every 2 hours based on pain intensity rated on the VAS. No significant differences were found in the need for morphine (0.28 mg/kg with ketorolac *v* 0.32 mg/kg with placebo; WMD –0.04 mg/kg, 95% CI –0.09 mg/kg to +0.01 mg/kg). No significant differences were found in the proportion of people requiring admission for further management of severe pain (9/22 [41%] with ketorolac *v* 10/19 [53%] with placebo; RR 0.78, 95% CI 0.40 to 1.50).

Harms: No severe adverse events were reported apart from one case of epistaxis in a person that received ketorolac.[26] Other adverse events (mostly gastrointestinal disturbances) did not differ remarkably between treatment groups.

Comment: None.

OPTION CODEINE

We found no RCTs of codeine for treating pain in sickle cell crisis.

Benefits: We found no systematic reviews or RCTs.

Harms: Codeine is widely used by clinicians to relieve moderate pain. Prolonged use of narcotic analgesics may lead to addiction. Codeine is known to be less addictive than other narcotic analgesics like morphine and meperidine.

Comment: None.

OPTION MORPHINE

One RCT found that controlled release oral morphine is as good as intravenous morphine in relieving pain in sickle cell crisis following a loading of parenteral morphine at onset of treatment.

Benefits: We found no systematic review. We found one double blind placebo controlled RCT (56 children aged 5–17 years) of controlled release morphine given orally (1.9 mg/kg every 12 hours) plus intravenous placebo (saline) compared with intravenous morphine (0.04 mg/kg) plus placebo tablets for sickle cell vaso-occlusive crisis.[28] No significant differences were found in the Children's Hospital of Eastern Ontario Pain Scale (see glossary, p 34) (WMD +0.10 units, 95% CI –0.09 units to +0.70 units) and clinical scales (Oucher, faces or clinical pain scales: –0.20 units, 95% CI –0.54 units to +0.14 units) throughout the observation period (at 0900, 1300, 1700, and 2100 every day). No significant differences were found for the mean frequency of rescue analgesia (WMD –0.12 doses/day, 95% CI –0.30 doses/day to +0.06 doses/day) and the mean duration of pain (WMD +1.2 days, 95% CI –0.01 days to +2.41 days) between the oral and intravenous morphine groups.

Harms: Frequency of spontaneously reported adverse events did not differ significantly between the groups (62 for oral *v* 52 for intravenous; 16 *v* 19 for severe intensity events). Common adverse events were fever, pruritus, nausea, vomiting, and constipation; these did not differ significantly between study groups.

Comment: None.

OPTION PATIENT CONTROLLED ANALGESIA

Two small RCTs found no ignificant difference between patient controlled analgesia using either meperidine or morphine and intermittent parenteral treatment. The incidence of adverse effects was also equal in both regimens.

Benefits: We found no systematic review. **Meperidine:** One RCT (20 adults, age range 17–39 years) compared patient controlled analgesia meperidine (infusion of 25–30 mg/hour plus oral hydroxyzine 50 mg every 6 hours) versus intermittent analgesia (intramuscular meperidine 75–100 mg plus intramuscular hydroxyzine 50–75 mg given

as necessary every 3–4 hours).[29] No significant differences in pain were observed over 3 days in mean scores on categorical and analogue pain scales (categorical scores on day 2: WMD +4.0 mm, 95% CI –1.09 mm to +9.09 mm; analogue scores: WMD +68.0 mm, 95% CI –25.35 mm to +161.35 mm); no significant differences were found in the amount of meperidine used each day after 3 days (WMD +451 mg, 95% CI –70 mg to +972 mg). The units being measured in the pain scales were not defined. **Morphine:** One RCT compared patient controlled analgesia (PCA) versus intermittent intravenous injections of morphine in two phases of high and low dose regimen, respectively, in adult patients with sickle cell crisis pain.[30] In the first phase (20 people), the intermittent therapy group received either 4 mg intravenous bolus of morphine sulphate every 30–60 minutes as needed to achieve a linear analogue pain intensity score < 50 mm. The PCA group received 2 mg bolus of intravenous morphine sulphate followed by 1 mg intravenous controlled by the patient with 6 minute lock out. The dose of morphine was increased to 6 mg for the intermittent therapy group, and 1.5 mg for the PCA group if pain control by the end of the first 30 minutes was inadequate (pain score > 50 mm). The second phase (25 people) was similar but used higher doses of morphine for the PCA (2.7 mg with 10 minutes' lock out) and the intermittent intravenous group (8 mg every 30–60 minutes). There was marked reduction in pain scores on the linear analogue scale, with no significant difference between treatment groups in both the first phase (WMD –0.10 mm, 95% CI –27.03 mm to +26.83 mm) and the second phase (WMD +9.0 mm, 95% CI –18.25 mm to +36.25 mm). The total amount of morphine administered did not differ significantly between the intermittent intravenous and PCA group in the first phase (WMD –6.70 mg, 95% CI –23.35 mg to +9.95 mg) and the second phase of the study (WMD +6.40 mg, 95% CI –8.71 mg to +12.51 mg).

Harms: Nausea, vomiting, and pruritus were common events observed with both high and low dose morphine, with 44% and 31% requiring antiemetic therapy (prochlorperazine) in the intermittent intravenous and PCA groups, respectively. The frequency of side effects did not differ significantly between treatment groups. Incidence of adverse effects was 53% and 47%, respectively, but no details were given about the types of adverse effects or their severity. Respiratory depression or clinically significant hypotension was not observed during the study. Respiratory depression is a well known adverse effect of narcotic drugs. The meperidine study reported no significant adverse event. Some severe advents like seizures and respiratory depression have been commonly associated with meperidine. There are concerns of possible addiction to narcotic analgesics, but some studies show a relatively low rate of addiction (0–11%) in sickle cell disease.[31]

Comment: None.

OPTION ACUPUNCTURE

We found no RCTs of acupuncture for treating pain in sickle cell crisis.

Benefits: We found no systematic reviews or RCTs.

Harms: Acupuncture is widely used to relieve pain. Adverse effects of acupuncture in different populations are discussed in other *Clinical Evidence* topics (see low back pain and sciatica acute, p 1500 and chronic, p 1516 and nausea and vomiting in early pregnancy, p 1840).

Comment: None.

OPTION OXYGEN

Two RCTs found insufficient evidence on the effects of oxygen therapy in sickle cell crisis.

Benefits: We found no systematic review. One RCT (25 children aged 3–18 years) compared 50% oxygen versus air as an adjunct to continuous intravenous morphine infusion.[32] There was no significant difference between 50% oxygen and air in the duration of severe pains (0.94 days with 50% oxygen *v* 0.95 days with air; WMD –0.19, 95% CI –0.91 to +0.89), amount of narcotic analgesic administered, or further hospitalisation for pain. No significant differences were found in the proportion of people with progression of crisis indicated by appearance of new pain sites (5/14 [36%] with 50% oxygen *v* 4/11 [36%] with air; RR 1.47, 95% CI 0.42 to 5.14).

Harms: None reported.

Comment: The RCT was reported twice.[32,33] Low tissue oxygen saturation is a dominant factor in the mechanism that results in sickling. Given that increased sickling is a key component of the pathophysiology of acute painful complications of sickle cell disease, namely vaso-occlusive crisis and acute chest syndrome (see glossary, p 34), oxygen therapy is expected to ameliorate these conditions. Oxygen therapy is recommended routinely for treatment of sickle cell acute chest syndrome. Patients with acute chest syndrome were excluded from the RCT appraised in this topic section.[32] That study was small and inadequately powered. The result should be interpreted with caution.

OPTION REHYDRATION

We found no systematic reviews or RCTs on the effects of rehydration in sickle cell crisis.

Benefits: We found no systematic review or RCTs.

Harms: We found insufficient evidence.

Comment: None.

OPTION CORTICOSTEROIDS

One RCT found that high dose intravenous methylprednisolone, given as an adjunct to intravenous morphine in sickle cell crisis, reduced the duration of inpatient analgesic therapy compared with placebo, but was associated with more episodes of recurrent pain shortly after discontinuation of treatment.

Sickle cell disease

Benefits: We found no systematic review. We found one RCT of high dose intravenous methylprednisolone compared with placebo, given as an adjunct to narcotic analgesia (intravenous morphine followed by oral codeine plus paracetamol) in 56 acute episodes of severe sickle cell painful crisis in 34 people aged 2–19 years. Pain episodes were the basis for randomisation.[34] A significant reduction in duration of inpatient analgesia was found with methylprednisolone compared with placebo (41.3 hours with methylprednisolone *v* 71.3 hours with placebo; P = 0.01).

Harms: No significant increase was found in readmissions associated with recurrent pain with methylprednisolone compared with placebo (4/26 [15%] with prednisolone *v* 1/30 [3%] with placebo; RR 4.62, 95% CI 0.55 to 38.74). However, the study may have lacked power to rule out clinically important differences. No complication related to corticosteroid use was observed in the study participants. Some of the known adverse effects of steroid therapy are increased risk of infections, weight gain, hypertension, poor glucose metabolism, cataracts, and poor growth in children.

Comment: There is evidence from one RCT that dexamethasone, another type of corticosteroid, reduced the number of doses and duration of analgesia in acute sickle cell chest syndrome.[35]

GLOSSARY

Acute chest syndrome Acute chest syndrome is a life-threatening complication of sickle cell disease characterised by fever, cough, chest pain, difficult breathing, worsening anaemia, and new pulmonary infiltrates on radiography. It is difficult to differentiate acute chest syndrome clinically from pneumonia and pulmonary infarctions.

Aplastic crisis Sudden cessation of the bone marrow from making new blood cells.

CHEOPS scale (Children's Hospital of Eastern Ontario Pain scale) A behavioural scale used to evaluate postoperative pain. It was initially validated in children aged 1–5 years, and subsequently validated in children from other populations and ages.[36] CHEOPS scale is used to monitor the effectiveness of interventions for reducing the pain and discomfort. Scores obtained from adding points from six different parameters range from 4–13.

Fetal haemoglobin (Hb F) This is the predominant type of normal haemoglobin (i.e. the oxygen carrying molecule in the human red blood cell) in the unborn child. Following birth, another type of normal haemoglobin (HbA) replaces HbF and remains predominant throughout life. HbF binds oxygen stronger than HbA and maintains higher tissue oxygen tension than HbA.

Haemoglobin S (Hb S) This is an inherited type of abnormal haemoglobin that has a tendency to form crystals when oxygen saturation is low. Under such conditions, red blood cells become deformed (many shaped like "sickle"), more rigid, and easily breakable. This is the main disorder responsible for the clinical syndrome experienced by people with sickle cell anaemia. People affected by sickle cell anaemia who also have high level of fetal haemoglobin (see glossary, p 34) tend to have fewer episodes of crisis because fetal hemoglobin maintains a higher level of tissue oxygen saturation.

Pneumococcal conjugate vaccines These are polysaccharide pneumococcal vaccines linked with proteins such as those of the outer membrane meningococcus, tetanus, or diphtheria toxoids. The conjugate pneumococcal vaccines have

been shown to be immunogenic in children younger than 2 years, and is recommended for routine use in infants beginning from the age of 2 months.[16,37]

Polyvalent polysaccharide pneumococcal vaccine (PPV) This type of vaccine contains the purified capsular polysaccharides of several *S pneumoniae* serotypes. Many of the polysaccharides contained in the vaccines do not induce protective immunity in children younger than 2 years. This type of pneumococcal vaccine is recommended for children aged 2 years and older affected by conditions that predispose them to increased risk of invasive pneumococcal infection.[37]

Sequestration crisis Sudden pooling of blood in spleen and liver, with the result that the patient becomes very anaemic and hypotensive, with the affected organ becoming remarkably enlarged and painful.

QUESTIONS

INTERVENTIONS

See glossary, p 54

Key Messages

Improving outcomes in acute myocardial infarction

- **Angiotensin converting enzyme inhibitors** One systematic review in people treated within 14 days of acute myocardial infarction has found that angiotensin converting enzyme inhibitors reduce mortality after 6 weeks compared with placebo. However, a non-systematic review found that angiotensin converting enzyme inhibitors increase persistent hypotension and renal dysfunction at 6 weeks compared with placebo.

Acute myocardial infarction

- **Aspirin** One systematic review in people with acute myocardial infarction has found that aspirin reduces mortality, reinfarction, and stroke at 1 month compared with placebo.
- **β Blockers** We found evidence from systematic reviews and one subsequent RCT that β blockers reduced mortality compared with no β blockers. One RCT in people receiving thrombolytic treatment found that immediate treatment with metoprolol reduced rates of reinfarction and chest pain at 6 days compared with delayed treatment, but had no significant effect on mortality at 6 days or at 1 year.
- **Primary percutaneous transluminal coronary angioplasty versus thrombolysis (performed in specialist centres)** One systematic review has found that primary percutaneous transluminal coronary angioplasty reduces a combined outcome of death, non-fatal reinfarction, and stroke compared with thrombolysis.
- **Thrombolysis** Two non-systematic reviews in people with acute myocardial infarction and ST segment elevation or bundle branch block on their initial electrocardiogram found that prompt thrombolytic treatment (within 6 hours and perhaps up to 12 hours and longer after the onset of symptoms) reduces mortality compared with placebo. RCTs comparing different types of thrombolytic agents versus each other found no significant difference in mortality. One non-systematic review found that thrombolytic treatment increased the risk of stroke or major bleeding compared with control. The review also found that intracranial haemorrhage is more common in people of advanced age and low body weight, those with hypertension on admission, and those given tissue plasminogen activator rather than another thrombolytic agent. One non-systematic review found conflicting results for intracerebral haemorrhage with bolus treatment compared with infusion of thrombolytic agents.
- **Nitrates (in the absence of thrombolysis)** One systematic review of the trials conducted in the prethrombolytic era found that nitrates reduced mortality in people with acute myocardial infarction compared with placebo.
- **Nitrates (in addition to thrombolysis)** Two RCTs in people with acute myocardial infarction (after thrombolysis was introduced) found no significant difference in mortality between nitrates and placebo.
- **Glycoprotein IIb/IIIa inhibitors** Two large RCTs have found that combined treatment with half dose thrombolysis plus abciximab does not reduce mortality at 1 month compared with full dose thrombolysis in people with acute myocardial infarction, but may prevent non-fatal cardiovascular events. However, the RCTs found that combined treatment with abciximab increased bleeding complications, particularly extracranial haemorrhage. Three RCTs found conflicting evidence about the benefits of adding abciximab to primary coronary angioplasty or stenting in people with acute myocardial infarction, although all found that adding abciximab increased bleeding risk.
- **Calcium channel blockers** We found evidence that neither dihydropyridines nor verapamil reduce mortality compared with placebo. One RCT found limited evidence that, in people with left ventricular dysfunction, nifedipine given in the first few days after myocardial infarction may increase mortality compared with placebo.

Treating cardiogenic shock after acute myocardial infarction

- **Early invasive cardiac revascularisation** One large RCT has found that early invasive cardiac revascularisation reduces mortality after 6 and 12 months compared with medical treatment alone in people with cardiogenic shock within 48 hours of acute myocardial infarction. A second smaller RCT found similar results, although the difference was not significant.
- **Intra-aortic balloon counterpulsation** We found limited evidence from an abstract of an RCT of no significant difference in mortality at 6 months between intra-aortic balloon counterpulsation plus thrombolysis with thrombolysis alone in people with cardiogenic shock.
- **Thrombolysis** Subgroup analysis of one RCT found no significant difference in mortality after 21 days between thrombolysis and no thrombolysis in people with cardiogenic shock.
- **Early cardiac surgery; positive inotropes and vasodilators; pulmonary artery catheterisation; ventricular assistance devices and cardiac transplantation** We found no evidence from RCTs about the effects of these interventions.

DEFINITION

Acute myocardial infarction (AMI): The sudden occlusion of a coronary artery leading to myocardial cell death. **Cardiogenic shock:** Defined clinically as a poor cardiac output plus evidence of tissue hypoxia that is not improved by correcting reduced intravascular volume.[1] When a pulmonary artery catheter is used, cardiogenic shock may be defined as a cardiac index (see glossary, p 54) below 2.2 L/minute/m^2 despite an elevated pulmonary capillary wedge pressure (≥ 15 mm Hg).[1–3]

INCIDENCE/ PREVALENCE

AMI: Acute myocardial infarction is one of the most common causes of mortality worldwide. In 1990, ischaemic heart disease was the world's leading cause of death, accounting for about 6.3 million deaths. The age standardised incidence varies among and within countries.[4] Each year, about 900 000 people in the USA experience AMI, about 225 000 of whom die. About half of these people die within 1 hour of symptoms and before reaching a hospital emergency room.[5] Event rates increase with age for both sexes and are higher in men than in women and in poorer than richer people at all ages. The incidence of death from AMI has fallen in many Western countries over the past 20 years. **Cardiogenic shock:** Cardiogenic shock occurs in about 7% of people admitted to hospital with AMI.[6] Of these, about half have established cardiogenic shock at the time of admission to hospital, and most of the others develop it during the first 24–48 hours after their admission.[7]

AETIOLOGY/ RISK FACTORS

AMI: See aetiology/risk factors under primary prevention, p 163. The immediate mechanism of AMI is rupture or erosion of an atheromatous plaque causing thrombosis and occlusion of coronary arteries and myocardial cell death. Factors that may convert a stable plaque into an unstable plaque (the "active plaque") have yet to be fully elucidated. Shear stresses, inflammation, and autoimmunity have been proposed. The changing rates of coronary heart disease in different populations are only partly explained by changes in the standard risk factors for ischaemic heart disease (particularly a fall in blood pressure and smoking). **Cardiogenic shock:** Cardiogenic shock after AMI usually follows a reduction in

functional ventricular myocardium, and is caused by left ventricular infarction (79% of people with cardiogenic shock) more often than by right ventricular infarction (3% of people with cardiogenic shock).[8] Cardiogenic shock after AMI may also be caused by cardiac structural defects, such as mitral valve regurgitation due to papillary muscle dysfunction (7% of people with cardiogenic shock), ventricular septal rupture (4% of people with cardiogenic shock), or cardiac tamponade after free cardiac wall rupture (1% of people with cardiogenic shock). Major risk factors for cardiogenic shock after AMI are previous myocardial infarction, diabetes mellitus, advanced age, hypotension, tachycardia or bradycardia, congestive heart failure with Killip class II–III (see glossary, p 54), and low left ventricular ejection fraction (ejection fraction < 35%).[7,8]

PROGNOSIS **AMI:** May lead to a host of mechanical and cardiac electrical complications, including death, ventricular dysfunction, congestive heart failure, fatal and non-fatal arrhythmias, valvular dysfunction, myocardial rupture, and cardiogenic shock. **Cardiogenic shock:** Mortality rates for people in hospital with cardiogenic shock after AMI vary between 50–80%.[2,3,6,7] Most deaths occur within 48 hours of the onset of shock (see figure 1, p 61). People surviving until discharge from hospital have a reasonable long term prognosis (88% survival at 1 year).[10]

AIMS OF INTERVENTION To relieve pain; to restore blood supply to heart muscle; to reduce incidence of complications (such as congestive heart failure, myocardial rupture, valvular dysfunction, and fatal and non-fatal arrhythmia); to prevent recurrent ischaemia and infarction; to decrease mortality, and with minimal adverse effects of treatments.

OUTCOMES **Efficacy outcomes:** Rates of major cardiovascular events, including death, recurrent acute myocardial infarction, refractory ischaemia, and stroke. **Safety outcomes:** Rates of major bleeding and intracranial haemorrhage.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION **Which treatments improve outcomes in acute myocardial infarction?**

Nicolas Danchin

OPTION ASPIRIN

One systematic review in people with acute myocardial infarction has found that aspirin reduces mortality, reinfarction, and stroke at 1 month compared with placebo.

Benefits: **Versus placebo:** We found one systematic review (search date 1990, 9 RCTs, 18 773 people) that compared antiplatelet agents begun soon after the onset of acute myocardial infarction (AMI) and for at least 1 month afterwards with placebo.[11] Almost all (> 95%) of the people in these studies were randomised to either aspirin or placebo. The absolute and relative benefits found in the systematic review are shown in figure 2, p 62. The largest of the RCTs identified by the review (17 187 people with suspected AMI) compared aspirin 162.6 mg versus placebo chewed and swallowed on the day

of AMI and continued daily for 1 month.[12] There was a 2.4% absolute reduction in vascular death at 35 days. The survival benefit was maintained for up to 4 years.[13] In the systematic review, the most widely tested aspirin regimens were 75–325 mg daily.[11] Doses throughout this range seemed similarly effective, with no evidence that "higher" doses were more effective (500–1500 mg/day aspirin *v* placebo; odds reduction for all vascular events 21%, 95% CI 14% to 27%) than "medium" doses (160–325 mg/day aspirin *v* placebo; odds reduction for all vascular events 28%, 95% CI 22% to 33%), or "lower" doses (75–160 mg/day aspirin *v* placebo; odds reduction 26%, 95% CI 5% to 42%). The review found insufficient evidence for efficacy of doses below 75 mg daily. One RCT identified by the review found that a loading dose of 160–325 mg daily achieved a prompt antiplatelet effect.[14]

Harms: The largest RCT identified by the review found no significant difference between aspirin and placebo in rates of cerebral haemorrhage or bleeds requiring transfusion (0.4% on aspirin and placebo).[12] It also found a small absolute excess of "minor" bleeding (ARI 0.6%, CI not reported; $P < 0.01$).

Comment: None.

OPTION THROMBOLYSIS

Two non-systematic reviews in people with acute myocardial infarction and ST segment elevation or bundle branch block on their initial electrocardiogram found that prompt thrombolytic treatment (within 6 hours and perhaps up to 12 hours and longer after the onset of symptoms) reduces mortality compared with placebo. RCTs comparing different types of thrombolytic agents with each other found no significant difference in mortality. One non-systematic review found that thrombolytic treatment increased the risk of stroke or major bleeding compared with control. The review also found that intracranial haemorrhage is more common in people of advanced age and low body weight, those with hypertension on admission, and those given tissue plasminogen activator rather than another thrombolytic agent. One non-systematic review found conflicting results for intracerebral haemorrhage with bolus treatment compared with infusion of thrombolytic agents.

Benefits: **Versus placebo:** We found one non-systematic review (9 RCTs, 58 600 people with suspected acute myocardial infarction [AMI]) comparing thrombolysis versus placebo.[15] Baseline electrocardiograms showed ST segment elevation in 68% of people and ST segment depression, T wave abnormalities, or no abnormality in the rest. The review found that thrombolysis reduced short term mortality compared with placebo (9.6% with thrombolysis *v* 11.5% with placebo; RR 0.82, 95% CI 0.77 to 0.87). The greatest benefit was found in the large subgroup of people presenting with ST elevation (RR 0.79, CI not reported) or bundle branch block (RR 0.75, CI not reported). Reduced death rates were seen in people with all types of infarction, but the benefit was several times greater in those with anterior infarction (ARR 3.7%) compared with those with inferior infarction (ARR 0.8%) or infarctions in other zones (ARR 2.7%). One

of the RCTs included in the overview found that thrombolysis significantly reduced mortality after 12 years compared with placebo (36/107 [34%] died with thrombolysis *v* 55/112 [49%] with placebo; ARR 15.0%, 95% CI 2.4% to 29.0%; RR 0.69, 95% CI 0.49 to 0.95; NNT 7, 95% CI 4 to 41).[16] **Timing of treatment:** The non-systematic review found that the earlier thrombolytic treatment was given after the onset of symptoms, the greater the absolute benefit of treatment (see figure 3, p 63).[15,17] For each hour of delay in thrombolytic treatment, the absolute risk reduction for death decreased by 0.16% (ARR for death if given within 6 hours of symptoms 3%; ARR for death if given 7–12 hours after onset of symptoms 2%).[15,17] Too few people in the review received treatment more than 12 hours after the onset of symptoms to determine whether the benefits of thrombolytic treatment given after 12 hours would outweigh the risks (see comment below). **Streptokinase versus tissue plasminogen activator (tPA):** We found one non-systematic review (3 RCTs;[18–20] see table 1, p 58)[17] comparing streptokinase versus tPA. The first RCT, in people with ST segment elevation and symptoms of AMI for less than 6 hours, was unblinded.[18] People were first randomised to intravenous tPA 100 mg over 3 hours or streptokinase 1.5 MU over 1 hour and then further randomised to subcutaneous heparin 12 500 U twice daily beginning 12 hours later, or no heparin. It found no significant difference in mortality between thrombolysis plus heparin and thrombolysis plus no heparin (AR of death in hospital 8.5% with thrombolysis plus heparin *v* 8.9% with thrombolysis plus no heparin; RR 0.95, 95% CI 0.86 to 1.04). There was no significant difference in mortality between tPA 100 mg and streptokinase (8.9% with tPA 100 mg *v* 8.5% with streptokinase; RR 1.05, 95% CI 0.95 to 1.16). In the second RCT, people with suspected AMI presenting within 24 hours of symptoms were first randomised to receive either streptokinase 1.5 MU over 1 hour, tPA 0.6 MU/kg every 4 hours, or anisoylated plasminogen streptokinase activator complex 30 U every 3 minutes, and then further randomised to subcutaneous heparin 12 500 U starting at 7 hours and continued for 7 days, or no heparin.[19] All people received aspirin on admission. The RCT found no significant difference between thrombolytic agents in mortality (streptokinase 10.6%, anisoylated plasminogen streptokinase activator complex 10.5%, tPA 10.3%) and no significant difference in mortality after 35 days between thrombolysis plus heparin and thrombolysis plus no heparin (AR of death 10.3% with thrombolysis plus heparin *v* 10.6% with thrombolysis plus no heparin). The third RCT was unblinded and included people with ST segment elevation presenting within 6 hours of symptom onset.[20] People were randomised to one of four regimens: streptokinase 1.5 MU over 1 hour plus subcutaneous heparin 12 500 U twice daily starting 4 hours after thrombolytic treatment; streptokinase 1.5 MU over 1 hour plus intravenous heparin 5000 U bolus followed by 1000 U every hour; accelerated tPA 15 mg bolus then 0.75 mg/kg over 30 minutes followed by 0.50 mg/kg over 60 minutes, plus intravenous heparin 5000 U bolus then 1000 U every hour; or tPA 1.0 mg/kg over 60 minutes, 10% given as a bolus, plus streptokinase 1.0 MU over 60 minutes.[20] Meta-analysis of the three trials, weighted by sample size, found no significant difference

between treatments in the combined outcome of any stroke or death (AR 9.4% for streptokinase only regimens *v* 9.2% for tPA based regimens, including the combined tPA and streptokinase arm in the third trial; ARR for tPA *v* streptokinase +0.2%, 95% CI –0.2% to +0.5%).[17] **Tissue plasminogen activator versus other thrombolytics:** We found two RCTs that compared tPA versus other thrombolytic agents in people with AMI also receiving treatment with aspirin and heparin.[21,22] The first RCT (15 059 people from 20 different countries with AMI evolving for < 6 hours, with ST segment elevation or with the appearance of a new left bundle branch block on their electrocardiogram) compared tPA (accelerated iv administration according to the GUSTO regimen) versus reteplase (recombinant plasminogen activator; two 10 MU iv boluses, 30 minutes apart).[21] It found no significant difference in mortality after 30 days (OR 1.03, 95% CI 0.91 to 1.18). The second RCT (16 949 people; see comment below) compared tPA (accelerated iv administration) versus tenecteplase (a genetically engineered variant of tPA; 30–50 mg iv according to body weight as a single bolus).[22] It found no significant difference between treatments in total mortality after 30 days (6% with tenecteplase *v* 6% with tPA; RR 1.0, 95% CI 0.91 to 1.10).

Harms:

Stroke/intracerebral haemorrhage: The overview found that thrombolytic treatment significantly increased the risk of stroke compared with control (ARI 0.4%, 95% CI 0.2% to 0.5%; NNH 250, 95% CI 200 to 500).[15] In the third RCT comparing streptokinase versus tPA, the overall incidence of stroke was 0.7%, of which 31% were severely disabling and 50% were intracerebral haemorrhages.[20] The RCT also found that tPA significantly increased the risk of haemorrhagic stroke compared with streptokinase plus subcutaneous heparin or streptokinase plus intravenous heparin (AR for combined streptokinase 0.54%; P = 0.03 for tPA compared with combined streptokinase arms). The RCT comparing reteplase with tPA found that the incidence of stroke was similar with both treatments, and the odds ratio for the incidence of death or disabling stroke was 1.0.[21] The RCT comparing tenecteplase with tPA found no significant difference between treatments in the rate of stroke or death (7% with tenecteplase *v* 7% with tPA; RR 1.01, 95% CI 0.91 to 1.13).[22] We found one non-systematic review that compared bolus thrombolytic treatment versus infusion treatment.[23] Meta-analysis of nine small phase II trials (3956 people) found no significant difference between bolus and standard infusion thrombolysis for intracerebral haemorrhage (bolus *v* infusion: OR 0.53, 95% CI 0.27 to 1.01). However, meta-analysis of six larger phase III trials (62 673 people) found that bolus treatment significantly increased the risk of intracerebral haemorrhage (OR 1.25, 95% CI 1.06 to 1.49). **Predictive factors for stroke/intracranial haemorrhage:** Multivariate analysis of data from a large database of people who experienced intracerebral haemorrhage after thrombolytic treatment identified four independent predictors of increased risk of intracerebral haemorrhage: age 65 years or older (OR 2.2, 95% CI 1.4 to 3.5); weight less than 70 kg (OR 2.1, 95% CI 1.3 to 3.2); hypertension on admission (OR 2.0, 95% CI 1.2 to 3.2); and use of tPA rather than another thrombolytic agent (OR 1.6, 95% CI 1.0 to 2.5).[21] Absolute risk of intracranial

haemorrhage was 0.26% on streptokinase in the absence of risk factors and 0.96%, 1.32%, and 2.17% in people with one, two, or three risk factors.[24] Analysis of 592 strokes in 41 021 people from the trials found seven factors to be predictors of intracerebral haemorrhage: advanced age, lower weight, history of cerebrovascular disease, history of hypertension, higher systolic or diastolic pressure on presentation, and use of tPA rather than streptokinase.[25,26] **Major bleeding:** The overview also found that thrombolytic treatment significantly increased the risk of major bleeding compared with placebo (ARI 0.7%, 95% CI 0.6% to 0.9%; NNH 143, 95% CI 111 to 166).[15] Bleeding was most common in people undergoing procedures (coronary artery bypass grafting or percutaneous transluminal coronary angioplasty). Spontaneous bleeds were observed most often in the gastrointestinal tract.[20]

Comment: Extrapolation of the data from the overview (see figure 3, p 63) suggests that, at least for people suspected of having an AMI and with ST segment elevation on their electrocardiogram, there may be some net benefit of treatment between 12–18 hours after symptom onset (ARR for death 1%).[15] The evidence from the RCT comparing reteplase versus tPA is consistent with a similar efficacy for both treatments, although formal equivalence cannot be established because the trial was designed as a superiority trial.[21] The evidence suggests that it is far more important to give prompt thrombolytic treatment than to debate which thrombolytic agent should be used. A strategy of rapid thrombolysis in a broad population is likely to lead to the greatest impact on mortality. When the results of RCTs are taken together, tPA based regimens do not seem to confer a significant advantage over streptokinase in the combined outcome of any stroke and death (unrelated to stroke). The legitimacy of combining the results of the three trials can be questioned, as the selection criteria and protocols differed in important aspects (see review for arguments to justify combining the results of these trials despite their apparent differences).[17]

OPTION GLYCOPROTEIN IIB/IIIA INHIBITORS

Two large RCTs have found that combined treatment with half dose thrombolysis plus abciximab does not reduce mortality at 1 month in people with acute myocardial infarction compared with full dose thrombolysis, but may prevent more non-fatal cardiovascular events. However, the RCTs found that combined treatment with abciximab increased bleeding complications, particularly extracranial haemorrhage. Three RCTs found conflicting evidence about the benefits of adding abciximab to primary coronary angioplasty or stenting in people with acute myocardial infarction, although all found that adding abciximab increased bleeding risk.

Benefits: We found two RCTs.[27,28] The first RCT (16 588 treated within 6 hours of ST segment elevation myocardial infarction; unblinded design) compared half dose reteplase plus abciximab (0.25 mg/kg bolus plus 0.125 μg/kg/minute for 12 hours) versus standard dose reteplase (total dose 20 U).[27] It found no significant difference in all cause mortality or stroke at 30 days between combined treatment with abciximab and full dose reteplase (mortality: AR 5.9% for

reteplase alone *v* 5.6% for combined treatment; OR 0.95, 95% CI 0.83 to 1.08; any stroke: AR 0.9% for reteplase *v* 1.0% for combined treatment; OR 1.10, 95% CI 0.80 to 1.51). It found that combined treatment reduced the composite end point of mortality or non-fatal reinfarction at 30 days (AR 8.8% for thrombolysis alone *v* 7.4% for combined treatment; OR 0.83, 95% CI 0.74 to 0.93). At one year, there was no significant difference in mortality between combination treatment and standard dose reteplase (692/8260 [8.4%] with standard reteplase *v* 698/8328 [8.4%] with combined therapy; HR 1.0, 95% CI 0.90 to 1.11).[29] The second RCT (6095 people treated within 6 hours of ST segment elevation myocardial infarction; unblinded design) compared three treatments: full dose tenecteplase (30–50 mg according to body weight) plus unfractionated heparin (60 U/kg bolus plus 12 U/kg/hour); full dose tenecteplase plus enoxaparin (30 mg immediately then 1 mg/kg every 12 hours); or half dose tenecteplase plus full dose abciximab (0.25 mg/kg bolus plus 0.125 μg/kg/minute for 12 hours).[28] It found no significant difference among groups in mortality at 30 days (AR 6.0% with unfractionated heparin *v* 5.4% with enoxaparin *v* 6.6% with abciximab; P = 0.25). It found that abciximab increased composite risk of death, non-fatal cardiovascular events, or haemorrhage at 30 days compared with enoxaparin but reduced risk compared with unfractionated heparin (AR 13.8% with enoxaparin, 14.2% with abciximab, 17.0% with unfractionated heparin).

Primary percutaneous transluminal coronary angioplasty with or without glycoprotein IIb/IIIa inhibitors: We found three RCTs.[30–32] The first RCT (483 people with ST segment elevation myocardial infarction in the past 12 hours referred for primary angioplasty) compared abciximab (bolus + 12 hour infusion) versus placebo, given before the procedure. It found no significant difference between abciximab and placebo in the composite end point of death, reinfarction, or need for revascularisation of the target vessel at 6 months (AR 28% in both groups; OR 1.01, 95% CI 0.68 to 1.50; P = 0.90).[30] The second RCT (300 people with acute myocardial infarction in the past 12 hours referred for primary coronary angioplasty) found that abciximab significantly reduced the composite end point of death, reinfarction, or urgent revascularisation of the target vessel at 30 days compared with placebo (AR 6.0% with abciximab *v* 14.6% with placebo; RR 0.41, 95% CI 0.18 to 0.93).[31] The third RCT (2082 people with acute myocardial infarction) compared percutaneous transluminal coronary angioplasty with or without stenting and with or without abciximab given during the procedure (2 x 2 unblinded factorial design).[32] At 6 months, it found that adding abciximab to angioplasty or stenting significantly reduced the risk of the composite end point of death, reinfarction, disabling stroke, or ischaemia-driven revascularisation of the target vessel compared with either procedure alone (AR 20.0% after angioplasty alone *v* 16.5% after angioplasty plus abciximab; CI and P values not reported; AR 11.5% after stenting alone *v* 10.2% after stenting plus abciximab; CI and P values not reported).

Harms:

Glycoprotein IIb/IIIa inhibitors plus thrombolysis versus thrombolysis alone: The first RCT found that abciximab plus half dose thrombolysis increased severe or moderate extracranial bleeding at 30 days compared with full dose thrombolysis (AR 4.6% with

combined treatment *v* 2.3% with full dose thrombolysis; OR 2.03, 95% CI 1.70 to 2.42).[27] However, it found no significant difference in rates of intracranial haemorrhage (AR 1.0% with combined treatment *v* 0.9% with thrombolysis alone; OR 1.10, 95% CI 0.80 to 1.81). The second RCT found that rates of any stroke and of intracranial haemorrhage were similar for thrombolysis plus abciximab, enoxaparin, or unfractionated heparin (AR for any stroke about 1.5%, AR for intracranial haemorrhage about 0.9%).[28] **Primary percutaneous transluminal coronary angioplasty with or without glycoprotein IIb/IIIa inhibitors:** The largest RCT found that abciximab given during percutaneous angioplasty or stenting increased transfusion requirements compared with no abciximab (5.4% *v* 3.4%; P = 0.02; RR and CI not reported).[32] The remaining two RCTs found that giving abciximab before percutaneous angioplasty increased minor bleeding[31] and major bleeding[29] compared with no abciximab (minor bleeding: AR 12% *v* 3%; RR 3.7, 95% CI 1.3 to 10.1;[31] major bleeding: AR 16.6% *v* 9.5%; P = 0.02; CI not reported[30]).

Comment: None.

OPTION β BLOCKERS

We found evidence from systematic reviews and one subsequent RCT that β blockers reduced mortality compared with no β blockers. One RCT in people receiving thrombolytic treatment found that immediate treatment with metoprolol reduced rates of reinfarction and chest pain at 6 days compared with delayed treatment, but had no significant effect on mortality at 6 days or at 1 year.

Benefits: **Versus no β blocker:** We found two systematic reviews (search dates 1997[33] and not stated[34]) of β blockers in people with acute myocardial infarction (AMI) and one subsequent RCT.[35] The first review (27 RCTs) found that, within 1 week of treatment, β blockers significantly reduced the risk of death and major vascular events (for the combined outcome of death, non-fatal cardiac arrest, or non-fatal reinfarction: 1110 events *v* 1298 events; RR 0.84, CI not reported; P < 0.001).[34] The more recent review (82 RCTs, 54 234 people) separately analysed 51 short term RCTs (people within 6 weeks after the onset of pain) and 31 long term RCTs (people treated for up to 48 months after AMI).[33] In most of the RCTs, the participants did not receive thrombolysis. In the short term studies, seven RCTs reported no deaths and many reported only a few. The short term RCTs reporting at least one death found no significant difference in mortality between β blockers and no β blockers (ARR 0.4%; OR 0.96, 95% CI 0.85 to 1.08). In the longer term RCTs, β blockers significantly reduced mortality over 6 months to 4 years compared with no β blockers (OR 0.77, 95% CI 0.69 to 0.85). See β blockers under secondary prevention of ischaemic cardiac events, p 197. No significant difference in effectiveness was found between different types of β blocker (based on cardioselectivity or intrinsic sympathomimetic activity). Most evidence was obtained with propranolol, timolol, and metoprolol. The subsequent RCT (1959 people within 3–21 days of AMI and with left ventricular dysfunction, of whom 46% had received thrombolysis or

percutaneous transluminal coronary angioplasty at the acute stage of their infarction, of whom 97% received angiotensin converting enzyme inhibitors) compared carvedilol (6.25 mg increased to a maximum of 25 mg over 4–6 weeks) versus placebo.[35] It found that carvedilol significantly reduced mortality (12% with carvedilol *v* 15% with placebo; HR 0.77, 95% CI 0.60 to 0.98) and non-fatal AMI (HR 0.59, 95% CI 0.39 to 0.90), but found no difference between treatments in the combined end point of total mortality and hospital admission for any cardiovascular event (HR 0.92, 95% CI 0.80 to 1.07) after a median of 1.3 years. **Early versus delayed treatment:** We found one RCT (1434 people with AMI who had received tissue plasminogen activator thrombolysis), which compared early versus delayed metoprolol treatment.[36] Early treatment began on day 1 (iv then oral) and delayed treatment on day 6 (oral). It found that early treatment significantly reduced rates of reinfarction (AR 2.7% with early treatment *v* 5.1% with delayed treatment; CI not reported; $P = 0.02$) and recurrent chest pain (AR 18.8% with early treatment *v* 24.1% with delayed treatment; $P < 0.02$) after 6 days. There were no significant differences observed in mortality or left ventricular ejection fraction between the two groups at 6 days or 1 year.

Harms: People with asthma or severe congestive cardiac failure were excluded from most trials. One RCT found that people given immediate versus delayed β blockers after tissue plasminogen activator experienced increased frequency of heart failure during the initial admission to hospital, although the result was not statistically significant (15.3% with immediate *v* 12.2% with delayed; $P = 0.10$).[36] The presence of first degree heart block and bundle branch block was associated with more adverse events.

Comment: Until recently, trials involving the use of β blockers in AMI were conducted mostly in people considered to be at low risk of heart failure (because of the supposed deleterious effect of β blockers on left ventricular function), and many of these trials took place in the prethrombolytic era. β Blockers may reduce rates of cardiac rupture and ventricular fibrillation. This may explain why people older than 65 years and those with large infarcts benefited most, as they have higher rates of these complications. The trial comparing early versus delayed β blockade after thrombolysis was too small to rule out an effect on mortality of β blockers when added to thrombolysis.[36]

OPTION ANGIOTENSIN CONVERTING ENZYME INHIBITORS

One systematic review in people treated within 14 days of acute myocardial infarction has found that angiotensin converting enzyme inhibitors reduce mortality after 6 weeks compared with placebo. However, a non-systematic review found that angiotensin converting enzyme inhibitors increase persistent hypotension and renal dysfunction at 6 weeks compared with placebo.

Benefits: We found one systematic review (search date 1997, 15 RCTs with at least ≥6 weeks' follow up, 15 104 people) that compared angiotensin converting enzyme (ACE) inhibitors started within 14 days of myocardial infarction versus placebo.[37] It found that ACE

inhibitors decreased overall mortality and sudden cardiac death compared with placebo after 2 to 42 months (overall mortality: 1105/7658 [14.4%] with ACE inhibitors *v* 1251/7446 [16.8%] with placebo; OR 0.83, 95% CI 0.71 to 0.97). Sudden cardiac death was also decreased (OR 0.80, 95% CI 0.70 to 0.92).[37]

Harms: One non-systematic review of RCTs (search date not stated, 4 RCTs, 98 496 people within 36 hours of acute myocardial infarction [AMI]) found that ACE inhibitors significantly increased persistent hypotension and renal dysfunction at 6 weeks compared with placebo (hypotension: AR 17.6% with ACE inhibitor *v* 9.3% with control; CI for difference not reported; $P < 0.01$; renal dysfunction: AR 1.3% *v* 0.6%; $P < 0.01$).[38] The relative and absolute risks of these adverse effects were uniformly distributed across both the high and lower cardiovascular risk groups. The systematic review did not report on harms.[37]

Comment: ACE inhibitors in people with AMI work best when treatment is started within 24 hours. The evidence does not answer the question of which people with an AMI should be offered ACE inhibitors, nor for how long after AMI it remains beneficial to start treatment. We found one systematic review (search date not stated; based on individual data from about 100 000 people in RCTs of ACE inhibitors) that found that people receiving both aspirin and ACE inhibitors had the same relative risk reduction as those receiving ACE inhibitors alone (i.e. there was no evidence of a clinically relevant interaction between ACE inhibitors and aspirin).[39] Of the 12 RCTs in the systematic review that reported on left ventricular function among participants, all reported a mean left ventricular ejection fraction of 54% or less. Six of these RCTs reported a mean left ventricular ejection fraction of 40% or less. However, there is debate over whether the benefits of ACE inhibitors also benefit people with normal left ventricular function after AMI.

OPTION NITRATES

One systematic review in people with acute myocardial infarction in the prethrombolytic era found that nitrates reduce mortality compared with placebo. Two RCTs in people with acute myocardial infarction (after thrombolysis was introduced) found no significant difference in mortality between nitrates and placebo.

Benefits: **Without thrombolysis:** We found one systematic review (search date not stated, 10 RCTs, 2000 people with acute myocardial infarction [AMI] who did not receive thrombolysis) that compared intravenous glyceryl trinitrate or sodium nitroprusside versus placebo.[40] The review found that nitrates significantly reduced mortality (RR 0.65, 95% CI 0.45 to 0.84). **With aspirin/thrombolysis:** We found two RCTs that compared nitrates (given acutely) versus placebo in people with AMI, of whom 90% received aspirin and about 70% received thrombolytic treatment.[41,42] The first RCT (58 050 people with AMI) compared oral controlled release isosorbide mononitrate 30–60 mg daily versus placebo.[41] It found no significant difference in mortality between isosorbide mononitrate and placebo (ARR nitrates *v* placebo 0.20%; OR 0.97, 95% CI 0.91

to 1.03). The other RCT (17 817 people with AMI) compared intravenous glyceryl trinitrate for 24 hours, followed by transdermal glyceryl trinitrate, versus placebo. It found no significant difference in mortality between nitrates and placebo (ARR nitrates *v* placebo 0.4%; OR 0.94, 95% CI 0.84 to 1.05). Neither RCT found significant differences in mortality in subgroups of people with different risks of dying.

Harms: The systematic review and the large RCTs found no significant harm associated with routine use of nitrates.[40–42]

Comment: Results for the two large RCTs were limited because a large proportion of people took nitrates outside the study, there was a high rate of concurrent use of other hypotensive agents, people were relatively low risk, and nitrates were not titrated to blood pressure and heart rate.[41,42] The RCTs found that nitrates were a useful adjunctive treatment to help control symptoms in people with AMI.

OPTION CALCIUM CHANNEL BLOCKERS

We found evidence that neither dihydropyridines nor verapamil reduce mortality compared with placebo. One RCT found limited evidence that, in people with left ventricular dysfunction, nifedipine given in the first few days after myocardial infarction may increase mortality compared with placebo.

Benefits: **Dihydropyridine calcium channel blockers:** We found two RCTs that compared short acting nifedipine versus placebo within the first few days of acute myocardial infarction (AMI).[43,44] The first RCT (4491 people) was terminated prematurely because of concerns about safety.[43] It found that nifedipine increased mortality by 33% compared with placebo, although the increase did not reach statistical significance. The second RCT (1006 people) found no significant difference in mortality between nifedipine and placebo (18.7% with nifedipine *v* 15.6% with placebo; OR 1.60, 95% CI 0.86 to 3.00).[44] We found no RCTs about sustained release nifedipine, amlodipine, or felodipine in this setting. **Verapamil:** We found one systematic review (search date 1997, 7 RCTs, 6527 people with AMI).[45] It found no significant difference in mortality between verapamil and placebo (RR 0.86, 95% CI 0.71 to 1.04).

Harms: Two systematic reviews (search dates not stated; included both randomised and observational trials) in people with AMI investigating the use of calcium channel blockers found non-significant increases in mortality of about 4% and 6%.[46,47] One RCT (2466 people with AMI) compared diltiazem (60 mg orally 4 times daily starting 3–15 days after AMI) versus placebo.[48] It found no significant difference in total mortality or reinfarction between diltiazem and placebo. Subgroup analysis in people with congestive heart failure found that diltiazem significantly increased death and reinfarction (RRI 1.41, 95% CI 1.01 to 1.96).

Comment: None.

OPTION PRIMARY PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY VERSUS THROMBOLYSIS

One systematic review has found that primary percutaneous transluminal coronary angioplasty reduces a combined outcome of death, non-fatal reinfarction, and stroke compared with thrombolysis.

Benefits: We found one systematic review (search date not stated, published 2003, 23 RCTs, 7739 people with or without cardiogenic shock) that compared primary percutaneous transluminal coronary angioplasty (PTCA) versus thrombolysis (streptokinase and fibrin specific agents) in people with acute ST segment myocardial infarction.[49] It found that PTCA significantly reduced the combined end point of death, non-fatal reinfarction, and stroke at 4–6 weeks compared with thrombolysis (253/3089 [8%] with PTCA *v* 442/3085 [14%] with thrombolysis; OR 0.53, 95% CI 0.45 to 0.63; no significant heterogeneity was detected; P = 0.35). It also found that PTCA significantly reduced the combined outcome at 6–18 months (approximately 11% *v* 20%, results presented graphically; P < 0.0001). Results were similar for PTCA compared with streptokinase and for PTCA compared with fibrin specific agents (PTCA *v* streptokinase, 8 RCTs, 1837 people: OR 0.40, 95% CI 0.28 to 0.58; PTCA *v* fibrin specific agents, 15 RCTs, 5902 people: OR 0.57, 95% CI 0.48 to 0.63). The review also found that emergent hospital transfer for primary PTCA (average delay 39 minutes) significantly reduced the combined outcome compared with on-site thrombolysis (5 RCTs, 2909 people: 8% with PTCA *v* 15% with thrombolysis, results presented graphically; P < 0.0001).

Harms: **Stroke:** The review found that PTCA reduced the risk of all types of stroke compared with thrombolysis (all stroke: 1.0% with PTCA *v* 2.0% with thrombolysis; P < 0.001; haemorrhagic stroke: 0.05% with PTCA *v* 1.1 % with thrombolysis; P = 0.03).[49] **Major bleeding:** The review also found that PTCA increased major bleeding at 4–6 weeks compared with thrombolysis (7% with PTCA *v* 5% with thrombolysis; OR 1.30, 95% CI 1.02 to 1.56).[49]

Comment: Although collectively the trials found an overall short term and long term reduction in deaths with PTCA compared with thrombolysis, there were several pitfalls common to individual RCTs, most of which may have inflated the benefit of PTCA.[50] RCTs comparing PTCA versus thrombolysis could not be easily blinded, and ascertainment of end points that required some judgement, such as reinfarction or stroke, may have been influenced by the investigators' knowledge of the treatment allocation (the vast majority of the earlier trials did not have blinded adjudication events committees). In addition, the RCTs conducted before the GUSTO RCT (published 1997[51]) should be viewed as hypothesis generating, in that the composite outcome (death, reinfarction, and stroke) was not prospectively defined, and attention was only placed on these end points after there seemed to be some benefit on *post hoc* analysis. The lower mortality and reinfarction rates reported with primary PTCA are promising but not conclusive, and the real benefits may well be smaller. Only in a minority of centres (such as those who participated in the randomised trials) that perform a high volume of

PTCA, and in the hands of experienced interventionists, may primary PTCA be clearly superior to thrombolytic treatment. Elsewhere, primary PTCA may be of greatest benefit in people with contraindications to thrombolysis, in people in cardiogenic shock, or in people in whom the mortality reduction with thrombolysis is modest and the risk of intracranial haemorrhage is increased, for example elderly people.[52] The value of PTCA over thrombolysis in people presenting to hospital more than 12 hours after onset of chest pain remains to be tested. In one large RCT, the collective rate of haemorrhagic stroke in people given thrombolysis was 1.1%, substantially higher than that observed in trials comparing thrombolysis versus placebo.[51] This may have been because the trials summarised above were in older people and used tissue plasminogen activator. However, the lower rates of haemorrhagic stroke with primary PTCA were consistent across almost all trials, and this may be the major advantage of PTCA over thrombolysis.

QUESTION Which treatments improve outcomes for cardiogenic shock after acute myocardial infarction?

Edoardo De Benedetti and Philip Urban

OPTION EARLY INVASIVE CARDIAC REVASCULARISATION

One large RCT has found that early invasive cardiac revascularisation reduces mortality after 6 and 12 months compared with medical treatment alone in people with cardiogenic shock within 48 hours of acute myocardial infarction. A second smaller RCT found similar results, although the difference was not significant.

Benefits: We found no systematic review. We found two RCTs in people with cardiogenic shock within 48 hours of acute myocardial infarction comparing early invasive cardiac revascularisation (see glossary, p 54) versus initial medical treatment alone (see comment below).[2,3,53] The first RCT (302 people) found that early invasive cardiac revascularisation significantly reduced mortality after 6 and 12 months (see table 2, p 60).[2,53] The second RCT (55 people) found that early invasive cardiac revascularisation reduced mortality after 30 days and at 12 months, although the difference was not significant (see table 2, p 60).[3] **Percutaneous transluminal coronary angioplasty versus coronary artery bypass graft:** We found no RCTs in people with cardiogenic shock after acute myocardial infarction comparing percutaneous transluminal coronary angioplasty versus coronary artery bypass grafting.

Harms: The first RCT (56 people aged ≥ 75 years) found that there was a non-significant increase in 30 day mortality with early invasive cardiac revascularisation compared with initial medical treatment alone (18/24 [75%] with early invasive cardiac revascularisation *v* 17/32 [53%] with medical treatment alone; RR 1.41, 95% CI 0.95 to 2.11).[2,53] The first RCT also found that acute renal failure (defined as a serum creatinine level > 265 μmol/L) was significantly more common in the medical treatment alone group than the early cardiac revascularisation group (36/150 [24%] *v* 20/152 [13%];

RR 1.82, 95% CI 1.1 to 3.0; NNH 9, 95% CI 5 to 48). Other harms reported by the RCT included major haemorrhage, sepsis, and peripheral vascular occlusion, although comparative data between groups for these harms were not provided. The second RCT did not report harms.[3]

Comment: In the first RCT, medical treatment included intra-aortic balloon counterpulsation (see glossary, p 54) and thrombolytic treatment.[2,53] In the second RCT, medical treatment was not defined.[3] The second RCT was stopped prematurely because of difficulties with recruitment. Both RCTs were conducted in centres with expertise in early invasive cardiac revascularisation. Their results may not necessarily be reproducible in other settings.[2,3,53]

OPTION THROMBOLYSIS

Subgroup analysis of one RCT found no significant difference in mortality after 21 days between thrombolysis and no thrombolysis in people with cardiogenic shock.

Benefits: We found no systematic review. We found one RCT (11 806 people with acute myocardial infarction) that compared streptokinase versus no thrombolysis and performed a subgroup analysis on people with cardiogenic shock (see comment below).[54] The subgroup analysis found no significant difference in inpatient mortality after 21 days (280 people; 102/146 [70%] with thrombolysis *v* 94/134 [70%] with no thrombolysis; RR 1.0, 95% CI 0.85 to 1.16).

Harms: The RCT did not specifically report harms in the subgroup of people with cardiogenic shock.[54] Overall, adverse reactions attributed to streptokinase were found in 705/5860 (12%) people either during or after streptokinase infusion. These adverse reactions included minor and major bleeding (3.7%), allergic reactions (2.4%), hypotension (3.0%), anaphylactic shock (0.1%), shivering/fever (1.0%), ventricular arrhythmias (1.2%), and stroke (0.2%). See harms of thrombolysis in acute myocardial infarction, p 43.

Comment: The RCT was not blinded.[54] Data presented are from a retrospective subgroup analysis. Randomisation was not stratified by the presence of cardiogenic shock.

OPTION POSITIVE INOTROPES (DOBUTAMINE, DOPAMINE, ADRENALINE [EPINEPHRINE], NORADRENALINE [NOREPINEPHRINE], AMRINONE) AND VASODILATORS (ANGIOTENSIN CONVERTING ENZYME INHIBITORS, NITRATES)

We found no RCTs comparing inotropes with placebo or comparing vasodilators with placebo.

Benefits: **Positive inotropes:** We found no systematic review or RCTs. We found three non-systematic reviews that did not include RCTs evaluating positive inotropes in people with cardiogenic shock after acute myocardial infarction.[1,55,56] **Vasodilators:** We found no systematic review or RCTs.

Harms: Positive inotropes may worsen cardiac ischaemia and induce ventricular arrhythmias.[1,55,56] We found no studies of harms specifically in people with cardiogenic shock after acute myocardial infarction (see harms of positive inotropic drugs and vasodilators under heart failure, p 122).

Comment: There is consensus that positive inotropes are beneficial in cardiogenic shock after acute myocardial infarction. We found no evidence to confirm or reject this view. The risk of worsening hypotension has led to concern about treating acute cardiogenic shock with any vasodilator.[56]

OPTION PULMONARY ARTERY CATHETERISATION

We found no RCTs comparing pulmonary artery catheterisation versus no catheterisation.

Benefits: We found no systematic review and no RCTs.

Harms: Observational studies have found an association between pulmonary artery catheterisation and increased morbidity and mortality, but it is unclear whether this arises from an adverse effect of the catheterisation or because people with a poor prognosis were selected for catheterisation.[57] Harms such as major arrhythmias, injury to the lung, thromboembolism (see thromboembolism, p 284), and sepsis occur in 0.1–0.5% of people undergoing pulmonary artery catheterisation.[57]

Comment: Pulmonary artery catheterisation helps to diagnose cardiogenic shock, guide correction of hypovolaemia, optimise filling pressures for both the left and right sides of the heart, and adjust doses of inotropic drugs.[1] There is consensus that pulmonary artery catheterisation benefits people with cardiogenic shock after acute myocardial infarction,[58,59] although we found no evidence to confirm or reject this view.

OPTION INTRA-AORTIC BALLOON COUNTERPULSATION

We found limited evidence from an abstract of an RCT of no significant difference in mortality at 6 months between intra-aortic balloon counterpulsation plus thrombolysis and thrombolysis alone in people with cardiogenic shock.

Benefits: We found no systematic review. We found one abstract of an RCT (57 people) that compared intra-aortic balloon counterpulsation (see glossary, p 54) plus thrombolysis versus thrombolysis alone in people with cardiogenic shock after acute myocardial infarction (AMI; see comment below).[60] The RCT found no significant difference in mortality after 6 months (22/57 [39%] with thrombolysis plus balloon counterpulsation *v* 25/57 [43%] with thrombolysis alone; RR 0.90, 95% CI 0.57 to 1.37; P = 0.3).

Harms: Harms were not reported in the abstract of the RCT.[60]

Comment: The abstract did not describe detailed methods for the trial, making interpretation of results difficult.[56] We also found two additional small RCTs (30 people[61] and 20 people[62]) that compared

intra-aortic balloon counterpulsation versus standard treatment in people after AMI. Neither RCT specifically recruited or identified data from people with cardiogenic shock after AMI. Neither RCT found a reduction in mortality with intra-aortic balloon counterpulsation. There is consensus that inra-aortic balloon counterpulsation is beneficial in people with cardiogenic shock after AMI. We found no evidence to confirm or reject this view.

OPTION VENTRICULAR ASSISTANCE DEVICES AND CARDIAC TRANSPLANTATION

We found no RCTs evaluating either ventricular assistance devices or cardiac transplantation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no evidence of harms specifically associated with ventricular assistance devices (see glossary, p 55) or cardiac transplantation in people with cardiogenic shock after acute myocardial infarction.

Comment: Reviews of observational studies[1,56,63] and retrospective reports[64,65] have suggested that ventricular assistance devices may improve outcomes in selected people when used alone or as a bridge to cardiac transplantation. The availability of ventricular assistance devices and cardiac transplantation is limited to a few specialised centres. Results may not be applicable to other settings.

OPTION EARLY CARDIAC SURGERY

We found no RCTs evaluating early surgical intervention for ventricular septal rupture, free wall rupture, or mitral valve regurgitation complicated by cardiogenic shock after acute myocardial infarction.

Benefits: We found no systematic review and no RCTs.

Harms: We found no evidence about the harms of surgery in people with cardiogenic shock caused by cardiac structural defects after acute myocardial infarction.

Comment: Non-systematic reviews of observational studies have suggested that death is inevitable after free wall rupture without early surgical intervention and that surgery for both mitral valve regurgitation and ventricular septal rupture is more effective when carried out within 24–48 hours.[1,56]

GLOSSARY

Cardiac index A measure of cardiac output derived from the formula: cardiac output/unit time divided by body surface area (L/minute/m^2).

Intra-aortic balloon counterpulsation A technique in which a balloon is placed in the aorta and inflated during diastole and deflated just before systole.

Invasive cardiac revascularisation A term used to describe either percutaneous transluminal coronary angioplasty or coronary artery bypass grafting.

Killip class A categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are Class I: no heart failure; Class II:

crackles audible half way up the chest; Class III: crackles heard in all the lung fields; Class IV: cardiogenic shock.

Ventricular assistance device A mechanical device placed in parallel to a failing cardiac ventricle that pumps blood in an attempt to maintain cardiac output. Because of the risk of mechanical failure, thrombosis, and haemolysis, ventricular assistance devices are normally used for short term support while preparing for a heart transplant.

chi²/2 heterogeneity of effects between 3 trials	0.7	5.6	7.0	5.4
P value	0.3	0.06	0.03	0.07
Weighted average of all 3 trials¶				
Effect/1000 people treated with tPA-based regimens instead of streptokinase	3.3 ± 0.8 more	2.9 ± 1.9 fewer	4.9 ± 1.8 fewer	1.6 ± 1.9 fewer
P value	< 0.001	> 0.1	0.01	0.4

Values are numbers (%). This table should not be used to make direct non-randomised comparisons between the absolute event rates in different trials, because the patient populations may have differed substantially in age and other characteristics. Deaths recorded throughout the first 35 days are included for GISSI-2 and ISIS-3 and throughout the first 30 days for GUSTO-1. Numbers randomised and numbers with follow up are from the ISIS-3 report[19] and GUSTO-1[20] (supplemented with revised GUSTO-1 data from the National Auxiliary Publications Service), and numbers with events and the percentages (based on participants with follow up) are from the ISIS-3 report[19] and Van de Werf, et al.[59] Plus-minus values are ± standard deviation. In all three trials, streptokinase was given in intravenous infusions of 1.5 MU over a period of 1 hour.

AMI, acute myocardial infarction; iv, intravenous; tPA, tissue plasminogen activator; sc, subcutaneous.

*Death not related to stroke was defined as death without recorded stroke.

†In the GISSI-2 trial, the tPA regimen involved an initial bolus of 10 mg, followed by 50 mg in the first hour and 20 mg in each of the second and third hours.

‡In the ISIS-3 trial, the tPA regimen involved 40 000 clot-lysis U/kg of body weight as an initial bolus, followed by 360 000 U/kg in the first hour and 67 000 U/kg in each of the next 3 hours.

§In the GUSTO-1 trial, the tPA alone regimen involved an initial bolus of 15 mg, followed by 0.75 mg/kg (up to 50 mg) in the first 30 minutes and 0.5 mg/kg (up to 35 mg) in the next hour; in the GUSTO-1 trial the other tPA based regimen involved 0.1 mg/kg of tPA (up to 9 mg) as an initial bolus and 0.9 mg/kg (up to 81 mg) in the remainder of the first hour, plus 1 MU of streptokinase in the first hour.

¶The weights are proportional to the sample sizes of the trials, so this average gives most weight to the GUSTO-1 trial and least to the GISSI-2 trials.[17]

TABLE 2 **Comparison of early invasive cardiac revascularisation versus initial medical treatment on mortality at 30 days, 6 months, and 12 months (see text, p 51).[2,3,53]**

Time after AMI	Mortality in early invasive cardiac revascularisation group Number dead/total number (%)	Mortality in medical treatment alone group Number dead/total number (%)	ARR (95% CI)	RR (95% CI)	NNT (95% CI)
SHOCK study[2,60]					
30 days	71/152 (47)	84/150 (56)	9.3% (–2 to +20.2)	0.83 (0.67 to 1.04)	NA
6 months	76/152 (50)	94/150 (63)	12.7% (1.5 to 23.4)	0.80 (0.65 to 0.98)	8 (5 to 68)
12 months	81/152 (53)	99/150 (66)	12.7% (1.6 to 23.3)	0.80 (0.67 to 0.97)	8 (5 to 61)
SMASH study[3]					
30 days	22/32 (69)	18/23 (78)	9.5% (–14.6 to +30.6)	0.88 (0.64 to 1.2)	NA
12 months	23/32 (74)	19/23 (83)	10.7% (–12.7 to +30.9)	0.87 (0.65 to 1.16)	NA

AMI, acute myocardial infarction; NA, not applicable.

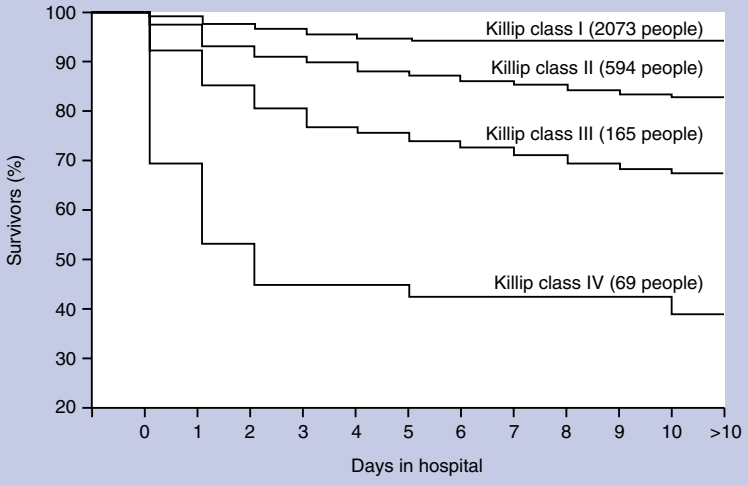

FIGURE 1 **The AMIS registry Kaplan–Meier survival curves as a function of Killip class (see glossary, p 54) at hospital admission for 3138 people (2901 evaluable) admitted in 50 Swiss hospitals between 1977 and 1998. Published with permission: Urban P, Bernstein MS, Costanza MC, et al, for the AMIS investigators. QUESTIONS

INTERVENTIONS

See glossary, p 74

Key Messages

- **Aspirin** One systematic review has found that aspirin reduces the risk of death, myocardial infarction, and stroke compared with placebo in people with unstable angina. The evidence suggests no added cardiovascular benefit, and possible added harm, from doses of aspirin over 325 mg daily.
- **Clopidogrel/ticlopidine** Two RCTs have found that clopidogrel or ticlopidine reduce mortality and myocardial infarction compared with placebo or conventional treatment alone. One RCT found that clopidogrel increased major bleeding, but not haemorrhagic strokes compared with placebo after 6–9 months. Ticlopidine may cause reversible neutropenia. These drugs may be an alternative in people who are intolerant of or allergic to aspirin.
- **Direct thrombin inhibitors** One systematic review has found that treatment with direct thrombin inhibitors for 7 days reduces death and myocardial infarction compared with heparin after 30 days.
- **Intravenous glycoprotein IIb/IIIa inhibitors** One systematic review found that intravenous glycoprotein IIb/IIIa inhibitors reduced the risk of death or myocardial infarction compared with placebo but increased the risk of major bleeding complications.
- **Low molecular weight heparins** One systematic review in people taking aspirin has found that adding low molecular weight heparin reduces the risk of death or myocardial infarction compared with placebo or no treatment and

does not significantly increase bleeding complications in the first 7 days after unstable angina. However, it found that longer term treatment with low molecular weight heparin did not significantly reduce death or myocardial infarction compared with placebo. One systematic review found no significant difference between low molecular weight heparin and unfractionated heparin in death or myocardial infarction. Long term low molecular weight heparin increased major bleeding compared with placebo, but not compared with unfractionated heparin.

- **Unfractionated heparin added to aspirin** One systematic review has found that adding unfractionated heparin to aspirin for 7 days in people with unstable angina reduced death or myocardial infarction at 1 week. However, a second review found no significant effect after 12 weeks.
- **β Blockers; nitrates** We found insufficient evidence of effects of these interventions on myocardial infarction or death rates. However, RCTs found that those interventions may reduce frequency and severity of chest pain.
- **Routine early invasive treatment** We found five RCTs that reported on different composite outcomes. Two of these found that early invasive treatment reduced death and other cardiac events compared with conservative treatment at 6 months. However, the remaining three RCTs found no significant difference in death or other cardiac events between early invasive treatment and conservative treatment at 12 months or more.
- **Calcium channel blockers** One systematic review found no significant difference between calcium channel blockers and either placebo or standard treatment on mortality or myocardial infarction. Observational studies suggest that short acting dihydropyridine calcium channel blockers may increase mortality.
- **Warfarin** One RCT found that adding warfarin to aspirin reduced cardiac events and death after 12 weeks. However, four RCTs found no significant effect after 5 months or more and one RCT found that warfarin was associated with an increase in major bleeding.
- **Oral glycoprotein IIb/IIIa inhibitors** One systematic review found that the oral glycoprotein IIb/IIIa inhibitor sibrafiban did not reduce the combined outcome of death, myocardial infarction, and recurrent ischaemia compared with aspirin. However, it found that oral glycoprotein IIb/IIIa inhibitors with or without aspirin increased bleeding compared with aspirin alone.

DEFINITION Unstable angina is distinguished from stable angina, acute myocardial infarction, and non-cardiac pain by the pattern of symptoms (characteristic pain present at rest or on lower levels of activity), the severity of symptoms (recently increasing intensity, frequency, or duration), and the absence of persistent ST segment elevation on a resting electrocardiogram. Unstable angina includes a variety of different clinical patterns: angina at rest of up to 1 week of duration; angina increasing in severity to moderate or severe pain; non-Q wave myocardial infarction; and post-myocardial infarction angina continuing for longer than 24 hours.

INCIDENCE/ PREVALENCE In industrialised countries, the annual incidence of unstable angina is about 6/10 000 people in the general population.

AETIOLOGY/ RISK FACTORS Risk factors are the same as for other manifestations of ischaemic heart disease: older age, previous atheromatous cardiovascular disease, diabetes mellitus, smoking cigarettes, hypertension,

hypercholesterolaemia, male sex, and a family history of ischaemic heart disease. Unstable angina can also occur in association with other disorders of the circulation, including heart valve disease, arrhythmia, and cardiomyopathy.

PROGNOSIS In people taking aspirin, the incidence of serious adverse outcomes (such as death, acute myocardial infarction, or refractory angina requiring emergency revascularisation) is 5–10% within the first 7 days and about 15% at 30 days. Between 5% and 14% of people with unstable angina die in the year after diagnosis, with about half of these deaths occurring within 4 weeks of diagnosis. No single factor identifies people at higher risk of an adverse event. Risk factors include severity of presentation (e.g. duration of pain, speed of progression, evidence of heart failure), medical history (e.g. previous unstable angina, acute myocardial infarction, left ventricular dysfunction), other clinical parameters (e.g. age, diabetes), electrocardiogram changes (e.g. severity of ST segment depression, deep T wave inversion, transient ST segment elevation), biochemical parameters (e.g. troponin concentration), and change in clinical status (e.g. recurrent chest pain, silent ischaemia, haemodynamic instability).

AIMS OF INTERVENTION To relieve pain and ischaemia; to prevent death and myocardial infarction; to identify people at high risk who require revascularisation; to facilitate early hospital discharge in people at low and medium risk; to modify risk factors; to prevent death, myocardial infarction, and recurrent ischaemia after discharge from hospital, with minimum adverse effects.

OUTCOMES Rate of death or myocardial infarction (often measured at 2, 7, and 30 days, and 6 months after randomisation); and adverse effects of treatment. Some RCTs include rates of refractory ischaemia or readmission for unstable angina.

METHODS *Clinical Evidence* search and appraisal November 2002.

QUESTION What are the effects of antiplatelet treatments?

OPTION ASPIRIN

One systematic review has found that aspirin reduces the risk of death, myocardial infarction, and stroke compared with placebo in people with unstable angina. The evidence suggests no added cardiovascular benefit, and possible added harm, from doses of aspirin over 325 mg daily.

Benefits: One systematic review (search date 1990, 145 RCTs, 100 000 people) compared antiplatelet treatment versus placebo.[1] Seven of these trials included a total of 4000 people with unstable angina. The review found that antiplatelet treatment (mostly medium dose aspirin, 75–325 mg/day) reduced the combined outcome of vascular death, myocardial infarction, or stroke at 6 months compared with placebo (AR 14% with placebo *v* 9% with antiplatelet treatment; RR 0.65, 95% CI 0.51 to 0.79; NNT 20, 95% CI 15 to 34). Individual trials within the systematic review found consistent benefit from daily aspirin in terms of reduced deaths and myocardial infarction.

Harms: The review found that people taking doses of aspirin of 75–1200 mg daily had no significant adverse events, including gastrointestinal intolerance or bleeding.[1] However, the sum of the evidence suggests no added cardiovascular benefit, and greater incidence of gastrointestinal effects, for aspirin doses greater than 325 mg daily. Some people are allergic to aspirin.

Comment: The systematic review covered a wide range of people with different morbidities and levels of risk. Its results probably generalise to routine practice.[1] People with unstable angina who are allergic or who do not respond to aspirin will need alternative antiplatelet treatment.

OPTION CLOPIDOGREL/TICLOPIDINE

Two RCTs have found that clopidogrel or ticlopidine reduce mortality and myocardial infarction compared with placebo or conventional treatment alone. One RCT found that clopidogrel increased major bleeding, but not haemorrhagic strokes, compared with placebo after 6–9 months. Ticlopidine may cause reversible neutropenia. These drugs may be an alternative in people who are intolerant of or allergic to aspirin.

Benefits: We found no systematic review. We found two RCTs comparing clopidogrel or ticlopidine versus placebo or conventional treatment.[2,3] The first RCT (12 562 people) compared clopidogrel (300 mg orally within 24 hours of onset of symptoms followed by 75 mg/day) versus placebo.[2] It found that clopidogrel significantly reduced the combined outcome of death, myocardial infarction, and stroke after 9 months compared with placebo (AR 9% with clopidogrel *v* 11% with placebo; OR 0.8, 95% CI 0.7 to 0.9). The second RCT (652 people) found that ticlopidine plus conventional treatment significantly reduced the combined outcome of vascular deaths and myocardial infarction after 6 months compared with conventional treatment alone (RR 0.5, 95% CI 0.2 to 0.9; NNT 16, 95% CI 9 to 62).[3]

Harms: In the first RCT, clopidogrel increased major bleeding complications compared with placebo, but not haemorrhagic strokes (major bleeding 3.7% with clopidogrel *v* 2.7% with placebo, OR 1.4, 95% CI 1.1 to 1.7; haemorrhagic stroke 0.1% with clopidogrel *v* 0.1% with placebo; P value and OR not provided).[2]

Comment: Reversible neutropenia has been reported in 1–2% of people taking ticlopidine. Clopidogrel and ticlopidine are also associated with other adverse effects, including diarrhoea and rash.

OPTION INTRAVENOUS GLYCOPROTEIN IIB/IIIA PLATELET RECEPTOR INHIBITORS

One systematic review found that intravenous glycoprotein IIb/IIIa inhibitors reduced death or myocardial infarction compared with placebo, but increased major bleeding complications.

Benefits: We found one systematic review (search date 2001, 8 RCTs, 30 006 people) comparing intravenous glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, lamifiban, and tirofiban) with placebo.[4] It found that intravenous glycoprotein IIb/IIIa inhibitors significantly reduced the combined outcome of death and myocardial

infarction at 30 days and 6 months compared with placebo (at 30 days: 8 RCTs, AR 10.8% with inhibitors *v* 11.8% with placebo; OR 0.91, 95% CI 0.85 to 0.98; at 6 months: 4 RCTs, AR 13.3% with inhibitors *v* 14.6% with placebo; OR 0.88, 95% CI 0.81 to 0.95).[4]

Harms: The systematic review found that intravenous glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, lamifiban, and tirofiban) increased major bleeding complications at 30 days compared with placebo (AR 4.2% with inhibitors *v* 3.2% with placebo; OR 1.38, 95% CI 1.04 to 1.85).[4]

Comment: One small trial found limited evidence that in people receiving standard treatment, a "dose ceiling" may exist, beyond which dose escalation of added glycoprotein IIb/IIIa inhibitor increases bleeding complications with no increase in efficacy.[5]

OPTION ORAL GLYCOPROTEIN IIB/IIIA PLATELET RECEPTOR INHIBITORS

One systematic review found that the oral glycoprotein IIb/IIIa inhibitor sibrafiban did not significantly reduce the combined outcome of death, myocardial infarction, and recurrent ischaemia compared with aspirin. However, it found that oral glycoprotein IIb/IIIa inhibitors with or without aspirin increased bleeding compared with aspirin alone.

Benefits: We found one systematic review (search date not stated, 4 RCTs, 26 462 people) comparing oral glycoprotein IIb/IIIa inhibitors with or without aspirin (sibrafiban with and without aspirin, orbofiban plus aspirin, and lefradafiban plus aspirin) versus aspirin alone.[5] Three of the RCTs were reported as abstracts only. The systematic review found that oral glycoprotein IIb/IIIa inhibitors did not reduce the combined outcome of death, myocardial infarction, and severe ischaemia compared with aspirin after 90 days (results from fully reported RCT: AR 10.1% with sibrafiban *v* 9.8% with aspirin; difference not statistically significant; OR and P value not reported).

Harms: The fully reported RCT in the systematic review found that sibrafiban increased major bleeding compared with aspirin (AR 27% with low dose sibrafiban *v* 19% with aspirin; OR and P value not provided). One RCT in the systematic review comparing sibrafiban plus aspirin versus placebo plus aspirin was stopped early because of the findings of the fully reported RCT. A further RCT in the systematic review comparing orbofiban plus aspirin versus placebo plus aspirin was stopped early because orbofiban plus aspirin increased mortality compared with placebo plus aspirin at 30 days (quantitative data not reported). One RCT in the systematic review comparing different doses of lefradafiban plus aspirin with placebo plus aspirin stopped recruiting to the high dose lefradafiban plus aspirin group because of increased bleeding (AR 11% with high dose lefradafiban *v* 3% with low and medium dose lefradafiban *v* 1% with placebo; P value not reported).

Comment: None.

QUESTION What are the effects of antithrombin treatments?

OPTION UNFRACTIONATED HEPARIN

One systematic review has found that adding unfractionated heparin to aspirin for 7 days in people with unstable angina reduced death or myocardial infarction at 1 week. However, a second review found no significant effect after 12 weeks.

Benefits: **Added to aspirin:** We found two systematic reviews (search dates 1995[6] and not stated[7]). Both included the same six RCTs in 1353 people with unstable angina who were treated with either unfractionated heparin plus aspirin or aspirin alone for 2–7 days. The more recent review found that unfractionated heparin plus aspirin reduced the risk of death or myocardial infarction after 7 days compared with aspirin alone (AR 8% with unfractionated heparin plus aspirin *v* 10% with aspirin alone; OR 0.67, 95% CI 0.45 to 0.99).[7] The older systematic review found that heparin plus aspirin did not reduce death or myocardial infarction after 12 weeks compared with aspirin alone (AR 12% with unfractionated heparin plus aspirin *v* 14% with aspirin; RR 0.82, 95% CI 0.56 to 1.20).[6] **Versus low molecular weight heparin:** See benefits of low molecular weight heparin, p 69.

Harms: The older systematic review found that heparin plus aspirin did not significantly increase major bleeding compared with aspirin alone (AR 1.5% with unfractionated heparin plus aspirin *v* 0.4% with aspirin; RR 1.89, 95% CI 0.66 to 5.38).[6]

Comment: None.

OPTION LOW MOLECULAR WEIGHT HEPARINS

One systematic review in people taking aspirin has found that adding low molecular weight heparin reduces death or myocardial infarction compared with adding placebo or no treatment and does not significantly increase bleeding complications in the first 7 days after unstable angina. However, it found that longer term treatment with low molecular weight heparin did not significantly reduce death or myocardial infarction compared with placebo. One systematic review found no significant difference between low molecular weight heparin and unfractionated heparin in death or myocardial infarction. Long term low molecular weight heparin increased major bleeding compared with placebo, but not compared with unfractionated heparin.

Benefits: **Versus placebo or no heparin treatment:** We found one systematic review (search date not stated, 7 RCTs) comparing low molecular weight heparin (LMWH) versus placebo or no heparin treatment.[7] The systematic review found two RCTs (1639 people already taking aspirin) comparing LMWH versus no heparin or placebo for up to 7 days. It found that LMWH reduced death or myocardial infarction compared with no heparin or placebo during treatment (OR 0.34, 95% CI 0.20 to 0.58). The systematic review found five RCTs (12 099 people) comparing longer term LMWH (≤ 90 days) versus placebo. It found that LMWH did not reduce death or

myocardial infarction after 90 days compared with placebo (OR 0.98, 95% CI 0.81 to 1.17). **Versus unfractionated heparin:** We found one systematic review (search date not stated, 5 RCTs, 12 171 people) comparing an equal duration (maximum 8 days) of LMWH versus unfractionated heparin.[7] It found that LMWH did not significantly reduce the combined outcome of death or myocardial infarction compared with unfractionated heparin (OR 0.88, 95% CI 0.69 to 1.12).

Harms: The systematic review found no significant difference between LMWH and unfractionated heparin in the frequency of major bleeds (OR 1.00, 95% CI 0.64 to 1.57)[7] (see harms of unfractionated heparin, p 69). Long term LMWH significantly increased the risk of major bleeding compared with placebo (OR 2.26, 95% CI 1.63 to 3.14): equivalent to an excess of 12 bleeds for every 1000 people treated.[7]

Comment: LMWH may be more attractive than unfractionated heparin for routine short term use because coagulation monitoring is not required and it can be self administered after discharge. A Cochrane systematic review comparing LMWH and unfractionated heparin for acute coronary syndromes has been published since the *Clinical Evidence* search date for this update, and will be included in the next update.[8]

OPTION DIRECT THROMBIN INHIBITORS

One systematic review has found that treatment with direct thrombin inhibitors for 7 days reduces death and myocardial infarction compared with heparin after 30 days.

Benefits: We found one systematic review (search date not stated, 11 RCTs, 35 070 people) comparing 7 days' treatment with direct thrombin inhibitors (hirudin, argatroban, bivalirudin, efegatran, inogatran) versus heparin.[9] It found that direct thrombin inhibitors reduced death or myocardial infarction compared with heparin after 30 days (AR 7.4% with direct thrombin inhibitors *v* 8.2% with heparin; RR 0.91, 95% CI 0.84 to 0.99).

Harms: The systematic review found that direct thrombin inhibitors reduced major bleeding during treatment compared with heparin (major bleeding; AR 1.9% with direct thrombin inhibitors *v* 2.3% with heparin; OR 0.75, 95% CI 0.65 to 0.87), and found no significant difference between the risk of stroke at 30 days (stroke; AR 0.6% with direct thrombin inhibitors *v* 0.6% with heparin; OR 1.01, 95% CI 0.78 to 1.31).[9]

Comment: None.

OPTION WARFARIN

One RCT found that adding warfarin to aspirin reduced cardiac events and death after 12 weeks. However, four RCTs found no significant effect after 5 months or more. One RCT found that warfarin was associated with an increase in major bleeding.

Benefits: We found no systematic review. We found five RCTs comparing warfarin versus no warfarin in addition to usual treatment.[10–13] Two of the RCTs were reported in the same journal article.[11] The first RCT (214 people) compared warfarin plus aspirin versus aspirin alone.[10] It found that warfarin (target international normalised ratio [see glossary, p 74] 2.0–2.5) plus aspirin reduced the combined outcome of recurrent angina, myocardial infarction, or death after 12 weeks, but the difference was not significant (AR 13% with warfarin plus aspirin *v* 25% with aspirin alone; P = 0.06). The second RCT (309 people) compared warfarin (fixed dose 3 mg/day) plus aspirin versus aspirin alone.[11] It found no significant difference between warfarin plus aspirin and aspirin alone in the combined outcome of refractory angina, myocardial infarction, and death after 6 months (AR 7% with warfarin plus aspirin *v* 4% with aspirin alone; RR 1.66, 95% CI 0.62 to 4.44).[11] The third RCT (197 people) compared warfarin (target international normalised ratio 2.0–2.5) plus aspirin versus aspirin alone.[11] It found no significant difference with adding warfarin to aspirin in the combined outcome of refractory angina, myocardial infarction, and death after 6 months (AR 5% with warfarin plus aspirin *v* 12% with aspirin alone; RR 0.42, 95% CI 0.15 to 1.15). The fourth RCT (3712 people) compared adding warfarin (target international normalised ratio 2.0–2.5) to standard treatment versus no warfarin.[12] It found no significant difference with adding warfarin in the combined outcome of death, myocardial infarction, and stroke after 5 months (8% with warfarin *v* 8% with no warfarin; RR 0.90, 95% CI 0.72 to 1.14).[12] The fifth RCT (135 people with prior coronary artery bypass grafts) compared warfarin plus aspirin, warfarin plus placebo, and aspirin plus placebo.[13] It found no significant difference between treatments in the combined outcome of death, myocardial infarction, and hospital admission for unstable angina after 1 year (AR 11% with warfarin plus aspirin *v* 14% with warfarin plus placebo *v* 12% with aspirin plus placebo; P = 0.76).[13]

Harms: In the fourth RCT, warfarin increased major bleeding compared with standard treatment alone (AR 2.7% with warfarin *v* 1.3% with no warfarin; RR 1.99, 95% CI 1.23 to 3.22; NNH 71; CI not provided).[12]

Comment: None.

QUESTION What are the effects of anti-ischaemic treatments?

OPTION NITRATES, β BLOCKERS, AND CALCIUM CHANNEL BLOCKERS

We found insufficient evidence on the effects of nitrates and β blockers on mortality or myocardial infarction, although RCTs suggested that these interventions may reduce frequency and severity of chest pain. One systematic review found no significant difference between calcium channel blockers and either placebo or standard treatment on mortality or myocardial infarction. Observational studies suggest that short acting dihydropyridine calcium channel blockers may increase mortality.

Angina (unstable)

Benefits: We found no systematic review. **Nitrates:** We found one RCT (162 people) comparing intravenous glyceryl trinitrate versus placebo for 48 hours.[14] It found that glyceryl trinitrate significantly reduced the proportion of people with more than two episodes of chest pain and one new episode lasting more than 20 minutes (18% with glyceryl trinitrate *v* 36% with placebo; RR 0.50, 95% CI 0.25 to 0.90) and the proportion of people needing more than two additional sublingual glyceryl trinitrate tablets (16% with glyceryl trinitrate *v* 31% with placebo; RR 0.52, 95% CI 0.26 to 0.97). We found one RCT (200 people within 6 months of percutaneous transluminal coronary angioplasty) comparing intravenous glyceryl trinitrate alone, heparin alone, glyceryl trinitrate plus heparin, and placebo.[15] It found that recurrent angina occurred significantly less frequently in people treated with glyceryl trinitrate alone and glyceryl trinitrate plus heparin compared with placebo, but there was no benefit from heparin alone or additional benefit from combination treatment ($P < 0.003$ for glyceryl trinitrate alone and for glyceryl trinitrate plus heparin *v* placebo; CI not reported). **β Blockers:** We found two RCTs.[16,17] The first RCT (338 people with rest angina not receiving a β blocker) compared nifedipine, metoprolol, both, or neither versus placebo.[16] It found that metoprolol significantly reduced the composite outcome of recurrent angina and myocardial infarction within 48 hours compared with nifedipine (28% with metoprolol *v* 47% with nifedipine; RR 0.66, 95% CI 0.43 to 0.98). The second RCT (81 people with unstable angina on "optimal doses" of nitrates and nifedipine) compared propranolol (≥ 160 mg/day) versus placebo.[17] It found no significant difference in death, myocardial infarction, and requirement for coronary artery bypass grafting or percutaneous coronary interventions at 30 days (38% with propranolol *v* 46% with placebo; RR 0.83, 95% CI 0.44 to 1.30). People taking propranolol had a lower cumulative probability of experiencing recurrent rest angina over the first 4 days of the trial. The mean number of clinical episodes of angina, duration of angina, glyceryl trinitrate requirement, and ischaemic ST changes by continuous electrocardiogram monitoring was also lower. **Calcium channel blockers:** We found one systematic review (search date not stated, 6 RCTs, 1109 people)[18] comparing calcium channel blockers versus control treatment (3 RCTs used propranolol as a control and 3 used placebo). The duration of the RCTs ranged from 48 hours (4 RCTs) to 4 months (2 RCTs). The review found no significant difference between calcium channel blockers and control in rates of myocardial infarction or death.

Harms: Hypotension is a potential adverse effect of nitrates. Both older and more recent large RCTs in people with other ischaemic conditions showed that nitrates were safe and well tolerated when used judiciously in clinically appropriate doses. Potential adverse effects of β blockers include bradycardia, exacerbation of reactive airways disease, and hypoglycaemia in people with diabetes. Observational studies have reported increased mortality with short acting calcium channel blockers (such as nifedipine) in people with coronary heart disease.[19,20]

Comment: We found no good evidence that anti-ischaemic drugs (nitrates, β blockers, calcium channel blockers) prevent death or myocardial infarction. Consensus suggests that until further data are available, intravenous nitrates remain the preferred treatment together with heparin and aspirin in unstable angina.

QUESTION What are the effects of invasive treatments?

OPTION EARLY ROUTINE CARDIAC CATHETERISATION AND REVASCULARISATION

We found five RCTs that reported on different composite outcomes. Two of these found that early invasive treatment reduced death and other cardiac events compared with conservative treatment at 6 months. However, the remaining three RCTs found no significant difference in death or other cardiac events between early invasive treatment and conservative treatment at 12 or more months.

Benefits: We found no systematic review. We found five RCTs (6 articles) comparing early routine angiography and revascularisation if appropriate versus medical treatment alone.[21–26] The first RCT (2457 people) compared invasive treatment within the first 7 days and non-invasive treatment plus planned coronary angiography.[21] Invasive treatment significantly reduced the combined outcome of death and myocardial infarction compared with non-invasive treatment after 6 months (AR 9% with invasive treatment *v* 12% with non-invasive treatment; RR 0.78, 95% CI 0.62 to 0.98; NNT 38; CI not provided). The second RCT (2220 people) compared cardiac catheterisation at 4–48 hours and revascularisation (if appropriate) after a cardiovascular event versus standard treatment.[22] It found that cardiac catheterisation reduced the combined outcome of death, myocardial infarction, and readmission for unstable angina after 6 months (AR 16% with catheterisation *v* 19% with standard treatment; OR 0.78, 95% CI 0.62 to 0.97; NNT 34; CI not reported). The third RCT (1473 people) compared early cardiac catheterisation at 18–48 hours versus standard treatment.[23,24] Early cardiac catheterisation did not significantly reduce death or myocardial infarction but did reduce hospital admissions after 1 year (death or myocardial infarction: 11% with cardiac catheterisation *v* 12% with standard treatment, $P = 0.42$; hospital admissions: 26% with cardiac catheterisation *v* 33% with standard treatment; $P < 0.005$; NNT 14; CI not reported). The fourth RCT (920 people) compared invasive with conservative treatment.[25] Invasive treatment did not significantly reduce the combined outcome of death or myocardial infarction compared with conservative treatment after 12–44 months (RR 0.87, 95% CI 0.68 to 1.10). The fifth RCT (1810 people) found that early intervention significantly reduced the composite outcome of death, non-fatal myocardial infarction, or refractory angina compared with conservative treatment at 4 months (4 months: 86/895 [9.6%] with early intervention *v* 133/915 [14.5%] with conservative treatment, RR 0.66, 95% CI 0.51 to 0.85).[26] The difference was mainly due to reduced refractory angina with early intervention. The RCT found no

significant difference in a combined outcome of death and myocardial infarction between early intervention and conservative treatment at 1 year (68/895 [7.6%] with early intervention *v* 76/915 [8.3%] with conservative treatment, RR 0.91, 95% CI 0.67 to 1.25).[26]

Harms: The first RCT found that early invasive treatment increased major bleeding, but not stroke, compared with non-invasive treatment (major bleeds: AR 1.6% with invasive treatment *v* 0.7% with non-invasive treatment; NNH 111; CI not reported).[21] The second RCT found that cardiac catheterisation increased bleeding compared with standard treatment (6% with cardiac catheterisation *v* 3% with standard treatment; $P < 0.01$: NNH 34; CI not reported).[22] The third RCT found that early cardiac catheterisation did not increase complication rates (death, myocardial infarction, emergency coronary artery bypass grafting, abrupt vessel closure, haemorrhage, serious hypotension) compared with conservative treatment (AR 14% with cardiac catheterisation *v* 13% with conservative treatment; $P = 0.38$; NNH 100; CI not reported).[23,24]

Comment: All trials have reported only short term and medium term follow up, so we cannot exclude a long term difference in effect between early invasive and early non-invasive strategies. There may be subgroups of people who benefit particularly from either invasive or conservative treatment. Advances in catheterisation and revascularisation technology and periprocedural management may reduce the early risks of invasive treatment in the future.

GLOSSARY

International normalised ratio (INR) A value derived from a standardised laboratory test that measures the effect of an anticoagulant. The laboratory materials used in the test are calibrated against internationally accepted standard reference preparations, so that variability between laboratories and different reagents is minimised. Normal blood has an international normalised ratio of 1.0. Therapeutic anticoagulation often aims to achieve an international normalised ratio value of 2.0–3.5.

QUESTIONS

INTERVENTIONS

Key Messages

Prevention of embolism

- **Antithrombotic treatment before cardioversion** We found no RCTs on use of aspirin, heparin, or warfarin as thromboprophylaxis before attempted cardioversion in acute atrial fibrillation.

Conversion to sinus rhythm

- **Flecainide** One RCT found that intravenous flecainide increased the proportion of people who reverted to sinus rhythm within 1 hour and in whom the sinus rhythm was maintained after 6 hours compared with placebo. Flecainide has been associated with serious adverse events such as severe hypotension and torsades de point. Two RCTs found that oral flecainide increased the proportion of people who reverted to sinus rhythm within 8 hours compared with intravenous amiodarone. We found insufficient evidence to draw any conclusions

about comparisons between intravenous flecainide and intravenous amiodarone and between flecainide and quinidine. Three RCTs found no significant difference in rates of conversion to sinus rhythm between flecainide and propafenone. Flecainide and propafenone are not used in people with known or suspected ischaemic heart disease because they may cause arrhythmias.

- **Propafenone** One systematic review and subsequent RCTs have found that propafenone increased the proportion of people converting to sinus rhythm within 1–4 hours compared with placebo. One RCT in people with onset of atrial fibrillation of less than 48 hours found no significant difference between intravenous propafenone and amiodarone in the proportion of people who converted to sinus rhythm within 1 hour. Another RCT in people with onset of atrial fibrillation of less than 2 weeks found that a higher proportion of people converted to sinus rhythm with oral propafenone within 2.5 hours compared with amiodarone but the difference did not remain significant at 24 hours. Three RCTs found insufficient evidence to compare rates of conversion to sinus rhythm between propafenone and flecqinide. Propafenone and flecainide are not used in people with known or suspected ischaemic heart disease.

- **Amiodarone** We found insufficient evidence from three RCTs about the effects of amiodarone as a single agent compared with placebo for conversion to sinus rhythm in people with acute atrial fibrillation in people who are haemodynamically stable. Four small RCTs found no significant difference in rate of conversion to sinus rhythm at 24–48 hours for amiodarone compared with digoxin, although the studies may have lacked power to exclude clinically important differences. One small RCT found that amiodarone increased rate of cardioversion compared with verapamil at 3 hours. One RCT in people with onset of atrial fibrillation of less than 48 hours found no significant difference between intravenous propafenone and amiodarone in conversion to sinus rhythm within 1 hour. Another RCT in people with onset of atrial fibrillation of less than 2 weeks found that a higher proportion of people converted to sinus rhythm with oral propafenone within 2.5 hours compared with amiodarone but the difference did not remain significant at 24 hours. Two RCTs found that intravenous amiodarone reduced the proportion of people who reverted to sinus rhythm within 8 hours compared with oral flecainide. We found insufficient evidence to draw any conclusion between intravenous flecainide compared with intravenous amiodarone. We found no RCTs comparing amiodarone with either DC cardioversion or diltiazem.

- **DC cardioversion** We found no RCTs of DC cardioversion in acute atrial fibrillation in people who are haemodynamically stable.

- **Quinidine** We found no RCTs of DC cardioversion that compared quinidine versus placebo. One small RCT in people with onset of atrial fibrillation of less than 48 hours found that quinidine plus digoxin increased the proportion of people converting to sinus rhythm within 12 hours compared with sotalol. We found insufficient evidence to draw any conclusions about comparisons between flecainide and quinidine.

- **Sotalol** We found no RCTs comparing sotalol versus placebo. One small RCT in people with onset of atrial fibrillation of less than 48 hours found that quinidine plus digoxin increased the proportion of people who converted to sinus rhythm within 12 hours compared with sotalol.

Atrial fibrillation (acute)

- **Digoxin** We found no placebo controlled RCTs limited to people with acute atrial fibrillation. Three RCTs in people with atrial fibrillation of up to 7 days' duration found no significant difference between digoxin and placebo in conversion to sinus rhythm. Four RCTs found no significant difference between amiodarone and digoxin in conversion to sinus rhythm at 24–48 hours, although these trials may have lacked power to detect clinically important differences.

Heart rate control

- **Digoxin** We found no placebo controlled RCTs limited to people with acute atrial fibrillation. Two RCTs found that compared with placebo, digoxin reduced ventricular rate after 30 minutes and after 2 hours in people with atrial fibrillation of up to 7 days' duration. One RCT found that compared with digoxin, intravenous diltiazem reduced heart rate within 5 minutes in people with acute atrial fibrillation and atrial flutter.
- **Diltiazem** One RCT in people with atrial fibrillation (of unspecified duration) or atrial flutter found that intravenous diltiazem reduced heart rate in people within 15 minutes compared with placebo. One RCT found that in people with acute atrial fibrillation and atrial flutter, intravenous diltiazem reduced heart rate within 5 minutes compared with intravenous digoxin. One RCT found no significant difference between intravenous verapamil and intravenous diltiazem in rate control or measures of systolic function in people with acute atrial fibrillation or atrial flutter, but verapamil caused hypotension in some people.
- **Timolol** We found no RCTs limited to people with acute atrial fibrillation. One small RCT in people with atrial fibrillation of unspecified duration found that intravenous timolol (a β blocker) reduced ventricular rate within 20 minutes compared with placebo.
- **Verapamil** Two RCTs found that intravenous verapamil reduced heart rate at 10 or 30 minutes compared with placebo in people with atrial fibrillation or atrial flutter. One RCT in people with atrial fibrillation or acute atrial flutter found no significant difference between intravenous verapamil and intravenous diltiazem in rate control or measures of systolic function, but verapamil caused hypotension in some people. The RCT found that amiodarone increased the rate of cardioversion compared with verapamil at 3 hours.
- **Amiodarone** We found no RCTs examining effects of amiodarone alone on heart rate in people with acute atrial fibrillation.
- **Sotalol** We found no RCTs comparing sotalol versus placebo.

DEFINITION **Acute atrial fibrillation** is rapid, irregular, and chaotic atrial activity of less than 48 hours' duration. It includes both the first symptomatic onset of chronic, or persistent, atrial fibrillation and episodes of paroxysmal atrial fibrillation (see glossary, p 93). It is sometimes difficult to distinguish new onset of atrial fibrillation from long standing atrial fibrillation that was previously undiagnosed. Atrial fibrillation within 72 hours of onset is sometimes called recent onset atrial fibrillation. By contrast, **chronic atrial fibrillation** is more sustained and can be described as paroxysmal (with spontaneous termination and sinus rhythm between recurrences), persistent, or permanent atrial fibrillation (see glossary, p 93). This review deals only with people with acute atrial fibrillation who are haemodynamically stable. The consensus is that people who are not haemodynamically stable should be treated with immediate DC cardiversion. We have excluded studies in people with atrial fibrillation arising during or soon after cardiac surgery.

INCIDENCE/ PREVALENCE

We found limited evidence of the incidence or prevalence of acute atrial fibrillation. Extrapolation from the Framingham study suggests an incidence in men of 3/1000 person years at age 55 years, rising to 38/1000 person years at 94 years.[1] In women, the incidence was 2/1000 person years at age 55 years and 32.5/1000 person years at 94 years. The prevalence of atrial fibrillation ranged from 0.5% for people aged 50–59 years to 9% in people aged 80–89 years. Among acute emergency medical admissions in the UK, 3–6% had atrial fibrillation, and about 40% were newly diagnosed.[2,3] Among acute hospital admissions in New Zealand, 10% (95% CI 9% to 12%) had documented atrial fibrillation.[4]

AETIOLOGY/ RISK FACTORS

Common precipitants of acute atrial fibrillation are acute myocardial infarction and the acute effects of alcohol. Age increases the risk of developing acute atrial fibrillation. Men are more likely to develop atrial fibrillation than women (38 years' follow up from the Framingham Study, RR after adjustment for age and known predisposing conditions 1.5).[5] Atrial fibrillation can occur in association with underlying disease (both cardiac and non-cardiac) or can arise in the absence of any other condition. Epidemiological surveys have found that risk factors for the development of acute atrial fibrillation include ischaemic heart disease, hypertension, heart failure, valve disease, diabetes, alcohol abuse, thyroid disorders, and disorders of the lung and pleura.[1] In a British survey of acute hospital admissions of patients with atrial fibrillation, a history of ischaemic heart disease was present in 33%, heart failure in 24%, hypertension in 26%, and rheumatic heart disease in 7%.[3] In some populations, the acute effects of alcohol explain a large proportion of the incidence of acute atrial fibrillation. Paroxysms of atrial fibrillation are more common in athletes.[6]

PROGNOSIS

Spontaneous reversion: Observational studies and placebo arms of RCTs have found that more than 50% of people with acute atrial fibrillation revert spontaneously within 24–48 hours, especially if atrial fibrillation is associated with an identifiable precipitant such as alcohol or myocardial infarction. **Progression to chronic atrial fibrillation:** We found no evidence about the proportion of people with acute atrial fibrillation who develop more chronic forms of atrial fibrillation (e.g. paroxysmal, persistent, or permanent atrial fibrillation). **Mortality:** We found little evidence about the effects on mortality and morbidity of acute atrial fibrillation where no underlying cause is found. Acute atrial fibrillation during myocardial infarction is an independent predictor of both short term and long term mortality.[7] **Heart failure:** Onset of atrial fibrillation reduces cardiac output by 10–20% irrespective of the underlying ventricular rate[8,9] and can contribute to heart failure. People with acute atrial fibrillation who present with heart failure have worse prognoses. **Stroke:** Acute atrial fibrillation is associated with a risk of imminent stroke.[10–13] One case series used transoesophageal echocardiography in people who had developed acute atrial fibrillation within the preceding 48 hours; 15% had atrial thrombi.[14] An ischaemic stroke associated with atrial fibrillation is more likely to be fatal, have a recurrence, and leave a serious functional deficit among survivors than a stroke not associated with atrial fibrillation.[15]

Atrial fibrillation (acute)

AIMS OF INTERVENTION To reduce symptoms, morbidity, and mortality, with minimum adverse effects.

OUTCOMES Major outcomes include measures of symptoms, recurrent strokes, or transient ischaemic attacks; thromboembolism; mortality; and major bleeding. Proxy measures include heart rhythm, ventricular rate, and time to restoration of sinus rhythm. Frequent spontaneous reversion to sinus rhythm makes it difficult to interpret short term studies of rhythm; treatments may accelerate restoration of sinus rhythm without increasing the proportion of people who eventually convert. The clinical importance of changes in mean heart rate is also unclear.

METHODS *Clinical Evidence* search and appraisal February 2003. Current contents, textbooks, review articles, and recent abstracts were reviewed. Many studies were not solely in people with acute atrial fibrillation. The text indicates where results have been extrapolated from studies of paroxysmal, persistent, or permanent atrial fibrillation. Atrial fibrillation that follows coronary surgery was excluded. We found no RCTs that reported on quality of life, functional capacity, or mortality.

QUESTION **What are the effects of interventions to prevent embolism in people with acute atrial fibrillation who are haemodynamically stable?**

OPTION ANTITHROMBOTIC TREATMENT BEFORE CARDIOVERSION

We found no RCTs on use of aspirin, heparin, or warfarin as thromboprophylaxis before attempted cardioversion in acute atrial fibrillation.

Benefits: We found no RCTs on use of aspirin, heparin, or warfarin as thromboprophylaxis before cardioversion in acute atrial fibrillation.

Harms: We found no RCTs.

Comment: There is consensus to give heparin to people who undergo cardioversion within 48 hours of the onset of arrhythmia, but we found insufficient evidence from trials. The decision to give anticoagulation both in the short term and after cardioversion is usually based on an individual's intrinsic risk of thromboembolism.[16] Warfarin is not used as an anticoagulant in acute atrial fibrillation because of its slow onset of action. One transoesophageal echocardiography study in people with a recent embolic event found left atrial thrombus in 15% of people with acute atrial fibrillation of less than 3 days' duration.[14] This would suggest that such people may benefit from formal anticoagulation or need to be evaluated by transoesophageal echocardiography before safe cardioversion. One ongoing trial is assessing the feasibility and effects of such a strategy by comparing low molecular weight and unfractionated heparin in people with atrial fibrillation of more than 2 days' duration who undergo transoesophageal echocardiographically guided early electrical or chemical cardioversion.[17]

QUESTION **What are the effects of interventions for conversion to sinus rhythm and for controlling heart rate in people with acute atrial fibrillation who are haemodynamically stable?**

OPTION DC CARDIOVERSION

We found no RCTs of DC cardioversion in acute atrial fibrillation in people who are haemodynamically stable.

Benefits: We found no systematic review. **Versus no cardioversion:** We found no RCTs. **Versus chemical conversion:** We found no RCTs.

Harms: Adverse events from synchronised DC cardioversion include those associated with a general anaesthetic, generation of a more serious arrhythmia, superficial burns, and thromboembolism.

Comment: It might be unethical to conduct RCTs of DC cardioversion in people with acute atrial fibrillation and haemodynamic compromise. The only evidence for DC cardioversion in acute atrial fibrillation is extrapolated from its use in chronic atrial fibrillation (see glossary, p 93). DC cardioversion has been used for the treatment of atrial fibrillation since the 1960s.[18] Consensus is that immediate DC cardioversion for acute atrial fibrillation should be attempted only if there are signs of haemodynamic compromise.[16] Otherwise, full anticoagulation is recommended (warfarin for 3 weeks before and 4 weeks after cardioversion) to reduce the risk of thromboembolism in people with acute atrial fibrillation of more than 48 hours' duration.[16] We found insufficient evidence on whether cardioversion or rate control is superior for the treatment of acute atrial fibrillation.

OPTION AMIODARONE

We found insufficient evidence from three RCTs about the effects of amiodarone as a single agent compared with placebo for conversion to sinus rhythm in people with acute atrial fibrillation who are haemodynamically stable. Four small RCTs found no significant difference in rate of conversion to sinus rhythm at 24–48 hours for amiodarone compared with digoxin, although the studies may have lacked power to exclude clinically important differences. One small RCT found that amiodarone increased rate of cardioversion compared with verapamil at 3 hours. One RCT in people with onset of atrial fibrillation of less than 48 hours found no significant difference between intravenous amiodarone and propafenone in conversion to sinus rhythm within 1 hour. Another RCT in people with onset of atrial fibrillation of less than 2 weeks found that a higher proportion of people converted to sinus rhythm with oral propafenone within 2.5 hours compared with amiodarone but the difference did not remain significant at 24 hours. Two RCTs found that intravenous amiodarone reduced the proportion of people who reverted to sinus rhythm within 8 hours compared with oral flecainide. We found insufficient evidence to draw any conclusions between intravenous flacainide. We found insufficient evidence to draw any conclusions between intravenous flacainide and intravenous amiodarone. We found no RCTs comparing amiodarone with either DC cardioversion or diltiazem.

Atrial fibrillation (acute)

Benefits: **Versus placebo:** We found two systematic reviews (search dates 2001, 2 RCTs that compared amiodarone as a single agent with placebo, 104 people with acute onset atrial fibrillation)[19,20] and one subsequent RCT.[21] Both RCTs included in the reviews found no significant difference in rates of conversion from atrial fibrillation to sinus rhythm between intravenous amiodarone and placebo at 8 hours (first RCT: 40 people; cardioversion rate 37% with amiodarone 5 mg/kg bolus plus 1800 mg/day *v* 48% with placebo; P value reported as not significant, CI not reported; second RCT: 64 people; cardioversion rate 59% with amiodarone 7 mg/kg bolus *v* 56% with placebo; P value reported as not significant, CI not reported).[22,23] The subsequent RCT (72 people) found higher cardioversion rates with oral amiodarone compared with placebo at 8 hours (50% cardioverted with amiodarone 30 mg/kg/day *v* 20% with placebo; $P < 0.0001$).[21] **Versus digoxin:** We found two systematic reviews (search date 2001, 3 RCTs, 148 people with acute onset atrial fibrillation;[19] search date 2001, 3 RCTs, 114 people, no statistical pooling of results[20]). Together, the reviews identified four small RCTs (34, 45, 50, and 30 people). None found any statistically significant difference in rates of conversion to sinus between amiodarone and digoxin at 24–48 hours. **Versus diltiazem:** We found no systematic review or RCTs in people with acute atrial fibrillation. **Versus verapamil:** We found two systematic reviews (both search dates 2001, 1 RCT, 24 people).[19,20] The RCT found that amiodarone increased conversion to sinus rhythm compared with verapamil at 3 hours (AR for cardioversion 77% with amiodarone *v* 0% with intravenous verapamil; $P < 0.05$).[24] **Versus propafenone:** See benefits of propafenone, p 87. **Versus DC cardioversion:** We found no systematic review or RCTs.

Harms: **Versus placebo:** One systematic review found that the most common adverse effects of intravenous amiodarone were phlebitis, hypotension, and bradycardia.[20] Pooled adverse event rates were higher with amiodarone than placebo (AR for any adverse effect 17% with amiodarone *v* 11% with placebo). Other reported adverse effects of amiodarone in the acute setting include heart failure and arrhythmia. **Versus propafenone:** One RCT that compared amiodarone versus propafenone found no serious adverse events.[25]

Comment: The RCTs were small. Those that found no significant difference between treatments may have lacked power to detect clinically important effects.

OPTION DIGOXIN

We found no placebo controlled RCTs limited to people with acute atrial fibrillation. Three RCTs in people with atrial fibrillation of up to 7 days' duration found no significant difference between digoxin and placebo in conversion to sinus rhythm but two of the RCTs found that digoxin reduced ventricular rate after 30 minutes and after 2 hours. Four RCTs found no significant difference between amiodarone and digoxin in conversion to sinus rhythm at 24–48 hours, although these trials may have lacked power to detect clinically important differences. One RCT found that compared with digoxin, intravenous diltiazem reduced heart rate within 5 minutes in people with acute atrial fibrillation and atrial flutter.

Benefits: We found no systematic review. We found no RCTs limited to people with acute atrial fibrillation **Versus placebo:** We found three RCTs in people with atrial fibrillation of up to 7 days' duration.[26–28] One RCT (239 people within 7 days of onset of atrial fibrillation, mean age 66 years, mean ventricular rate 122 beats/minute) found that intravenous digoxin (mean 0.88 mg) did not increase the restoration of sinus rhythm at 16 hours compared with placebo (51% with digoxin *v* 46% with placebo).[26] It found a rapid and clinically important reduction in ventricular rate at 2 hours (to 105 beats/minute with digoxin *v* 117 beats/minute with placebo; P = 0.0001). The second RCT (40 people within 7 days of the onset of atrial fibrillation, mean age 64 years, 23 men) compared high dose intravenous digoxin 1.25 mg versus placebo.[27] Restoration to sinus rhythm was not significantly different (9/19 [47%] with digoxin *v* 8/20 [40%] with placebo; P = 0.6). The ventricular rate after 30 minutes was significantly lower with digoxin versus placebo (P < 0.02). The third RCT (36 people within 7 days of the onset of atrial fibrillation) compared oral digoxin (doses of 0.6, 0.4, 0.2, and 0.2 mg at 0, 4, 8, and 14 hours, or until conversion to sinus rhythm, whichever occurred first) versus placebo. Conversion to sinus rhythm at 18 hours was not significantly different (50% with digoxin *v* 44% with placebo; ARR +6%, 95% CI −11% to +22%).[28] **Versus amiodarone:** See benefits of amiodarone, p 82. **Versus diltiazem:** See benefits of diltiazem, p 84.

Harms: **Versus placebo:** In one RCT, some people developed asymptomatic bradycardia and one person with previously undiagnosed hypertrophic cardiomyopathy suffered circulatory distress.[26] In the second RCT, two people developed bradyarrhythmias.[27] No adverse effects were stated in the third RCT.[28] Digoxin at toxic doses could result in visual, gastrointestinal, and neurological symptoms; heart block; and arrhythmias. **Versus amiodarone:** Two RCTs did not report adverse events.[29,30] One RCT reported episodes of bradycardia occurring in two patients (4%) in the control group on digoxin after conversion to sinus rhythm, but this was not significantly greater than in the amiodarone group (P = 0.24).[31] The final RCT reported hypotension developing in four patients, vomiting in two patients, one episode of atrial flutter, and one episode of a transient junctional rhythm in the group given digoxin.[32] **Versus diltiazem:** The RCT was not large enough to report adverse effects adequately.

Comment: The evidence suggests that digoxin is no better than placebo for restoring sinus rhythm in people with recent onset atrial fibrillation. The peak action of digoxin is delayed for up to 6–12 hours. We found one systematic review (search date 1998)[33] and RCTs of digoxin versus placebo in people with chronic atrial fibrillation (see glossary, p 93), which found that control of the ventricular rate during exercise was poor unless a β blocker or rate limiting calcium channel blocker (verapamil or diltiazem) was used in combination.[34,35]

OPTION DILTIAZEM

One RCT in people with atrial fibrillation of unspecified duration or atrial flutter found that intravenous diltiazem reduced heart rate in people within 15 minutes compared with placebo. One RCT found that in people

with acute atrial fibrillation and atrial flutter, intravenous diltiazem reduced heart rate within 5 minutes compared with intravenous digoxin. One RCT found no significant difference between intravenous verapamil and intravenous diltiazem (both calcium channel blockers) in rate control or measures of systolic function in people with acute atrial fibrillation or atrial flutter, but verapamil caused hypotension in some people.

Benefits: We found no systematic review but found three RCTs.[36–38] **Versus placebo:** One RCT (113 people; 89 with atrial fibrillation of unspecified duration and 24 with atrial flutter [see glossary, p 93]; ventricular rate > 120 beats/minute; systolic blood pressure ≥ 90 mm Hg without severe heart failure; 108 people with at least one underlying condition that may explain atrial arrhythmia; mean age 64 years) compared intravenous diltiazem versus placebo.[36] After randomisation, a dose of intravenous diltiazem (or equivalent placebo) 0.25 mg/kg every 2 minutes was given; if the first dose had no effect after 15 minutes, then the code was broken and diltiazem 0.35 mg/kg every 2 minutes was given regardless of randomisation. The RCT found that intravenous diltiazem significantly decreased heart rate during a 15 minute observation period compared with placebo (ventricular rate below 100 beats/minute 42/56 [75%] with diltiazem *v* 4/57 [7%] with placebo; $P < 0.001$; average decrease in heart rate, 22% with diltiazem *v* 3% with placebo; median time from start of drug infusion to maximal decrease in heart rate 4.3 minutes; mean rate decreased from 139 beats/minute to 114 beats/minute with diltiazem).[36] The RCT found no difference in response rate to diltiazem in people with atrial fibrillation compared with those with atrial flutter. **Versus digoxin:** One RCT (30 consecutive people, 10 men, mean age 72 years, 26 with acute atrial fibrillation, four with atrial flutter, unspecified duration) compared intravenous diltiazem versus intravenous digoxin versus both drugs given on admission to the emergency department.[37] Heart rate control was defined as a ventricular rate of < 100 beats/minute. Intravenous digoxin (25 mg as a bolus at 0 and 30 minutes) and intravenous diltiazem (initially 0.25 mg/kg over the first 2 minutes, followed by 0.35 mg/kg at 15 minutes and then a titratable infusion at a rate of 10–20 mg/hour) were given to maintain heart rate control. The dosing regimens were the same whether the drugs were given alone or in combination. The RCT found that diltiazem significantly decreased ventricular heart rate within 5 minutes compared with digoxin ($P = 0.0006$; mean rates 111 beats/minute with diltiazem *v* 144 beats/minute with digoxin). The decrease in heart rate achieved with digoxin did not reach statistical significance until 180 minutes ($P = 0.01$; mean rates 90 beats/minute with diltiazem *v* 117 beats/minute with digoxin). No additional benefit was found with the combination of digoxin and diltiazem. **Versus verapamil:** See benefits of verapamil, p 92.[38]

Harms: **Versus placebo:** In one RCT, in the diltiazem treated group, seven people developed asymptomatic hypotension (systolic blood pressure < 90 mm Hg), three developed flushing, three developed itching, and one developed nausea and vomiting; these were not

significantly different from placebo.[36] **Versus digoxin:** The RCT was not large enough to adequately assess adverse effects, and none were apparent.[37] **Versus verapamil:** See harms of verapamil, p 92. Rate limiting calcium channel blockers may exacerbate heart failure and hypotension.

Comment: The evidence suggests that calcium channel blockers such as verapamil and diltiazem reduce ventricular rate in acute or recent onset atrial fibrillation, but they are probably no better than placebo for restoring sinus rhythm. We found no studies of the effect of rate limiting calcium channel blockers on exercise tolerance in people with acute or recent onset atrial fibrillation, but studies in people with chronic atrial fibrillation (see glossary, p 93) have found improved exercise tolerance.

OPTION FLECAINIDE

One RCT found that intravenous flecainide increased the proportion of people who reverted to sinus rhythm within 1 hour and in whom sinus rhythm was maintained after 6 hours compared with placebo. Flecainide has been associated with serious adverse events such as severe hypotension and torsades de pointes. Two RCTs found that oral flecainide increased the proportion of people who reverted to sinus rhythm within 8 hours compared with intravenous amiodarone. We found insufficient evidence to draw any conclusions about comparisons between intravenous flecainide and intravenous amiodarone and between flecainide and quinidine. Three RCTs found no significant difference in rates of cardioversion to sinus rhythm between flecainide and propafenone. Flecainide and propafenone are not used in people with known or suspected ischaemic heart disease because they may cause arrhythmias.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs.[22,23,39] One single-blind RCT (62 patients, recent onset atrial fibrillation [< 1 week], found that flecainide increased the rate of conversion to sinus rhythm compared with placebo at 8 hours (20/22 patients [91%] with flecainide *v* 10/21 [48%] with placebo; $P < 0.01$).[22] In the second RCT (98 patients, duration of atrial fibrillation AF < 72 hours, included postsurgical patients) flecainide increased the rate of conversion to sinus rhythm by 2 hours compared with placebo (20/34 [58%] with intravenous flecainide *v* 7/32 [22%] with placebo; $P = 0.007$), but this difference was no longer significant at 8 hours.[23] The third RCT (102 people with recent onset atrial fibrillation [< 72 hours]) also found that intravenous flecainide significantly increased the proportion of people who reverted to sinus rhythm within 1 hour and in whom the sinus rhythm was maintained after 6 hours (reversion to sinus rhythm within 1 hour of starting treatment compared with placebo; 29/51 [57%] with flecainide *v* 7/51 [14%] with placebo; OR 8.3, 95% CI 2.9 to 24.8; maintenance of sinus rhythm after 6 hours: 34/51 [67%] *v* 18/51 [35%]; OR 3.67, 95% CI 1.50 to 9.10). Participants were randomised to receive flecainide 2 mg/kg over 30 minutes (maximum dose 150 mg) or placebo and were monitored in intensive care or coronary care units. Intravenous digoxin 500 μg over 30 minutes was given to all people who had not previously received

digoxin.[39] **Versus amiodarone or propafenone:** We found five RCTs.[40–44] The first RCT (five arm study, 417 people, onset of atrial fibrillation ≤ 7 days) found no significant difference between oral flecainide and intravenous amiodarone in the proportion of people who converted to sinus rhythm at 1 and 3 hours but found a higher rate of conversion to sinus rhythm with oral flecainide at 8 hours (conversion to sinus rhythm at 1 hour: 9/69 [13%] with oral flecainide *v* 3/51 [6%] with intravenous amiodarone; RR 2.2, 95% CI 0.6 to 7.8: at 3 hours, 39/69 [57%] with oral flecainide *v* 13/51 [25%] with intravenous amiodarone; RR 2.20, 95% CI 0.96 to 1.51; and at 8 hours: 52/69 [75%] with oral flecainide *v* 29/51 [57%] with intravenous amiodarone; RR 1.30, 95% CI 1.01 to 1.74).[40] The other groups in the RCT were placebo, intravenous propafenone, and oral propafenone. The RCT found no significant difference between oral flecainide and oral propafenone in the proportion of people who converted to sinus rhythm at 1, 3, or 12 hours (at 1 hour: 9/69 [13%] with oral flecainide *v* 10/119 [8%] with oral propafenone; RR 1.55, 95% CI 0.66 to 3.63; at 3 hours: 39/69 [57%] with oral flecainide *v* 54/119 [45%] with oral propafenone; RR 1.25, 95% CI 0.94 to 1.66; at 8 hours: 52/69 [75%] with oral flecainide *v* 91/119 [76%] with oral propafenone; RR 0.99, 95% CI 0.83 to 1.17).[40] The second RCT (three arm study, 62 people aged > 75 years, onset of atrial fibrillation ≤ 7 days) found that oral flecainide significantly increased the proportion of people who converted to sinus rhythm at 8 hours compared with intravenous amiodarone (20/22 [91%] with flecainide *v* 7/19 [37%] with amiodarone; RR 2.47, 95% CI 1.35 to 4.51).[41] The RCT also found that significantly higher proportion of people converted to sinus rhythm with flecainide compared with placebo ($P < 0.01$).[41] The third RCT (three arm study, 150 people, onset of atrial fibrillation ≤ 48 hours) found that intravenous flecainide significantly increased the proportion of people who converted to sinus rhythm at 1, 8, and 12 hours compared with intravenous amiodarone (at 1 hour: 29/50 [58%] with flecainide *v* 7/50 [14%] with amiodarone; RR 4.14, 95% CI 2.00 to 8.57; at 8 hours: 41/50 [82%] with flecainide *v* 21/50 [42%] with amiodarone; RR 1.95, 95% CI 1.38 to 2.77; at 12 hours: 45/50 [90%] with flecainide *v* 32/50 [64%] with amiodarone; RR 1.41, 95% CI 1.12 to 1.77).[44] The RCT found no significant difference between intravenous flecainide and intravenous propafenone in the proportion of people who converted to sinus rhythm at 1 and 8 hours. It found a significantly higher conversion rate at 12 hours with flecainide compared with propafenone (at 1 hour, 29/50 [58%] with flecainide *v* 30/50 [60%] with propafenone; RR 0.97, 95% CI 0.70 to 1.34; at 8 hours: 41/50 [82%] with flecainide *v* 34/50 [68%] with propafenone; RR 1.21, 95% CI 0.96 to 1.51; and at 12 hours: 45/50 [90%] with flecainide *v* 36/50 [72%] with propafenone; RR 1.25, 95% CI 1.03 to 1.52).[39] The fourth RCT (three arm study, 98 people, onset of atrial fibrillation ≤ 72 hours) found no significant difference between intravenous flecainide and intravenous amiodarone in the proportion of people who converted to sinus rhythm within 2 hours (20/34 [59%] with flecainide *v* 11/32 [34%] with amiodarone; RR 1.71, 95% CI 0.98 to 2.98). The RCT also found that significantly higher proportion of people converted to sinus rhythm with flecainide

compared with placebo within 2 hours (20/34 [59%] with flecainide *v* 7/32 [22%] with placebo; RR 2.69, 95% CI 1.32 to 5.48).[42] The fifth RCT (three arm study, 352 people) found significantly faster conversion to sinus rhythm with intravenous flecainide within 1 hour after treatment compared with propafenone (72.5% with flecainide *v* 54.3% with propafenone; P = 0.05; absolute numbers not given).[43] **Versus quinidine:** One small RCT found insufficient evidence to draw any conclusions about the effectiveness of flecainide versus quinidine for conversion to sinus rhythm (60 people aged 16–92 years, of whom 36 people had atrial fibrillation < 10 days; conversion to sinus rhythm [time period not given], 18/21 [86%] with flecainide *v* 12/15 [80%] with quinidine; RR 1.07, 95% CI 0.79 to 1.46).[45]

Harms: **Versus placebo:** One RCT reported an asymptomatic pause of 9.3 seconds in a patient who took flecainide.[22] The second RCT reported hypotension during the study period but this was not significantly different between flecainide and placebo (8/34 [24%] of patients in the flecainide group versus 8/32 [25%] with placebo).[23] However, another RCT found that a higher proportion of people developed severe hypotension (a decrease in systolic arterial pressure by ≥ 33%) with flecainide compared with placebo (11/51 [22%] with flecainide *v* 3/51 [6%] with placebo; OR 4.40, 95% CI 1.03 to 18.60). One person in the flecainide group with no history of ventricular arrhythmia and a normal QT interval developed torsades de pointes.[39]

Comment: Following the increased mortality observed in post-myocardial infarction patients randomised to flecainide or ecainide in the Cardiac Arrhythmia Suppression Trial, flecainide is not used for the treatment of atrial fibrillation in patients with known ischaemic heart disease because of the risk of proarrhythmia.[46]

OPTION PROPAFENONE

One systematic review and subsequent RCTs have found that propafenone increased the proportion of people converting to sinus rhythm within 1–4 hours compared with placebo. One RCT in people with onset of atrial fibrillation of less than 48 hours found no significant difference between intravenous propafenone and amiodarone in the proportion of people who converted to sinus rhythm within 1 hour. Another RCT in people with onset of atrial fibrillation of less than 2 weeks found that a higher proportion of people converted to sinus rhythm with oral propafenone within 2.5 hours compared with amiodarone but the difference did not remain significant at 24 hours. Propafenone and flecainide are not used in people with known or suspected ischaemic heart disease because they may cause arrhythmias.

Benefits: **Versus placebo:** We found one systematic review (search date 1997, 27 controlled clinical trials including some non-randomised trials, 1843 people),[47] one additional RCT,[48] and five subsequent RCTs (see table 1, p 96).[49–53] The systematic review found that people treated with propafenone were more likely to convert to sinus rhythm at 4 and 8 hours after initial treatment compared with placebo but the difference between the groups did not remain

significant after 24 hours (at 4 hours: ARR 31.5%, 95% CI 24.5% to 38.5%; at 8 hours: ARR 32.9%, 95% CI 24.3% to 41.5%; P < 0.01 for both time points; at 24 hours: ARR +11.0%, 95% CI –0.6% to +22.4%; absolute numbers not given).[47] In the trials included in the systematic review, propafenone was given either intravenously (2 mg/kg as initial bolus followed by infusion) or orally (450–600 mg).[47] The systematic review included people with either acute or chronic fibrillation (see glossary, p 93), but it did not stratify the data. The number of RCTs was not stated clearly. All of the five subsequent RCTs found propafenone to be more effective than placebo in terms of conversion to sinus rhythm within 6 hours (see table 1). The additional RCT (75 people aged 18–75 years, onset of atrial fibrillation < 72 hours) found that intravenous propafenone significantly increased the proportion of people who converted to sinus rhythm within 3 hours compared with placebo (24/41 [58.5%] with propafenone *v* 10/34 [29.4%] with placebo; OR 3.2, 95% CI 1.3 to 7.9; see table 1, p 96).[48] The first subsequent multicentre RCT (240 people, mean age 59 years with atrial fibrillation duration < 7 days) found that propafenone significantly increased the proportion of people in sinus rhythm at 3 and 8 hours after treatment compared with placebo (at 3 hours: 54/119 [45%] with propafenone *v* 22/121 [18%] with placebo; ARR 27%, 95% CI 17% to 39%; RR 2.5, 95% CI 1.6 to 3.8; at 8 hours: 91/119 [76%] with propafenone *v* 45/121 [37%] with placebo; ARR 39%, 95% CI 29% to 52%; RR 2.1, 95% CI 1.6 to 2.6; see table 1, p 96).[49] After stratification by age (≤ 60 years or > 60 years of age), the RCT found that conversion to sinus rhythm with propafenone was more likely in people aged under 60 years old compared with older people (in people ≤ 60 years of age: OR 3.78, 95% CI 1.80 to 7.92 at 3 hours *v* OR 4.74, 95% CI 2.12 to 10.54 at 8 hours; in people aged > 60 years of age: OR 5.03, 95% CI 2.08 to 12.12 at 3 hours *v* OR 6.75, 95% CI 3.38 to 73.86 at 8 hours).[54] The second subsequent RCT (55 people, mean age 59 years, duration of atrial fibrillation < 7 days) found that a significantly higher proportion of people converted to sinus rhythm within 2 hours with propafenone compared with placebo, and the significant difference was maintained up to 6 hours but not at 12 or 24 hours (at 2 hours: 12/29 [41%] with propafenone *v* 2/26 [8%] with placebo, P = 0.005; at 6 hours: 65% with propafenone *v* 31% with placebo, P = 0.015; at 12 hours: 69% with propafenone *v* 31% with placebo, P = 0.06; and at 24 hours: 79% with propafenone *v* 73% with placebo, P = 0.75; see table 1, p 96).[50] The third subsequent RCT (156 people aged 18–80 years, onset of atrial fibrillation < 72 hours) found that intravenous propafenone significantly increased the proportion of people who converted to sinus rhythm within 2 hours compared with placebo: 57/81 [70.3%] with propafenone *v* 13/75 [17.3%] with placebo; ARR 53%, 95% CI 42% to 68%; RR 4.06, 95% CI 2.43 to 6.79; (see table 1, p 96).[51] The fourth subsequent RCT (123 people, onset of atrial fibrillation < 72 hours) found that intravenous or oral propafenone significantly increased the proportion of people who converted to sinus rhythm within 1 and 4 hours but not at 8 hours after initial treatment compared with placebo (within 1 hour: 25/81 [31%] with propafenone *v* 7/42 with placebo [17%]; RR 1.85, 95% CI 0.87 to 3.92; within 4 hours, 49/81 [61%]

with propafenone *v* 14/42 [33%] with placebo; RR 1.82, 95% CI 1.14 to 2.88; and within 8 hours: 53/81 [65%] *v* 20/42 [48%]; RR 1.37, 95% CI 0.96 to 1.96; see table 1, p 96).[52] The RCT also found that the time to conversion to sinus rhythm was significantly shorter with intravenous propafenone compared with oral propafenone (1 hour: 19/40 [48%] with intravenous propafenone *v* 6/41 [15%] with oral propafenone; RR 3.25, 95% CI 1.45 to 7.28; within 4 hours: 20/40 [50%] with intravenous propafenone *v* 29/41 [71%] with oral propafenone; RR 0.71, 95% CI 0.49 to 1.02; see table 1, p 96).[52] The fifth subsequent RCT (three arm study, 123 people aged 18–75 years, onset of atrial fibrillation < 72 hours) found that a significantly higher proportion of people converted to sinus rhythm with propafenone compared with placebo but found no significant difference between digoxin and placebo conversion to sinus rhythm with 1 hour (20/41 [49%] with propafenone *v* 6/42 [14%] with placebo; RR 3.42, 95% CI 1.53 to 7.63; 13/40 [33%] with digoxin *v* 6/42 [14%] with placebo; RR 2.28, 95% CI 0.96 to 5.40; see table 1, p 96).[53] After 1 hour, people who had not converted to sinus rhythm were switched to the alternative drug (see table 1, p 96).[53] **Versus amiodarone:** We found no systematic review. We found two RCTs.[25,55] The first RCT (three arm study, 143 people, onset of atrial fibrillation < 48 hours) found no significant difference between intravenous propafenone and amiodarone in the proportion of people who converted to sinus rhythm within 1 hour (36/46 [78.2%] with propafenone *v* 40/48 [83.3%] with amiodarone; RR 0.94, 95% CI 0.77 to 1.15).[55] The RCT also found that a significantly higher proportion of people converted to sinus rhythm within 1 hour with propafenone and amiodarone than with placebo; (36/46 [78.2%] with propafenone *v* 27/49 [55.1%] with placebo; RR 1.42, 95% CI 1.06 to 1.91; 40/48 [83.3%] with amiodarone *v* 27/49 [55.0%] with placebo; RR 1.51, 95% CI 1.14 to 2.01). Intravenous propafenone was given as 2 mg/kg in 15 minutes then 10 mg/kg in 24 hours. Amiodarone was given as 300 mg in 1 hour then 20 mg/kg over 24 hours plus 1800 mg daily in three oral doses.[55] The second RCT (86 people, onset of atrial fibrillation < 2 weeks) found a faster rate of conversion to sinus rhythm with oral propafenone compared with amiodarone but no significant difference in the proportion of people who converted to sinus rhythm at 24 and 48 hours (median time to sinus rhythm; 2.4 hours with propafenone *v* 6.9 hours with amiodarone; P = 0.05; conversion to sinus rhythm at 24 hours, 56% with propafenone *v* 47% with amiodarone; NS, results presented graphically).[25] **Versus flecainide:** See benefits of flecainide, p 85.

Harms:

Versus placebo: The systematic review did not comment on adverse events.[47] One RCT that included people with structural heart disease and hypertension found no significant difference between propafenone and placebo in terms of adverse events (sustained atrial flutter [see glossary, p 93] or tachycardia lasting > 1 minute: 8/119 [7%] with propafenone *v* 7/121 [6%] with placebo, P > 0.2; pauses of > 2 seconds: 1/119 [1%] with propafenone *v* 3/121 [2%] with placebo, P > 0.2). No cases of ventricular proarrhythmia were reported.[49] Five other RCTs that compared propafenone versus placebo reported no serious adverse events.[48,50–52,54] **Other comparisons:** We found one RCT (246

people with onset of atrial fibrillation < 48 hours) that evaluated the safety of an oral loading dose of propafenone (600 mg for > 60 kg body weight, then 300 mg if persistent) compared with that of digoxin plus propafenone, digoxin plus quinidine, or placebo.[56] The RCT found no serious adverse events. The RCT found transient atrial flutter (13/66 [20%] with propafenone *v* 12/70 [17%] with digoxin plus propafenone *v* 9/70 [13%] with digoxin plus quinidine *v* 3/40 [8%] with placebo), asymptomatic salvos of up to four ventricular beats (4/70 [6%] with digoxin plus propafenone *v* 1/70 [1%] with digoxin plus quinidine), transient left bundle branch block (3/66 [5%] with propafenone *v* 2/70 [3%] with digoxin plus propafenone *v* 2/70 [3%] digoxin plus quinidine), transient Wenkebach 2 : 1 heart block (2/66 [3%] with propafenone *v* 2/70 [3%] with digoxin plus quinidine), and transient mild hypotension (5/66 [8%] propafenone *v* 1/70 [1%] digoxin plus quinidine). The RCT found no significant difference between groups for non-cardiac adverse events such as nausea, headache, gastrointestinal disturbance, dizziness, and paraesthesia.[56]

Comment: Extrapolation of the results of the cardiac arrhythmia suppression trial mean that other class 1c antiarrhythmic agents including propafenone tend not to be used in patients with ischaemic heart disease because of concerns over a possible increase in proarrhythmic effects in this group of people.[46] In addition, the increased frequency of cardiac adverse events with long term propafenone noted in people with structural heart disease means that trials in acute atrial fibrillation have, for the main part, excluded people with significant heart disease.[57]

OPTION QUINIDINE

We found no RCTs that compared quinidine versus placebo. One small RCT in people with onset of atrial fibrillation of less than 48 hours found that quinidine plus digoxin increased the proportion of people converting to sinus rhythm within 12 hours compared with sotalol. We found insufficient evidence to draw any conclusions about comparisons between flecainide and quinidine.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs that compared quinidine versus placebo. **Quinidine plus digoxin versus sotalol:** One small RCT (61 people aged 18–75 years, mean age about 54 years, with recent onset atrial fibrillation of < 48 hours) found that quinidine plus digoxin significantly increased the proportion of people who converted to sinus rhythm within 12 hours compared with sotalol (24/28 [85.7%] with quinidine plus digoxin *v* 17/33 [51.5%] with sotalol; ARR 34%, 95% CI 16% to 58%; RR 1.66, 95% CI 1.16 to 2.39; NNT 3, 95% CI 2 to 6).[58] Quinidine was given as 200 mg orally up to three times with 2 hour intervals, and up to 0.75 mg of digoxin was given intravenously if the initial heart rate was greater than 100 beats/minute. Sotalol 80 mg was given orally, and the dose was repeated at 2, 6, and 10 hours after the initial dose if sinus rhythm was not achieved.[58] **Versus flecainide:** See benefits of flecainide, p 85.

Harms: One RCT reported broad complex tachycardia in 7/28 (27%) people with quinidine plus digoxin compared with 4/33 (13%) people with sotalol. Electrocardiogram R-R interval prolongation was also reported in both groups (total three people, longest R–R 3.8 seconds with digoxin plus quinidine *v* 6.4 seconds with sotalol).[58]

Comment: None.

OPTION SOTALOL

We found no RCTs comparing sotalol versus placebo. One small RCT in people with onset of atrial fibrillation of less than 48 hours found that quinidine plus digoxin increased the proportion of people converting to sinus rhythm within 12 hours compared with sotalol.

Benefits: **Versus placebo:** We found no systematic review or RCTs that compared sotalol versus placebo in people with acute atrial fibrillation for conversion to sinus rhythm or heart rate control. **Versus quinidine plus digoxin:** See benefits of quinidine, p 90.

Harms: We found no RCTs that compared sotalol versus placebo.

Comment: We found one systematic review (search date 1996) that identified one open label RCT in people with acute atrial fibrillation.[59] The RCT compared oral sotalol 80 mg versus quinidine, but digoxin was also given to people with a heart rate of less than 100 beats/minute in the quinidine group. The RCT found insufficient evidence to draw any conclusions.[59] We also found another systematic review that compared β blockers with placebo in people with acute or chronic atrial fibrillation (see glossary, p 93).[33] See comment on timolol, p 92.

OPTION TIMOLOL

We found no RCTs limited to people with acute atrial fibrillation. One small RCT found that timolol (a β blocker) reduced ventricular rate within 20 minutes compared with placebo.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs limited to people with acute atrial fibrillation. We found one RCT (61 people with atrial fibrillation of unspecified duration, ventricular rate > 120 beats/minute) that compared intravenous timolol 1 mg (a β blocker) versus intravenous placebo given immediately and repeated twice at 20 minute intervals if sinus rhythm was not achieved.[60] It found that 20 minutes after the last injection, intravenous timolol significantly increased the proportion of people who had a ventricular rate below 100 beats/minute compared with placebo (41% with timolol *v* 3% with placebo; $P < 0.01$).

Harms: In the RCT, the most common adverse effects were bradycardia (2%) and hypotension (9%).[60] β Blockers may exacerbate heart failure and hypotension in acute atrial fibrillation. β Blockers plus rate limiting calcium channel blockers (diltiazem and verapamil) may increase the risk of asystole and sinus arrest.[61–63] β Blockers can precipitate bronchospasm.[64]

Comment: We found one systematic review of β blockers versus placebo in people with acute or chronic atrial fibrillation (see glossary, p 93).[33] It found that in 7/12 (58%) comparisons at rest and in all during exercise, β blockers reduced ventricular rate compared with placebo.

OPTION VERAPAMIL

Two RCTs found that intravenous verapamil reduced heart rate at 10 or 30 minutes compared with placebo in people with atrial fibrillation or atrial flutter. One RCT found no significant difference between intravenous verapamil and intravenous diltiazem in rate control or measures of systolic function in people with acute atrial fibrillation or atrial flutter, but verapamil caused hypotension in some people. One small RCT found that amiodarone increased cardioversion rate compared with verapamil at 3 hours.

Benefits: We found no systematic review in people with acute atrial fibrillation. **Versus placebo:** We found two RCTs.[65,66] Both found that that intravenous verapamil reduced heart rate at 10 or 30 minutes compared with placebo in people with atrial fibrillation or atrial flutter. The first RCT (21 men with atrial fibrillation and a rapid ventricular rate, age 37–70 years) was a crossover comparison of intravenous verapamil versus placebo (saline).[65] It found that intravenous verapamil reduced ventricular rate within 10 minutes compared with placebo (reduction > 15% of the initial rate: 17/20 [85%] with verapamil *v* 2/14 [14%] with saline; $P < 0.001$). The second RCT (double blind, crossover study of 20 people with atrial fibrillation or atrial flutter [see glossary, p 93] for 2 hours to 2 years) compared intravenous low dose verapamil 0.075 mg/kg versus placebo.[66] A positive response was defined as conversion to sinus rhythm or a decrease of the ventricular response to less than 100 beats a minute or by more than 20% of the initial rate. If a positive response did not occur within 10 minutes, then a second bolus injection was given (placebo for people who initially received verapamil, and verapamil for people who initially received placebo). With the first bolus injection, verapamil versus placebo significantly reduced ventricular rate (mean heart rate 118 beats/minute with verapamil *v* 138 with placebo), and more people converted to sinus rhythm within 30 minutes but the difference was not significant (3/20 [15%] with verapamil *v* 0/15 [0%] with placebo; $P = 0.12$). **Versus diltiazem:** We found one small double blind, crossover RCT (17 men, five with acute atrial fibrillation, 10 with atrial flutter, and two with a combination of atrial fibrillation and atrial flutter; ventricular rate ≥ 120 beats/minute, systolic blood pressure > 100 mm Hg) compared intravenous verapamil versus intravenous diltiazem.[38] It found no significant differences in rate control or measures of systolic function. **Versus amiodarone:** See benefits of amiodarone, p 81.

Harms: **Versus placebo:** One RCT reported that intravenous verapamil caused a transient drop in systolic and diastolic blood pressure greater than with placebo (saline), which did not require treatment, but it did not state the number of people affected.[65] The second RCT reported development of 1 : 1 flutter in one person with previous Wolff Parkinson White syndrome (see glossary, p 93) and 2 : 1 flutter.[66] **Versus diltiazem:** In the third RCT, which compared verapamil versus diltiazem, 3/17 (18%) people who received verapamil as the first drug developed symptomatic hypotension and

were withdrawn from the study before crossover.[38] Two people recovered, but the episode in the third person was considered to be life threatening. In people with Wolff Parkinson White syndrome, verapamil may increase ventricular rate and can cause ventricular arrhythmias.[67] Rate limiting calcium channel blockers may exacerbate heart failure and hypotension.

Comment: See comment on diltiazem, p 85.

GLOSSARY

Atrial flutter A similar arrhythmia to atrial fibrillation but the atrial electrical activity is less chaotic and has a characteristic saw tooth appearance on an electrocardiogram.
Chronic atrial fibrillation Refers to more sustained or recurrent forms of atrial fibrillation, which can be subdivided into paroxysmal, persistent, or permanent atrial fibrillation.
Paroxysmal atrial fibrillation If the atrial fibrillation recurs intermittently with sinus rhythm, with spontaneous recurrences or termination, it is designated as "paroxysmal", and the objective of management is suppression of paroxysms and maintenance of sinus rhythm.
Permanent atrial fibrillation If cardioversion is inappropriate, and has not been indicated or attempted, atrial fibrillation is designated as "permanent", where the objective of management is rate control and antithrombotic treatment.
Persistent atrial fibrillation When atrial fibrillation is more sustained than paroxysmal, atrial fibrillation is designated "persistent" and needs termination with pharmacological treatment or electrical cardioversion.
Torsades de pointes A form of ventricular tachycardia with atypical QRS complexes ECG pattern.
Wolff Parkinson White syndrome Occurs when an additional electrical pathway exists between the atria and ventricles as a result of anomalous embryonic development. The extra pathway may cause rapid arrhythmias. Worldwide it affects about 0.2% of the general population. In people with Wolff Parkinson White syndrome, β blockers, calcium channel blockers, and digoxin can increase the ventricular rate and cause ventricular arrhythmias.

TABLE 1 **RCTs comparing propafenone versus placebo in conversion to sinus rhythm in people with acute atrial fibrillation (see text, p 87).**

RCT	Population	Intervention	Control	Outcome	Time	Result
48	75 people aged 18–75 years, onset of atrial fibrillation < 72 hours	Propafenone intravenous	Placebo	Conversion to sinus rhythm	3 hours	24/41 (58.5%) with propafenone *v* 10/34 (29.4%) with placebo (OR 3.2, 95% CI 1.3 to 7.9)
49	240 people, mean age 59 years, duration of atrial fibrillation < 7 days	Propafenone	Placebo	Conversion to sinus rhythm	3 hours	54/119 (45%) with propafenone *v* 22/121 (18%) with placebo (ARR 27%, 95% CI, 17% to 39%)
					8 hours	91/119 (76%) with propafenone *v* 45/121 (37%) with placebo (ARR 39%, 95%, 29% to 52%)
50	55 people, mean age 59 years, duration of atrial fibrillation < 7 days	Propafenone	Placebo	Conversion to sinus rhythm	2 hours	12/29 (41%) with propafenone *v* 2/26 (8%) with placebo (P = 0.005)
					6 hours	65% with propafenone *v* 31% with placebo (P = 0.015)
					12 hours	69% with propafenone *v* 31% with placebo (P = 0.06)
					24 hours	79% with propafenone *v* 73% with placebo (P = 0.75)
51	156 people aged 18–80 years, onset of atrial fibrillation < 72 hours	Propafenone	Placebo	Conversion to sinus rhythm	2 hour	57/81 (70.3%) with propafenone *v* 13/75 (17.3%) with placebo (ARR 53% 95% CI, 42% to 68%, 95% CI; RR 4.06, 95% CI, 2.43 to 6.79)

TABLE 1 continued

RCT	Population	Intervention	Control	Outcome	Time	Result
52	123 people, onset of atrial fibrillation < 72 hours	Propafenone intravenous or oral	Placebo	Conversion to sinus rhythm	1 hour	25/81 (31%) with propafenone *v* 7/42 with placebo (17%) (RR 1.85, 95% CI, 0.87 to 3.92)
					4 hours	49/81 (61%) with propafenone *v* 14/42 (33%) with placebo (RR 1.82, 95% CI, 1.14 to 2.88)
					8 hours	53/81 (65%) *v* 20/42 (48%) (RR 1.37, 95% CI, 0.96 to 1.96)
					1 hour	19/40 (48%) with intravenous propafenone *v* 6/41 (15%) with oral propafenone (RR 3.25, 95% CI, 1.45 to 7.28)
		Propafenone intravenous	Propafenone oral		4 hours	20/40 (50%) with intravenous propafenone *v* 29/41 (71%) with oral propafenone (RR 0.71, 95% CI, 0.49 to 1.02)
53	Three arm study, 123 people aged 18–75 years, onset of atrial fibrillation < 72 hours	Propafenone	Placebo	Conversion to sinus rhythm	1 hour	20/41 (49%) with propafenone *v* 6/42 (14%) with placebo (RR 3.42, 95% CI, 1.53 to 7.63)

Key Messages

- **Advice from physicians and trained counsellors to quit smoking** Systematic reviews have found that simple, one off advice from a physician during a routine consultation is associated with 2% of smokers quitting smoking without relapse for 1 year. Advice from trained counsellors who are neither doctors nor nurses also increases quit rates compared with minimal intervention.
- **Advice on cholesterol lowering diet** Systematic reviews have found that advice on cholesterol lowering diet (i.e. advice to lower total fat intake or increase the ratio of polyunsaturated : saturated fatty acid) leads to a small reduction in blood cholesterol concentrations in the long term (≥ 6 months).
- **Advice on diet and exercise supported by behavioural therapy for the encouragement of weight loss** Systematic reviews and subsequent RCTs have found that a combination of advice on diet and exercise supported by behavioural therapy is probably more effective than either diet or exercise advice alone in the treatment of obesity, and might lead to sustained weight loss.
- **Advice on reducing sodium intake to reduce blood pressure** One systematic review has found that, compared with usual care to reduce sodium intake, intensive interventions, unsuited to primary care or population prevention programmes, provide only small reductions in blood pressure. Effects on deaths and cardiovascular events are unclear.
- **Bupropion as part of a smoking cessation programme** One systematic review of antidepressants used as part of a smoking cessation programme has found that bupropion increases quit rates at 1 year.
- **Counselling people at high risk of disease to quit smoking** Systematic reviews and one subsequent RCT have found that antismoking advice improves smoking cessation in people at high risk of smoking related disease.
- **Counselling pregnant women to quit smoking** Two systematic reviews have found that antismoking interventions in pregnant women increase abstinence rates during pregnancy. Interventions without nicotine replacement were as effective as nicotine replacement in healthy non-pregnant women.
- **Exercise advice to women over 80 years** One RCT found that exercise advice delivered in the home by physiotherapists increased physical activity and reduced the risk of falling in women over 80 years.
- **Nicotine replacement in smokers who smoke at least 10 cigarettes daily** One systematic review and one subsequent RCT have found that nicotine replacement is an effective additional component of cessation strategies in smokers who smoke at least 10 cigarettes daily. We found no evidence that any method of delivery of nicotine is more effective than others. We found limited evidence from three RCTs with follow up of 2–6 years that the additional benefit of nicotine replacement treatment on quit rates reduced with time.
- **Advice from nurses to quit smoking** One systematic review has found that advice to quit smoking increased quitting at 1 year compared with no advice.
- **Counselling sedentary people to increase physical activity** We found weak evidence from systematic reviews and subsequent RCTs that counselling sedentary people increases physical activity compared with no intervention. Limited evidence from RCTs suggests that consultation with an exercise specialist rather than a physician may increase physical activity at 1 year. We found limited evidence that interventions delivered by new media can lead to short term changes in physical activity.

Changing behaviour

- **Self help materials for people who want to stop smoking** One systematic review found that self help materials slightly improve smoking cessation compared with no intervention. It found that individually tailored materials were more effective than standard or stage based materials and that telephone counselling increased the effectiveness of postal self help materials.
- **Physical exercise to aid smoking cessation** One systematic review found limited evidence that exercise may increase smoking cessation.
- **Training health professionals to give advice on smoking cessation (increases frequency of antismoking interventions, but may not improve effectiveness)** One systematic review has found that training professionals increases the frequency of antismoking interventions being offered. It found no good evidence that antismoking interventions are more effective if the health professionals delivering the interventions received training. One RCT found that a structured intervention delivered by trained community pharmacists increased smoking cessation rates compared with usual care delivered by untrained community pharmacists.
- **Acupuncture for smoking cessation** One systematic review has found no significant difference between acupuncture and control in smoking cessation rates at 1 year.
- **Anxiolytics for smoking cessation** One systematic review found no significant difference in quit rates with anxiolytics compared with control.

DEFINITION Cigarette smoking, diet, and level of physical activity are important in the aetiology of many chronic diseases. Individual change in behaviour has the potential to decrease the burden of chronic disease, particularly cardiovascular disease. This topic focuses on the evidence that specific interventions lead to changed behaviour.

INCIDENCE/ PREVALENCE In the developed world, the decline in smoking has slowed and the prevalence of regular smoking is increasing in young people. A sedentary lifestyle is becoming increasingly common and the prevalence of obesity is increasing rapidly.

AIMS OF INTERVENTION To encourage individuals to reduce or abandon unhealthy behaviours and to take up healthy behaviours; to support the maintenance of these changes in the long term.

OUTCOMES Ideal outcomes are clinical, and relate to the underlying conditions (longevity, quality of life, and rate of stroke or myocardial infarction). However, the focus of this topic and the outcomes reported by most studies are proxy outcomes, such as the proportion of people changing behaviour (e.g. stopping smoking) in a specified period.

METHODS *Clinical Evidence* search and appraisal January 2003.

QUESTION **Which interventions reduce cigarette smoking?**

OPTION **ADVICE TO QUIT SMOKING**

Systematic reviews have found that simple, one off advice from a physician during a routine consultation is associated with at least 2% of smokers quitting smoking and not relapsing for 1 year. Additional encouragement or support may increase the effectiveness of the advice (by a further 3%). Individual advice from a psychologist achieves a similar quit rate (3%), and advice from trained nurse counsellors, or from trained

counsellors who are neither doctors nor nurses, increases quit rates compared with minimal intervention or no advice. We found limited evidence from one systematic review that telephone counselling may improve quit rates compared with interventions with no personal contact. One systematic review found that self help materials slightly improve smoking cessation compared with no intervention. It found that individually tailored materials were more effective than standard or stage based materials and that telephone counselling increased the effectiveness of postal self help materials.

Benefits: We found five systematic reviews[1–4,6] and one subsequent RCT.[5] **Physicians:** The first review (search date 2000, 34 RCTs, 28 000 smokers) considered advice given by physicians, most often in the primary care setting, but also in hospitals and other clinics.[1] It found that brief advice improved quit rates compared with no advice (16 trials, 12 with follow up for at least 1 year; 451/7705 [5.9%] with brief advice *v* 241/5870 [4.1%] with no advice; meta-analysis OR 1.69, 95% CI 1.45 to 1.98). Intensive advice slightly improved quit rates compared with minimal advice among smokers not at high risk of disease (10 trials, 7 with follow up for at least 1 year; OR with intensive *v* minimal advice 1.23, 95% CI 1.02 to 1.49). One subsequent RCT tested a brief (10 minute) intervention given by general practitioners who had received 2 hours of training.[5] The intervention increased the abstinence rate at 12 months (7.3% with control *v* 13.4% with intervention; $P < 0.05$). **Counsellors:** The second systematic review (search date 2002, 15 RCTs) examined individual counselling of at least 10 minutes by professionals trained in smoking cessation (social work, psychology, psychiatry, health education, and nursing).[2] Follow up was at 6–12 months. The review found that counselling increased the rate of quitting (rate of quitting 340/2590 [13%] with counselling *v* 232/2592 [9%] with control; OR of quitting 1.64, 95% CI 1.33 to 2.01).[2] The authors did not find a greater effect of intensive counselling compared with brief counselling (3 RCTs; OR 0.98, 95% CI 0.61 to 1.56). **Nurses:** The third review (search date 2001, 22 RCTs, 5 with follow up for < 1 year) considered the effectiveness of smoking interventions delivered by a nurse. It found that advice from a nurse increased the rate of quitting by the end of follow up (meta-analysis of 18 studies: 646/4836 [13.4%] quit with advice *v* 405/3356 [12.1%] with control; OR 1.50, 95% CI 1.29 to 1.73).[3] **Telephone advice:** The fourth systematic review (search date 2000, 23 RCTs) considered counselling delivered by telephone.[4] Ten of the included trials (9 with follow up for at least 12 months) compared proactive telephone counselling versus minimum intervention (involving no person to person contact). Pooled analysis was not possible because of statistical heterogeneity among trials. However, three trials found that telephone counselling was significantly more effective than minimum intervention; four trials found a non-significant benefit, and none of the trials found significant harms of telephone counselling. **Self help materials:** We found one systematic review (search date 2002, 51 RCTs) that examined effects of providing materials giving advice and information to smokers attempting to give up on their own.[6] The review found that self help materials without face to face contact slightly improved smoking cessation

compared with no intervention (11 RCTs, including 8 RCTs with at least 12 months' follow up; OR 1.24, 95% CI 1.07 to 1.49). Individually tailored materials were more effective than standard or stage based materials (10 RCTs; OR for cessation 1.36, 95% CI 1.13 to 1.64).

Harms: We found no evidence of harm.

Comment: The effects of advice may seem small, but a year on year reduction of 2% in the number of smokers would represent a significant public health gain (see smoking cessation under primary prevention, p 163). In the systematic review of advice provided by nurses,[3] there was significant heterogeneity of the study results and many studies may not have been adequately randomised (7/18 studies [39%] did not specify the randomisation method and 3/18 [17%] used an inadequate form of randomisation).

OPTION NICOTINE REPLACEMENT

One systematic review and one subsequent RCT have found that nicotine replacement is an effective additional component of cessation strategies in smokers who smoke at least 10 cigarettes daily. We found no evidence of any particular method of nicotine delivery having superior efficacy. We found limited evidence from three RCTs (follow up 2–6 years) that the benefit of nicotine replacement treatment on quit rates decreased with time.

Benefits: **Abstinence at 12 months:** We found one systematic review (search date 2002)[7] that identified 51 trials of nicotine chewing gum, 34 trials of nicotine transdermal patches, four of nicotine intranasal spray, four of inhaled nicotine, and three of sublingual tablets. All forms of nicotine replacement were more effective than placebo. When the abstinence rates for all trials were pooled according to the longest duration of follow up available, nicotine replacement increased the odds of abstinence compared with placebo (3335/19 783 [16.8%] with nicotine replacement *v* 1835/17 977 [10.2%] with placebo; OR 1.74, 95% CI 1.64 to 1.86). The review found no significant difference in abstinence with different forms of nicotine replacement in indirect comparisons (OR 1.66 for nicotine chewing gum *v* 2.27 for nicotine nasal spray) or direct comparisons (1 RCT, inhaler *v* patch; OR 0.57, 95% CI 0.19 to 1.65). In trials that directly compared 4 mg with 2 mg nicotine chewing gum, the higher dose improved abstinence in highly dependent smokers (OR 2.18, 95% CI 1.49 to 3.17). High dose patches slightly increased abstinence compared with standard dose patches (6 RCTs; OR 1.21, 95% CI 1.03 to 1.42). The review found no significant difference in effectiveness for 16 hour compared with 24 hour patches, and no difference in effect in trials where the dose was tapered compared with those where the patches were withdrawn abruptly. Use of the patch for 12 weeks was as effective as longer use and there was suggestive evidence that repeated use of nicotine replacement treatment in people who have relapsed after an initial course may produce further quitters, though the absolute effect was small. One included RCT (3585 people) found that abstinence at 1 week was a strong predictor of 12 month abstinence (25% of those abstinent at 1 week were abstinent at 12

months *v* 2.7% of those not abstinent at 1 week).[8] One meta-analysis of relapse rates in nicotine replacement trials found that nicotine replacement increased abstinence at 12 months, but that continued nicotine replacement did not significantly affect relapse rates between 6 weeks and 12 months.[9] **Longer term abstinence:** We found three RCTs[10–12] that found nicotine replacement does not affect long term abstinence. In one RCT that compared nicotine spray with placebo, 47 people abstinent at 1 year were followed for up to a further 2 years and 5 months, after which there was still a significant, although smaller, difference in abstinence (in the longer term 15.4% abstinent with nicotine spray *v* 9.3% with placebo; NNT [for 1 extra person to abstain] 7 at 1 year *v* 11 at 3.5 years).[10] The second RCT compared 5 months of nicotine patches plus nicotine spray versus the same patches plus a placebo spray. It found no significant difference between treatments after 6 years (16.2% abstinent with nicotine spray *v* 8.5% with placebo spray; P = 0.08).[11] The third RCT compared patches delivering different nicotine doses versus placebo patches. The trial followed everyone that quit at 6 weeks for a further 4–5 years and found no significant difference in relapse between the groups. Overall, 73% of people who quit at 6 weeks relapsed.[12]

Harms: Nicotine chewing gum has been associated with hiccups, gastrointestinal disturbances, jaw pain, and orodental problems. Nicotine transdermal patches have been associated with skin sensitivity and irritation. Nicotine inhalers and nasal spray have been associated with local irritation at the site of administration. Nicotine sublingual tablets have been reported to cause hiccups, burning, smarting sensations in the mouth, sore throat, coughing, dry lips, and mouth ulcers.[13]

Comment: Nicotine replacement may not represent an "easy cure" for nicotine addiction, but it does improve the cessation rate. The evidence suggests that the most of smokers attempting cessation fail at any one attempt or relapse over the next 5 years. Multiple attempts may be needed.

OPTION ACUPUNCTURE

One systematic review has found no significant difference between acupuncture and control in smoking cessation rates at 1 year.

Benefits: We found one systematic review (search date 2002, 22 RCTs, 4158 adults, 330 young people aged 12–18 years)[14] comparing acupuncture with sham acupuncture, other treatment, or no treatment. Seven RCTs (2701 people) reported abstinence after at least 12 months. The review found no significant difference in smoking cessation with acupuncture compared with control at 12 months (OR 1.08, 95% CI 0.77 to 1.52).

Harms: None were documented.

Comment: None.

OPTION PHYSICAL EXERCISE

One systematic review found limited evidence that physical exercise may increase smoking cessation.

Changing behaviour

Benefits: We found one systematic review (search date 1999, 8 RCTs)[15] of exercise versus control interventions. Four small RCTs in the review reported point prevalence of non-smoking at 12 months and found no significant benefit from exercise, but these studies were insufficiently powered to exclude a clinically important effect. One RCT (281 women) found that three exercise sessions a week for 12 weeks plus a cognitive behavioural programme (see glossary, p 117) improved continuous abstinence from smoking at 12 months compared with the behavioural programme alone (16/134 [12%] with exercise *v* 8/147 [5%] with control; ARR +6.5%, 95% CI −19% to 0%; RR 2.2, 95% CI 0.98 to 4.5).[16]

Harms: None were documented.

Comment: None.

OPTION ANTIDEPRESSANT AND ANXIOLYTIC TREATMENT

Systematic reviews have found that quit rates are increased by bupropion, but not by moclobemide or anxiolytics.

Benefits: **Antidepressants:** We found one systematic review of antidepressants (search date 2001, 18 RCTs).[17] Eight of the RCTs (2649 people) reported 12 month cessation rates. It found that bupropion increased quit rates compared with placebo at 6–12 months (calculated by combining results of 4 RCTs with 12 month follow up and 3 RCTs with 6 month follow up; OR of quitting with bupropion *v* placebo 2.54, 95% CI 1.90 to 3.41). The review found no evidence of statistical heterogeneity between the two follow up times.[17] One RCT included in the review compared combined bupropion plus a nicotine patch versus patch alone. It found that combined treatment improved cessation compared with patch alone (OR 2.65, 95% CI 1.58 to 4.45), but was not more effective than bupropion alone. Another included RCT compared different doses of bupropion (100–300 mg/day) and found that cessation rate was linearly related to dose. Three other included RCTs (2 with 6 months' and 1 with 12 months' follow up) found that nortriptyline improved long term (6–12 month) abstinence rates compared with placebo (OR 2.77, 95% CI 1.73 to 4.44). One RCT of moclobemide found no significant difference in abstinence at 12 months. **Anxiolytics:** We found one systematic review of anxiolytics (search date 2000, 6 RCTs).[18] Four of the RCTs (626 people) reporting 12 month cessation rates found no significant increase in abstinence between anxiolytics and control treatment.[18]

Harms: Headache, insomnia, and dry mouth were reported in people using bupropion.[18] Nortriptyline can cause sedation and urinary retention, and can be dangerous in overdose. One large RCT found that discontinuation rates caused by adverse events were 3.8% with placebo, 6.6% for nicotine replacement treatment, 11.9% for bupropion, and 11.4% for bupropion plus nicotine replacement treatment.[19] Anxiolytics may cause dependence and withdrawal problems, tolerance, paradoxical effects, and impair driving ability. Allergic reactions to bupropion have been reported in about 1/1000 people.

Comment: None.

QUESTION **Are smoking cessation interventions more effective in people at high risk of smoking related disease?**

OPTION IN PREGNANT WOMEN

Two systematic reviews have found that antismoking interventions in pregnant women increase abstinence rates during pregnancy. Interventions without nicotine replacement were as effective as nicotine replacement in healthy non-pregnant women.

Benefits: We found two systematic reviews[20,21] and three additional RCTs.[22–24] The most recent review (search date 1998, 44 RCTs) assessed smoking cessation interventions in pregnancy. It found that smoking cessation programmes improved abstinence (OR of continued smoking in late pregnancy with antismoking programmes *v* no programmes 0.53, 95% CI 0.47 to 0.60).[21] The findings were similar if the analysis was restricted to trials in which abstinence was confirmed by means other than self reporting. The review calculated that of 100 smokers attending a first antenatal visit, 10 stopped spontaneously and a further six or seven stopped as the result of a smoking cessation programme. Five included trials examined the effects of interventions to prevent relapse in 800 women who had quit smoking. Collectively, these trials found no evidence that the interventions reduced relapse rate.[21] One earlier systematic review (search date not stated, 10 RCTs, 4815 pregnant women)[20] of antismoking interventions included one trial of physician advice, one trial of advice by a health educator, one trial of group sessions, and seven trials of behavioural therapy based on self help manuals. Cessation rates among trials ranged from 1.9–16.7% in the control groups and from 7.1–36.1% in the intervention groups. The review found that antismoking interventions significantly increased the rate of quitting (ARI with intervention *v* no intervention 7.6%, 95% CI 4.3% to 10.8%).[20] One additional RCT found that nicotine patches did not significantly alter quit rates in pregnant women compared with placebo.[22] The second additional RCT (1120 pregnant women) compared a brief (10–15 minute) smoking intervention delivered by trained midwives at booking interviews versus usual care.[23] It found no significant difference in smoking behaviour between women receiving intervention compared with usual care (abstinence in final 12 weeks of pregnancy until birth 17% in each group; abstinence for 6 months after birth 7% with intervention *v* 8% with control). The intervention was difficult to implement (see comment below). The third RCT compared motivational interviewing (see glossary, p 117) with usual care in 269 women in their 28th week of pregnancy who had smoked in the past month.[24] It found no significant differences in cessation rate between intervention and control group at 34th week or at 6 months post partum.

Harms: None documented.

Comment: The recent review found that some women quit smoking before their first antenatal visit, and most of these will remain abstinent.[21] Recruitment to the RCT comparing midwife delivered intervention versus usual care was slow. Midwives reported that the intervention was difficult to implement because of a lack of time to deliver the intervention at the booking appointment.[23]

OPTION IN PEOPLE AT HIGH RISK OF DISEASE

Systematic reviews and one subsequent RCT have found that antismoking advice improves smoking cessation in people at high risk of smoking related disease.

Benefits: We found no trials in which the same intervention was used in high and low risk people. We found one systematic review (search date not stated, 4 RCTs, 13 208 healthy men at high risk of heart disease),[20] one systematic review among people admitted to hospital (search date 2002, 17 RCTs),[25] and one subsequent RCT.[26] The first review found that antismoking advice improved smoking cessation rates compared with control interventions among healthy men at high risk of heart disease (ARI of smoking cessation 21%, 95% CI 10% to 31%; NNT 5, 95% CI 4 to 10).[20] One early trial (223 men) that was included in the review used non-random allocation after myocardial infarction. The intervention group was given intensive advice by the therapeutic team while in the coronary care unit. The trial found that the self reported cessation rate at 1 year or more was higher in the intervention group than the control group (63% quit in the intervention group *v* 28% in the control group; ARI of quitting 36%, 95% CI 23% to 48%).[27] The second review included seven trials (6 of them with at least 12 months' duration) of high intensity behavioural interventions (defined as contact in hospital plus active follow up for at least 1 month) among smokers admitted to hospital. The review found that active intervention increased quit rates compared with usual care (OR 1.82, 95% CI 1.49 to 2.22).[25] The subsequent RCT compared postal advice on smoking cessation versus no intervention in men aged 30–45 years with either a history of asbestos exposure, or forced expiratory volume in 1 second in the lowest quartile for their age. Postal advice increased the self reported sustained cessation rate at 1 year compared with no intervention (5.6% with postal advice *v* 3.5% with no intervention; $P < 0.05$).[26]

Harms: None were documented.

Comment: There was heterogeneity in the four trials included in the review among healthy men at high risk of heart disease, partly because of a less intense intervention in one trial and the recording of a change from cigarettes to other forms of tobacco as success in another.[20] One of the included trials was weakened by use of self reported smoking cessation as an outcome and non-random allocation to the intervention.[27]

QUESTION **Does training of professionals increase the effectiveness of smoking cessation interventions?**

OPTION **TRAINING HEALTH PROFESSIONALS TO GIVE ADVICE ON SMOKING CESSATION**

One systematic review has found that training professionals increases the frequency of antismoking interventions being offered, but found no good evidence that antismoking interventions are more effective if the health professionals delivering the interventions received training. One RCT found that a structured intervention delivered by trained community pharmacists increased smoking cessation rates compared with usual care delivered by untrained community pharmacists.

Benefits: We found one systematic review[28] and one subsequent RCT.[29] The review (search date 2000, 9 RCTs) included eight RCTs of training medical practitioners and one RCT of training dental practitioners to give antismoking advice.[28] All the trials took place in the USA. The training was provided on a group basis, and variously included lectures, videotapes, role plays, and discussion. The importance of setting quit dates and offering follow up was emphasised in most of the training programmes. The review found no good evidence that training professionals leads to higher quit rates in people receiving antismoking interventions from those professionals, although training increased the frequency with which such interventions were offered. Three of the trials used prompts and reminders to practitioners to deploy smoking cessation techniques, and found that prompts increased the frequency of health professional interventions.[28] The later RCT compared a structured smoking cessation intervention delivered by community pharmacists, who had received 3 hours of training versus no specific training or antismoking intervention.[29] Intervention delivered by trained pharmacists improved abstinence compared with usual care (AR of abstinence at 12 months 14.3% with intervention *v* 2.7% with usual care; RR 5.3; NNT 9; CIs not reported; $P < 0.001$).

Harms: None were documented.

Comment: The results of the systematic review should be interpreted with caution because there were variations in the way the analysis allowed for the unit of randomisation.

QUESTION **Which interventions increase physical activity in sedentary people?**

OPTION **COUNSELLING**

We found weak evidence from systematic reviews and subsequent RCTs that counselling sedentary people increases physical activity compared with no intervention. Limited evidence from RCTs suggests that consultation with an exercise specialist rather than a physician may increase physical activity at 1 year. We found limited evidence that interventions delivered by new media can lead to short term changes in physical activity.

Changing behaviour

Benefits: We found three systematic reviews that focused on different types of interventions[30–32] and seven subsequent RCTs.[33–39] The first review (search date 1996, 11 RCTs based in the USA, 1699 people) assessed the effect of single factor physical activity promotion on exercise behaviour.[30] Seven trials evaluated advice to undertake exercise from home (mainly walking, but including jogging and swimming), and six evaluated advice to undertake facility based exercise (including jogging and walking on sports tracks, endurance exercise, games, swimming, and exercise to music classes). An increase in activity in the intervention groups was seen in trials in which home based moderate exercise was encouraged and regular brief follow up of participants was provided. In most of the trials, participants were self selected volunteers, so the effects of the interventions may have been exaggerated. The second systematic review (search date not stated, 3 RCTs, 420 people) compared "lifestyle" physical activity interventions with either standard exercise treatment or a control group.[31] Lifestyle interventions were defined as those concerned with the daily accumulation of moderate or vigorous exercise as part of everyday life. The first RCT in the review (60 adults, 65–85 years old) found significantly more self reported physical activity in the lifestyle group than a standard exercise group. The second RCT in the review (235 people, 35–60 years old) found no significant difference in physical activity between the groups. The third RCT in the review (125 women, 23–54 years old) of encouraging walking found no significant difference in walking levels at 30 months' follow up between people receiving an 8 week behavioural intervention and those receiving a 5 minute telephone call and written information about the benefits of exercise, although both groups increased walking. The third review (search date 2002, 7 RCTs and 1 quasi-randomised trial, 9054 people) examined the efficacy of exercise counselling from a primary care clinician compared with a control or comparison group.[32] Counselling was delivered using advice only, the promotion of self efficacy, posted educational materials, referral to community resources, and written exercise prescriptions. The review found equivocal results and at least one methodological limitation in most studies. There was limited evidence that the interventions in these studies led to short term (< 3 months) improvements in physical activity. There were insufficient studies to consider the relationship between the components of the interventions and the reported efficacy. Only two RCTs were rated as good quality. One good quality RCT (874 people) compared 3 minutes of physician advice plus educational materials, all the above plus behavioural counselling plus interactive mail, and all the above plus telephone counselling plus classes.[40] It found no significant difference in self reported activity between interventions at 24 months. The other good quality RCT (355 sedentary people) compared a brief 5 minute message, a prescription for exercise, and a follow up visit with usual care. It found no significant difference in the proportion of people meeting the Healthy People 2010 goal after 8 months (28% with advice or prescription *v* 23% with usual care; difference +5%, 95% CI −6% to +14%).[41] All but one of the subsequent trials[39] involved primary care delivered interventions, although they were not restricted to clinician led interventions.[33–38] Two of the three trials in which

advice was delivered by an exercise specialist rather than a physician found significant improvement in self reported physical activity at long term (> 6 months) follow up compared with controls.[35,36] A third RCT (1658 people in a primary care setting), which compared a client centred, negotiating style to direct advice and a no intervention control group, did not find any significant difference in changes in physical activity.[38] Short term improvement was found in two further trials, but not maintained at 9 months or 1 year.[33,34] One RCT (298 people) compared physical activity counselling with nutrition counselling, both delivered with automated telephone conversations using digitised human speech.[39] The system used information about current behaviour and some known determinants to counsel people on either physical activity or nutrition. The percentage of individuals meeting current physical activity recommendations at 3 months follow up was significantly greater in the physical activity group compared with the nutrition group at 3 months, but there was no significant difference at 6 months (3 months 26% with activity counselling *v* 19.6% with dietary counselling; P = 0.04). One RCT (229 women) of encouraging women to increase walking found significantly increased walking in the intervention group at 10 years' follow up (86% of women available for follow up, median estimated calorie expenditure from self reported amount of walking 1344 kcal/week with encouragement *v* 924 kcal/week with no encouragement; P = 0.01).[42] A further RCT (260 people in a primary care setting) compared the additional offer of community walks (led by lay people) with fitness tests and advice alone.[37] It found no significant difference in physical activity at 12 months' follow up (ARR for achieving at least 120 minutes of moderate intensity activity a week +6%, 95% CI –5% to +16.4%).

Harms: Insufficient detail is available from these studies to judge the potential harm of exercise counselling. In the RCT comparing behavioural counselling with brief advice, 60% of participants experienced a musculoskeletal event during the 2 years of the study.[40] About half of these required a visit to the physician. About 5% of all participants were admitted to hospital for a suspected cardiovascular event. The trial lacked a non-intervention control group. We found no evidence that counselling people to increase activity levels increased adverse events compared with no counselling.

Comment: Self reporting of effects by people in a trial, especially where blinding to interventions is not possible (as is the case with advice or encouragement), is a potential source of bias. Few studies conduct intention to treat analyses, which may lead to an exaggeration of the true effect of interventions. Methodological problems in RCTs included in the third review included only moderate follow up rates, highly motivated providers, differences in physical activity levels at baseline between intervention groups, uncertain or low provided adherence, inclusion of some counselling advice in usual care control groups, and inadequate power to detect a clinically important difference.[32]

QUESTION What are effects of exercise advice in high risk people?

OPTION IN WOMEN AGED OVER 80 YEARS

One RCT found that exercise advice increased physical activity in women aged over 80 years and decreased the risk of falling.

Benefits: We found no systematic review. One RCT (233 women > 80 years old, conducted in New Zealand) compared four visits from a physiotherapist who advised a course of 30 minutes of home based exercises three times a week that was appropriate for the individual versus a similar number of social visits.[43] After 1 year, women who had received physiotherapist visits were significantly more active than women in the control group, and 42% were still completing the recommended exercise programme at least three times a week. The mean annual rate of falls in the intervention group was 0.87 compared with 1.34 in the control group, a difference of 0.47 falls a year (95% CI 0.04 to 0.90).

Harms: No additional harms in the intervention group were reported.

Comment: None.

QUESTION What are the effects on blood cholesterol of dietary advice to reduce fat, increase polyunsaturated fats, and decrease saturated fats?

OPTION COUNSELLING

Systematic reviews have found that advice on eating a cholesterol lowering diet (i.e. advice to reduce fat intake or increase the polyunsaturated : saturated fatty acid ratio in the diet) leads to a small reduction in blood cholesterol concentrations in the long term (≥ 6 months). We found no evidence to support the effectiveness of such advice in primary care.

Benefits: **Effects on blood cholesterol:** We found three systematic reviews[13,44,45] and two subsequent RCTs[46,47] that reported biochemical rather than clinical end points. None of the reviews included evidence after 1996. One review (search date 1993) identified five trials of cholesterol lowering dietary advice (principally advice from nutritionists or specially trained counsellors) with follow up for 9–18 months.[44] It found a reduction in blood cholesterol concentration in the intervention group of 0.22 mmol/L (95% CI 0.05 mmol/L to 0.39 mmol/L) compared with the control group. There was significant heterogeneity ($P < 0.02$), with two outlying studies — one showing no effect and one showing a larger effect. This review excluded trials in people at high risk of heart disease. Another systematic review (search date 1994) identified 13 trials of more than 6 months' duration and included people at high risk of heart disease.[13] It found that dietary advice reduced blood cholesterol (mean reduction in blood cholesterol concentration with advice 4.5%, 95% CI 3.9% to 5.1%; given a mean baseline cholesterol of 6.3 mmol/L, mean AR about 0.3 mmol/L). The third systematic review (search date 1996, 1 trial,[48] 76 people) found no

significant difference between brief versus intensive advice from a general practitioner and dietician on blood cholesterol at 1 year.[45] The first subsequent RCT (186 men and women at high risk of coronary heart disease) compared advice on healthy eating versus no intervention. At 1 year it found no significant differences between groups in total and low density lipoprotein cholesterol concentrations for either sex, even though the reported percentage of energy from fat consumed by both women and men in the advice group decreased significantly compared with that reported by the women and men in the control group.[46] These results may reflect bias caused by self reporting of dietary intake. The second RCT, in 531 men with hypercholesterolaemia (with and without other hyperlipidaemias) and fat intake of about 35%, compared dietary advice aimed at reducing fat intake to 30% versus 26% versus 22%. All interventions were similarly effective for reducing fat intake (total fat intake after intervention about 26% in all groups).[47] **Effects on clinical outcomes:** We found two systematic reviews that reported on morbidity and mortality.[13,49] The first review (search date 1994) compared 13 separate and single dietary interventions.[13] It found no significant effect of dietary interventions on total mortality or coronary heart disease mortality but found a reduction in non-fatal myocardial infarction (total mortality: OR 0.93, 95% CI 0.84 to 1.03; coronary heart disease mortality: OR 0.93, 95% CI 0.82 to 1.06; non-fatal myocardial infarction: OR 0.77, 95% CI 0.67 to 0.90). The second review (search date 1999, 27 studies including 40 intervention arms, 30 901 person years) found dietary advice to reduce or modify dietary fat had no significant effect on total mortality or cardiovascular disease mortality compared with no dietary advice but significantly reduced cardiovascular disease events (total mortality: HR 0.98, 95% CI 0.86 to 1.12; cardiovascular disease mortality: HR 0.98, 95% CI 0.77 to 1.07; cardiovascular disease events: HR 0.84, 95% CI 0.72 to 0.99).[49] RCTs in which people were followed for more than 2 years showed significant reductions in the rate of cardiovascular disease events. The relative protection from cardiovascular disease events was similar in both high and low risk groups, but was significant only in high risk groups.

Harms: We found no evidence about harms.

Comment: The finding of a 0.2–0.3 mmol/L reduction in blood cholesterol in the two systematic reviews accords with the findings of a meta-analysis of the plasma lipid response to changes in dietary fat and cholesterol.[50] The analysis included data from 244 published studies (trial duration 1 day to 6 years), and concluded that adherence to dietary recommendations (30% energy from fat, < 10% saturated fat, and < 300 mg cholesterol/day) compared with average US dietary intake would reduce blood cholesterol by about 5%.

QUESTION **Does dietary advice to reduce sodium intake lead to a sustained fall in blood pressure?**

OPTION **ADVICE ON REDUCING SODIUM INTAKE TO REDUCE BLOOD PRESSURE**

One systematic review has found that, compared with usual care, intensive interventions to reduce sodium intake, unsuited to primary care or population prevention programmes, provide only small reductions in blood pressure, and effects on deaths and cardiovascular events are unclear.

Benefits: We found one systematic review (search date 2000).[51] The review (5 RCTs in 2326 normotensive people and 3 RCTs in 801 people being treated for hypertension with follow up of ≥6 months) compared the effects of advice to restrict dietary sodium (involving intensive group or individual nutrition counselling programmes) versus usual or control diet. It found that systolic blood pressure was significantly reduced at 13–60 months (reduction 1.1 mm Hg, 95% CI 0.4 mm Hg to 1.8 mm Hg). It found no significant difference in diastolic blood pressure (reduction +0.6 mm Hg, 95% CI +1.5 mm Hg to –0.3 mm Hg). Mortality and cardiovascular deaths were inconsistently reported, and effects were unclear.[51]

Harms: None reported.

Comment: None.

QUESTION **What are the effects of lifestyle interventions to achieve sustained weight loss?**

OPTION **ADVICE ON DIET AND EXERCISE SUPPORTED BY BEHAVIOURAL THERAPY FOR THE ENCOURAGEMENT OF WEIGHT LOSS**

Systematic reviews and subsequent RCTs have found that combined advice on diet and exercise, supported by behavioural therapy, is probably more effective in achieving weight loss than either diet or exercise advice alone. A low energy diet is the most effective lifestyle intervention for weight loss. Combined personal and computerised tailoring of weight loss programmes may improve maintenance of weight loss. RCTs have found no significant differences in weight loss between interventions to promote physical activity. Weight regain is likely, but weight loss of 2–6 kg may be sustained over at least 2 years.

Benefits: We found three systematic reviews[52–54] and 19 additional RCTs.[55–73] One systematic review (search date 1995) identified one relevant RCT that found that the combination of diet and exercise in conjunction with behavioural therapy produced significantly greater weight loss than diet alone at 1 year (mean weight loss: 7.9 kg with diet and exercise *v* 3.8 kg with diet alone; significance result not reported).[52] The second systematic review of the detection, prevention, and treatment of obesity (search date 1999) included eight RCTs comparing dietary prescriptions versus exercise, counselling, or behavioural therapy for the treatment of obesity, and three RCTs

comparing dietary counselling alone versus no intervention. In both comparisons, initial weight loss was followed by gradual weight regain once treatment had stopped (mean difference in weight change at least 2 years after baseline, 2–6 kg with dietary prescription and 2–4 kg with dietary counselling).[53] The third systematic review (search date 1997) of RCTs and observational studies similarly found that a combination of diet and exercise, supported by behavioural therapy, was more effective than any one or two of these individual interventions.[54] The first additional RCT compared advice on an energy restricted diet to advice on a fat restricted diet.[60] Weight loss was greater on an energy restricted diet than on the fat restricted diet at 6 months (–11.2 kg with energy restricted diet *v* –6.1 kg with fat restricted diet; $P < 0.001$) and at 18 months (–7.5 kg with energy restricted diet *v* –1.8 kg with fat restricted diet; $P < 0.001$). The next seven additional RCTs focused on physical activity.[56–58,62-64,67] The heterogeneity of interventions makes pooling of data inappropriate, but no major differences were found between the various behavioural therapies and exercise regimes. The ninth additional RCT found behavioural choice therapy increased weight loss at 12 months compared with standard behavioural therapy (see glossary, p 117) (–10.1 kg with behavioural choice therapy *v* –4.3 kg with standard behavioural therapy; $P < 0.01$).[59] The 10th additional RCT (166 people) compared standard behavioural therapy plus support from friends with standard behavioural therapy without support. It found no additional weight loss at 16 months with social support from friends (–4.7 kg with behavioural therapy plus support *v* –3.0 kg with behavioural therapy without support, $P > 0.05$).[61] The 11th additional RCT (results from 89 overweight women with impaired glucose tolerance analysed) published only in abstract form compared three interventions: behaviour modification plus nutritional information at quarterly visits; dietary advice only at quarterly visits; and one dietary advice session only.[65] It found that weight reduction after 2 years was greater with the behaviour modification programme but levels of statistical significance were not reported (percentage weight change from baseline: –5.5% with behaviour modification *v* –3.2% with dietary advice quarterly *v* –1.2% with one diet session only). The 12th additional RCT (76 women, 58 analysed) found no statistically significant difference between a 10 week standard cognitive behavioural programme (see glossary, p 117) compared with a modified cognitive behavioural programme after 1 year follow up (weight change from baseline: –2.1 kg with modified programme *v* –3.8 kg with standard programme; P value not reported).[66] The 13th additional RCT[68] has found that adding meal replacements to a dietician led group intervention improved weight loss at 1 year (9.1% weight loss with replacements *v* 4.1% without) although the 14th additional RCT[69] found that adding body image treatment did not significantly improve weight loss compared with dietician led treatment alone. The 15th and 16th RCTs examined effects of advice to lose weight among people who were overweight and hypertensive.[55,70] The 15th RCT (1191 people) found that weight loss advice reduced weight and hypertension more than no weight loss advice at 3 years (weight change at 3 years: –0.2 kg with advice *v* +1.8 kg with control; RR for hypertension with advice *v* control

0.81, 95% CI 0.70 to 0.95).[70] Subgroup analysis of the 16th RCT (585 overweight elderly people with hypertension) found that weight loss advice reduced body weight more than no weight loss advice, but the statistical significance of the difference was not reported (weight change at 30 months –4.7 kg with weight loss programme *v* –0.9 kg with no weight loss programme).[55] The 17th RCT (588 overweight people) compared three different cognitive behavioural approaches for tailoring lifestyle modification goals: workbook alone (no tailoring of goals); adding computerised tailoring using computer kiosks with touch screen monitors to help participants tailor goals; and adding both computers and staff consultation to tailor goals.[71] After 12 months, it found that all groups achieved a statistically significant mean weight loss from baseline. It found that combined personal and computerised tailoring improved weight loss compared with workbook alone (mean weight change –1 kg with workbook *v* –2.1 kg with computerised tailoring *v* –3.3 kg with combined personal and computerised tailoring; P = 0.02 for workbook *v* combined group). The 18th additional RCT (78 obese female chronic dieters, 52 analysed) compared the effects of a 24 week "non-diet" wellness programme intervention with a traditional "weight loss" programme. It found that the weight loss programme increased weight loss compared with the non-diet programme at 1 year (diet 101.1 kg at baseline to 95.2 kg at 1 year *v* non-diet 99.6 kg at baseline to 99.9 kg at 1 year; P < 0.001).[72] The 19th additional RCT (101 obese men and women) compared the effects of a moderate fat (based on the Mediterranean diet), low energy diet compared with a low fat, low energy diet.[73] It found that the moderate fat diet increased weight loss compared with the low fat diet after 18 months (difference in weight change 7.0 kg, 95% CI 5.3 kg to 8.7 kg). There was a mean decrease in body weight of 4.1 kg in the moderate fat group compared with an increase in body weight of 2.9 kg in the low fat group.

Harms: The systematic reviews and RCTs provided no evidence about harms resulting from diet or exercise for weight loss.

Comment: In one RCT (78 obese women), the withdrawal rate for a diet programme was 41% compared with 8% in a non-diet control.[72]

QUESTION **What are the effects of lifestyle interventions to maintain weight loss?**

OPTION **LIFESTYLE INTERVENTIONS TO MAINTAIN WEIGHT LOSS**

One systematic review and additional RCTs have found that most types of maintenance strategy result in smaller weight gains or greater weight losses compared with no contact. Strategies that involve personal contact with a therapist, family support, walking training programmes, or multiple interventions, or are weight focused, seem most effective.

Benefits: We found one systematic review[52] and nine additional RCTs.[74–82] The systematic review (search date 1995, 21 studies) compared different types and combinations of interventions. It found that increased contact with a therapist in the long term produced

smaller weight gain or greater weight loss, and that additional self help peer groups, self management techniques, or involvement of the family or spouse may increase weight loss. The largest weight loss was seen in programmes using multiple strategies. Two additional small RCTs (102 people[74] and 100 people in two trials[78]) assessed simple strategies without face to face contact with a therapist. Frequent telephone contacts, optional food provision, continued self monitoring, urge control, or relapse prevention did not reduce the rate of weight regain. One small RCT (117 people) found that telephone contacts plus house visits did reduce the rate of weight regain compared with no intervention (3.65 kg with telephone contacts plus house visits *v* 6.42 kg with no intervention; P = 0.048).[75] One further small RCT (80 obese women) found no difference in weight change at 1 year between participants offered relapse prevention training or problem solving compared with no further contact.[80] One RCT (82 women) compared two walking programmes (4.2 or 8.4 MJ/week) plus diet counselling versus diet counselling alone after a 12 week intensive weight reduction programme.[79] Both walking programmes reduced weight regain at 1 year (reduction in weight gain compared with dietary counselling alone 2.7 kg, 95% CI 0.2 kg to 5.2 kg with low intensity programme and 2.6 kg, 95% CI 0 kg to 5.1 kg with high intensity programme). At 2 years, weight regain was not significantly different between high intensity programme and control, but was reduced in the low intensity group (reduction in weight gain 3.5 kg, 95% CI 0.2 kg to 6.8 kg with low intensity programme and +0.2 kg, 95% CI −3.1 kg to +3.6 kg with high intensity programme). One additional small RCT (67 people) found that people on a weight focused programme maintained weight loss better than those on an exercise focused programme (0.8 kg with weight focused programme *v* 4.4 kg with exercise focused programme; P < 0.01).[76] One 5 year RCT (489 menopausal women) compared behavioural intervention in two phases aimed at lifestyle changes in diet and physical activity with lifestyle assessment. People in the intervention group were encouraged to lose weight during the first 6 months (phase I), and thereafter maintain this weight loss for a further 12 months (phase II). The intervention resulted in weight loss compared with control during the first 6 months (−8.9 lb [−4.0 kg] *v* −0.8 lb [−0.4 kg]; P < 0.05), most of which was sustained over phase II (−6.7 lb [−3.0 kg] *v* −0.6 lb [−0.3 kg]; P < 0.05).[77] One RCT (90 obese men) compared the effects of walking, resistance training of moderate dose 6 at months, and no increase in exercise control after a 2 month weight loss programme with a very low energy diet.[82] It found no significant difference in long term weight maintenance between walking and resistance training programmes and control at 23 months (adjusted mean difference in weight compared with control: +0.8 kg with walking, 95% CI −4.0 kg to +5.6 kg *v* −0.5 kg with resistance, 95% CI −5.0 kg to +4.0 kg; P between interventions = 0.8). There was poor adherence to prescribed exercise (82% with walking *v* 66% with resistance).[82] One RCT (122 overweight men and women, 101 analysed) compared the effects of a weight maintenance programme conducted in person (frequent support or minimal support) or over the Internet for 1 year, after a

6 month weight loss programme.[81] It found significantly less weight loss with Internet support compared with in person support (weight loss: –5.7 kg with Internet support *v* –10.4 kg with minimal in person support *v* –10.4 kg with frequent in person support, $P < 0.05$).[81]

Harms: We found no direct evidence that interventions designed to maintain weight loss are harmful.

Comment: Weight regain is common. The resource implication of providing long term maintenance of any weight loss may be a barrier to the routine implementation of maintenance programmes. One RCT (122 obese people) comparing in person and Internet support for weight maintenance, found attrition rates of 18% after 6 months and 24% after 18 months.[81]

QUESTION What are the effects of lifestyle advice to prevent weight gain?

OPTION LIFESTYLE ADVICE TO PREVENT WEIGHT GAIN

One small RCT found that low intensity education increased weight loss. A second RCT found no significant effect on weight gain from a postal newsletter with or without a linked financial incentive. One RCT found that lifestyle advice prevented weight gain in perimenopausal women compared with assessment alone.

Benefits: We found three systematic reviews (search dates 1995,[52] 1999,[53] and not stated[83]) that included the same two RCTs[84,85] and two subsequent RCTs.[86,87] The first RCT (219 people) compared low intensity education with a financial incentive to maintain weight versus an untreated control group. It found significantly greater average weight loss in the intervention group than in the control group (–0.95 kg with intervention *v* –0.14 kg with control; $P = 0.03$).[84] The second RCT (228 men and 998 women) compared a monthly newsletter versus the newsletter plus a lottery incentive versus no contact. There was no significant difference in weight gain after 3 years between the groups (1.6 kg with newsletter *v* 1.5 kg with newsletter plus lottery incentive *v* 1.8 kg with no contact).[85] The first subsequent RCT (535 perimenopausal women) found that lifestyle advice reduced weight gain over 2 years compared with assessment alone (weight gain 0.5 kg with advice *v* 11.5 kg with assessment alone).[86] The second small subsequent RCT (40 female students, 33 analysed) compared the effects of a one semester nutrition course (4 months) with no such course.[87] It found no significant change from mean baseline weight in either group 1 year after the end of intervention (66.7 kg at baseline to 67.7 kg at 1 year with course *v* 65.7 kg at baseline to 68.9 kg at 1 year with no course).

Harms: None reported.

Comment: None.

QUESTION **What are the effects of training professionals in promoting reduction of body weight?**

OPTION **TRAINING HEALTH PROFESSIONALS TO PROMOTE REDUCTION OF BODY WEIGHT**

One systematic review of poor quality RCTs found little evidence on the sustained effect of interventions to improve health professionals' management of obesity. One subsequent small RCT found limited evidence that training for primary care doctors in nutrition counselling plus a support programme reduced body weight of the people in their care over 1 year.

Benefits: We found one systematic review (search date 2000, 18 RCTs, 8 with follow up > 1 year)[88] and one subsequent RCT.[89] The studies in the review were heterogeneous and poor quality. The subsequent RCT (45 people) compared nutrition counselling training plus a support programme for primary care doctors versus usual care.[89] The nutrition supported intervention compared with usual care increased weight loss at 1 year (additional weight loss 2.3 kg; $P < 0.001$).

Harms: None reported.

Comment: The doctors were randomly allocated to treatment but the analysis of results was based on the people in the care of those doctors. No allowance was made for cluster bias. This increases the likelihood that the additional weight loss could have occurred by chance.

GLOSSARY

Behavioural choice therapy A cognitive behavioural intervention based on a decision making model of women's food choice. This relates situation specific eating behaviour to outcomes and goals using decision theory. The outcomes and goals governing food choice extend beyond food related factors to include self esteem and social acceptance.

Cognitive behavioural programme Traditional cognitive behavioural topics (e.g. self monitoring, stimulus control, coping with cravings and high risk situations, stress management, and relaxation techniques) along with topics of particular importance to women (e.g. healthy eating, weight management, mood management, and managing work and family).

Motivational interviewing A goal directed counselling style that helps participants to understand and resolve areas of ambivalence that impede behavioural change.

Standard behavioural therapy A behavioural weight management programme that incorporates moderate calorie restriction to promote weight loss.

QUESTIONS

INTERVENTIONS

See glossary, p 146

Key Messages

- **Angiotensin converting enzyme inhibitors** Systematic reviews and RCTs have found that angiotensin converting enzyme inhibitors reduce ischaemic events, mortality, and hospital admission for heart failure compared with placebo. Relative benefits are similar in different groups of people, but absolute benefits are greater in people with severe heart failure. RCTs in people with asymptomatic left ventricular systolic dysfunction and in people with other risk factors have found that angiotensin converting enzyme inhibitors delay the onset of symptomatic heart failure and reduce cardiovascular events compared with placebo.

Clin Evid 2004;11:122–148.

- **β Blockers** Systematic reviews have found strong evidence that adding a β blocker to an angiotensin converting enzyme inhibitor decreases mortality and hospital admission. Limited evidence from a subgroup analysis of one RCT found no significant effect on mortality in black people.
- **Digoxin (improves morbidity in people already receiving diuretics and angiotensin converting enzyme inhibitors)** One large RCT in people already receiving diuretics and angiotensin converting enzyme inhibitors found that digoxin reduced the proportion of people admitted to hospital for worsening heart failure at 37 months compared with placebo, but found no significant difference between groups in mortality.
- **Angiotensin II receptor blockers** One systematic review found no significant difference between angiotensin receptor blockers and placebo in all cause mortality and hospital admission in people with New York Heart Association class II–IV heart failure, although a smaller proportion of people died or were admitted with heart failure with angiotensin receptor blockers. This lack of significant effect may be explained by the small number of deaths and admissions reported. The review found no significant difference between angiotensin receptor blockers and angiotensin converting enzyme inhibitors in all cause mortality or hospital admission. It found that angiotensin receptor blockers plus angiotensin converting enzyme inhibitors reduced admission for heart failure compared with angiotensin converting enzyme inhibitors alone, but found no significant difference between groups in all cause mortality.
- **Eplerenone (in people with myocardial infarction complicated by left ventricular dysfunction and heart failure already on medical treatment)** One large RCT in people with recent myocardial infarction complicated by left ventricular dysfunction and clinical heart failure already on medical treatment (which could include angiotensin converting enzyme inhibitors, angiotensin receptor blockers, diuretics, β blockers, or coronary reperfusion therapy) found that adding eplerenone (an aldosterone receptor antagonist) reduced mortality compared with placebo.
- **Exercise** One systematic review found that exercise training improved physiological measures compared with control. One included RCT that assessed clinical outcomes found that exercise improved quality of life, and reduced cardiac events, mortality, and hospital admission for heart failure at 12 months compared with control. One subsequent RCT found no significant difference between 3 months of supervised aerobic plus resistance training followed by 9 months of home based training and usual care in 6 minute walk distance, total mortality, or quality of life at 12 months.
- **Implantable cardiac defibrillators (in people with heart failure and near fatal arrhythmia)** One RCT has found good evidence that an implantable cardiac defibrillator reduces mortality in people with heart failure who have experienced a near fatal ventricular arrhythmia.
- **Multidisciplinary interventions** One systematic review has found that multidisciplinary programmes reduce admissions to hospital compared with conventional care, but found no significant difference in mortality. The review found that telephone contact plus improved coordination of primary care had no significant effect on admission rate. Two RCTs included in the review found that that home based support reduced cardiovascular events at 3–6 years compared with usual care. Subsequent RCTs found that education, nurse led support, and multidisciplinary programmes reduced death and hospital readmission and improved quality of life at 12 weeks to 1 year compared with usual care.

Heart failure

- **Prophylactic use of implantable cardiac defibrillators in people at high risk of arrhythmia** Two RCTs have found that implantable cardiac defibrillators reduce mortality compared with medical treatment in people with heart failure and at high risk of arrhythmia, whereas one RCT found no significant difference in mortality.
- **Spironolactone in people with severe heart failure** One large RCT in people with severe heart failure taking diuretics, angiotensin converting enzyme inhibitors, and digoxin has found that adding spironolactone compared with placebo reduces mortality after 2 years.
- **Amiodarone** Systematic reviews found weak evidence suggesting that amiodarone may reduce mortality compared with placebo. However, we were not able to draw firm conclusions about the effects of amiodarone in people with heart failure.
- **Anticoagulation** A preliminary report from one RCT found no significant difference between warfarin and no antithrombotic treatment or between warfarin and aspirin in the combined outcome of death, myocardial infarction, and stroke after 27 months. However, the RCT may have lacked power to detect a clinically important difference.
- **Antiplatelet agents** A preliminary report from one RCT found no significant difference between aspirin and no antithrombotic treatment or between aspirin and warfarin in the combined outcome of death, myocardial infarction, and stroke after 27 months. However, the RCT may have lacked power to detect a clinically important difference.
- **Treatments for diastolic heart failure** We found no RCTs in people with diastolic heart failure.
- **Calcium channel blockers** One systematic review has found no significant difference in mortality between second generation dihydropyridine calcium channel blockers and placebo. RCTs comparing other calcium channel blockers versus placebo also found no evidence of benefit.
- **Non-amiodarone antiarrhythmic drugs** Evidence extrapolated from one systematic review in people treated after a myocardial infarction suggests that other antiarrhythmic drugs (apart from β blockers) may increase mortality.
- **Positive inotropes (other than digoxin)** RCTs in people with heart failure found that positive inotropic drugs other than digoxin (ibopamine, milrinone, and vesnarinone) increased mortality over 6–11 months compared with placebo. One systematic review in people with heart failure found a non-significant increase in mortality with intravenous inotropic drugs that act through the adrenergic pathway compared with placebo or control, and insufficient data to determine whether symptoms improved. It suggested that their use may not be safe.

DEFINITION Heart failure occurs when abnormality of cardiac function causes failure of the heart to pump blood at a rate sufficient for metabolic requirements under normal filling pressure. It is characterised clinically by breathlessness, effort intolerance, fluid retention, and poor survival. It can be caused by systolic or diastolic dysfunction and is associated with neurohormonal changes.[1] Left ventricular systolic dysfunction (LVSD) is defined as a left ventricular ejection fraction below 0.40. It may be symptomatic or asymptomatic. Defining and diagnosing diastolic heart failure can be difficult. Recently proposed criteria include: (1) clinical evidence of heart

failure; (2) normal or mildly abnormal left ventricular systolic function; and (3) evidence of abnormal left ventricular relaxation, filling, diastolic distensibility, or diastolic stiffness.[2] However, assessment of some of these criteria is not standardised.

INCIDENCE/ PREVALENCE

Both the incidence and prevalence of heart failure increase with age. Studies of heart failure in the USA and Europe found that under 65 years of age the incidence is 1/1000 men a year and 0.4/1000 women a year. Over 65 years, incidence is 11/1000 men a year and 5/1000 women a year. Under 65 years the prevalence of heart failure is 1/1000 men and 1/1000 women; over 65 years the prevalence is 40/1000 men and 30/1000 women.[3] The prevalence of asymptomatic LVSD is 3% in the general population.[4–6] The mean age of people with asymptomatic LVSD is lower than that for symptomatic individuals. Both heart failure and asymptomatic LVSD are more common in men.[4–6] The prevalence of diastolic heart failure in the community is unknown. The prevalence of heart failure with preserved systolic function in people in hospital with clinical heart failure varies from 13–74%.[7,8] Less than 15% of people with heart failure under 65 years have normal systolic function, whereas the prevalence is about 40% in people over 65 years.[7]

AETIOLOGY/ RISK FACTORS

Coronary artery disease is the most common cause of heart failure.[3] Other common causes include hypertension and idiopathic dilated congestive cardiomyopathy. After adjustment for hypertension, the presence of left ventricular hypertrophy remains a risk factor for the development of heart failure. Other risk factors include cigarette smoking, hyperlipidaemia, and diabetes mellitus.[4] The common causes of left ventricular diastolic dysfunction are coronary artery disease and systemic hypertension. Other causes are hypertrophic cardiomyopathy, restrictive or infiltrative cardiomyopathies, and valvular heart disease.[8]

PROGNOSIS

The prognosis of heart failure is poor, with 5 year mortality ranging from 26–75%.[3] Up to 16% of people are readmitted with heart failure within 6 months of first admission. In the USA, heart failure is the leading cause of hospital admission among people over 65 years of age.[3] In people with heart failure, a new myocardial infarction increases the risk of death (RR 7.8, 95% CI 6.9 to 8.8). About a third of all deaths in people with heart failure are preceded by a major ischaemic event.[9] Sudden death, mainly caused by ventricular arrhythmia, is responsible for 25–50% of all deaths, and is the most common cause of death in people with heart failure.[10] The presence of asymptomatic LVSD increases an individual's risk of having a cardiovascular event. One large prevention trial found that for a 5% reduction in ejection fraction, the risk ratio for mortality was 1.20 (95% CI 1.13 to 1.29). For hospital admission for heart failure, the risk ratio was 1.28 (95% CI 1.18 to 1.38) and the risk ratio for heart failure was 1.20 (95% CI 1.13 to 1.26).[4] The annual mortality for people with diastolic heart failure varies in observational studies (1.3–17.5%).[7] Reasons for this variation include age, the presence of coronary artery disease, and variation in the partition value used to define abnormal ventricular systolic function. The annual mortality for left ventricular diastolic dysfunction is lower than that found in people with systolic dysfunction.[11]

AIMS OF INTERVENTION To relieve symptoms; to improve quality of life; to reduce morbidity and mortality; with minimum adverse effects.

OUTCOMES Functional capacity (assessed by the New York Heart Association [see glossary, p 146] functional classification or more objectively by using standardised exercise testing or the 6 minute walk test);[12] quality of life (assessed with questionnaires);[13] mortality; adverse effects of treatment. Proxy measures of clinical outcome (e.g. left ventricular ejection fraction and hospital readmission rates) are used only when clinical outcomes are unavailable.

METHODS *Clinical Evidence* search and appraisal June 2003. Generally, RCTs with fewer than 500 people have been excluded because of the number of large RCTs available. If for any comparison very large RCTs exist then much smaller RCTs have been excluded, even if they have more than 500 people.

QUESTION What are the effects of non-drug treatments?

OPTION MULTIDISCIPLINARY INTERVENTIONS

One systematic review has found that multidisciplinary programmes reduce admission to hospital compared with conventional care, but found no significant difference in mortality. The review found that telephone contact plus improved coordination of primary care had no significant effect on admission rate. Two RCTs included in the review found that home based support reduced cardiovascular events at 3–6 years compared with usual care. Subsequent RCTs found that education, nurse led support, and multidisciplinary programmes reduced death and hospital readmission and improved quality of life at 12 weeks to 1 year compared with usual care.

Benefits: We found one systematic review (search date 1999, 11 RCTs, 2067 people with heart failure)[14] and seven subsequent RCTs.[15–21] Multidisciplinary programmes in the review included treatments such as nutrition advice, counselling, patient education, and exercise training. The review found that multidisciplinary interventions significantly reduced hospital admission compared with conventional care (11 RCTs; 406/1001 [40.6%] with multidisciplinary programme *v* 474/1011 [46.9%] with conventional care; RR 0.87, 95% CI 0.79 to 0.96), but found no significant difference in mortality (7 RCTs; 104/534 [19.5%] with multidisciplinary programme *v* 121/572 [21.2%] with conventional care; RR 0.94, 95% CI 0.75 to 1.19). However, the hospital admission results were heterogeneous by intervention. Specialised follow up by a multidisciplinary team significantly reduced admissions to hospital (9 RCTs; 1366 people with heart failure; RR 0.77, 95% CI 0.68 to 0.86), but there was no benefit from telephone contact plus improved coordination of primary care services (2 RCTs; 646 people with heart failure; RR 1.15, 95% CI 0.96 to 1.37). One subsequent report of two RCTs included in the review (297 people living at home with at least 1 hospital admission for heart failure) found that home based support significantly increased event free survival at 3–6 years compared with usual care (median event free survival: 7 months with support *v* 3 months with usual care; $P < 0.01$).[22] However, it

found no significant difference in mortality between support and usual care at 5 years (83/149 [56%] with support *v* 96/148 [65%] with usual care; P = 0.06). The first subsequent RCT (88 people recently discharged after admission for heart failure) found that, compared with usual care, nurse led education and support significantly reduced the proportion of people who either died or had at least one readmission at 1 year (25/44 [57%] with support *v* 36/44 [82%] with usual care; RR 0.69, 95% CI 0.52 to 0.92).[15] The second subsequent RCT (200 people admitted with chronic heart failure) found no significant difference between protocol driven support plus management by nurses and usual care in mortality at 6 months (7/102 [7%] with support *v* 13/98 [13%] with usual care; P = 0.14).[16] It found that support significantly improved quality of life compared with usual care at 6 months (Minnesota Living with Heart Failure Questionnaire: final score 35.7 with support *v* 45.3 with usual care; P = 0.01). The third subsequent RCT (98 people) found that nurse led education plus specialist dietician advice significantly reduced readmission rate for heart failure compared with usual care at 12 weeks (readmission for heart failure: 1/51 [2%] with support *v* 11/47 [23%] with usual care; P < 0.01; OR 0.07, 95% CI 0.01 to 0.53).[17] The fourth subsequent RCT (216 people with heart failure) compared home nurse visit management (3 visits during the first week, 2 visits during the second and third weeks, 1 visit during the fourth and fifth week, then as needed) versus a nurse telemanagement programme (home monitoring device to measure weight, blood pressure, heart rate, and oxygen saturation, which transmitted data daily to a secure internet site to be reviewed by an advanced practice nurse and cardiologist) after hospital discharge.[18] It found that the nurse telemanagement programme significantly reduced heart failure readmissions after 3 months compared with the home nurse visit programme (13 with nurse telemanagement *v* 24 with home nurse visit; P < 0.001) and significantly reduced length of stay (49.5 days with nurse telemanagement *v* 105 days with home nurse visit; P < 0.001). The fifth subsequent cluster RCT (197 people with heart failure) compared an integrated primary and secondary care programme (involving review at a hospital based heart failure clinic, individual and group education sessions, personal diary to record medication and body weight, booklets, and follow up alternating between the hospital and general practitioner) versus usual care after hospital discharge.[19] The unit of randomisation was the person's general practitioner. The RCT found no significant difference between the integrated programme and usual care in the combined end point of death or readmission after 1 year. It found that the integrated programme significantly reduced multiple admissions after 1 year compared with usual care (56 with integrated programme *v* 95 with usual care; P = 0.015). The sixth subsequent cluster RCT (358 people with heart failure) compared a telephone case management programme (including a registered nurse using a decision support software programme, printed educational material, reports sent to the person's physician, guidelines for treatment of heart failure) versus usual care after hospital discharge.[20] The unit of randomisation was the person's general practitioner. The RCT found that the

telephone programme significantly reduced heart failure hospitalisation rate after 3 and 6 months compared with usual care (3 months: 45.7% lower, P = 0.03; 6 months: 47.8% lower, P = 0.01). It found that, compared with usual care, the telephone programme significantly reduced heart failure hospital days (P = 0.03) and multiple readmission (P = 0.03) after 6 months. The seventh subsequent RCT (234 people with heart failure) compared a heart failure management programme delivered by a day hospital (staff included a cardiologist, nurses, physiotherapist, with a plan of care structured for each person) versus usual care after hospital discharge.[21] It found that the programme significantly reduced readmissions to hospital after 12 months compared with usual care (13 with programme *v* 78 with usual care; P < 0.00001). It also found that the programme significantly reduced cardiac death after 1 year compared with usual care (3/112 [3%] with programme *v* 21/112 [17%] with usual care; P < 0.0007).

Harms: The review and subsequent RCTs did not report on harms (see comment below).

Comment: RCTs in the review were small, involved highly selected patient populations, lasted less than 6 months, and were usually performed in academic centres, so results may not generalise to longer term outcomes based in smaller community centres. The review suggested that disease management programmes may fragment care such that peoples' other conditions are overlooked.[14] However, it did not provide evidence to support this.

OPTION EXERCISE

One systematic review has found that exercise training improved physiological measures compared with control. One included RCT that assessed clinical outcomes found that exercise improved quality of life, and reduced cardiac events, mortality, and hospital readmission for heart failure at 12 months compared with control. One subsequent RCT found no significant difference between 3 months of supervised aerobic plus resistance training followed by 9 months of home based training and usual care in 6 minute walk distance, total mortality, or quality of life at 12 months.

Benefits: We found one systematic review (search date 2000, 14 RCTs, 582 people)[23] and one subsequent RCT.[24] The included RCTs predominantly excluded people with other illnesses and most used a cycle ergometer or combined exercise programme. Only one identified RCT lasted longer than 6 months. The review did not perform a meta-analysis. Overall, the review reported that 12 of the 14 RCTs found a positive effect for exercise training on physiological measures compared with control.[23] One RCT (99 people with heart failure, 88 men) evaluated clinical outcomes.[25] It compared 12 months of exercise training versus no exercise training. It found that exercise significantly improved quality of life, reduced fatal or non-fatal cardiac events, and reduced mortality and hospital readmission for heart failure at 12 months (quality of life assessed using Minnesota Living with Heart Failure Questionnaire, P < 0.001

in favour of exercise; fatal or non-fatal cardiac events: 17/50 [34%] with exercise *v* 37/49 [76%] without exercise; ARR 42%, 95% CI 20% to 58%; RR 0.45, 95% CI 0.23 to 0.73; NNT 2, 95% CI 2 to 5; mortality: 9/50 [18%] with exercise *v* 20/49 [41%] without exercise; RR 0.44, 95% CI 0.20 to 0.87; NNT 4, 95% CI 3 to 19; hospital readmission for heart failure: 5/50 [10%] with exercise *v* 14/49 [29%] without exercise; ARR 19%, 95% CI 3% to 25%; RR 0.35, 95% CI 0.12 to 0.88; NNT 5, 95% CI 4 to 30).[25] The subsequent RCT (181 people with New York Heart Association [see glossary, p 146] class I–III) found no significant difference between aerobic plus resistance training (3 months supervised followed by 9 months home based) and usual care in 6 minute walk distance or quality of life at 12 months (not by intent to treat; increase in walk distance from baseline in 139 people: 17 m with exercise *v* 20 m with usual care, P = 0.81; change in Minnesota Living with Heart Failure Questionnaire score for 124 people: –3.4 points with exercise *v* –3.3 points with usual care, P = 0.98).[24] It also found no significant difference for total mortality or admission to hospital for heart failure (results presented graphically; mortality about 30% for both groups, P = 0.95; death or admission to hospital about 40% for both groups, P = 0.73).[24]

Harms: The review and RCTs reported no important adverse effects associated with prescribed exercise training.[23–25]

Comment: The studies were small, involved highly selected patient populations, and were performed in well resourced academic centres. The results may not generalise to smaller community centres. The specific form of exercise training varied among studies and the relative merits of each strategy are unknown. The studies generally lasted less than 1 year and long term effects are unknown. Larger studies over a longer period are needed.

QUESTION What are the effects of drug and invasive treatments in heart failure?

OPTION ANGIOTENSIN CONVERTING ENZYME INHIBITORS

Systematic reviews and RCTs have found that angiotensin converting enzyme inhibitors reduce ischaemic events, mortality, and hospital admission for heart failure compared with placebo. Relative benefits are similar in different groups of people, but absolute benefits are greater in people with severe heart failure.

Benefits: We found two systematic reviews (search dates 1994[26] and not reported[27]) of angiotensin converting enzyme (ACE) inhibitors versus placebo in heart failure. The first review (search date 1994, 32 RCTs, duration 3–42 months, 7105 people, New York Heart Association [see glossary, p 146] class III or IV) found that ACE inhibitors significantly reduced mortality compared with placebo (611/3870 [16%] with ACE inhibitors *v* 709/3235 [22%] with placebo; ARR 6%, 95% CI 4% to 8%; OR 0.77, 95% CI 0.67 to 0.88).[26] Relative reductions in mortality were similar in different subgroups (stratified by age, sex, cause of heart failure, and New York Heart Association class). The second review (search date not reported, 5

RCTs, 12 763 people with left ventricular dysfunction or heart failure of mean duration 35 months) analysed long term results from large RCTs that compared ACE inhibitors versus placebo.[27] Three RCTs examined effects of ACE inhibitors in people for 1 year after myocardial infarction. In these three postinfarction trials (5966 people), ACE inhibitors significantly reduced mortality compared with placebo (702/2995 [23.4%] with ACE inhibitors *v* 866/2971 [29.1%] with placebo; OR 0.74, 95% CI 0.66 to 0.83), readmission for heart failure (355/2995 [11.9%] with ACE inhibitors *v* 460/2971 [15.5%] with placebo; OR 0.73, 95% CI 0.63 to 0.85), and reinfarction (324/2995 [10.8%] with ACE inhibitors *v* 391/2971 [13.2%] with placebo; OR 0.80, 95% CI 0.69 to 0.94). For all five trials, ACE inhibitors significantly reduced mortality compared with placebo (1467/6391 [23.0%] with ACE inhibitors *v* 1710/6372 [26.8%] with placebo; OR 0.80, 95% CI 0.74 to 0.87), reinfarction (571/6391 [8.9%] with ACE inhibitors *v* 703/6372 [11.0%] with placebo; OR 0.79, 95% CI 0.70 to 0.89), and readmission for heart failure (876/6391 [13.7%] with ACE inhibitors *v* 1202/6372 [18.9%] with placebo; OR 0.67, 95% CI 0.61 to 0.74). The relative benefits began soon after the start of treatment, persisted in the long term, and were independent of age, sex, and baseline use of diuretics, aspirin, and β blockers. Although there was a trend towards greater relative reduction in mortality or readmission for heart failure in people with lower ejection fraction, benefit was apparent over the range examined. **Other ischaemic events:** RCTs that studied high risk groups found that ACE inhibitors significantly reduced some ischaemic event rates. One RCT in people with left ventricular dysfunction found that, compared with placebo, ACE inhibitors significantly reduced myocardial infarction (combined fatal or non-fatal myocardial infarction: 9.9% with ACE inhibitors *v* 12.3% with placebo; RR 0.77, 95% CI 0.61 to 0.98), hospital admission for angina (15% with ACE inhibitors *v* 19% with placebo; RR 0.73, 95% CI 0.60 to 0.88), and the combined end point of cardiac death, non-fatal myocardial infarction, or hospital admission for angina (43% with ACE inhibitors *v* 51% with placebo; RR 0.77, 95% CI 0.68 to 0.86).[9] Effects on hospital readmissions were observed shortly after starting ACE inhibitor treatment, although effects on ischaemic events were not apparent for at least 6 months and peaked at 36 months. **Dose:** We found one large RCT (3164 people with New York Heart Association class II–IV heart failure) that compared low dose lisinopril (2.5 or 5.0 mg/day) versus high dose lisinopril (32.5 or 35.0 mg/day).[28] It found no significant difference in mortality (717/1596 [44.9%] with low dose *v* 666/1568 [42.5%] with high dose; ARR 2.4%; CI not reported; HR 0.92, 95% CI 0.80 to 1.03; P = 0.128), but found that high dose lisinopril reduced the combined outcome of death or hospital admission for any reason (events: 1338/1596 [83.8%] with low dose *v* 1250/1568 [79.7%] with high dose; ARR 4.1%; CI not reported; HR 0.88, 95% CI 0.82 to 0.96), and reduced admissions for heart failure (admissions: 1576/1596 [98.7%] with low dose *v* 1199/1568 [76.5%] with high dose; ARR 22.2%; CI not reported; P = 0.002). **Comparison of different ACE inhibitors:** The first systematic review found similar benefits with different ACE inhibitors.[26]

Harms: The main adverse effects in large RCTs were cough, hypotension, hyperkalaemia, and renal dysfunction. Compared with placebo, ACE inhibitors increased cough (37% with ACE inhibitor *v* 31% with placebo; ARI 7%, 95% CI 3% to 11%; RR 1.23, 95% CI 1.11 to 1.35), dizziness or fainting (57% with ACE inhibitor *v* 50% with placebo; ARI 7%, 95% CI 3% to 11%; RR 1.14, 95% CI 1.06 to 1.21), increased creatinine concentrations above 177 μmol/L (10.7% with ACE inhibitor *v* 7.7% with placebo; ARI 3.0%, 95% CI 0.6% to 6.0%; RR 1.38, 95% CI 1.09 to 1.67), and increased potassium concentrations above 5.5 mmol/L (AR 6.4% with ACE inhibitor *v* 2.5% with placebo; ARI 4%, 95% CI 2% to 7%; RR 2.56, 95% CI 1.92 to 3.20).[29] Risk of angio-oedema was similar with ACE inhibitors and placebo (3.8% with enalapril *v* 4.1% with placebo; ARI +0.3%, 95% CI −1.4% to +1.5%).[29] The trial comparing low and high doses of lisinopril found that most adverse effects were more common with high dose (no P value provided; dizziness: 12% with low dose *v* 19% with high dose; hypotension: 7% with low dose *v* 11% with high dose; worsening renal function: 7% with low dose *v* 10% with high dose; significant change in serum potassium concentration: 7% with low dose *v* 7% with high dose), although there was no difference in withdrawal rates between groups (18% discontinued with low dose *v* 17% with high dose). The trial found that cough was less commonly experienced with high dose compared with low dose lisinopril (cough: 13% with low dose *v* 11% with high dose).

Comment: The relative benefits of ACE inhibitors were similar in different subgroups of people with heart failure. Most RCTs evaluated left ventricular function by assessing left ventricular ejection fraction, but some studies defined heart failure clinically, without measurement of left ventricular function in people at high risk of developing heart failure (soon after myocardial infarction). It is unclear whether there are additional benefits from adding ACE inhibitor to antiplatelet treatment in people with heart failure (see antiplatelet agents, p 142).

OPTION ANGIOTENSIN II RECEPTOR BLOCKERS

One systematic review found no significant difference between angiotensin receptor blockers and placebo in all cause mortality and hospital admission in people with New York Heart Association class II–IV heart failure, although a smaller proportion of people died or were admitted with heart failure with angiotensin receptor blockers. This lack of significant effect may be explained by the small numbers of deaths and admissions reported. The review found no significant difference between angiotensin receptor blockers and angiotensin converting enzyme inhibitors in all cause mortality or hospital admission. It found that angiotensin receptor blockers plus angiotensin converting enzyme inhibitors reduced admission for heart failure compared with angiotensin converting enzyme inhibitors alone, but found no significant difference between groups in all cause mortality.

Benefits: **Versus placebo:** We found one systematic review (search date 2001, 11 RCTs, 2259 people with New York Heart Association [see glossary, p 146] class II–IV, follow up 4 weeks to 2 years).[30] It found

no significant difference between angiotensin receptor blockers and placebo in all cause mortality and admission for heart failure, although a smaller proportion of people died or were admitted with heart failure with angiotensin receptor blockers (all cause mortality: 7 RCTs; AR 2% with angiotensin receptor blockers *v* 3% with placebo; OR 0.68, 95% CI 0.38 to 1.22; admission for heart failure: 1 RCT; 8% with angiotensin receptor blockers *v* 12% with placebo; OR 0.67, 95% CI 0.29 to 1.51). The numbers of deaths and admissions were small, which may explain why the difference did not reach significance. **Versus angiotensin converting enzyme (ACE) inhibitors:** The systematic review identified six RCTs (4682 people with New York Heart Association class II–IV, follow up 4 weeks to 1.5 years) comparing angiotensin receptor blockers versus ACE inhibitors.[30] It found no significant difference between treatments for all cause mortality or rate of admission for heart failure (all cause mortality: 6 RCTs; OR 1.09, 95% CI 0.92 to 1.29; admission for heart failure: 3 RCTs; OR 0.95, 95% CI 0.8 to 1.13). **Plus ACE inhibitors versus ACE inhibitors alone:** The systematic review identified six RCTs (5712 people with New York Heart Association class II–IV heart failure) comparing angiotensin receptor blockers plus ACE inhibitors versus ACE inhibitors alone.[30] It found that combined treatment significantly reduced hospital admission for heart failure (3 RCTs; OR 0.74, 95% CI 0.64 to 0.86). However, it found no significant difference between treatments for all cause mortality (6 RCTs; OR 1.04, 95% CI 0.91 to 1.20).

Harms: The systematic review did not report on harms.[30]

Comment: In people who are truly intolerant of ACE inhibitors, the evidence supports the use of angiotensin II receptor blockers, with the expectation of at least symptomatic improvement of the heart failure.

OPTION POSITIVE INOTROPIC AGENTS

One systematic review found that in people in sinus rhythm with heart failure digoxin reduced clinical worsening of heart failure compared with placebo. One large RCT in people already receiving diuretics and angiotensin converting enzyme inhibitors found that digoxin reduced the proportion of people admitted to hospital for worsening heart failure at 37 months compared with placebo, but found no significant difference between groups in mortality. RCTs in people with heart failure found that positive inotropic drugs other than digoxin (ibopamine, milrinone, and vesnarinone) increased mortality over 6–11 months compared with placebo. One systematic review in people with heart failure found a non-significant increase in mortality with intravenous inotropic drugs that act through the adrenergic pathway compared with placebo or control, and insufficient data to determine whether symptoms improved. It suggested that their use may not be safe.

Benefits: **Digoxin:** We found one systematic review (search date 1992, 13 RCTs, duration 3–24 weeks, 1138 people with heart failure and sinus rhythm)[31] and one subsequent large RCT.[32] The systematic review found that six of the 13 RCTs enrolled people without assessment of ventricular function and may have included some

people with mild or no heart failure. Other limitations of the older trials included crossover designs and small sample sizes. In people who were in sinus rhythm with heart failure, the review found significantly fewer people with clinical worsening of heart failure (52/628 [8.3%] with digoxin *v* 131/631 [20.8%] with placebo; ARR 12.5%, 95% CI 9.5% to 14.7%; RR 0.40, 95% CI 0.29 to 0.54) but found no significant difference in mortality (16/628 [2.5%] with digoxin *v* 15/631 [2.4%] with placebo; ARR –0.2%, 95% CI –2.6% to +1.1%; RR 1.07, 95% CI 0.53 to 2.23). The subsequent large RCT (6800 people, 88% male, mean age 64 years, New York Heart Association [see glossary, p 146] class I–III, 94% already taking angiotensin converting enzyme inhibitors, 82% taking diuretics) compared blinded additional treatment with either digoxin or placebo for a mean of 37 months.[32] It found no significant difference between digoxin and placebo in all cause mortality (1181/3397 [34.8%] with digoxin *v* 1194/3403 [35.1%] with placebo; ARR +0.3%, 95% CI –2.0% to +2.6%; RR 0.99, 95% CI 0.93 to 1.06). It found that digoxin significantly reduced admission rates for heart failure over 37 months compared with placebo (910/3397 [27%] with digoxin *v* 1180/3403 [35%] with placebo; ARR 8%, 95% CI 6% to 10%; RR 0.77, 95% CI 0.72 to 0.83; NNT 13, 95% CI 10 to 17) and reduced the combined outcome of death or hospital admission caused by worsening heart failure (1041/3397 [31%] with digoxin *v* 1291/3403 [38%] for placebo; ARR 7.3%, 95% CI 5.1% to 9.4%; RR 0.81, 95% CI 0.75 to 0.87).

Other inotropic agents: One non-systematic review (6 RCTs, 8006 people) of RCTs found that non-digitalis inotropes increased mortality compared with placebo.[10] The largest RCT in the review (3833 people with heart failure) found significantly increased mortality with vesnarinone (60 mg/day) compared with placebo over 9 months (292/1275 [23%] with vesnarinone *v* 242/1280 [19%] with placebo; ARI 4%, 95% CI 1% to 8%; RR 1.21, 95% CI 1.04 to 1.40).[10,33] Another large RCT (1088 people with heart failure) found that milrinone significantly increased mortality over 6 months compared with placebo (168/561 [30%] with milrinone *v* 127/527 [24%] with placebo; ARI 6.0%, 95% CI 0.5% to 12.0%; RR 1.24, 95% CI 1.02 to 1.49).[34] A third large RCT (1906 people with heart failure) compared ibopamine versus placebo over 11 months.[35] It found that ibopamine significantly increased mortality compared with placebo (232/953 [25%] with ibopamine *v* 193/953 [20%] with placebo; RR 1.26, 95% CI 1.04 to 1.53). The review found that some RCTs reported improved functional capacity and quality of life, but this was not consistent across all RCTs. One systematic review (search date 2000, 21 RCTs, 632 people) examined the use of intravenous inotropic agents that act through the adrenergic pathway in people with heart failure.[36] Sixteen RCTs (474 people) contributed data from acute invasive haemodynamic studies of symptomatically severe heart failure, and five RCTs (158 people) were based on intermittent inotropic treatment in an outpatient context. Included RCTs were often small. It found 11 RCTs comparing inotropic agents (including dobutamine, dopexamine, toborinone, and milrinone) versus placebo or control. The review found that, compared with placebo or control, intravenous inotropes that

act through the adrenergic pathway tended to increase mortality although this did not reach significance (11 RCTs; OR 1.50, 95% CI 0.51 to 3.92; absolute numbers not reported). It reported that there were insufficient data to determine whether symptoms improved (see comment below).[36]

Harms: We found no systematic review. **Digoxin:** The RCT (6800 people) found that significantly more people had suspected digoxin toxicity in the digoxin group compared with placebo (11.9% with digoxin *v* 7.9% with placebo; ARI 4.0%, 95% CI 2.4% to 5.8%; RR 1.50, 95% CI 1.30 to 1.73).[32] The RCT found no significant difference between digoxin and placebo in the risk of ventricular fibrillation or tachycardia (37/3397 [1.1%] with digoxin *v* 27/3403 [0.8%] with placebo; ARI +0.3%, 95% CI −0.1% to +1.0%; RR 1.37, 95% CI 0.84 to 2.24). It found that, compared with placebo, digoxin significantly increased rates of supraventricular arrhythmia (2.5% with digoxin *v* 1.2% with placebo; ARI 1.3%, 95% CI 0.5% to 2.4%; RR 2.08, 95% CI 1.44 to 2.99) and second or third degree atrioventricular block (1.2% with digoxin *v* 0.4% with placebo; ARI 0.8%, 95% CI 0.2% to 1.8%; RR 2.93, 95% CI 1.61 to 5.34). **Other inotropic agents:** Most RCTs found that inotropic agents other than digoxin increased risk of death (see benefits above).

Comment: The systematic review on intravenous inotropic agents in people with heart failure concluded that "intravenous inotropic agents acting through the adrenergic pathway are often used in patients with worsening heart failure to achieve arbitrary haemodynamic targets. Our analyses show that there is very little evidence that such treatment improves symptoms or patient outcomes and may not be safe."[36]

OPTION β BLOCKERS

Systematic reviews have found strong evidence that adding a β blocker to an angiotensin converting enzyme inhibitor decreases mortality and hospital admission. Limited evidence from a subgroup analysis of one RCT found no significant effect on mortality in black people.

Benefits: We found two systematic reviews (search dates 2000[37] and not reported[38]) and two subsequent RCTs[39,40] of the effects of β blockers in heart failure. **In people with any severity of heart failure:** The first systematic review (search date 2000, 22 RCTs, 10 315 people with heart failure, most people receiving triple therapy, in particular, angiotensin converting enzyme inhibitors) found that β blockers significantly reduced the risk of death and hospital admission compared with placebo (death: 444/5273 [8.4%] with β blockers *v* 624/4862 [12.8%] with placebo; OR 0.65, 95% CI 0.53 to 0.80; hospital admissions: 540/5244 [10.3%] with β blockers *v* 754/4832 [15.6%] with placebo; OR 0.64, 95% CI 0.53 to 0.79).[37] This is equivalent to three fewer deaths and four fewer hospital admissions per 100 people treated for 1 year. The results were consistent for selective and non-selective β blockers. Sensitivity analysis and funnel plots found that publication bias was unlikely. **In people with severe heart failure:** We found one systematic review[38] and two subsequent RCTs.[39,40] The systematic

review (search date not reported, 4 RCTs, 635 people with class IV heart failure, on angiotensin converting enzyme inhibitors and diuretic with or without digitalis) found that β blockers significantly reduced the risk of death compared with placebo (56/313 [17.9%] with β blockers *v* 81/322 [25.1%] with placebo; RR 0.71, 95% CI 0.52 to 0.96).[38] The two subsequent RCTs compared β blockers versus placebo in people with New York Heart Association class III or IV heart failure.[39,40] The first RCT (2289 people with class IV heart failure, who were euvolaemic [defined as the absence of rales and ascites and the presence of no more than minimal peripheral oedema] and who had an ejection fraction of < 25%, but were not receiving intensive care, iv vasodilators, or positive inotropic drugs) compared carvedilol versus placebo over 10.4 months. It was stopped early because of a significant beneficial effect on survival that exceeded the pre-specified interim monitoring boundaries.[39] It found that β blockers significantly reduced mortality compared with placebo (130/1156 [11.2%] with β blockers *v* 190/1133 [16.8%] with placebo; RR 0.65, 95% CI 0.52 to 0.81) and the combined outcome of death or hospital admission (425/1156 [36.8%] with β blockers *v* 507/1133 [44.7%] with placebo; RR 0.76, 95% CI 0.67 to 0.87). The second RCT compared bucindolol versus placebo in people with severe heart failure (2708 people with class III or IV heart failure and ejection fraction ≤ 35%; about 70% of the people were white and 24% were black).[40] The RCT was stopped early because of accumulated evidence from other studies. It found that death was more common with placebo, but the difference did not reach significance (411/1354 [30.4%] with bucindolol *v* 449/1354 [33.1%] with placebo; HR 0.90, 95% CI 0.78 to 1.02). The RCT found a significant interaction of treatment effect with race (black *v* non-black people). There was no evidence of benefit in black people (HR 1.17, 95% CI 0.89 to 1.53), although there was a significant effect for non-black people (HR 0.82, 95% CI 0.70 to 0.96).[40]

Harms: One subsequent RCT found that fewer people with carvedilol required permanent discontinuation of treatment because of adverse events other than death compared with placebo (P = 0.02).[39] Cumulative withdrawals at 1 year were 14.8% with carvedilol compared with 18.5% with placebo. For the subgroup of people with recent or recurrent cardiac decompensation or severely depressed cardiac function the difference in withdrawal rates was greater (17.5% with carvedilol *v* 24.2% with placebo).[39] A subsequent report of this RCT found that, compared with placebo, carvedilol significantly reduced days in hospital for any reason (6.2 days per person *v* 8.5 days per person; P = 0.0005) and days in hospital for heart failure (2.9 days per person *v* 4.9 days per person; P < 0.0001).[41] After 6 months of maintenance treatment, it found significantly more people felt improved and fewer felt worse with carvedilol compared with placebo (P = 0.0009). It also found a significantly smaller proportion of people with carvedilol experienced a serious adverse event compared with placebo (39% with carvedilol *v* 45.5% with placebo; P = 0.002). Another subsequent report of this RCT examined the short term risks of initiating carvedilol in severe heart failure.[42] During the first 8 weeks of treatment it found that, compared with placebo, the carvedilol group had fewer deaths (19 with carvedilol *v* 25 with placebo;

HR 0.75, 95% CI 0.41 to 1.35); death or hospitalisation for any reason (134 *v* 153; HR 0.85, 95% CI 0.67 to 1.07); or death, hospitalisation, or permanent study drug withdrawal (162 *v* 188; HR 0.83, 95% CI 0.68 to 1.03), although differences did not reach significance. It noted differences in favour of carvedilol became apparent as early as 14–21 days after starting treatment.[42] The subsequent RCT comparing bucindolol versus placebo found that 23% of people in the bucindolol group and 25% of people in the placebo group permanently discontinued the medication.[40]

Comment: Fears that β blockers may cause excessive problems with worsening heart failure, bradyarrhythmia, or hypotension have not been confirmed. Good evidence was found for β blockers in people with moderate symptoms (New York Heart Association class II or III) receiving standard treatment, including angiotensin converting enzyme inhibitors. The value of β blockers is uncertain in heart failure with preserved ejection fraction and in asymptomatic left ventricular systolic dysfunction. One recent RCT (1959 people) has found that carvedilol reduced all cause mortality compared with placebo (AR for death: 12% with carvedilol *v* 15% with placebo; HR 0.77, 95% CI 0.60 to 0.98) in people with acute myocardial infarction and left ventricular ejection fraction 40% or less.[43] The RCTs of β blockers have consistently found a mortality benefit, but it is not clear whether or not this is a class effect. One recent small RCT (150 people) of metoprolol versus carvedilol found some differences in surrogate outcomes, but both drugs produced similar improvements in symptoms, submaximal exercise tolerance, and quality of life.[44] Another recent RCT (3029 people) compared carvedilol versus metoprolol tartrate in people with heart failure.[45] It found that carvedilol significantly reduced all cause mortality compared with metoprolol (512/1511 [34%] with carvedilol *v* 600/1518 [40%] with metoprolol; HR 0.83, 95% CI 0.74 to 0.93). It found no significant difference between groups for the composite outcome of mortality or all cause admission (P = 0.122). The results of this RCT suggest carvedilol extends survival compared with metoprolol. However, potential limitations to this RCT were that the target dose of metoprolol was less than usually suggested, and metoprolol was not the long acting formulation used in a previous RCT[37] that had shown significant clinical benefit. The results for non-black people were consistent between bucindolol and carvedilol. The lack of observed benefit for black people in one RCT[40] raises the possibility that there may be race specific responses to pharmacological treatment for cardiovascular disease.

OPTION CALCIUM CHANNEL BLOCKERS

One systematic review has found no significant difference in mortality between second generation dihydropyridine calcium channel blockers and placebo. RCTs comparing other calcium channel blockers versus placebo also found no evidence of benefit.

Benefits: **After myocardial infarction:** See calcium channel blockers under acute myocardial infarction, p 37. **Other heart failure:** We found one systematic review (search date not reported, 18 RCTs, 3128

people with moderate to advanced heart failure for > 2 months) of second generation dihydropyridine calcium channel blockers,[46] one non-systematic review of all calcium channel blockers (3 RCTs, 1790 people with heart failure),[10] and one subsequent RCT.[47] The systematic review found no significant difference in mortality (2 RCTs, 1603 people; OR 0.94, 95% CI 0.79 to 1.12; significant heterogeneity was found; P = 0.48).[46] The largest RCT in the non-systematic review (1153 people [New York Heart Association — see glossary, p 146 — class III or IV], left ventricular ejection fraction < 0.30, using diuretics, digoxin, and angiotensin converting enzyme inhibitors) found no significant difference between amlodipine and placebo on the primary combined end point of all cause mortality and hospital admission for cardiovascular events over 14 months (222/571 [39%] with amlodipine *v* 246/582 [42%] with placebo; ARR +3.4%, 95% CI –2.3% to +8.8%; RR 0.92, 95% CI 0.79 to 1.06).[10,48] Subgroup analysis of people with primary cardiomyopathy found a significant reduction in mortality with amlodipine (45/209 [22%] with amlodipine *v* 74/212 [35%] with placebo; ARR 13%, 95% CI 5% to 20%; RR 0.62, 95% CI 0.43 to 0.85). There was no significant difference in the group with heart failure caused by coronary artery disease. The second RCT (186 people, idiopathic dilated cardiomyopathy, New York Heart Association class I–III) compared diltiazem versus placebo.[10] It found no evidence of a difference in survival between diltiazem and placebo in those who did not have a heart transplant, although people on diltiazem had improved cardiac function, exercise capacity, and subjective quality of life. The third RCT (451 people with mild heart failure, New York Heart Association class II or III) compared felodipine versus placebo.[10] It found no significant effect. The subsequent RCT (2590 people with New York Heart Association class II–IV heart failure, mean follow up of 1.5 years with mibefradil and 1.6 years with placebo) found no significant difference in death rates between mibefradil and placebo (350/1295 [27.0%] with mibefradil *v* 319/1295 [24.6%] with placebo; RR 1.10, 95% CI 0.96 to 1.25).[47]

Harms: Calcium channel blockers have been found to exacerbate symptoms of heart failure or increase mortality in people with pulmonary congestion after myocardial infarction or ejection fraction less than 0.40 (see calcium channel blockers under acute myocardial infarction, p 37).[10] One RCT found mibefradil increased risk of death in people taking digoxin, class I or II antiarrhythmics, amiodarone, or drugs associated with torsade de pointes compared with placebo.[47] The review found that second generation dihydropyridine calcium channel blockers did not cause significant adverse effects.[46]

Comment: Many of the RCTs were underpowered and had wide confidence intervals. One RCT of amlodipine in people with primary dilated cardiomyopathy is in progress.

OPTION ALDOSTERONE RECEPTOR ANTAGONISTS

One large RCT in people with severe heart failure taking diuretics, angiotensin converting enzyme inhibitors, and digoxin has found that adding spironolactone compared with placebo reduces mortality after 2

years. One large RCT in people with recent myocardial infarction complicated by left ventricular dysfunction and clinical heart failure already on medical treatment (which could include angiotensin converting enzyme inhibitors, angiotensin receptor blockers, diuretics, β blockers, or coronary reperfusion therapy) found that adding eplerenone (an aldosterone receptor antagonist) reduced mortality compared with placebo.

Benefits: We found no systematic review but found two RCTs.[49,50] The first RCT (1663 people with heart failure, New York Heart Association [see glossary, p 146] class III or IV, left ventricular ejection fraction < 0.35, all taking angiotensin converting enzyme inhibitors and loop diuretics, and most taking digoxin) compared spironolactone (25 mg/day) versus placebo.[49] The trial was stopped early because spironolactone significantly reduced all cause mortality compared with placebo after 2 years (mortality: 284/822 [35%] with spironolactone *v* 386/841 [46%] with placebo; ARR 11%, 95% CI 7% to 16%; RR 0.75, 95% CI 0.66 to 0.85; NNT 9, 95% CI 6 to 15).[49] The second RCT compared eplerenone (a selective aldosterone receptor antagonist) versus placebo in people found to have left ventricular dysfunction (ejection fraction of ≤ 40%) and clinical symptoms of heart failure after an acute myocardial infarction within the previous 3–14 days.[50] People were already receiving "optimal" medical treatment which could include angiotensin converting enzyme inhibitors, angiotensin receptor blockers, diuretics, β blockers, or coronary reperfusion therapy, but excluded potassium sparing diuretics. The RCT found that eplerenone significantly reduced death from any cause after 16 months compared with placebo (478/3319 [14%] with eplerenone *v* 554/3313 [17%] with placebo; RR 0.85, 95% CI 0.75 to 0.96). It found that, compared with placebo, eplerenone significantly reduced death from cardiovascular causes (407/3319 [12%] with eplerenone *v* 483/3313 [15%] with placebo; RR 0.83, 95% CI 0.72 to 0.94) and significantly reduced the composite end point of death from cardiovascular causes or hospitalisation for cardiovascular events (885/3319 [27%] with eplerenone *v* 993/3313 [30%] with placebo; RR 0.87, 95% CI 0.79 to 0.95).[50]

Harms: The first RCT found no evidence that adding spironolactone to an angiotensin converting enzyme inhibitor increases risk of clinically important hyperkalaemia. Gynaecomastia or breast pain were reported in 10% of men given spironolactone and 1% of men given placebo.[49] In the RCT comparing eplerenone versus placebo, the rate of serious hyperkalaemia was significantly higher in the eplerenone group (180/3307 [5.5%] with eplerenone *v* 126/3301 [3.9%] with placebo; P = 0.002).[50]

Comment: The first RCT was large and well designed. As only people with New York Heart Association functional class III or IV were included, these results cannot necessarily be generalised to people with milder heart failure.

OPTION ANTIARRHYTHMIC DRUG TREATMENT

Systematic reviews found weak evidence suggesting that amiodarone may reduce mortality compared with placebo. However, we were not able to draw firm conclusions about the effects of amiodarone in people with heart failure. Evidence extrapolated from one systematic review in people treated after a myocardial infarction suggests that other antiarrhythmic agents (apart from β blockers) may increase mortality in people with heart failure.

Benefits:

Amiodarone: We found two systematic reviews comparing amiodarone versus placebo in heart failure.[51,52] The most recent review (search date 1997, 10 RCTs, 4766 people) included people with a wide range of conditions (symptomatic and asymptomatic heart failure, ventricular arrhythmia, recent myocardial infarction, and recent cardiac arrest).[51] Eight of these RCTs reported the number of deaths. The review found that treatment with amiodarone over 3–24 months significantly reduced the risk of death from any cause compared with placebo or conventional treatment (436/2262 [19%] with amiodarone *v* 507/2263 [22%] with control; ARR 3.0%, 95% CI 0.8% to 5.3%; RR 0.86, 95% CI 0.76 to 0.96). This review did not perform any subgroup analyses in people with heart failure. The earlier systematic review (search date not reported) found eight RCTs (5101 people after myocardial infarction) comparing prophylactic amiodarone versus placebo or usual care, and five RCTs (1452 people) in people with heart failure.[52] Mean follow up was 16 months. Analysis of results from all 13 RCTs found a lower total mortality with amiodarone than control (annual mortality: 10.9% with amiodarone *v* 12.3% with control). The effect was significant with some methods of calculation (fixed effects model: OR 0.87, 95% CI 0.78 to 0.99) but not with others (random effects model: OR 0.85, 95% CI 0.71 to 1.02). The effect of amiodarone was significantly greater in RCTs that compared amiodarone versus usual care than in placebo controlled RCTs. It found that amiodarone significantly reduced arrhythmic death or sudden death compared with placebo (OR 0.71, 95% CI 0.59 to 0.85). Subgroup analysis found that amiodarone significantly reduced mortality in the five heart failure RCTs compared with placebo (annual mortality: 19.9% with amiodarone *v* 24.3% with placebo; OR 0.83, 95% CI 0.70 to 0.99). **Other antiarrhythmics:** Apart from β blockers, other antiarrhythmic drugs increase mortality in people at high risk (see class I antiarrhythmic agents under secondary prevention of ischaemic cardiac events, p 197).

Harms:

Amiodarone: Amiodarone did not significantly increase non-arrhythmic death rate (OR 1.02, 95% CI 0.87 to 1.19).[52] In placebo controlled RCTs, after 2 years, 41% of people in the amiodarone group and 27% in the placebo group had permanently discontinued study medication.[52] In 10 RCTs comparing amiodarone versus placebo, amiodarone increased the odds of reporting adverse drug reactions compared with placebo (OR 2.22, 95% CI 1.83 to 2.68). Nausea was the most common adverse effect. Hypothyroidism was the most common serious adverse effect (7.0% with amiodarone *v* 1.1% with placebo). Hyperthyroidism

(1.4% with amiodarone *v* 0.5% with placebo), peripheral neuropathy (0.5% with amiodarone *v* 0.2% with placebo), lung infiltrates (1.6% with amiodarone *v* 0.5% with placebo), bradycardia (2.4% with amiodarone *v* 0.8% with placebo), and liver dysfunction (1.0% with amiodarone *v* 0.4% with placebo) were all more common in the amiodarone group.[52] **Other antiarrhythmics:** These agents (particularly class I antiarrhythmics) may increase mortality (see class I antiarrhythmic agents under secondary prevention of ischaemic cardiac events, p 197).

Comment: **Amiodarone:** RCTs of amiodarone versus usual treatment found larger effects than placebo controlled trials.[52] These findings suggest bias; unblinded follow up may be associated with reduced usual care or improved adherence with amiodarone. Further studies are required to assess the effects of amiodarone treatment on mortality and morbidity in people with heart failure.

OPTION IMPLANTABLE CARDIAC DEFIBRILLATORS

One RCT has found good evidence that an implantable cardiac defibrillator reduces mortality in people with heart failure who have experienced a near fatal ventricular arrhythmia. Two RCTs have found that implantable cardiac defibrillators reduce mortality compared with medical treatment in people with heart failure and at high risk of arrhythmia, whereas one RCT found no significant difference in mortality.

Benefits: We found no systematic review. We found four RCTs examining the effects of implantable cardiac defibrillators (ICDs) in people with left ventricular dysfunction.[53–56] The first RCT (1016 people resuscitated after ventricular arrhythmia and either syncope or other serious cardiac symptom and left ventricular ejection fraction ≤ 0.40) compared an ICD versus an antiarrhythmic drug (mainly amiodarone).[53] It found that ICDs improved survival at 1, 2, and 3 years (1 year survival: 89.3% with ICD *v* 82.3% with antiarrhythmic; 2 year survival: 81.6% with ICD *v* 73.7% with antiarrhythmic; 3 year survival: 75.4% with ICD *v* 64.1% with antiarrhythmic; $P < 0.02$). The second RCT included 196 people with New York Heart Association (see glossary, p 146) class I–III heart failure and previous myocardial infarction, a left ventricular ejection fraction 0.35 or less, a documented episode of asymptomatic unsustained ventricular tachycardia, and inducible non-suppressible ventricular tachyarrhythmia on electrophysiological study.[54] The RCT found that ICDs significantly reduced mortality over a mean of 27 months compared with conventional treatment (deaths: 15/95 [16%] with ICD [11 from cardiac cause] *v* 39/101 [39%] with conventional treatment [27 from cardiac cause]; HR 0.46, 95% CI 0.26 to 0.82). The third RCT included 1055 people aged less than 80 years who were scheduled for coronary artery bypass surgery, had a left ventricular ejection fraction less than 0.36, and had electrocardiographic abnormalities. It found that ICD at the time of bypass surgery versus no ICD produced no significant difference in mortality over a mean of 32 months (deaths: 101/446 [23%] with ICD [71 from cardiac causes] *v* 95/454 [21%] with control [72 from cardiac causes]; HR 1.07, 95% CI 0.81 to 1.42).[55] The fourth RCT (1232 people with prior myocardial infarction and left ventricular ejection fraction

< 0.30) compared an ICD (742 people) versus conventional medical treatment (490 people).[56] It found that ICD reduced all cause mortality after 20 months' mean follow up compared with conventional treatment (AR 14.2% with ICD *v* 19.8% with conventional treatment; HR 0.69, 95% CI 0.51 to 0.93).

Harms: The RCTs found that the main adverse effects of ICDs were infection (about 5%), pneumothorax (about 2%), bleeding requiring further operation (about 1%), serious haematomas (about 3%), cardiac perforation (about 0.2%), problems with defibrillator lead (about 7%), and malfunction of defibrillator generator (about 3%).[53–56]

Comment: The RCTs were in people with reduced left ventricular function and included people with and without previous cardiac arrest or inducible arrhythmia. It is uncertain whether asymptomatic ventricular arrhythmia is in itself a predictor of sudden death in people with moderate or severe heart failure.[57] Several RCTs of prophylactic ICD treatment in people with heart failure and in survivors of acute myocardial infarction are ongoing.[58]

OPTION ANTICOAGULATION

A preliminary report from one RCT found no significant difference between warfarin and no antithrombotic treatment or between warfarin and aspirin in the combined outcome of death, myocardial infarction, and stroke after mean follow up of 27 months. However, the RCT may have lacked power to detect clinically important effects.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 1 RCT, 279 people, 70% with New York Heart Association [see glossary, p 146] class III).[59] The RCT identified by the review was a pilot study comparing warfarin (international normalised ratio 2.5), aspirin (300 mg/day), and no antithrombotic treatment.[60] The RCT found no significant difference between warfarin and no antithrombotic treatment in the combined outcome of death, myocardial infarction, and stroke after mean follow up of 27 months (combined outcome: 26% with warfarin *v* 27% with no antithrombotic treatment; P value not reported).[60] **Versus antiplatelets:** See antiplatelets, p 142.

Harms: **Versus placebo:** The RCT found four haemorrhagic events with warfarin versus none with no antithrombotic treatment (total number of people in each group not reported).[60]

Comment: The systematic review (search date 2000)[59] found three additional non-randomised trials. Meta-analysis of these trials and the RCT[60] found that anticoagulant significantly reduced death from all causes and cardiovascular event rates compared with control (death from all causes in 1087 people: OR 0.64, 95% CI 0.45 to 0.90; cardiovascular event rates in 1130 people: OR 0.26, 95% CI 0.16 to 0.43).[59] Meta-analysis of two non-randomised trials (645 people) found no significant difference in bleeding complications between warfarin and no warfarin (OR 1.52, 95% CI 0.56 to 4.10).[59] The non-randomised controlled studies were performed in the early 1950s in hospitalsed people with a high prevalence of rheumatic heart disease and atrial fibrillation and the methods used may be

considered unreliable today. One retrospective analysis assessed the effect of anticoagulants used at the discretion of individual investigators in RCTs on the incidence of stroke, peripheral arterial embolism, and pulmonary embolism.[61] The first cohort was from one RCT (642 men with chronic heart failure) comparing hydralazine plus isosorbide dinitrate versus prazosin versus placebo. The second cohort was from another RCT (804 men with chronic heart failure) comparing enalapril versus hydralazine plus isosorbide dinitrate. All people were given digoxin and diuretics. The retrospective analysis found that without treatment, the incidence of all thromboembolic events was low (2.7/100 patient years in the first RCT; 2.1/100 patient years in the second RCT) and that anticoagulation did not reduce the incidence of thromboembolic events (2.9/100 patient years in the first RCT; 4.8/100 patient years in the second RCT). In this group of people, atrial fibrillation was not found to be associated with a higher risk of thromboembolic events. The second retrospective analysis was from two large RCTs (2569 people with symptomatic and asymptomatic left ventricular dysfunction) that compared enalapril versus placebo.[62] The analysis found that people treated with warfarin at baseline had significantly lower risk of death during follow up (HR adjusted for baseline differences 0.76, 95% CI 0.65 to 0.89). Warfarin use was associated with a reduction in the combined outcome of death plus hospital admission for heart failure (adjusted HR 0.82, 95% CI 0.72 to 0.93). The benefit with warfarin use was not significantly influenced by the presence of symptoms, randomisation to enalapril or placebo, sex, presence of atrial fibrillation, age, ejection fraction, New York Heart Association classification, or cause of heart failure. Warfarin reduced cardiac mortality, specifically deaths that were sudden, or associated with either heart failure or myocardial infarction. Neither of the retrospective studies was designed to determine the incidence of thromboembolic events in heart failure or the effects of treatment. Neither study included information about the intensity of anticoagulation or warfarin use. We found several additional cohort studies that showed a reduction in thromboembolic events with anticoagulation, but they all reported results for too few people to provide useful results. An RCT is needed to compare anticoagulation versus no anticoagulation in people with heart failure.

OPTION ANTIPLATELET AGENTS

A preliminary report from one RCT found no significant difference between aspirin and no antithrombotic treatment or between aspirin and warfarin in the combined outcome of death, myocardial infarction, and stroke after mean follow up of 27 months. However, the RCT may have lacked power to detect a clinically important difference.

Benefits: We found one systematic review (search date 2000, 1 RCT, 279 people, 70% with New York Heart Association [see glossary, p 146] class III).[59] The RCT identified by the review was a pilot study comparing aspirin (300 mg/day) versus warfarin (international normalised ratio 2.5) versus no antithrombotic treatment.[60] **Versus placebo:** The RCT found no significant difference between aspirin and no antithrombotic treatment for the combined outcome of death, myocardial infarction, and stroke after mean follow up of 27

months (combined outcome: 32% with aspirin *v* 27% with no antithrombotic treatment; P value not reported).[60] It found that aspirin significantly increased all cause hospital admission compared with placebo (P < 0.05; no data reported). **Versus warfarin:** The RCT found no significant difference between aspirin and warfarin for the combined outcome of death, myocardial infarction, and stroke after mean follow up of 27 months (combined outcome: 32% with aspirin *v* 26% with warfarin; P value not reported).[60] It found that all cause hospital admissions were significantly higher for aspirin compared with warfarin (P = 0.05; no data reported).

Harms: Preliminary information on one RCT reported five haemorrhagic events with aspirin compared with four with warfarin (total number of people in each group not reported).[60] The total number of serious adverse reactions were similar in all groups (198 with aspirin *v* 173 with warfarin *v* 178 with no antithrombotic treatment).[63]

Comment: **In people not taking angiotensin converting enzyme (ACE) inhibitors:** We found no systematic review and no RCTs. We found one retrospective cohort analysis within one RCT in 642 men with heart failure.[61] The RCT compared hydralazine plus isosorbide dinitrate versus prazosin versus placebo in men receiving digoxin and diuretics. Aspirin, dipyridamole, or both were used at the discretion of the investigators. The number of thromboembolic events was low in both groups (1 stroke, 0 peripheral, and 0 pulmonary emboli in 184 people years of treatment with antiplatelet agents *v* 21 strokes, 4 peripheral, and 4 pulmonary emboli in 1068 people years of treatment without antiplatelet agents; 0.5 events/100 people years with antiplatelet agents *v* 2.0 events/100 patient years without antiplatelet agents; P = 0.07). **In people taking ACE inhibitors:** We found no RCTs. We found two large retrospective cohort studies.[61,64] The first retrospective analysis assessed the effect of antiplatelet agents used at the discretion of individual investigators on the incidence of stroke, peripheral arterial embolism, and pulmonary embolism within one RCT.[61] The RCT (804 men with chronic heart failure) compared enalapril versus hydralazine plus isosorbide dinitrate. It found that the incidence of all thromboembolic events was low without antiplatelet treatment and found no significant difference between groups (1.6 events/100 patient years with antiplatelet treatment *v* 2.1 events/100 people years with no antiplatelet treatment; P = 0.48). The second cohort analysis was from two large RCTs that compared enalapril versus placebo (2569 people with symptomatic and asymptomatic left ventricular dysfunction). It found that people treated with antiplatelet agents at baseline had a significantly lower risk of death (HR adjusted for baseline differences 0.82, 95% CI 0.73 to 0.92).[64] Subgroup analysis suggested that antiplatelet agents might have an effect in people randomised to placebo (mortality HR for antiplatelet treatment at baseline *v* no antiplatelet treatment at baseline 0.68, 95% CI 0.58 to 0.80), but not in people randomised to enalapril (mortality HR for antiplatelet treatment *v* no antiplatelet treatment 1.00, 95% CI 0.85 to 1.17). Both retrospective studies have important limitations common to studies with a retrospective cohort design. One study did not report on the proportions of people taking aspirin and other antiplatelet agents.[61] The other study noted

that more than 95% of people took aspirin, but the dosage and consistency of antiplatelet use was not recorded.[64] One retrospective non-systematic review (4 RCTs, 96 712 people) provided additional evidence about the effect of aspirin on the benefits of early ACE inhibitors in heart failure.[65] It found a similar reduction in 30 day mortality with ACE inhibitor versus control for those people not taking aspirin compared with those taking aspirin (aspirin: OR 0.94, 95% CI 0.89 to 0.99; no aspirin: OR 0.90, 95% CI 0.81 to 1.01). However, the analysis may not be valid because the people who did not receive aspirin were older and had a worse baseline prognosis than those taking aspirin. The effects of antiplatelet treatment in combination with ACE inhibitors in people with heart failure requires further research.

QUESTION **What are the effects of angiotensin converting enzyme inhibitors in people at high risk of heart failure?**

OPTION **ANGIOTENSIN CONVERTING ENZYME INHIBITORS IN PEOPLE AT HIGH RISK OF HEART FAILURE**

RCTs in people with asymptomatic left ventricular systolic dysfunction and in people with other risk factors have found that angiotensin converting enzyme inhibitors delay the onset of symptomatic heart failure and reduce cardiovascular events compared with placebo.

Benefits:

In people with asymptomatic left ventricular systolic dysfunction: We found no systematic review but found two RCTs.[66,67] The first large RCT (4228 people) compared an angiotensin converting enzyme (ACE) inhibitor (enalapril) versus placebo over 40 months in people with asymptomatic left ventricular systolic dysfunction (ejection fraction < 0.35).[66] It found no significant difference between enalapril and placebo in total mortality and cardiovascular mortality (all cause mortality: 313/2111 [14.8%] with ACE inhibitor *v* 334/2117 [15.8%] with placebo; ARR +0.9%, 95% CI −1.3% to +2.9%; RR 0.94, 95% CI 0.81 to 1.08; cardiovascular mortality: 265/2111 [12.6%] with ACE inhibitor *v* 298/2117 [14.1%] with placebo; ARR +1.5%, 95% CI −0.6% to +3.3%; RR 0.89, 95% CI 0.76 to 1.04). During the study more people assigned to the placebo received digoxin, diuretics, or ACE inhibitors that were not part of the study protocol, which may have contributed to the lack of significant difference in mortality between the two groups. The RCT found that, compared with placebo, enalapril significantly reduced symptomatic heart failure, hospital admission for heart failure, and fatal or non-fatal myocardial infarction (symptomatic heart failure: 438/2111 [21%] with ACE inhibitor *v* 640/2117 [30%] with placebo; ARR 9.5%, 95% CI 7.0% to 12.0%; RR 0.69, 95% CI 0.61 to 0.77; admission for heart failure: 306/2111 [15%] with ACE inhibitor *v* 454/2117 [21%] with placebo; ARR 7%, 95% CI 5% to 9%; RR 0.68, 95% CI 0.59 to 0.77; fatal or non-fatal myocardial infarction: 7.6% with ACE inhibitor *v* 9.6% with placebo; ARR 2%, 95% CI 0.4% to 3.4%; RR 0.79, 95% CI 0.65 to 0.96).[9,66] The second RCT in asymptomatic people after myocardial infarction with documented left ventricular systolic dysfunction found that an ACE inhibitor (captopril) reduced mortality

and reduced the risk of ischaemic events compared with placebo.[67]
In people with other risk factors: We found one large RCT comparing ramipril 10 mg daily versus placebo, for a mean of 5 years, in 9297 high risk people (people with vascular disease or diabetes plus one other cardiovascular risk factor) who were not known to have left ventricular systolic dysfunction or heart failure.[68] It found that ramipril significantly reduced the risk of heart failure compared with placebo (9.0% with ramipril *v* 11.5% with placebo; RR 0.77, 95% CI 0.67 to 0.87; P < 0.001). Ramipril also reduced the combined risk of myocardial infarction or stroke or cardiovascular death, the risk of these outcomes separately, and all cause mortality (see ACE inhibitors under secondary prevention of ischaemic cardiac events, p 197). During the trial, 496 people had an echocardiography; 2.6% of these people were found to have ejection fraction less than 0.4. Retrospective review of charts found that left ventricular function had been documented in 5193 people; 8.1% had a reduced ejection fraction.

Harms: **In people with asymptomatic left ventricular systolic dysfunction:** The first RCT over 40 months found that a high proportion of people in both groups reported adverse effects (76% with enalapril *v* 72% with placebo).[66] Dizziness or fainting (46% with enalapril *v* 33% with placebo) and cough (34% with enalapril *v* 27% with placebo) were reported more often in the enalapril group (P value not reported). The incidence of angio-oedema was the same in both groups (1.4%). Study medication was permanently discontinued by 8% of the people in the enalapril group versus 5% in the placebo group (P value not reported).

Comment: Asymptomatic left ventricular systolic dysfunction is prognostically important, but we found no prospective studies that have evaluated screening to detect its presence.

QUESTION What are the effects of treatments for diastolic heart failure?

OPTION TREATMENTS FOR DIASTOLIC HEART FAILURE

We found no RCTs in people with diastolic heart failure.

Benefits: We found no systematic review or RCTs in people with diastolic heart failure.

Harms: We found no RCTs.

Comment: The causes of diastolic dysfunction vary among people with diastolic heart failure. Current treatment is empirical, based on the results of small clinical studies and consists of treating the underlying cause and coexistent conditions with interventions optimised for individuals.[6,69,70] RCTs with clinically relevant outcome measures are needed to determine the benefits and harms of treatment in diastolic heart failure.

GLOSSARY

New York Heart Association classification Classification of severity by symptoms. Class I: no limitation of physical activity; ordinary physical activity does not cause undue fatigue or dyspnoea. Class II: slight limitation of physical activity; comfortable at rest, but ordinary physical activity results in fatigue or dyspnoea. Class III: limitation of physical activity; comfortable at rest, but less than ordinary activity causes fatigue or dyspnoea. Class IV: unable to carry out any physical activity without symptoms; symptoms are present even at rest; if any physical activity is undertaken, symptoms are increased.

Substantive changes

Multidisciplinary Four RCTs added;[18–21] categorisation unchanged.

Positive inotropic agents One systematic review added;[36] categorisation unchanged.

β Blockers Two subsequent reports of an already included RCT added;[41,42] categorisation unchanged.

Aldosterone receptor antagonists One RCT added;[50] eplerenone (in people with myocardial infarction complicated by left ventricular dysfunction and heart failure already on medical treatment) recategorised as Likely to be beneficial.

QUESTIONS

INTERVENTIONS

Key Messages

- **Antiplatelet treatment** Systematic reviews have found strong evidence that antiplatelet agents reduce major cardiovascular events over an average of about 2 years compared with control treatment. Systematic reviews have found that antiplatelet agents reduce the risk of arterial occlusion and revascularisation procedures compared with placebo or no treatments. The balance of benefits and harms is in favour of treatment for most people with symptomatic peripheral arterial disease, because as a group they are at much greater risk of cardiovascular events.
- **Exercise** Systematic reviews and subsequent RCTs in people with chronic stable claudication have found that regular exercise at least three times weekly for between 3 and 6 months improves total walking distance and maximal exercise time after 3–12 months compared with no exercise. One RCT found that a "stop smoking and keep walking" intervention increased the maximal walking distance at 12 months compared with usual care.
- **Bypass surgery (*v* thrombolysis in people with acute limb ischaemia)** One systematic review found that surgery reduced amputation rate and pain compared with thrombolysis, but found no significant difference in mortality after 1 year.

Peripheral arterial disease

- **Percutaneous transluminal angioplasty (transient benefit only)** Two small RCTs in people with mild to moderate intermittent claudication found limited evidence that percutaneous angioplasty improved walking distance after 6 months compared with no angioplasty but found no significant difference after 2 or 6 years. Two small RCTs identified by a systematic review and three small additional RCTs in people with femoro–popliteal artery stenoses found no significant difference between angioplasty alone and angioplasty plus stent placement in patency rates, occlusion rates, or clinical improvement. The RCTs may lack power to rule out an important clinical effect.
- **Smoking cessation** RCTs of advice to stop smoking would be considered unethical. The consensus view is that smoking cessation improves symptoms in people with intermittent claudication. One systematic review of observational studies found inconclusive results from stopping smoking, both in terms of increasing absolute claudication distance and reducing the risk of symptom progression compared with people who continue to smoke.
- **Cilostazol** Six RCTs found that cilostazol improved claudication distance at 12 to 24 weeks compared with placebo. However, adverse effects of cilostazol were common in the RCTs, and included headache, diarrhoea, and palpitations. We found limited evidence from one RCT that pentoxifylline reduced absolute claudication distance compared with cilostazol.
- **Bypass surgery (*v* percutaneous transluminal angioplasty)** One systematic review found that surgery improved primary blood vessel patency after 12–24 months compared with percutaneous transluminal angioplasty, but found no significant difference after 4 years. The review found no significant difference in mortality after 12–24 months. Although the consensus view is that bypass surgery is the most effective treatment for people with debilitating symptomatic peripheral arterial disease, we found inadequate evidence from RCTs reporting long term clinical outcomes to confirm this view.
- **Pentoxifylline** One systematic review and one subsequent RCT found insufficient evidence to compare pentoxifylline with placebo. One RCT found that pentoxifylline reduced absolute claudication distance compared with cilostazol.

DEFINITION Peripheral arterial disease arises when there is significant narrowing of arteries distal to the arch of the aorta. Narrowing can arise from atheroma, arteritis, local thrombus formation, or embolisation from the heart or more central arteries. This topic includes treatment options for people with symptoms of reduced blood flow to the leg that are likely to arise from atheroma. These symptoms range from calf pain on exercise (intermittent claudication — see glossary, p 160) to rest pain, skin ulceration, or symptoms of ischaemic necrosis (gangrene) in people with critical limb ischaemia (see glossary, p 160).

INCIDENCE/ PREVALENCE Peripheral arterial disease is more common in people aged over 50 years than in younger people, and is more common in men than women. The prevalence of peripheral arterial disease of the legs (assessed by non-invasive tests) is about 3% in people under the age of 60 years, but rises to over 20% in people over 75 years.[1] The overall annual incidence of intermittent claudication is 1.5–2.6/1000 men and 1.2–3.6/1000 women.[2]

AETIOLOGY/ RISK FACTORS Factors associated with the development of peripheral arterial disease include age, gender, cigarette smoking, diabetes mellitus, hypertension, hyperlipidaemia, obesity, and physical inactivity. The

strongest association is with smoking (RR 2.0–4.0) and diabetes (RR 2.0–3.0).[3] Acute limb ischaemia (see glossary, p 160) may result from thrombosis arising within a peripheral artery or from embolic occlusion.

PROGNOSIS The symptoms of intermittent claudication can resolve spontaneously, remain stable over many years, or progress rapidly to critical limb ischaemia. About 15% of people with intermittent claudication eventually develop critical leg ischaemia, which endangers the viability of the limb. The annual incidence of critical limb ischaemia in Denmark and Italy in 1990 was 0.25–0.45/1000 people.[4,5] Coronary heart disease is the major cause of death in people with peripheral arterial disease of the legs. Over 5 years, about 20% of people with intermittent claudication have a non-fatal cardiovascular event (myocardial infarction or stroke).[6] The mortality rate of people with peripheral arterial disease is two to three times higher than that of age and sex matched controls. Overall mortality after the diagnosis of peripheral arterial disease is about 30% after 5 years and 70% after 15 years.[6]

AIMS OF INTERVENTION To reduce symptoms (intermittent claudication), local complications (arterial leg ulcers, critical leg ischaemia), and general complications (myocardial infarction and stroke).

OUTCOMES **Primary outcome:** Initial claudication distance. **Secondary outcomes:** Absolute claudication distance, generic/disease specific quality of life, clinical end points (intervention rates, post-intervention morbidity/mortality), physiological measures (ankle brachial pressure index), and all cause cardiovascular morbidity/mortality).

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of treatments for people with chronic peripheral arterial disease?

OPTION ANTIPLATELET AGENTS

Systematic reviews have found strong evidence that antiplatelet agents reduce major cardiovascular events over an average of about 2 years compared with control treatment. Systematic reviews have found that antiplatelet agents reduce the risk of arterial occlusion and revascularisation procedures compared with placebo or no treatments. The balance of benefits and harms is in favour of treatment for most people with symptomatic peripheral arterial disease, because as a group they are at much greater risk of cardiovascular events.

Benefits: **Peripheral arterial disease complications:** We found two systematic reviews.[7,8] The first systematic review (search date 1997, 42 RCTs; 9214 people with intermittent claudication [see glossary, p 160], bypass surgery of the leg, or peripheral artery angioplasty) found that antiplatelet treatment significantly reduced the risk of arterial occlusion over 19 months compared with no additional

treatment (arterial occlusion: RRR 30%; P < 0.00001).[8] The second systematic review (search date 1998, 54 RCTs of antithrombotic drugs) found that aspirin significantly reduced arterial occlusion or revascularisation procedures at 3 months compared with placebo (1 RCT, 2810 people: OR at 3 months 0.46, 95% CI 0.27 to 0.77).[7] It found that ticlopidine (2 RCTs, 1302 people) significantly reduced arterial occlusion or revascularisation procedures compared with placebo at up to 7 years (OR 0.62, 95% CI 0.41 to 0.93).[7] **Cardiovascular events:** We found two systematic reviews.[8,9] The first review (search date 1997, 42 RCTs, 9506 people with peripheral arterial disease) found that antiplatelet treatment significantly reduced the combined outcome of vascular death, myocardial infarction, or stroke over an average of 2 years compared with control (280/4844 [6.0%] with antiplatelet treatment *v* 347/4662 [7.0%] with control; RR 0.78, 95% CI 0.67 to 0.90; NNT 61, 95% CI 38 to 153).[8] The second systematic review (search date 1999, 39 RCTs) found that antiplatelet treatment significantly reduced the combined end point of myocardial infarction, stroke, or vascular death compared with control (6.5% with antiplatelet treatment *v* 8.1% with control; OR 0.78, 95% CI 0.63 to 0.96).[9]

Harms: One earlier systematic review (later updated;[8] original search date 1990, 35 RCTs, 8098 people with peripheral arterial disease) found no significant difference between antiplatelet and control treatment in the risk of non-fatal major bleeds (14/2545 [0.55%] *v* 9/2243 [0.40%]; RR 1.37, 95% CI 0.60 to 3.16).[10] The second review (search date 1999, 39 RCTs, 8449 people with peripheral arterial disease) found no significant difference between antiplatelet treatment and placebo in major bleeding (47/4349 [1%] with antiplatelet treatment *v* 33/4100 [< 1%] with placebo; OR 1.40, 95% CI 0.90 to 2.20).[9] The review also found no significant difference between aspirin and other antiplatelet agents in major bleeding (68/3467 [2%] with aspirin *v* 59/3561 [2%] with other antiplatelet agents; RR 1.18, 95% CI 0.84 to 1.67). The number of events was too low to exclude a clinically important increase in major bleeding.[9,10] Across a wide range of people, antiplatelet agents have been found to significantly increase the risk of major haemorrhage (see harms of antiplatelet agents under primary prevention, p 163).

Comment: We found no evidence about the effects of combined clopidogrel and aspirin compared with a single antiplatelet agent in people with peripheral arterial disease. Peripheral arterial disease increases the risk of cardiovascular events, so for most people the risk of bleeding is outweighed by the benefits of regular antiplatelet use.

OPTION EXERCISE

Systematic reviews and subsequent RCTs in people with chronic stable claudication have found that regular exercise at least three times weekly for between 3 and 6 months improves total walking distance and maximal exercise time after 3–12 months compared with no exercise. One RCT found that a "stop smoking and keep walking" intervention increased the maximal walking distance at 12 months compared with usual care.

Benefits:

Walking exercise versus no exercise: We found two systematic reviews comparing exercise versus no exercise in people with chronic stable intermittent claudication (see glossary, p 160) (search dates 1996,[11] and not stated;[12] see comment below) and two subsequent RCTs.[13,14] The first review found that exercise programmes (at least 30 minutes of walking as far as claudication permits, at least 3 times weekly, for 3–6 months in people also being treated with surgery, aspirin, or dipyridamole) significantly increased both the initial claudication distance and the absolute claudication distance (see glossary, p 160) compared with no exercise (initial claudication distance, 4 RCTs; 94 people; mean difference 139 m, 95% CI 31 m to 247 m; absolute claudication distance, 5 RCTs; 115 people; mean difference 179 m, 95% CI 60 m to 298 m) after 3–12 months.[11] Control treatments were placebo tablets (2 RCTs) or "instructed to continue with normal lifestyle". The second review (10 RCTs, including all those in the first review) found that exercise increased maximal exercise time compared with no exercise after 12 weeks to 15 months' follow up (3 RCTs; 53 people: WMD 6.5 minutes, 95% CI 4.4 to 8.7 minutes).[12] The first subsequent RCT (52 people) compared a 24 week programme of initially supervised, regular polestriding (walking exercise using modified ski poles) with a no exercise programme.[13] All participants received standard medical treatment. At 24 weeks, it found that regular exercise significantly increased exercise tolerance compared with no exercise on a controlled work treadmill test (tolerance to exercise, walking at 1.8 miles/hour with a 12% gradient: mean increase in exercise duration about 28 minutes with exercise programme *v* 11 minutes without exercise programme, $P < 0.0001$).[13] The second subsequent RCT (64 people, excluding people with rest pain or exertional angina) compared treadmill exercise three times weekly versus no exercise.[14] People in the exercise group were encouraged to exercise for up to 30 minutes with mild to moderate claudication pain. The RCT found that exercise significantly increased time to onset of claudication compared with no exercise after 12 weeks (3.3 minutes at baseline to 6.2 minutes with exercise *v* 2.9 minutes at baseline to 3.2 minutes with no exercise, $P = 0.01$). **Exercise as part of multicomponent intervention versus usual care placebo:** We found one subsequent RCT (882 men with early peripheral vascular disease identified by population screening), which compared a "stop smoking and keep walking" intervention package versus usual care (see comment).[15] The RCT found that the intervention significantly increased the proportion of men who improved their maximal walking distance at 12 months compared with usual care (23% with intervention *v* 15% with control, $P = 0.008$). It found no significant difference between intervention and usual care in intermittent claudication grade (Edinburgh Claudication Questionnaire: $P = 0.26$). **Different types of exercise:** All the RCTs included in the systematic reviews involved walking exercise. We found one RCT (67 people with moderate to severe intermittent claudication), which compared arm with leg exercise of similar intensity.[16] A third group of 15 people was non-randomly allocated to no exercise. The RCT found no

significant difference between arm and leg exercises in improvement in initial claudication distance or absolute claudication distance, although both groups improved after 6 weeks (improvement in initial claudication distance: 122% with arm exercise *v* 93% with leg exercise; improvement in absolute claudication distance: 147% with arm exercise *v* 150% with leg exercise).

Harms: The reviews and subsequent RCTs did not report on harms of the exercise programmes.[11,13–15,17]

Comment: The RCTs in the systematic reviews had low withdrawal rates, but it is unclear whether those assessing the outcomes were blind to the group allocation. Concealment of the allocation to participants was not possible.[11,12] Most (5/6) exercise programmes in the second review occurred under supervision.[12] In the RCT examining exercise as a part of a multicomponent intervention, participants in the intervention group received an educational package, a brochure about community physiotherapy services, and information on the benefits of smoking cessation. The general practitioners of these participants received a letter plus educational material, including information about effects of smoking cessation, nicotine replacement products, and about peripheral arterial disease, and a recommendation to refer the person to community physiotherapy. The community physiotherapist received details about likely referrals. Physiotherapists provided a community based mobility programme for senior citizens, consisting of supervised or home based exercise sessions and advice to walk at least 30 minutes per day.[15] We found one further systematic review (search date 1993, 21 observational studies or RCTs of exercise, 564 people with peripheral arterial disease).[15] It calculated effects based on the differences in claudication distance before and after exercise treatment, but it made no allowance for any spontaneous improvement that might have occurred in the participants. It reported large increases with exercise in the initial claudication distance (126–351 m) and in the absolute claudication distance (325–723 m), but these estimates were based on observational data. An ongoing Australian RCT is examining the effect of exercise treatment in 1400 men.[12] The benefit from arm exercise remains unconfirmed, but suggests that improved walking may be caused by generally improved cardiovascular function rather than local changes in the peripheral circulation.

OPTION SMOKING CESSATION

RCTs of advice to stop smoking would be considered unethical. The consensus view is that smoking cessation improves symptoms in people with intermittent claudication. One systematic review of observational studies found inconclusive results from stopping smoking, both in terms of increasing absolute claudication distance and reducing the risk of symptom progression compared with people who continue to smoke.

Benefits: RCTs of advice to stop smoking are considered unethical. The consensus view is that smoking cessation improves symptoms in people with intermittent claudication (see glossary, p 160). We found one systematic review (search date 1996, 4 observational

studies, 866 people) of advice to quit cigarette smoking versus no advice.[11] One large observational study in the systematic review found no significant increase in absolute claudication distance (see glossary, p 160) after cessation of smoking.[11] Two other studies found conflicting results about the risk of deteriorating from moderate to severe claudication in people who successfully quit smoking compared with current smokers. The fourth study provided no numerical results. Overall, the review found no good evidence to confirm or refute the consensus view that advice to stop smoking improves symptoms in people with intermittent claudication.

Harms: We found no RCTs.

Comment: None.

OPTION CILOSTAZOL

Six RCTs found that cilostazol improved claudication distance at 12–24 weeks compared with placebo. However, adverse effects of cilostazol were common in the RCTs, and included headache, diarrhoea, and palpitations. We found limited evidence from one RCT that pentoxifylline reduced absolute claudication distance compared with cilostazol.

Benefits: We found no systematic review. **Versus placebo:** We found one non-systematic meta-analysis[18] (search date not stated, 6 RCTs; 1751 people with claudication for 6 months or more, treated between 12 and 24 weeks, 90% were current or previous smokers, 27% had diabetes mellitus, 60% had hypertension) and one additional RCT (see comment below).[19] The meta-analysis (5 published RCTs plus data from 1 RCT held on file by a pharmaceutical company) found that cilostazol 100 mg twice daily significantly increased mean maximal treadmill walking distance and pain free treadmill walking distance compared with placebo (maximal distance: 250 m at baseline to 350 m with cilostazol *v* 252 m at baseline to 302 m with placebo, $P < 0.001$; pain free distance: 127 m at baseline to 210 m with cilostazol *v* 132 m at baseline to 185 m with placebo, $P < 0.001$).[18] One of the RCTs included in the meta-analysis also evaluated a lower dose of cilostazol (100 mg/day).[20] It found no significant difference between this dose of cilostazol and placebo for mean maximum walking distance (167 m with cilostazol 100 mg daily *v* 141 m with placebo; $P = 0.18$). The additional RCT (81 people with stable intermittent claudication for 6 months or more) found that cilostazol 100 mg twice daily significantly increased initial claudication distance and absolute claudication distance (see glossary, p 160) at 12 weeks compared with placebo (intention to treat analysis; initial distance: 112.5 m with cilostazol *v* 84.6 m with placebo, $P = 0.007$; absolute distance: 231.7 m with cilostazol *v* 152.1 m with placebo, $P = 0.002$).[19] **Versus pentoxifylline:** See benefits of pentoxifylline, p 156.[21]

Harms: Harms were not reported in the meta-analysis.[18] Two RCTs included in the meta-analysis found that cilostazol significantly increased the risk of withdrawal from the trial because of adverse effects or concerns about safety compared with placebo (1 RCT: 39/227 [17%] with cilostazol *v* 24/239 [10%] with placebo; RR 1.71, 95%

CI 1.06 to 2.75; NNH 14, 95% CI 8 to 111; 1 RCT: 22.6% with cilostazol 200 mg *v* 12.1% with cilostazol 100 mg *v* 10.1% with placebo, CI not reported).[20,21] The second of these RCTs found that cilostazol 200 mg increased withdrawal due to headache and cardiovascular events compared with placebo (headache: 4.5% with cilostazol 200 mg *v* 0% with placebo; cardiovascular event: 12/133 with cilostazol *v* 5/129 with placebo, CI not reported). The additional RCT found that cilostazol 100 mg increased gastrointestinal complaints compared with placebo (44% *v* 15%, CI not reported).[19] The most common complaints with cilostazol were diarrhoea, loose stools, flatulence, and nausea. Adverse effects of cilostazol included headache (28% *v* 12% with placebo), diarrhoea (19% *v* 8%), abnormal stools (15% *v* 5%), palpitations (17% *v* 2%), and dizziness.[19,21–23] Cilostazol is a phosphodiesterase inhibitor; RCTs have found that other phosphodiesterase inhibitors (milrinone, vesnarinone) are associated with increased mortality in people with heart failure. However, results aggregated from other studies have not found an excess of cardiovascular events with cilostazol.[24]

Comment: The meta-analysis comparing cilostazol with placebo was not based on studies identified systematically, and hence the selection of studies may be biased.[18] However, the meta-analysis included all the studies identified by our own systematic search. Analysis was on an intention to treat basis. Although the overall results of cilostazol compared with placebo indicate a significant effect of cilostazol on increasing walking distance, the RCTs have some weakness in their methods, which may limit the applicability of the results.[19,21–23] Firstly, none of the RCTs evaluated cilostazol beyond 24 weeks. In addition, some of the RCTs had high withdrawal rates after randomisation (up to 29%).[22] In most of the RCTs withdrawals were more common with cilostazol than with placebo.[19–23] To allow for these problems, the authors performed intention to treat analyses using "last available observation carried forward". However, the analyses did not include people with no observations to carry forward, and the effect of the difference in withdrawals between the groups was not explored adequately. If people with worsening claudication were more likely to withdraw, then the observed differences might have been artefactual. We found one further trial, written in Chinese, which compared cilostazol versus dipyridamole in 32 people with peripheral vascular disease and type 2 diabetes.[25] This study is awaiting translation and appraisal for inclusion in *Clinical Evidence*. Although cilostazol appears promising, the balance of its benefits and harms remains unclear.

OPTION PENTOXIFYLLINE

One systematic review and one subsequent RCT found insufficient evidence to compare pentoxifylline versus placebo. One RCT found limited evidence that pentoxifylline reduced absolute claudication distance compared with cilostazol.

Benefits: We found one systematic review (search date 1999)[26] and one subsequent RCT.[21] The review found two RCTs (192 people) that met its reliability criteria for inclusion, but did not pool results.

Neither RCT in the review found any significant difference between pentoxifylline and placebo for change in pain free walking distance or maximum walking distance (follow up time not stated; improvement in mean pain free walking distance for pentoxifylline *v* placebo 15 m, 95% CI −5 to +35 m *v* −30 m, 95% CI −138 to +78 m; improvement in mean maximum walking distance +21 m, 95% CI −10 to +52 m *v* +69 m, 95% CI −44 to 182 m).[26] The subsequent RCT (438 people; see comment below) compared three treatments: pentoxifylline, cilostazol, and placebo.[21] It similarly found no significant difference between pentoxifylline and placebo in the proportion of people who had no change or deterioration in the claudication distance (72/212 [34%] with pentoxifylline *v* 68/226 [30%] with placebo; RR 1.13, 95% CI 0.86 to 1.48).[21] **Versus cilostazol:** The subsequent RCT (see comment below) found that pentoxifylline significantly increased the proportion of people who had no change or deterioration in the claudication distance compared with cilostazol (72/212 [34%] with pentoxifylline *v* 47/205 [23%] with cilostazol; RR 1.48, 95% CI 1.08 to 2.03; ARR 11%, 95% CI 2.4% to 20.0%; NNT 9, 95% CI 5 to 42), the initial claudication distance (202 m with pentoxifylline *v* 218 m with cilostazol; mean difference −16 m; P = 0.0001), and the absolute claudication distance (see glossary, p 160) (308 m with pentoxifylline *v* 350 m with cilostazol; mean difference −42 m; P = 0.0005) after 24 weeks.[21]

Harms: The subsequent RCT found that pentoxifylline significantly increased the risk of withdrawal from the RCT because of adverse effects or concerns about safety compared with placebo (44/232 [19%] with pentoxifylline *v* 24/239 [10%] with placebo; RR 1.89, 95% CI 1.19 to 3.00; NNH 12, 95% CI 7 to 39).[21] Side effects of pentoxifylline included sore throat (14% *v* 7%), dyspepsia, nausea, diarrhoea (8% *v* 5% with placebo; P = 0.31), and vomiting.[21] No life threatening adverse effects of pentoxifylline have been reported, although RCTs have been too small to date to assess this reliably.

Comment: The subsequent RCT had a high withdrawal rate after randomisation, which could be a source of bias (60/232 [26%] with pentoxifylline *v* 61/237 [26%] with cilostazol).[21]

OPTION PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Two small RCTs in people with mild to moderate intermittent claudication found limited evidence that percutaneous angioplasty improved walking distance after 6 months compared with no angioplasty but found no significant difference after 2 or 6 years. Two small RCTs identified by a systematic review and three small additional RCTs in people with femoro–popliteal artery stenoses found no significant difference between angioplasty alone and angioplasty plus stent placement in patency rates, occlusion rates, or clinical improvement. The RCTs may lack power to rule out an important clinical effect.

Benefits: **Percutaneous transluminal angioplasty (PTA) versus no PTA:** We found one systematic review (search date not stated, 2 RCTs, 78 men and 20 women with mild to moderate intermittent claudication [see glossary, p 160]) comparing PTA of the aorto–iliac or

femoro–popliteal arteries with no angioplasty.[27] The first RCT identified by the review found that PTA significantly increased the median claudication distance after 6 months compared with no PTA, but found no significant difference in median claudication distance or quality of life after 2 years (median claudication distance at 6 months: 667 m *v* 172 m, P < 0.05).[28] The second RCT found that PTA significantly increased the absolute claudication distance (see glossary, p 160) at 6 months compared with an exercise programme (130 m *v* 50 m; WMD 80 m), but found no significant difference in absolute claudication distance after 6 years (180 m *v* 130 m; WMD 50 m; P > 0.05).[29,30] **PTA versus PTA plus stents:** We found one systematic review (search date 2002, 2 RCTs, 104 people with aorto–iliac or femoro–popliteal lesions on angiography) and three additional RCTs comparing PTA versus PTA plus stent.[31–34] The RCTs in the systematic review used different techniques and different definitions of restenosis, and data were not pooled.[31] The first RCT in the review (51 people who had received an intravenous bolus of heparin and oral aspirin) found no significant difference in patency assessed by colour flow duplex ultrasound or in occlusion rate (patency: 62% with PTA plus stent *v* 74% with PTA alone, P = 0.22; occlusion rate: 5/24 [21%] with PTA plus stent *v* 7% [2/27] with PTA alone, P = 0.16).[35] The second RCT in the review (53 people who had received an intravenous bolus of heparin and oral aspirin) found no significant difference in patency after 34 months' follow up (62% with PTA plus stent placement *v* 68.4% with PTA).[36] People in the PTA plus stent group also received preoperative intravenous heparin bolus 500 units plus 1 g aspirin. The first additional RCT (279 people with intermittent claudication and iliac artery stenosis) compared PTA plus routine stent placement versus PTA plus selective stent placement.[32] It found no significant difference in short or long term patency rates. The second additional RCT (32 people) found no significant difference between PTA plus stent and PTA alone in "clinical improvement" after 1 year (60% with PTA plus stent *v* 71% with PTA, P = 0.17).[34] The third additional RCT (141 people, 154 limbs) found no significant difference between PTA plus stent placement and PTA alone in patency, as determined by angiography after 1 year (63% of limbs with PTA plus stent placement *v* 63% with PTA).[33] **PTA versus surgery:** See benefits of bypass surgery, p 159.

Harms: The systematic review did not report on harms.[31] Prospective cohort studies have found that PTA complications include puncture site major bleeding (3.4%), pseudoaneurysms (0.5%), limb loss (0.2%), renal failure secondary to intravenous contrast (0.2%), cardiac complications such as myocardial infarction (0.2%), and death (0.2%).[37,38]

Comment: This limited evidence suggests transient benefit from angioplasty compared with no angioplasty. The longer term effects of angioplasty or stent placement on symptoms, bypass surgery, and amputation remain unclear, and the available RCTs are too small to rule out clinically important effects of stent placement. The long

term patency of femoro–popliteal angioplasties is poor, and there is no evidence that the addition of stents confers any additional benefit.[33,34,36] The small number of RCTs and their small sample sizes and methodological weaknesses suggests that further clinical trials are needed to establish clinical effects reliably.

OPTION BYPASS SURGERY

One systematic review found that surgery in people with chronic progressive peripheral arterial disease improved primary patency after 12–24 months compared with percutaneous transluminal angioplasty, but found no significant difference after 4 years. The review found no significant difference in mortality after 12–24 months. One systematic review found that surgery reduced the amputation rate and pain compared with thrombolysis, but it found no significant difference in mortality after 1 year. Although the consensus view is that bypass surgery is the most effective treatment for people with debilitating symptomatic peripheral arterial disease, we found inadequate evidence from RCTs reporting long term clinical outcomes to confirm this view.

Benefits:

Surgery versus exercise: We found no RCTs. **Surgery versus percutaneous transluminal angioplasty (PTA):** We found one systematic review (search date 2001, 2 RCTs, 365 people with chronic progressive peripheral arterial disease), which found no significant difference between surgery and PTA in mortality after 12–24 months (OR 1.08, 95% CI 0.61 to 1.89).[39] The review found that surgery significantly improved patency after 12–24 months compared with PTA (OR 0.62, 95% CI 0.39 to 0.99), but found no significant difference in primary patency after 4 years ($P = 0.14$). The review found no significant difference in mortality or amputation rates. **Surgery versus thrombolysis:** We found one systematic review (search date 2001, 1 RCT in people with acute limb ischaemia [see glossary, p 160]), which compared surgery with thrombolysis using tissue plasminogen activator or urokinase.[39] The review found no significant difference in mortality after 1 year (OR 1.59, 95% CI 0.70 to 3.59). The review found that surgery significantly reduced the amputation rate and significantly reduced the proportion of people reporting ongoing ischaemic pain after 1 year compared with thrombolysis (amputation rate: OR 0.19, 95% CI 0.06 to 0.59; ongoing ischaemic pain: OR 0.30, 95% CI 0.17 to 0.50). **Surgery versus PTA plus stent placement:** We found no RCTs comparing surgery with PTA plus stent placement that reported long term outcomes.

Harms:

Surgery increased early procedural complications compared with PTA. Among people having aorto–iliac surgery, perioperative mortality (within 30 days of the procedure) was 3.3%, and complications having a major health impact occurred in 8.3%.[40] Among people having infrainguinal bypass surgery, perioperative mortality was about 2% and serious complications occurred in 8%.[41] Among people having PTA with or without stent placement, perioperative mortality was about 1% and serious complications occurred in about 5%.[42]

Peripheral arterial disease

Comment: The RCTs are small, have different follow up periods, and assessed different outcomes. Indirect comparisons from observational studies of proxy outcomes (primary patency rates) suggest that for aorto–iliac stenosis or occlusion, greater patency rates 5 years after intervention are achieved with surgery (6250 [89%] people) compared with PTA (1300 [34–85%] people) or compared with combined PTA and stent placement (816 [54–74%] people).[34,37,38] Too few people with infrainguinal lesions were included in the RCTs to provide good evidence about surgical management. Indirect comparisons of proxy outcomes in people with infrainguinal lesions suggest worse results after PTA (after 5 years, patency 38%, range 34–42%) compared with surgery (patency 80%).[43] Although the consensus view is that bypass surgery is the most effective treatment for people with debilitating symptomatic peripheral arterial disease, we found inadequate evidence from RCTs reporting long term clinical outcomes to confirm this view.

GLOSSARY

Absolute claudication distance Also known as the total walking distance; the maximum distance a person can walk before stopping.

Acute limb ischaemia An ischaemic process that threatens the viability of the limb, and is associated with pain, neurological deficit, inadequate skin capillary circulation, and/or inaudible arterial flow signals by Doppler examination. This acute process often leads to hospitalisation.

Critical limb ischaemia results in a breakdown of the skin (ulceration or gangrene) or pain in the foot at rest. Critical limb ischaemia corresponds to the Fontaine classification III and IV (see below).

Fontaine's classification I: asymptomatic; II: intermittent claudication (see below); II-a: pain free, claudication walking more than 200 metres; II-b: pain free, claudication walking less than 200 metres; III: rest/nocturnal pain; IV: necrosis/gangrene.

Initial claudication distance The distance a person can walk before the onset of claudication symptoms.

Intermittent claudication Pain, stiffness, or weakness in the leg that develops on walking, intensifies with continued walking until further walking is impossible, and is relieved by rest.

Substantive changes

Exercise Two RCTs added;[14,15] categorisation unchanged.

Cilostazol One non-systematic meta-analysis added;[18] categorisation unchanged.

Percutaneous transluminal angioplasty One systematic review added;[31] categorisation unchanged.

QUESTIONS

INTERVENTIONS

Primary prevention

Key Messages

Exercise

- **Physical activity** One RCT and many observational studies have found that moderate to high physical activity reduces coronary heart disease and stroke. They also found that sudden death soon after strenuous exercise was rare, more common in sedentary people, and did not outweigh the benefits.

Diet

- **Eating more fruit and vegetables** Observational studies found limited evidence that eating fruit and vegetables reduces ischaemic heart disease and stroke. The size and nature of effects are uncertain.
- **Antioxidants (other than β carotene and vitamin E)** We found insufficient evidence on the effects of vitamin C, copper, zinc, manganese, or flavonoids.
- **β Carotene** Systematic reviews of RCTs found no evidence of benefit from β carotene supplements, and RCTs suggest that they may be harmful.
- **Vitamin E** Systematic reviews of RCTs found no evidence of benefit from vitamin E supplements, and RCTs suggest that they may be harmful.

Smoking

- **Smoking cessation** We found no direct evidence from RCTs that advice to stop smoking reduces cardiovascular risk compared with no advice. However, we found robust evidence from observational studies that smoking is an important risk factor for overall mortality, coronary heart disease, and stroke, and that smoking cessation should therefore be encouraged. The evidence is strongest for stroke.

Antithrombotic drugs

- **Anticoagulant treatment (warfarin)** One RCT found that the benefits and harms of oral anticoagulation (to a target international normalised ratio of 1.5) among people without symptoms of cardiovascular disease were finely balanced, and that net effects were uncertain.
- **Aspirin in low risk people** We found insufficient evidence to identify which asymptomatic individuals would benefit overall and which would be harmed by regular treatment with aspirin. Benefits are likely to outweigh risks in people at higher risk.

Interventions aimed at lowering blood pressure

- **Antihypertensive drug treatments in people with hypertension** Systematic reviews have found that initial treatment with diuretics, angiotensin converting enzyme inhibitors, or β blockers reduce morbidity and mortality compared with placebo, with minimal adverse effects. RCTs found no significant differences in morbidity or mortality among these agents. We found limited evidence from two systematic reviews that diuretics, β blockers, and angiotensin converting enzyme inhibitors reduced coronary heart disease and heart failure more than calcium channel antagonists. However, calcium channel antagonists reduced risk of stroke more than the other agents. One RCT found that a thiazide diuretic reduced cardiovascular events, particularly congestive heart failure, compared with an α blocker. One RCT found that losartan (an angiotensin receptor blocker) reduced cardiovascular events compared with atenolol in people with hypertension and left ventricular hypertrophy.

- **Diuretics in high risk people** Systematic reviews have found that diuretics decrease the risk of fatal and non-fatal stroke, cardiac events, and total mortality compared with placebo. The biggest benefit is seen in people with the highest baseline risk. Systematic reviews have found no significant difference in mortality or morbidity between diuretics and β blockers.
- **Dietary salt restriction** We found no RCTs of the effects of salt restriction on morbidity or mortality. One systematic review has found that a low salt diet may lead to modest reductions in blood pressure compared with a usual diet, with more benefit in people older than 45 years than in younger people.
- **Fish oil supplementation** We found no RCTs examining the effects of fish oil supplementation on morbidity or mortality in people with primary hypertension. One systematic review has found that fish oil supplementation in large doses of 3 g daily modestly lowers blood pressure.
- **Low fat, high fruit and vegetable diet** We found no systematic review and no RCTs examining the effects of low fat, high fruit and vegetable diet on morbidity or mortality of people with raised blood pressure. One RCT found that a low fat, high fruit and vegetable diet modestly reduced blood pressure compared with control diet.
- **Physical activity** We found no RCTs in people with primary hypertension examining the effects of exercise on morbidity or mortality. One systematic review has found that aerobic exercise reduces blood pressure compared with no exercise.
- **Potassium supplementation** We found no RCTs examining the effects of potassium supplementation on morbidity or mortality in people with primary hypertension. One systematic review has found that a daily potassium supplementation of about 60 mmol (2 g, which is about the amount contained in 5 bananas) reduces blood pressure by small amounts.
- **Smoking cessation** Observational studies have found that smoking is a risk factor for cardiovascular disease. We found no direct evidence in people with hypertension that stopping smoking decreases blood pressure.
- **Weight loss** We found no RCTs examining the effects of weight loss on morbidity and mortality. One systematic review and additional RCTs have found that modest weight reduction in obese people with hypertension leads to a modest reduction in blood pressure.
- **Calcium supplementation** We found insufficient evidence about the effects of calcium supplementation on blood pressure, morbidity, or mortality specifically in people with hypertension. One systematic review in people with and without hypertension found that calcium supplementation may reduce systolic blood pressure by a small amount.
- **Magnesium supplementation** We found no RCTs examining the effects of magnesium supplementation on morbidity or mortality in people with hypertension. We found limited and conflicting evidence on the effect of magnesium supplementation on blood pressure in people with hypertension and normal magnesium concentrations.
- **Reduced alcohol consumption** We found no RCTs examining the effects of reducing alcohol consumption on morbidity or mortality. One systematic review in moderate drinkers (25–50 drinks/week) found inconclusive evidence regarding effects of alcohol reduction on blood pressure.

Primary prevention

Interventions aimed at lowering cholesterol

- **Cholesterol reduction in high risk people** Systematic reviews have found that reducing cholesterol concentration in asymptomatic people lowers the rate of cardiovascular events. RCTs have found that the magnitude of the benefit is related to an individual's baseline risk of cardiovascular events, and to the degree of cholesterol lowering, rather than to the individual's cholesterol concentration.
- **Low fat diet** Systematic reviews and RCTs have found that combined use of cholesterol lowering diet and lipid lowering drugs reduces cholesterol concentration more than lifestyle interventions alone.

DEFINITION Primary prevention in this context is the long term management of people at increased risk but with no evidence of cardiovascular disease. Clinically overt ischaemic vascular disease includes acute myocardial infarction, angina, stroke, and peripheral vascular disease. Many adults have no symptoms or obvious signs of vascular disease, even though they have atheroma and are at increased risk of ischaemic vascular events because of one or more risk factors (see aetiology below). In this topic, we have taken primary prevention to apply to people who have not had clinically overt cardiovascular disease, or people at low risk of ischaemic cardiovascular events. Prevention of cerebrovascular events is discussed in detail elsewhere in *Clinical Evidence* (see stroke prevention topic, p 257).

INCIDENCE/ PREVALENCE According to the World Health Report 1999, ischaemic heart disease was the leading single cause for death in the world, the leading single cause for death in high income countries, and second to lower respiratory tract infections in low and middle income countries. In 1998 it was still the leading cause for death, with nearly 7.4 million estimated deaths a year in member states of the World Health Organization. This condition had the eighth highest burden of disease in the low and middle income countries (30.7 million disability adjusted life years).[1]

AETIOLOGY/ RISK FACTORS Identified major risk factors for ischaemic vascular disease include increasing age, male sex, raised low density lipoprotein cholesterol, reduced high density lipoprotein cholesterol, raised blood pressure, smoking, diabetes, family history of cardiovascular disease, obesity, and sedentary lifestyle. For many of these risk factors, observational studies show a continuous gradient of increasing risk of cardiovascular disease with increasing levels of the risk factor, with no obvious threshold level. Although by definition event rates are higher in high risk people, most ischaemic vascular events that occur in the population are in people with intermediate levels of absolute risk because there are many more of them than there are people at high risk; see Appendix 1.[2]

PROGNOSIS A study carried out in Scotland found that about half of people who suffer an acute myocardial infarction die within 28 days, and two thirds of acute myocardial infarctions occur before the person reaches hospital.[3] The benefits of intervention in unselected people with no evidence of cardiovascular disease (primary prevention) are small because in such people the baseline risk is small. However,

absolute risk of ischaemic vascular events varies widely, even among people with similar levels of blood pressure or cholesterol. Estimates of absolute risk can be based on simple risk equations or tables; see Appendix 1.[4,5]

AIMS OF INTERVENTION To reduce morbidity and mortality from cardiovascular disease, with minimum adverse effects.

OUTCOMES Incidence of fatal and non-fatal cardiovascular events (including coronary, cerebrovascular, renal, and eye disease, and heart failure). Surrogate outcomes include changes in levels of individual risk factors, such as blood pressure.

METHODS *Clinical Evidence* search and appraisal November 2002.

QUESTION Does physical activity reduce the risk of vascular events in asymptomatic people?

Charles Foster and Michael Murphy

OPTION PHYSICAL ACTIVITY

We found one RCT and strong observational evidence that moderate to high levels of physical activity reduce the risk of non-fatal and fatal coronary heart disease and stroke. People who are physically active (those who undertake moderate levels of activity daily or almost daily, e.g. walking) typically experience 30–50% reductions in relative risk of coronary heart disease compared with people who are sedentary after adjustment for other risk factors. The absolute risk of sudden death after strenuous activity is small (although greatest in people who are habitually sedentary) and does not outweigh observed benefits.

Benefits:

Effects of physical activity on coronary heart disease: One systematic review (search date 2001)[6] identified one RCT (196 women aged 50–65 years with no previous heart disease). The RCT found that an exercise programme consisting of regular walking significantly reduced coronary heart disease (CHD) compared with no exercise programme at 10 years (RR for participants reporting that their physician had diagnosed heart disease 0.18, 95% CI 0.04 to 0.80). The systematic review also identified 11 further observational studies, although it was not clear that they were only in people with no previous heart disease (see comment below). This systematic review[6] and three further systematic reviews (search dates 1995[7] and not stated[8,9]) evaluated observational studies and found increased risk of CHD in sedentary compared with active people. Since 1992, 17 large, well conducted prospective, non-randomised studies, with follow up periods ranging from 18 months to 29 years, have specifically examined the association between physical activity and risk of non-fatal or fatal CHD.[10–26] The studies found that risk declined with increasing levels of physical activity (for examples of activity levels see table 1, p 193) (AR for CHD death in people with sedentary lives [rare or no physical activity] 70/10 000 person-years *v* 40/10 000 person-years in people with the highest level of activity [> 3500 kcal/week]; absolute benefit of high levels of physical activity 30 lives saved/10 000 person-years). One subsequent observational study of women found that at least 1 hour of

walking a week predicted lower risk compared with no walking a week (OR 0.49, 95% CI 0.28 to 0.86).[27] **Effects of physical fitness on coronary heart disease:** We found no RCTs. One systematic review (search date not stated)[28] identified seven large, well designed, prospective, non-randomised studies of the effects of physical fitness on CHD. All used reproducible measures of physical fitness. Five studies adjusted for other CHD risk factors. These found an increased risk of death from CHD in people with low levels of physical fitness compared with those with high levels (RR of death lowest quartile *v* highest quartile ranged from 1.2–4.0). Most studies reported only baseline measures of physical fitness and thus not could assess effects of changes in fitness. One large follow up study found lower risk among people who increased their fitness level (RR for cardiovascular disease death compared with those whose level of fitness did not change 0.48, 95% CI 0.31 to 0.74).[29] One study showed that high fitness levels seem to slow down the development of atherosclerosis compared with lower levels of fitness.[30] A new meta-analysis examining fitness and activity as separate risk factors for CHD concluded that being unfit warrants consideration as a risk factor.[31] **Effects of physical activity on stroke:** We found no RCTs and no systematic review of observational studies. We found 12 observational studies (published between 1990 and 1999), based on people with a total of 3680 strokes among North American, Japanese, and European populations.[32–45] Most of these found that moderate activity was associated with reduced risk of stroke compared with inactivity (RR of stroke, moderate activity *v* inactivity about 0.5). One cohort study from Japan found that "heavy" physical activity reduced the risk of stroke compared with "moderate" activity (RR of stroke, "heavy" *v* "moderate" activity about 0.3; $P < 0.05$).[43] In most studies, the benefits were greater in older people and in men. Most studies were conducted in white men in late middle age, which potentially limits their applicability to other groups of people. The results usually persisted after adjustment for other known risk factors for stroke (blood pressure, blood lipids, body mass index, and smoking) and after exclusion of people with pre-existing diseases that might limit physical activity and increase risk of stroke. The more recent studies found maximum reduction in the risk of stroke with moderate as opposed to high levels of physical exercise levels. See stroke prevention topic, p 257.

Harms: The identified studies provided no direct evidence of harm from exercise. Injury is likely to be the most common adverse event, but we found too few population data to measure its risk. We found two studies in people who had experienced non-fatal myocardial infarction, conducted in the USA and Germany. Each involved more than 1000 events and found that 4–7% of these events occurred within 1 hour of strenuous physical activity.[46–48] Strenuous activity was estimated to have raised the relative risk of acute myocardial infarction between two- and sixfold in the hour after activity, with risks returning to baseline after that. However, the absolute risk remained low, variously estimated at six deaths per 100 000 middle aged men a year[49] or 0.3–2.7 events per 10 000 person-hours of exercise.[50] Both studies found that the relative risk of acute

myocardial infarction after strenuous activity was much higher in people who were habitually sedentary (RR 107, 95% CI 67 to 171) compared with the relative risk in those who engaged in heavy physical exertion on five or more occasions a week (RR 2.4, 95% CI 1.5 to 3.7).[47]

Comment: The most recent systematic review (search date 2001) also identified nine prospective cohort studies and two case-control studies in about 20 000 older adults, mostly men.[6] It reported that increased physical activity or cardiovascular fitness significantly reduced CHD in five out of 11 studies, and non-significantly reduced CHD in three further studies.[6] Findings from observational studies identified by all the reviews should be interpreted with caution. The studies varied in definitions of levels of activity and fitness. The level of activity or fitness experienced by each person was not experimentally assigned by an investigator (as in an RCT) but resulted from self selection. Active (or fit) people are likely to differ from inactive (or unfit) people in other ways that also influence their risk of cardiovascular disease. Confounding of this type can be partially controlled by adjustment for other known risk factors (such as age, smoking status, and body mass index), but it is likely that some residual confounding will remain, which could overestimate the effect of exercise. The studies have found that the absolute risk of sudden death during or immediately after physical activity is small and does not outweigh the observed benefits.

QUESTION What intensity and frequency of physical activity improves fitness?

Charles Foster and Michael Murphy

Small RCTs found that at least moderate intensity exercise (equivalent to brisk walking) is necessary to improve fitness. We found insufficient evidence on the effects of short bouts of exercise several times daily compared with longer daily bouts.

Benefits: **Intensity:** We found no systematic review. Numerous small RCTs of varying quality have been conducted in different subpopulations. In general, these found that over a period of 6–12 months low intensity activity programmes produced no measurable changes in maximum oxygen consumption (Vo_2max), whereas moderate intensity activity programmes (equivalent to brisk walking) typically produced improvements of 20% in oxygen consumption in sedentary people. Table 1, p 193 gives the intensity of effort required for a range of physical activities. Two recent RCTs compared structured aerobic exercise (such as step and aerobics classes) with lifestyle activity programmes (such as regular walking and using stairs instead of lifts) among obese women[51] and sedentary men and women.[52] Both studies reported similar, significant changes in measures of cardiovascular fitness and blood pressure with each intervention, and these changes were sustained for at least 2 years after intervention. One prospective follow up study of women previously involved in a randomised trial of physical activity found that women who start a programme of regular walking maintain higher levels of physical activity 10 years after the intervention.[53]

Frequency: We found no systematic review. One RCT (36 men) compared 8 weeks of a single daily session of 30 minutes of exercise versus three daily sessions of 10 minutes each.[54] It found no significant difference in fitness between groups after the end of the programme.

Harms: None reported.

Comment: None.

QUESTION **What are the effects of dietary interventions on the risk of myocardial infarction and stroke in asymptomatic people?**

Bazian Ltd

OPTION **EATING MORE FRUIT AND VEGETABLES**

Cohort studies have found that eating more fruit and vegetables reduces the risk of myocardial infarction and stroke. The size and nature of any protective effect is uncertain.

Benefits: **Ischaemic heart disease:** We found no RCTs. We found three systematic reviews of observational studies.[55–58] With addition of recently published studies[59–67] to those reported in the first review (search date 1995),[55] a protective association was observed for ischaemic heart disease in 14/25 (56%) cohort studies. In the second review (search date not stated),[56] the authors calculated a summary measure of the protective association of 15% between those above the 90th centile and those below the 10th centile for fruit and vegetable consumption. In the third review (search date 1998),[57,58] the authors estimated that increased intake of fruit and vegetables of about 150 g daily was associated with a reduced risk of coronary heart disease of 20–40%. The validity of these estimates has been questioned. One large, high quality cohort study found that eating more vegetables was associated with decreased coronary mortality (≥ 117 g vegetables/day *v* < 61 g vegetables/day: RR 0.66, 95% CI 0.46 to 0.96); for fruit, the association was more modest and not significant (≥ 159 g fruit/day *v* < 75 g fruit/day: RR 0.77, 95% CI 0.54 to 1.12).[68] **Stroke:** We found no RCTs but we found two systematic reviews examining the evidence from observational studies for stroke.[55,57,58] With addition of recently published studies[59–66,68] to those reported in the first review (search date 1995),[55] a protective association was observed in 10/16 (63%) cohort studies for stroke. In the second review (search date not stated),[57,58] the authors estimated that increased intake of fruit and vegetables of about 150 g daily was associated with a reduced risk of stroke of 0–25%. The basis for this estimate is not clear. One large, high quality cohort study in US health professionals found that increased fruit and vegetable intake was associated with a decreased risk of ischaemic stroke (RR per daily serving of fruit and vegetables 0.94, 95% CI 0.90 to 0.99; RR in the fifth of the population eating the most fruit and vegetables *v* the fifth eating the least 0.69, 95% CI 0.52 to 0.92).[69]

Harms: None were identified.

Comment: Lack of RCT evidence and deficiencies in the data available from observational studies mean that the size and nature of any real protective effect is uncertain.[70,71] The observed associations could be the result of confounding as people who eat more fruit and vegetables often come from higher socioeconomic groups and have other healthy lifestyles.[72]

OPTION ANTIOXIDANTS

Systematic reviews of RCTs found no evidence of benefit from β carotene or vitamin E supplements, and RCTs suggest that they may be harmful. We found insufficient evidence about effects of other antioxidants.

Benefits: **β Carotene:** We found two systematic reviews of prospective studies and RCTs (search date not stated, published in 1997[73] and search date 2001[74]). The most recent systematic review (6 RCTs, 86 056 people) found no significant difference between β carotene and control for cardiovascular disease (OR 1.02, 95% CI 0.96 to 1.08).[74] However, β carotene was combined with other antioxidants in some treatment groups, and it was not clear whether the systematic review accounted for effects of multiple interventions compared with control. It was also not clear whether all control groups received placebo only. **Vitamin C (ascorbic acid):** We found three systematic reviews (search dates not stated,[73] 1996, [75] and 2001[74]). The most recent systematic review (2 RCTs; 16 700 people, most people from 1 large RCT) found no significant difference between vitamin C and control for cardiovascular disease risk (OR 0.98, 95% CI 0.75 to 1.26).[74] However, vitamin C was combined with molybdenum in the larger trial, which may have contributed to the observed effect. It was also not clear from the review whether all control groups received placebo only. **Vitamin E:** We found two systematic reviews and additional prospective studies.[72,74] The most recent systematic review (4 RCTs, 48 346 people) compared vitamin E versus control.[74] It found no significant difference between vitamin E and control for cardiovascular disease (OR 0.96, 95% CI 0.88 to 1.04). However, vitamin E was combined with other antioxidants in some treatment groups, which may have contributed to the observed effect. It was also not clear whether all control groups received placebo only. **Antioxidant minerals:** We found little epidemiological evidence about the cardioprotective effect of copper, zinc, or manganese on the heart.[76] Cohort studies reported an increased risk of ischaemic heart disease in people with low blood selenium concentrations.[77] Most of these were carried out in Finland, a country with low intakes of antioxidants.[78] **Flavonoids:** We found no systematic review. We found five cohort studies,[78–82] three of which reported a reduced risk of ischaemic heart disease with increased flavonoid intake.[78–80] One of four observational studies reported a reduced risk of stroke with increased flavonoid intake.[58,79,83,84]

Harms: One of the RCTs identified in the most recent systematic review found that vitamin E may increase death from subarachnoid haemorrhage compared with control (RR for subarachnoid haemorrhage

1.50, 95% CI 0.97 to 2.32; RR death 2.81, 95% CI 1.37 to 5.79).[74,85] Pooled analysis of four of the β carotene RCTs found that β carotene may increase cardiovascular mortality (RR for cardiovascular death 1.12, 95% CI 1.04 to 1.22).[86] Effects may be dependent on the isomer or dose.[87,88]

Comment: RCTs of antioxidants such as β carotene and vitamin E have not found any evidence of benefit. Routine use of antioxidant supplements is not justified by the currently available evidence. Most of the RCTs identified in the most recent systematic review were designed to investigate whether antioxidants protect against cancer, and not specifically to investigate their effect on cardiovascular disease. Some of the trials were limited to smokers and there may be an interaction between antioxidants and smoking. Further RCTs of antioxidant supplementation are under way.[89]

QUESTION By how much does smoking cessation, or avoiding starting smoking, reduce risk?

Julian J Nicholas

OPTION SMOKING CESSATION

We found no direct evidence from RCTs that advice to stop smoking reduces cardiovascular risk compared with no advice. However, we found robust evidence from observational studies that smoking is an important risk factor for overall mortality, coronary heart disease, and stroke, and that smoking cessation should therefore be encouraged. The evidence is strongest for stroke.

Benefits: We found one RCT of advice encouraging smoking cessation in 1445 men aged 40–59 years that found that more men given advice to stop smoking gave up cigarettes (mean absolute reduction in men continuing to smoke after advice *v* control 53%).[90] The RCT found no evidence that men given advice to stop smoking had a significantly lower mortality from coronary heart disease (CHD; RR 0.82, 95% CI 0.57 to 1.18). However, it is not clear how many people advised to stop smoking actually quit. The wide confidence intervals mean that there could have been anything from a 43% decrease to an 18% increase in rates of CHD death in men given advice to quit, regardless of whether they actually gave up smoking. We found strong observational evidence that smoking is an important risk factor for cardiovascular disease. Several large cohort studies examining the effects of smoking have been reviewed extensively by the US Surgeon General[91] and the UK Royal College of Physicians.[92] The reviews concluded that cigarette smoking was causally related to disease and that smoking cessation substantially reduced the risk of cancer, respiratory disease, CHD, and stroke. **Death from all causes:** The longest prospective cohort study, in 34 439 male British doctors whose smoking habits were periodically assessed over 40 years (1951–1991), found a strong association between smoking and increased mortality.[93] It found that smokers were about three times more likely to die in middle age (45–64 years) and twice as likely to die in older age (65–84 years)

compared with lifelong non-smokers (CI not reported). The prospective nurses' health study followed 117 001 middle aged female nurses for 12 years.[94] It found that the total mortality in current smokers was nearly twice that in lifelong non-smokers (RR of death 1.87, 95% CI 1.65 to 2.13). **Coronary heart disease:** One review (published in 1990) identified 10 cohort studies, involving 20 million person-years of observation.[91] All studies found a higher incidence of CHD among smokers (pooled RR of death from CHD compared with non-smokers 1.7, CI not reported). People smoking more than 20 cigarettes daily were more likely to have a coronary event (RR 2.5, CI not provided).[92] Middle aged smokers were more likely to experience a first non-fatal acute myocardial infarction compared with people who had never smoked (RR in men 2.9, 95% CI 2.4 to 3.4; RR in women 3.6, 95% CI 3.0 to 4.4).[95,96] **Stroke:** One systematic review (search date 1998) found 32 studies (17 cohort studies with concurrent or historical controls, 14 case control studies, and one hypertension intervention RCT).[97] It found good evidence that smoking was associated with an increased risk of stroke (RR of stroke in cigarette smokers *v* non-smokers 1.5, 95% CI 1.4 to 1.6). Smoking was associated with an increased risk of cerebral infarction (RR 1.92, 95% CI 1.71 to 2.16) and subarachnoid haemorrhage (RR 2.93, 95% CI 2.48 to 3.46), and a reduced risk of intracerebral haemorrhage (RR 0.74, 95% CI 0.56 to 0.98). The relative risk of stroke in smokers compared with non-smokers was highest in those aged under 55 years (RR 2.90, 95% CI 2.40 to 3.59) and lowest in those aged over 74 years (RR 1.11, 95% CI 0.96 to 1.28).

Harms: We found no evidence that stopping smoking increases mortality in any subgroup of smokers.

Comment: We found no evidence of publication or other overt bias that may explain the observed association between smoking and stroke. There was a dose related effect between the number of cigarettes smoked and the relative risk for stroke, consistent with a causal relation. The absolute risk reduction from stopping smoking will be highest for those with the highest absolute risk of vascular events. Effects on quit rates of different methods of encouraging people to stop smoking are discussed elsewhere in *Clinical Evidence* (see changing behaviour topic, p 98).

QUESTION How quickly do risks diminish when smokers stop smoking?

Julian J Nicholas

OPTION STOPPING SMOKING: RISK REDUCTION

Observational studies have found that the risk of death and cardiovascular events falls when people stop smoking. The risk can take many years to approach that of non-smokers, particularly in those with a history of heavy smoking.

Benefits: **Death from all causes:** In people who stopped smoking, observational studies found that death rates fell gradually to lie between those of lifelong smokers and people who had never smoked.

Estimates for the time required for former smokers to bring their risk of death in line with people who had never smoked varied among studies but may be longer than 15 years.[98] Actuarial projections from one study among British doctors predicted that life expectancy would improve even among people who stopped smoking in later life (≥ 65 years).[93] **Coronary heart disease:** Observational studies found that, in both male and female ex-smokers, the risk of coronary events rapidly declined to a level comparable with that of people who had never smoked after 2–3 years and was independent of the number of cigarettes smoked before quitting.[91] **Stroke:** The US Surgeon General's review of observational studies found that the risk of stroke decreased in ex-smokers compared with smokers (RR of stroke, smokers *v* ex-smokers 1.2, CI not reported) but remained raised for 5–10 years after cessation compared with those who had never smoked (RR of stroke, ex-smokers *v* never smokers 1.5, CI not reported).[91] One recent study in 7735 middle aged British men found that 5 years after smoking cessation the risk of stroke in previously light smokers (< 20 cigarettes/day) was identical to that of lifelong non-smokers, but the risk in previously heavy smokers (> 20 cigarettes/day) was still raised compared with lifelong non-smokers (RR of stroke, previously heavy smokers *v* never smokers 2.2, 95% CI 1.1 to 4.3).[99] One observational study in 117 001 middle aged female nurses also found a fall in risk on stopping smoking and found no difference between previously light and previously heavy smokers (RR in all former smokers 2–4 years after stopping smoking 1.17, 95% CI 0.49 to 2.23).[94]

Harms: We found no evidence that stopping smoking increases mortality in any subgroup of smokers.

Comment: For a review of the evidence on methods of changing smoking behaviour, see secondary prevention of ischaemic cardiac events, p 197.

QUESTION What are the effects of lifestyle changes in asymptomatic people with primary hypertension?

Michael Pignone

OPTION PHYSICAL ACTIVITY

One systematic review has found that aerobic exercise reduces blood pressure.

Benefits: We found no RCTs in people with primary hypertension examining the effects of exercise on morbidity, mortality, or quality of life. One systematic review (search date 2001, 54 RCTs, 2419 sedentary adults aged > 18 years) examined the effects on blood pressure of at least 2 weeks of regular exercise compared with no exercise.[100] Compared with non-exercising control groups, groups randomised to aerobic exercise reduced their systolic blood pressure by 3.8 mm Hg (95% CI 2.7 mm Hg to 5.0 mm Hg) and diastolic blood pressure by 2.6 mm Hg (95% CI 1.8 mm Hg to 3.4 mm Hg). Reductions in blood pressure were seen in hypertensive and non-hypertensive people, and in overweight and normal weight people.

RCTs with interventions lasting longer than 6 months in adults aged 45 years or over with hypertension found non-significant mean reductions in blood pressure, with wide confidence intervals (systolic reduction 0.8 mm Hg, 95% CI 5.9 mm Hg reduction to 4.2 mm Hg increase).[101]

Harms: Musculoskeletal injuries can occur, but their frequency was not documented.

Comment: Many adults find aerobic exercise programmes difficult to sustain. The clinical significance of the observed reductions in blood pressure is uncertain. The type and amount of exercise most likely to result in benefits are unclear, with some recent studies showing some benefits with simple increases in lifestyle activity. One cohort study (173 men with hypertension) found that "regular heavy activity several times weekly" compared with no or limited spare time physical activity reduced all cause and cardiovascular mortality (all cause mortality RR 0.43, 95% CI 0.22 to 0.82; cardiovascular mortality RR 0.33, 95% CI 0.11 to 0.94).[102]

OPTION LOW FAT, HIGH FRUIT AND VEGETABLE DIET

We found no systematic review and no RCTs examining the effects of low fat, high fruit and vegetable diet on morbidity or mortality in people with primary hypertension. One RCT found that a low fat, high fruit and vegetable diet modestly reduced blood pressure.

Benefits: We found no systematic review and no RCTs examining the effects of low fat, high fruit and vegetable diet on morbidity or mortality in people with primary hypertension. For evidence in asymptomatic people in general see question on effects of dietary interventions, p 170. One RCT (459 adults with systolic blood pressures of < 160 mm Hg and diastolic blood pressures of 80–90 mm Hg) compared effects on blood pressure of three diets (control diet low in both magnesium and potassium *v* fruit and vegetable diet high in both potassium and magnesium *v* combination of the fruit and vegetable diet with a low fat diet high in both calcium and protein).[103] After 8 weeks the fruit and vegetable diet reduced systolic and diastolic blood pressure compared with the control diet (mean change in systolic blood pressure –2.8 mm Hg, 97.5% CI –4.7 mm Hg to –0.9 mm Hg; mean change in diastolic blood pressure –1.1 mm Hg, 97.5% CI –2.4 mm Hg to +0.3 mm Hg). The combination diet also reduced systolic and diastolic blood pressure compared with the control diet (mean change in systolic blood pressure –5.5 mm Hg, 97.5% CI –7.4 mm Hg to –3.7 mm Hg; mean change in diastolic blood pressure –3.0 mm Hg, 97.5% CI –4.3 to –1.6 mm Hg).[103]

Harms: We found no direct evidence that a low fat, high fruit and vegetable diet is harmful.

Comment: The RCT was of short duration and people were supplied with food during the intervention period.[103] Other studies have found that long term maintenance of particular diets is difficult for many people, although low fat, high fruit and vegetable diets may have multiple benefits (see changing behaviour, p 98).

OPTION REDUCED ALCOHOL CONSUMPTION

One systematic review found inconclusive evidence regarding effects of alcohol reduction on blood pressure among people with primary hypertension and moderate to high alcohol intake.

Benefits: We found no RCTs examining the effects of reducing alcohol consumption on morbidity or mortality in people with primary hypertension. Over 60 population studies have reported associations between alcohol consumption and blood pressure. The relation was found to be generally linear, although several studies reported a threshold effect at about two to three standard drinks daily.[104] Any adverse effects of up to two drinks daily on blood pressure was found to be either small or non-existent. One systematic review (search date 1999, 7 RCTs, 751 people with hypertension; mainly men) found that data were inconclusive on the benefits of reducing alcohol among moderate to heavy drinkers (25–50 drinks/week).[105]

Harms: We found no direct evidence that reducing alcohol intake to as few as two drinks daily was harmful.

Comment: Most data were from observational studies. RCTs were small and lacked reliable information about adherence. Substantial reductions in alcohol use in both control and intervention groups were observed, with limited ability to detect differences between groups.

OPTION SALT RESTRICTION

One systematic review has found that salt restriction may lead to modest reductions in blood pressure, with more benefit in people older than 45 years than in younger people.

Benefits: We found no RCT examining the effects of salt restriction on morbidity or mortality in people with primary hypertension. We found one systematic review (search date 1997, 58 RCTs, 2161 people with hypertension, age 23–73 years)[106] and two subsequent RCTs,[107,108] which examined the effects of salt restriction on blood pressure. Interventions were low salt diets with or without weight reduction. People in the control groups took their usual diet. Changes in salt intake varied among RCTs in the systematic review; a mean reduction in sodium intake of 118 mmol (6.7 g) daily for 28 days led to reductions of 3.9 mm Hg (95% CI 3.0 mm Hg to 4.8 mm Hg) in systolic blood pressure and 1.9 mm Hg (95% CI 1.3 mm Hg to 2.5 mm Hg) in diastolic blood pressure.[106] One RCT (875 people with hypertension, age 60–80 years, duration 30 months) found that a mean decrease in salt intake of about 40 mmol (2.4 g) daily reduced systolic blood pressure by 2.6 mm Hg (95% CI 0.4 mm Hg to 4.8 mm Hg) and diastolic blood pressure by 1.1 mm Hg (95% CI 0.3 mm Hg rise in diastolic to 2.5 mm Hg fall).[107] Another RCT (412 people with systolic/diastolic blood pressure > 120/80 mm Hg, mean age 48 years, duration 30 days) that tested three different target levels of sodium intake (150, 100, and 50 mmol/day [8.6, 5.7, and 2.9 g/day]) found significantly lower systolic blood pressure levels with lower sodium

intakes.[108] An earlier systematic review (search date 1994) identified 28 RCTs in 1131 people with hypertension. It found that lesser reductions of 60 mmol (3.4 g) daily led to smaller reductions in systolic/diastolic blood pressure of 2.2/0.5 mm Hg and found greater effects in RCTs in which mean age was over 45 years (6.3/2.2 mm Hg).[109]

Harms: We found no direct evidence that low salt diets may increase morbidity or mortality.

Comment: Small RCTs tended to report larger reductions in systolic and diastolic blood pressure than larger RCTs. This may be explained by publication bias or less rigorous methodology in small RCTs.[109]

OPTION SMOKING CESSATION

We found no direct evidence that stopping smoking decreases blood pressure in people with hypertension. However, we found robust epidemiological data that smoking is an important risk factor for cardiovascular disease.

Benefits: We found no direct evidence that stopping smoking reduces blood pressure in people with hypertension, although we found good evidence that smoking is an important risk factor for cardiovascular disease (see question on how much does smoking cessation, or avoiding starting smoking, reduce risk, p 172).

Harms: We found insufficient evidence in this context.

Comment: None.

OPTION WEIGHT LOSS

One systematic review and additional RCTs have found that modest weight reductions of 3–9% of body weight are achievable in motivated middle aged and older adults, and lead to modest reductions in blood pressure in obese people with hypertension. Many adults find it difficult to maintain weight loss.

Benefits: We found no RCTs examining the effects of weight loss on morbidity and mortality in people with primary hypertension. We found one systematic review (search date 1998, 18 RCTs, 2611 middle aged people, mean age 50 years, mean weight 85 kg, mean systolic/diastolic blood pressure 152/98 mm Hg, 55% men)[110] and two subsequent RCTs[111,112] that examined the effects of weight loss on blood pressure. In the systematic review, caloric intakes ranged from 450–1500 kcal daily. Most diets led to weight reductions of 3–9% of body weight. Combined data from the six RCTs that did not vary antihypertensive regimens during the intervention period found that reducing weight reduced systolic and diastolic blood pressures (mean reduction in systolic pressure, weight loss *v* no weight loss 3.0 mm Hg, 95% CI 0.7 mm Hg to 6.8 mm Hg; mean reduction in diastolic blood pressure, weight loss *v* no weight loss 2.9 mm Hg, 95% CI 0.1 mm Hg to 5.7 mm Hg). RCTs that allowed adjustment of

antihypertensive regimens found that lower doses and fewer antihypertensive drugs were needed in the weight reduction groups compared with control groups. The two subsequent RCTs found that sustained weight reduction of 2–4 kg significantly reduced systolic blood pressure at 1–3 years by about 1 mm Hg.[111,112]

Harms: We found no direct evidence that intentional gradual weight loss of less than 10% of body weight is harmful in obese adults with hypertension.

Comment: None.

OPTION POTASSIUM SUPPLEMENTATION

One systematic review has found that a daily potassium supplementation of about 60 mmol (2 g, which is about the amount contained in 5 bananas) is feasible for many adults and reduces blood pressure by small amounts.

Benefits: We found no RCTs examining the effects of potassium supplementation on morbidity or mortality in people with primary hypertension. One systematic review (search date 1995, 21 RCTs, 1560 adults with hypertension, age 19–79 years) compared the effects on blood pressure of potassium supplements (60–100 mmol/day [2–3 g/day] potassium chloride) versus placebo or no supplement.[113] It found that, compared with the control interventions, potassium supplements reduced systolic and diastolic blood pressures (mean decrease in systolic blood pressure with potassium supplements 4.4 mm Hg, 95% CI 2.2 mm Hg to 6.6 mm Hg; mean decrease in diastolic blood pressure 2.5 mm Hg, 95% CI 0.1 mm Hg to 4.9 mm Hg).

Harms: We found no direct evidence of harm in people without kidney failure and in people not taking drugs that increase serum potassium concentration. Gastrointestinal adverse effects such as belching, flatulence, diarrhoea, or abdominal discomfort occurred in 2–10% of people.[113]

Comment: None.

OPTION FISH OIL SUPPLEMENTATION

One systematic review has found that fish oil supplementation in large doses of 3 g daily modestly lowers blood pressure.

Benefits: We found no RCTs examining the effects of fish oil supplementation on morbidity or mortality in people with hypertension. One systematic review (search date not stated, 7 brief RCTs, 339 people with hypertension, mainly middle aged white men, mean age 50 years) compared effects on blood pressure of fish oil (usually 3 g/day as capsules) versus no supplements or "placebo".[114] The contents of placebo capsules varied among RCTs. Some used oil mixtures containing omega-3 polyunsaturated fatty acids, some did not. The review found that fish oil supplements reduced blood pressure

compared with control interventions (mean decrease in systolic blood pressure in treatment *v* control 4.5 mm Hg, 95% CI 1.2 mm Hg to 7.8 mm Hg, and mean decrease in diastolic blood pressure in treatment *v* control 2.5 mm Hg, 95% CI 0.6 mm Hg to 4.4 mm Hg).

Harms: Belching, bad breath, fishy taste, and abdominal pain occurred in about a third of people taking high doses of fish oil.[114]

Comment: The RCTs were of short duration and used high doses of fish oil. Such high intake may be difficult to maintain. We found no evidence of beneficial effect on blood pressure at lower intakes.

OPTION CALCIUM SUPPLEMENTATION

We found insufficient evidence on the effects of calcium supplementation specifically in people with hypertension. One systematic review in people both with and without hypertension found that calcium supplementation may reduce systolic blood pressure by small amounts.

Benefits: We found no RCTs examining the effects of calcium supplementation on morbidity or mortality in people with primary hypertension. One systematic review (search date 1994, 42 RCTs, 4560 middle aged people with and without hypertension) compared the effects on blood pressure of calcium supplementation 500–2000 mg daily versus placebo or no supplements.[115] It found that calcium supplements reduced blood pressure by a small amount (mean systolic blood pressure reduction, supplement *v* control 1.4 mm Hg, 95% CI 0.7 mm Hg to 2.2 mm Hg; mean diastolic reduction 0.8 mm Hg, 95% CI 0.2 mm Hg to 1.4 mm Hg).

Harms: Adverse gastrointestinal effects, such as abdominal pain, were generally mild and varied among particular preparations.

Comment: Data relating specifically to people with hypertension are limited by few studies with small sample sizes and short durations.

OPTION MAGNESIUM SUPPLEMENTATION

We found no RCTs examining the effects of magnesium supplementation on morbidity or mortality in people with hypertension. We found limited and conflicting evidence on the effect of magnesium supplementation on blood pressure in people with hypertension and normal magnesium concentrations.

Benefits: We found no RCTs examining the effects of magnesium supplementation on morbidity or mortality. A few small, short term RCTs found mixed results on effects on blood pressure reduction in people with hypertension and normal magnesium levels.

Harms: We found insufficient evidence.

Comment: None.

QUESTION **What are the effects of drug treatment in primary hypertension?**

Michael Pignone

OPTION ANTIHYPERTENSIVE DRUGS VERSUS PLACEBO

Many systematic reviews have found that antihypertensive drug treatment decreases the risk of fatal and non-fatal stroke, cardiac events, and total mortality in people with primary hypertension. The greatest benefit is seen in people with highest baseline risk of cardiovascular disease.

Benefits: We found many systematic reviews. One review (search date 1997, 17 RCTs with morbidity and mortality outcomes, duration > 1 year, 37 000 people) found that antihypertensive drugs produced variable reductions of systolic/diastolic blood pressure that averaged about 12–16/5–10 mm Hg compared with placebo.[116] It found evidence of benefit in total death rate, cardiovascular death rate, stroke, major coronary events, and congestive cardiac failure, but the absolute results depended on age and the severity of the hypertension (see target diastolic blood pressure below). The biggest benefit was seen in those with the highest baseline risk. The RCTs mainly compared placebo versus diuretics (usually thiazides with the addition of amiloride or triamterene) and versus β blockers (usually atenolol or metoprolol) in a stepped care approach. One systematic review (search date 1999, 8 RCTs, 15 693 people) found that, in people aged over 60 years with systolic hypertension, treatment of systolic pressures greater than 160 mm Hg decreased total mortality and fatal and non-fatal cardiovascular events.[117] Absolute benefits were greater in men than women, in people aged over 70 years, and in those with prior cardiovascular events or wider pulse pressure. The relative hazard rates associated with a 10 mm Hg higher initial systolic blood pressure were 1.26 (P = 0.0001) for total mortality, 1.22 (P = 0.02) for stroke, but only 1.07 (P = 0.37) for coronary events. Active treatment reduced total mortality (RR 0.87, 95% CI 0.78 to 0.98; P = 0.02).[117]
Target diastolic blood pressure: We found one RCT (18 790 people, mean age 62 years, diastolic blood pressures 100–115 mm Hg), which aimed to evaluate the effects on cardiovascular risk of target diastolic blood pressures of 90, 85, and 80 mm Hg.[118] However, mean achieved diastolic blood pressures were 85, 83, and 81 mm Hg, which limited power to detect differences among groups. There were no significant differences in major cardiovascular events among the three groups.

Harms: **Mortality and major morbidity:** One systematic review (search date 1997)[116] comparing diuretics and β blockers versus placebo found no increase in non-cardiovascular mortality in treated people.
Quality of life and tolerability: One systematic review (search date 1990)[119] and several recent RCTs found that quality of life was not adversely affected and may be improved in those who remain on treatment.[120]

Comment: RCTs included people who were healthier than the general population, with lower rates of cardiovascular risk factors, cardiovascular disease, and comorbidity. People with higher cardiovascular risk can expect greater short term absolute risk reduction than seen in the RCTs, whereas people with major competing risks such as terminal cancer or end stage Alzheimer's disease can expect smaller risk reduction. In the systematic review,[116] five of the RCTs were in middle aged people with mild to moderate hypertension. Seven of the RCTs were in people older than 60 years. On average, every 1000 person-years of treatment in older adults prevented five strokes (95% CI 2 to 8), three coronary events (95% CI 1 to 4), and four cardiovascular deaths (95% CI 1 to 8). Drug treatment in middle aged people prevented one stroke (95% CI 0 to 2) for every 1000 person-years of treatment and did not significantly affect coronary events or mortality. One meta-analysis (7 RCTs, 40 233 people with hypertension) found an increased risk of total and cardiovascular mortality with diastolic blood pressure levels below 85 mm Hg that was not related to antihypertensive treatment.[121]

OPTION COMPARING ANTIHYPERTENSIVE DRUG TREATMENTS

Systematic reviews have found that initial treatment with diuretics, angiotensin converting enzyme inhibitors, or β blockers reduce morbidity and mortality, with minimal adverse effects. RCTs found no significant differences in morbidity or mortality among these agents. We found limited evidence from two systematic reviews that diuretics, β blockers, and angiotensin converting enzyme inhibitors reduced coronary heart disease and heart failure more than calcium channel antagonists. However, calcium channel antagonists reduced risk of stroke more than the other agents. One RCT found that a thiazide diuretic reduced cardiovascular events, particularly congestive heart failure, compared with an α blocker. One RCT found that losartan (an angiotensin receptor blocker) reduced cardiovascular events compared with atenolol in people with hypertension and left ventricular hypertrophy.

Benefits: **β Blockers versus diuretics:** One systematic review (search date 1995, > 48 000 people) identified RCTs comparing effects of high and low dose diuretics versus β blockers.[122] A second systematic review (search date 1998) was limited to 10 RCTs in 16 164 elderly people.[123] These reviews did not summarise direct comparisons of diuretics versus β blockers but compared results of RCTs that used diuretics as preferred treatment versus results of RCTs that used β blockers as preferred treatment. The reviews found no significant difference between diuretics and β blockers for lowering blood pressure. They found that diuretics reduced coronary events, but found no evidence that β blockers reduced coronary events. **Comparison of β blockers, diuretics, angiotensin converting enzyme inhibitors, and calcium channel antagonists:** One systematic review (search date 2000, 8 RCTs) compared different antihypertensive regimens, and found no significant differences in outcome among people initially treated with β blockers, diuretics, or angiotensin converting enzyme (ACE) inhibitors.[124] However, it found that β blockers or diuretics decreased coronary events compared with calcium channel antagonists and increased stroke rate, although there was no significant difference for all cause

mortality (OR for mortality, β blockers or diuretics *v* calcium channel antagonists 1.01, 95% CI 0.92 to 1.11). ACE inhibitors did not significantly alter all cause mortality or stroke rate compared with calcium channel antagonists (OR for ACE inhibitors *v* calcium channel antagonist 1.03, 95% CI 0.91 to 1.18 for all cause mortality; 1.02, 95% CI 0.85 to 1.21 for stroke). However, ACE inhibitors decreased coronary events (OR for ACE inhibitors *v* calcium channel antagonist 0.81, 95% CI 0.68 to 0.97 for coronary events).[124] A second review of similar trials (search date 2001, 9 RCTs, 62 605 hypertensive people) found that diuretics, β blockers, ACE inhibitors, and calcium channel antagonists were all associated with similar reductions in cardiovascular risk.[125] However, calcium channel antagonists reduced risk of stroke and increased risk of myocardial infarction compared with other agents (RR for stroke 0.87, 95% CI 0.76 to 0.99; RR for myocardial infarction 1.19, 95% CI 1.04 to 1.37).[125] **Comparison of α blockers and diuretics:** One double blind RCT (24 335 high risk people with hypertension), which was included in the systematic review,[125] found no significant differences in coronary heart disease outcomes between doxazosin, an α blocker, and chlorthalidone (chlortalidone). However, doxazosin increased the total number of cardiovascular events after 4 years compared with chlorthalidone (25% with doxazosin *v* 22% with chlorthalidone; HR 1.25, 95% CI 1.17 to 1.33) and, in particular, increased congestive heart failure (8% with doxazosin *v* 4% with chlorthalidone; HR 2.04, 95% CI 1.79 to 2.32).[126] **Comparison of angiotensin receptor blockers and β blockers:** We found one RCT (9193 people aged 55–80 years with primary hypertension and left ventricular hypertrophy, but with no history of coronary events), which compared losartan versus atenolol.[127] It found that losartan reduced cardiovascular events compared with atenolol after 4 years (composite of death, myocardial infarction, or stroke: 11% with losartan *v* 13% with atenolol; RR 0.87, 95% CI 0.77 to 0.98). **Drug treatment in people with diabetes:** See prevention of cardiovascular events in diabetes, p 777.

Harms: **Quality of life and tolerability:** In the three long term, double blind comparisons of low dose diuretics, β blockers, ACE inhibitors, and calcium channel antagonists, tolerability and overall quality of life indicators tended to be more favourable for diuretics and β blockers than for newer drugs.[128–130] One systematic review (search date 1998) of RCTs comparing thiazides versus β blockers found that thiazides were associated with fewer withdrawals because of adverse effects (RR 0.69, 95% CI 0.63 to 0.76).[131] Adverse effects are agent specific. The recent unblinded RCT comparing diuretics, β blockers, calcium channel antagonists, and ACE inhibitors found that after 5 years' follow up, 26% of people receiving felodipine or isradipine (calcium channel antagonists) reported ankle oedema, 30% receiving enalapril or lisinopril (ACE inhibitors) reported cough, and 9% receiving diuretics, β blockers, or both reported cold hands and feet.[118] **Major harm controversies:** Case control, cohort, and randomised studies suggest that short and intermediate acting dihydropyridine calcium channel antagonists, such as nifedipine and isradipine, may increase cardiovascular morbidity and mortality.[132]

Comment: None.

QUESTION What are the effects of lowering cholesterol concentration in asymptomatic people?

Michael Pignone

OPTION LOWERING CHOLESTEROL

Systematic reviews have found that in people with an annual risk of coronary heart disease events of 0.6–1.5% a year, cholesterol reduction reduces non-fatal myocardial infarction (see cholesterol reduction under secondary prevention of ischaemic cardiac events for additional information, p 197). RCTs have found that absolute benefit is related to an individual's baseline risk of cardiovascular events and to the degree of cholesterol lowering rather than to the individual's cholesterol concentration. The effect of lipid lowering therapies in people with low short to medium term risk of coronary heart disease events (< 0.6%/year) has not been well studied to date.

Benefits:

Cholesterol lowering drug treatment: We found two systematic reviews which compared any type of cholesterol lowering drug treatment versus placebo or no treatment in people without a diagnosis of coronary heart disease (CHD).[133,134] Both systematic reviews found similar results. The most recent systematic review (search date 1999) found four RCTs (2 with statins, 1 with fibrates, and 1 with cholestyramine, 21 087 people).[133] It found that cholesterol reduction treatment significantly reduced CHD events and CHD mortality compared with placebo, but found no significant effect on overall mortality (OR for treatment *v* placebo; 0.70, 95% CI 0.62 to 0.79 for CHD events; 0.71, 95% CI 0.56 to 0.91 for CHD mortality; 0.94, 95% CI 0.81 to 1.09 for overall mortality). **Statins:** We found five systematic reviews (search dates 1995,[135] 1997,[136] 1998,[137] 1999,[133] and not stated[134]) and two subsequent RCTs[138,139] that considered the effect of 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) on clinical outcomes in people given long term (≥ 6 months) treatment compared with placebo. All the systematic reviews included the same two RCTs of statins in primary prevention (13 200 people).[140,141] All the systematic reviews found similar results. After 4–6 years of treatment for primary prevention, statins did not reduce significantly all cause mortality or CHD mortality compared with placebo (all cause mortality: OR 0.87, 95% CI 0.71 to 1.06). However, they did reduce major coronary events and cardiovascular mortality (CHD mortality OR 0.73, 95% CI 0.51 to 1.05; major coronary events OR 0.66, 95% CI 0.57 to 0.76; cardiovascular mortality OR 0.68, 95% CI 0.50 to 0.93).[137] The absolute risk reduction for CHD events, CHD mortality, and total mortality varied with the baseline risk (see figure 1, p 196). The first subsequent RCT (15 454 men and 5082 women) included 7150 people with no diagnosis of CHD but at high risk (1820 had cerebrovascular disease, 2701 had peripheral arterial disease, and 3982 had diabetes).[138] In people with no diagnosis of CHD, simvastatin reduced the risk of a major vascular event (major coronary event, stroke, or revascularisation) after 5 years compared with placebo (risk of major vascular event: event rate ratio 0.75, 95% CI 0.67 to 0.84). The second subsequent RCT

(246 men with hyperlipidaemia) compared three treatments: diet alone, diet with pravastatin, and diet and probucol. It found that pravastatin reduced cardiovascular events compared with diet alone after 2 years (AR for any cardiovascular event 4.8% with pravastatin *v* 13.6% with diet alone, P value and CI not reported).[139]
Low fat diet: See changing behaviour topic, p 98.

Harms: Specific harms of statins are discussed under secondary prevention of ischaemic cardiac events topic, p 197.

Comment: The CHD event rate in the placebo group of the two large primary prevention RCTs using statins was 0.6%[140] and 1.5%[141] a year. If the 17% relative reduction in total mortality observed in the higher risk west of Scotland RCT is real, then about 110 high risk people without known CHD would need to be treated for 5 years to save one life. One regression analysis of all the major statin trials found that mortality benefits of statins outweigh risks in people with a 10 year CHD risk of more than 13%.[145] **Cholesterol lowering treatment in older people:** We found no RCTs specifically evaluating the effect of cholesterol lowering treatment in asymptomatic people aged over 75 years. One large RCT comparing statin with placebo included more than 5000 people over the age of 70 years.[138] It found major vascular events were reduced to a similar extent in people above and below the age of 70 years. **Cholesterol lowering treatment in women:** Subgroup analyses of two RCTs have found conflicting results. One RCT (5608 men, 997 women) compared statins with placebo for primary prevention in women.[140] It found that lovastatin reduced the risk of CHD events in women but this was not statistically significant (RR 0.54, 95% CI 0.22, 1.35). In the second RCT, the reduction in major event rate was similar in men and women (quantitative results not reported).[138] Other treatments are discussed under changing behaviour, p 098, or were performed in people with known CHD (see secondary prevention of ischaemic cardiac events, p 197). We found one systematic review (search date 1996, 59 RCTs, 173 160 people receiving drug treatments, dietary intervention, or ileal bypass), which did not differentiate primary and secondary prevention and included RCTs of any cholesterol lowering intervention, irrespective of duration, as long as mortality data were reported.[146] Overall, baseline risk was similar in people allocated to all interventions. Among non-surgical treatments, the review found that only statins reduced CHD mortality (RR *v* control 0.69, 95% CI 0.59 to 0.80 for statins; 0.44, 95% CI 0.18 to 1.07 for n-3 fatty acids; 0.98, 95% CI 0.78 to 1.24 for fibrates; 0.71, 95% CI 0.51 to 0.99 for resins; 1.04, 95% CI 0.93 to 1.17 for hormones; 0.95, 95% CI 0.83 to 1.10 for niacin; 0.91, 95% CI 0.82 to 1.01 for diet), and that only statins and n-3 fatty acids reduced all cause mortality (RR *v* control 0.79, 95% CI 0.71 to 0.89 for statins; 0.68, 95% CI 0.53 to 0.88 for n-3 fatty acids; 1.06, 95% CI 0.78 to 1.46 for fibrates; 0.85, 95% CI 0.66 to 1.08 for resins; 1.09, 95% CI 1.00 to 1.20 for hormones; 0.96, 95% CI 0.86 to 1.08 for niacin; 0.97, 95% CI 0.81 to 1.15 for diet).[146] The effect of lipid-lowering therapies in people with low short to medium term risk of CHD events (< 0.6%/year) has not been well studied to date.

QUESTION **What is the role of antithrombotic treatment in asymptomatic people?**

Michael Pignone

OPTION **ASPIRIN**

We found the role of antiplatelet treatment in individuals without symptoms of cardiovascular disease to be uncertain. We found insufficient evidence from RCTs to identify which individuals would benefit overall and which would be harmed by regular treatment with aspirin, although those at high and intermediate rather than low risk, would be more likely to gain benefit.

Benefits: We found five systematic reviews,[147–151] which included five large RCTs comparing regular aspirin versus control among individuals with no prior history of vascular disease, with or without vascular risk factors.[118,152–155] The earliest two trials recruited a total of about 30 000 healthy, mainly middle aged, male doctors (5139 in the UK, randomised between aspirin 500 mg/day and control, and 22 071 in the USA, randomised between aspirin 325 mg every other day and placebo).[153,154] Three later RCTs included asymptomatic people with identifiable risk factors for vascular events. All three had a factorial design. The first compared aspirin 75 mg daily versus placebo and low intensity warfarin versus placebo in 5000 middle aged men with coronary heart disease risk score in the top 20–25% of the population distribution.[156] The second compared aspirin 75 mg daily versus placebo in three groups with different intensities of blood pressure reduction in a total of about 19 000 people with hypertension, most of whom had no history of vascular disease.[118] The third compared aspirin 100 mg daily versus placebo and vitamin E versus placebo in about 4500 people aged more than 50 years, with at least one major cardiovascular risk factor (hypertension, hypercholesterolaemia, diabetes, obesity, family history of premature myocardial infarction, or age ≥ 65 years).[77] The average control group risk of a serious vascular event (myocardial infarction, stroke, or death from a vascular cause) in each of these trials was low (about 1% a year). Data from these five RCTs were pooled in our own meta-analysis, which currently includes about 55 000 low risk people. Results are summarised in table 2, p 194 and table 3, p 195. We found that, overall, aspirin slightly reduced the risk of a serious vascular event (OR 0.86, 95% CI 0.80 to 0.90; ARR 1/1000 people/year), reduced the relative risk of myocardial infarction by about a third (OR 0.71, 95% CI 0.60 to 0.80), but had an uncertain effect on stroke (OR 1.05, 95% CI 0.90 to 1.20). The systematic reviews found similar results.[147–151] One of these systematic reviews[147] also included an RCT in about 3000 people with diabetes[155] who were at substantially higher average risk of vascular events (about 4% a year) than the low risk individuals in the primary prevention RCTs included in our meta-analysis.

Harms: Serious, potentially life threatening bleeding is the most important adverse effect of aspirin. **Intracranial haemorrhage:** These are uncommon, but they are often fatal or cause substantial disability in survivors. We found one relevant systematic review (search date

1997)[158] in which people were randomised to aspirin or control treatment for at least 1 month. It found that aspirin produced a small increased risk of intracranial haemorrhage in about 1/1000 (0.1%) people treated for 3 years.[158] Our meta-analysis of the primary prevention RCTs found a somewhat smaller absolute overall excess of about 0.1/1000 (0.01%) people treated with aspirin a year (see table 3, p 195). **Extracranial haemorrhage:** Major extracranial bleeds occur mainly in the gastrointestinal tract and may require hospital admission or blood transfusion, but do not generally result in permanent disability and are rarely fatal. We found one relevant systematic review of aspirin versus control with a scheduled treatment duration of at least 1 year. It found the relative excess risk of gastrointestinal bleeding with aspirin to be about 70% (OR 1.7, 95% CI 1.5 to 1.9).[159] A recent overview of 15 observational studies, including over 10 000 cases of upper gastrointestinal bleeding or perforation requiring admission to hospital, found the relative risk with aspirin to be 2.5 (95% CI 2.4 to 2.7). If only those studies that had a prospective (and so methodologically more rigorous) design were considered, the relative risk fell to 1.9 (95% CI 1.7 to 2.1), similar to that found in the RCTs.[160] Meta-analysis of primary prevention RCTs found a similar relative excess risk of major extracranial (mainly gastrointestinal) haemorrhage and an absolute excess of about 0.7 major extracranial haemorrhages per 1000 people treated with aspirin a year (see table 3, p 195).

Comment: Currently available information suggests that some asymptomatic individuals would gain net benefit whereas others would experience net harm with regular aspirin treatment. People at intermediate risk of vascular disease (≥ 1%/year risk of coronary heart disease events) may benefit overall, but we found insufficient evidence to be certain.[149,150] One large overview of randomised trials of antiplatelet treatment among people at high risk of vascular events (> 3%/year), including people with diabetes, found clear evidence of net benefit (see stroke prevention, p 257, secondary prevention of ischaemic cardiac events, p 197, and prevention of cardiovascular events in diabetes, p 777).[161]

OPTION ANTICOAGULANT TREATMENT

We found evidence from one RCT that the benefits and risks of low intensity oral anticoagulation among individuals without evidence of cardiovascular disease are finely balanced, and the net effects are uncertain.

Benefits: We found no systematic review. We found one RCT assessing anticoagulation (with a low target international normalised ratio of 1.5) among people without evidence of cardiovascular disease.[156] It found that the proportional effects of warfarin were similar among people allocated aspirin or placebo, and overall warfarin non-significantly reduced the odds of a vascular event over about 6.5 years compared with placebo (253 events in 2762 people allocated to warfarin, AR 9.2% *v* 288 events in 2737 people allocated to placebo, AR 10.5%; mean ARR warfarin *v* placebo about 2 events/1000 individuals/year; reduction in odds of vascular event warfarin *v* placebo +14%, 95% CI −2% to +28%). Compared with placebo,

warfarin produced a relative reduction in the rate of all ischaemic heart disease (RRR 21%, 95% CI 4% to 35%), but had no significant effect on the rate of stroke (increase in RR +15%, 95% CI –22% to +68%) or other causes of vascular death.[156]

Harms: Warfarin was associated with a non-significant excess of about 0.4 intracranial bleeds per 1000 individuals a year (14/2762 [0.5%] with warfarin *v* 7/2737 [0.3%] with placebo) and a non-significant excess of extracranial bleeds of about 0.5/1000 individuals a year (21/2545 [0.8%] with warfarin *v* 12/2540 [0.5%] with placebo; RR 1.75, 95% CI 0.86 to 3.50).[156]

Comment: As for aspirin, the benefits and risks of low intensity oral anticoagulation among people without evidence of cardiovascular disease are finely balanced. The proportion of individuals randomised to date is only about 10% of the number included in primary prevention RCTs of aspirin (see aspirin, p 185), and so the reliable identification of those who may benefit from such treatment will require further large scale, randomised evidence.

TABLE 1 **Examples of common physical activities by intensity of effort required in multiples of the resting rate of oxygen consumption during physical activity (see text, p 167). Published in *JAMA* 1995;273:402–407.[27]**

Activity type	Light activity (< 3.0 METs)	Moderate activity (3.0–6.0 METs)	Vigorous activity (> 6.0 METs)
Walking	Slowly (1–2 mph)	Briskly (3–4 mph)	Briskly uphill or with a load
Swimming	Treading slowly	Moderate effort	Fast treading or swimming
Cycling	NA	For pleasure or transport (≤ 10 mph)	Fast or racing (> 10 mph)
Golf	Power cart	Pulling cart or carrying clubs	NA
Boating	Power boat	Canoeing leisurely	Canoeing rapidly (> 4 mph)
Home care	Carpet sweeping	General cleaning	Moving furniture
Mowing lawn	Riding mower	Power mower	Hand mower

Key Messages

Antithrombotic treatment

- **Anticoagulants in the absence of antiplatelet treatment** One systematic review and subsequent RCTs have found that high or moderate intensity oral anticoagulants given alone reduce the risk of serious vascular events compared with placebo or no anticoagulants in people with coronary artery disease, but are associated with substantial risk of haemorrhage.
- **Any oral antiplatelet treatment** One systematic review has found that prolonged antiplatelet treatment compared with placebo or no antiplatelet treatment reduces the risk of serious vascular events in people at high risk of ischaemic cardiac events.
- **Aspirin** One systematic review has found that, for prolonged use, aspirin 75–150 mg daily is as effective as higher doses, but found insufficient evidence that doses below 75 mg daily are as effective.
- **Thienopyridines** One systematic review has found that clopidogrel is at least as safe and effective as aspirin in people at high risk of cardiovascular events.
- **Oral glycoprotein IIb/IIIa receptor inhibitors** Systematic reviews in people with acute coronary syndromes or undergoing percutaneous coronary interventions have found that oral glycoprotein IIb/IIIa receptor inhibitors (with or without aspirin) increase risk of mortality and bleeding compared with aspirin alone.
- **Adding anticoagulants to antiplatelet treatment** One systematic review and subsequent RCTs found no consistent evidence that addition of oral anticoagulation at low (international normalised ratio < 1.5) or moderate (international normalised ratio 1.5–3.0) intensity to aspirin reduced risk of death or recurrent cardiac events, but found an increased risk of major haemorrhage compared with aspirin alone.

Other drug treatments

- **Amiodarone in people at high risk of arrhythmic death** Two systematic reviews have found that amiodarone reduces the risk of sudden cardiac death and overall mortality at 1 year compared with placebo in people at high risk of arrhythmic death after myocardial infarction.
- **Angiotensin converting enzyme inhibitors in high risk people without left ventricular dysfunction** One large RCT in high risk people without left ventricular dysfunction found that ramipril reduced the combined outcome of cardiovascular death, stroke, and myocardial infarction compared with placebo after about 5 years.
- **Angiotensin converting enzyme inhibitors in people with left ventricular dysfunction** One systematic review has found that, in people who have had a myocardial infarction and have left ventricular dysfunction, angiotensin converting enzyme inhibitors reduce mortality, admission to hospital for congestive heart failure, and recurrent non-fatal myocardial infarction compared with placebo after 2 years' treatment.

- **β Blockers** Systematic reviews in people after myocardial infarction have found that long term β blockers reduce all cause mortality, coronary mortality, recurrent non-fatal myocardial infarction, and sudden death. One RCT found that about 25% of people suffer adverse effects.
- **Hormone replacement therapy** Large RCTs found no significant difference between hormone replacement therapy and placebo in major cardiovascular events in postmenopausal women with established coronary artery disease. Observational studies and one large RCT found that hormone replacement therapy increased risk of breast cancer, venous thromboembolism, and gall bladder disease compared with placebo.
- **Sotalol** One RCT found limited evidence that sotalol increased mortality within 1 year compared with placebo.
- **Calcium channel blockers** One systematic review found non-significantly higher mortality with dihydropyridines compared with placebo. One systematic review found no benefit from calcium channel blockers in people after myocardial infarction or with chronic coronary heart disease. Diltiazem and verapamil may reduce rates of reinfarction and refractory angina in people after myocardial infarction who do not have heart failure.
- **Class I antiarrhythmic agents** One systematic review has found that class I antiarrhythmic agents given after myocardial infarction increase the risk of cardiovascular mortality and sudden death compared with placebo.

Cholesterol reduction

- **Cholesterol lowering drugs** Systematic reviews and large subsequent RCTs have found that lowering cholesterol in people at high risk of ischaemic coronary events substantially reduces overall mortality, cardiovascular mortality, and non-fatal cardiovascular events. We found good evidence from systematic reviews and subsequent RCTs that statins were the only non-surgical treatment for cholesterol reduction that reduced mortality. One systematic review has found that the absolute benefits increase as baseline risk increases, but are not additionally influenced by the person's absolute blood cholesterol concentration.

Blood pressure reduction

- **Blood pressure lowering in people at high risk of ischaemic coronary events** We found no direct evidence of the effects of blood pressure lowering in people with established coronary heart disease. Observational studies, and extrapolation of primary prevention trials of blood pressure reduction, support the lowering of blood pressure in those at high risk of ischaemic coronary events. The evidence for benefit is strongest for β blockers, although not specifically in people with hypertension. The optimum target blood pressure in people with hypertension is not clear. Effects of angiotensin converting enzyme inhibitors, calcium channel blockers, and β blockers are discussed separately.

Non-drug treatments

- **Cardiac rehabilitation** One systematic review has found that cardiac rehabilitation including exercise reduces the risk of major cardiac events. One subsequent RCT found no significant difference in quality of life between standard rehabilitation and early return to normal activities, although the study may have lacked power to detect a clinically important difference between groups.
- **Exercise without cardiac rehabilitation** One systematic review has found that exercise alone reduces mortality compared with usual care.

Secondary prevention of ischaemic cardiac events

- **Eating more fish (particularly oily fish)** One RCT has found that advising people with coronary heart disease to eat more fish (particularly oily fish) reduced mortality at 2 years. A second RCT found that fish oil capsules reduced mortality at 3.5 years.
- **Mediterranean diet** One RCT has found that advising people with coronary artery disease to eat more bread, fruit, vegetables, and fish, and less meat, and to replace butter and cream with rapeseed margarine reduces mortality at 27 months.
- **Psychosocial treatment** RCTs found limited evidence that psychosocial treatments reduced cardiac events or cardiac death compared with no psychosocial treatment in people with coronary heart disease. Two RCTs found that psychological treatments improved quality of life compared with no psychological treatment.
- **Smoking cessation** We found no RCTs of the effects of smoking cessation on cardiovascular events in people with coronary heart disease. Moderate quality evidence from epidemiological studies indicates that people with coronary heart disease who stop smoking rapidly reduce their risk of recurrent coronary events or death. Treatment with nicotine patches seems safe in people with coronary heart disease.
- **Stress management** One systematic review of mainly poor quality RCTs found that stress management may decrease rates of myocardial infarction or cardiac death in people with coronary heart disease.
- **Advice to eat less fat** RCTs found no strong evidence that low fat diets reduced mortality at 2 years.
- **Vitamin C** We found insufficient evidence about effects of vitamin C alone.
- **Vitamin E** We found no consistent evidence from four RCTs about effects of vitamin E versus placebo or other antioxidants in people with high cardiovascular risk.
- **β carotene** Four large RCTs of β carotene supplementation in primary prevention found no cardiovascular benefits, and two of the RCTs raised concerns about increased mortality.

Surgical treatments

- **Coronary artery bypass grafting versus medical treatment alone** One systematic review found that coronary artery bypass grafting reduced the risk of death from coronary artery disease at 5 and 10 years compared with medical treatment alone. Greater benefit occurred in people with poor left ventricular function. One subsequent RCT in people with asymptomatic disease found that revascularisation with coronary artery bypass grafting or coronary percutaneous transluminal angioplasty reduced mortality at 2 years compared with medical treatment alone.
- **Coronary percutaneous transluminal angioplasty versus medical treatment alone in people with stable coronary artery disease** One systematic review found that coronary percutaneous transluminal angioplasty improved angina compared with medical treatment alone, but was associated with a higher rate of coronary artery bypass grafting. The review found higher mortality and rates of myocardial infarction with percutaneous transluminal angioplasty than with medical treatment but the difference was not significant. RCTs have found that percutaneous transluminal angioplasty is associated with increased risk of emergency coronary artery bypass grafting and myocardial infarction during and soon after the procedure. One RCT found that percutaneous transluminal angioplasty reduced cardiac events and improved angina severity compared with medical treatment alone in people over the age of 75 years.

- **Intracoronary stents (better than coronary percutaneous transluminal angioplasty alone)** One systematic review found that intracoronary stents reduce the need for repeat vascularisation compared with coronary percutaneous transluminal angioplasty alone. It found no significant difference in mortality or myocardial infarction, but crossover rates from angioplasty to stent were high. RCTs found that intracoronary stents improved outcomes after 4–9 months compared with percutaneous transluminal angioplasty in people with previous coronary artery bypass grafting, chronic total occlusions, and for treatment of restenosis after initial percutaneous transluminal angioplasty.
- **Coronary artery bypass grafting versus percutaneous revascularisation for multivessel disease (less need for repeat procedures)** One systematic review has found no significant difference between coronary artery bypass grafting and percutaneous transluminal angioplasty in death, myocardial infarction, or quality of life. Percutaneous transluminal angioplasty is less invasive but increased the number of repeat procedures.

DEFINITION Secondary prevention in this context is the long term management of people with a prior acute myocardial infarction, and of people at high risk of ischaemic cardiac events for other reasons, such as a history of angina or coronary surgical procedures.

INCIDENCE/ PREVALENCE Coronary artery disease is the leading cause of mortality in developed countries and is becoming a major cause of morbidity and mortality in developing countries. There are pronounced international, regional, and temporal differences in death rates. In the USA, the prevalence of overt coronary artery disease approaches 4%.[1]

AETIOLOGY/ RISK FACTORS Most ischaemic cardiac events are associated with atheromatous plaques that can cause acute obstruction of coronary vessels. Atheroma is more likely in elderly people, in those with established coronary artery disease, and in those with risk factors (such as smoking, hypertension, high cholesterol, and diabetes mellitus).

PROGNOSIS Of people admitted to hospital with acute myocardial infarction, 7–15% die in hospital and another 7–15% die during the following year. People who survive the acute stage of myocardial infarction fall into three prognostic groups, based on their baseline risk (see table 1, p 237);[2–4] high (20% of all survivors), moderate (55%), and low (25%) risk. Long term prognosis depends on the degree of left ventricular dysfunction, the presence of residual ischaemia, and the extent of any electrical instability. Further risk stratification procedures include assessment of left ventricular function (by echocardiography or nuclear ventriculography) and of myocardial ischaemia (by non-invasive stress testing).[4–8] Those with low left ventricular ejection fraction, ischaemia, or poor functional status can be assessed further by cardiac catheterisation.[9]

AIMS OF INTERVENTION To improve long term survival and quality of life; to prevent (recurrent) myocardial infarction, unstable angina, left ventricular dysfunction, heart failure, and sudden cardiac death; and to restore and maintain normal activities.

OUTCOMES Mortality (total, cardiovascular, coronary, sudden death, non-cardiovascular); morbidity (myocardial infarction, severe angina, stroke); quality of life.

METHODS *Clinical Evidence* search and appraisal November 2002.

QUESTION **What are the effects of antithrombotic treatment?**

Bazian Ltd

OPTION **ANY ORAL ANTIPLATELET TREATMENT**

One systematic review has found that prolonged antiplatelet treatment reduces the risk of serious vascular events in people at high risk of ischaemic cardiac events.

Benefits: **Oral antiplatelet treatment versus no antiplatelet treatment:** We found one systematic review (search date 1997, 195 RCTs, > 140 000 high risk people) comparing an antiplatelet regimen (mostly aspirin) versus no antiplatelet treatment (including placebo).[10] It found that antiplatelet treatment reduced the odds of a serious vascular event (myocardial infarction, stroke, or vascular death) by 25% among all types of high risk people (OR 0.75, 95% CI 0.72 to 0.78), excluding those with acute ischaemic stroke (among whom the proportional benefits were smaller).[10] The proportional effects of antiplatelet treatment were similar regardless of whether the people were included on the basis of a prior or acute myocardial infarction, prior stroke or transient ischaemic attack, stable or unstable angina, peripheral arterial disease, atrial fibrillation, or other high risk condition. Most of these people were at high risk of ischaemic cardiac events, and some (including those with a history of myocardial infarction, those with stable angina, and those who had undergone coronary revascularisation procedures) were at particularly high risk. Among the 20 000 people with a prior myocardial infarction it was estimated that antiplatelet treatment prevented 18 non-fatal recurrent myocardial infarctions, five non-fatal strokes, and 14 vascular deaths per 1000 people treated for about 2 years. The review also found that antiplatelet treatment reduced the risk of all cause mortality (see figure 1, p 238).

Harms: **Oral antiplatelet treatment:** The most important adverse effect of antiplatelet treatment is haemorrhage, particularly intracranial haemorrhage because it is frequently fatal or disabling. The systematic review (search date 1997) found a proportional increase in the risk of intracranial haemorrhage of about a quarter (OR 1.22, 95% CI 1.03 to 1.44). However, the absolute excess risk was no more than one or two events per 1000 people a year.[10] Antiplatelet treatment was associated with about a 60% increased odds of extracranial haemorrhage (mainly from the gastrointestinal tract) (OR 1.6, 95% CI 1.4 to 1.8) corresponding to an absolute excess risk of about 1–2/1000 people treated a year with a prior myocardial infarction. Most of the extracranial haemorrhages were non-fatal.[10]

Comment: Among people at high risk of cardiac events, the large absolute reductions in serious vascular events associated with antiplatelet treatment far outweigh any absolute risks.

OPTION ASPIRIN

One systematic review has found that for prolonged use, aspirin 75–150 mg daily is as effective as higher doses, but found insufficient evidence that doses below 75 mg daily are as effective. It found no clear evidence that any alternative antiplatelet regimen reduced recurrent vascular events compared with aspirin in the long term, but found that clopidogrel is at least as effective and as safe as aspirin.

Benefits:

Versus no aspirin: We found one systematic review (search date 1997, 195 RCTs, > 140 000 high risk people) comparing an antiplatelet regimen versus no antiplatelet treatment (including placebo).[10] Aspirin was by far the most widely studied antiplatelet drug in the systematic review. Among almost 60 000 people (excluding those with acute ischaemic stroke) aspirin reduced the odds of a serious vascular event by about a quarter compared with control (OR 0.77, 95% CI 0.73 to 0.81).[10] **Different daily doses:** Direct comparisons (3197 high risk people) between daily doses of 500–1500 mg versus 75–325 mg found no significant difference in effect (OR higher versus lower dose 0.97, 95% CI 0.79 to 1.19).[10] A subsequent RCT (2849 high risk people) compared four doses of aspirin, two lower doses of 81 or 325 mg daily, and two higher doses of 650 or 1300 mg daily. It found that the combined rate of myocardial infarction, stroke, or death was slightly lower in the lower dose than in the higher dose groups at 3 months (AR 6.2% with lower doses *v* 8.4% with higher doses; P = 0.03).[11] Direct comparisons (3570 people in the review) between daily doses of 75 mg or more and less than 75 mg daily found no significant difference, but the confidence intervals included a potentially clinically important difference (OR higher *v* lower doses 1.08, 95% CI 0.90 to 1.31).[10] Indirect comparisons of trials in the review comparing different daily aspirin doses versus control among people at high risk (excluding those with acute ischaemic stroke) found similar reductions in serious vascular events for the higher daily doses 500–1500 mg daily (OR 0.81, 95% CI 0.75 to 0.87), 160–325 mg daily (OR 0.74, 95% CI 0.69 to 0.80), 75–150 mg daily (OR 0.68, 95% CI 0.59 to 0.79), but somewhat smaller effect with less than 75 mg daily (OR 0.87, 95% CI 0.74 to 1.03) (see figure 2, p 239).[10] **Versus or with thienopyridines:** See benefits of thienopyridines, p 204. **Versus or with anticoagulants:** See benefits of oral anticoagulants in absence of antiplatelet treatment, p 206 and benefits of oral anticoagulants in addition to antiplatelet treatment, p 207.

Harms:

Intracranial haemorrhage: A systematic review of aspirin versus control for at least 1 month found that aspirin produced a small increased risk of intracranial haemorrhage of about 1/1000 (0.1%) people treated for 3 years.[12] There was no clear variation in risk with the dose of aspirin used. In RCTs directly comparing different daily doses there was no significant difference in the risk of intracranial haemorrhage, but the number of events was small and the confidence intervals wide.[11,13,14] Two observational studies (1 case control and 1 cohort study) found a dose dependent association between aspirin and intracranial haemorrhage, but the methods of these studies prevent firm conclusions being drawn.[15,16] **Extracranial haemorrhage:** The systematic review (search date

1997) found that aspirin slightly increased the risk of major extracranial haemorrhage, similar to the risk for antiplatelet treatment in general (see harms of antiplatelet treatment, p 202). It found that the risk of major extracranial haemorrhage was similar with different daily doses (numerical results not presented).[10] **Gastrointestinal haemorrhage:** A systematic review (search date 1999) of aspirin versus control found an increased risk of gastrointestinal haemorrhage with aspirin (OR 1.68, 95% CI 1.51 to 1.88), with no definite variation in risk between doses or different formulations.[17] RCTs directly comparing different doses of aspirin found a trend towards more gastrointestinal haemorrhages with high (500–1500 mg/day) versus medium (75–325 mg/day) doses (OR 1.7, 95% CI 0.9 to 2.1). There was no difference between medium (283 mg/day) and low (30 mg/day) doses (OR 1.2, 95% CI 0.7 to 2.0).[11,13,14] A recent overview of 15 observational studies including over 10 000 cases of upper gastrointestinal haemorrhage or perforation requiring admission to hospital, found a more than doubled increased risk with aspirin (RR 2.5, 95% CI 2.4 to 2.7).[18] Restricting the analysis to prospective studies gave a lower risk (RR 1.9, 95% CI 1.7 to 2.1), similar to that found in the RCTs.[17,18] **Upper gastrointestinal symptoms:** RCTs directly comparing different doses of aspirin found that high dose (500–1500 mg/day) significantly increased the odds of upper gastrointestinal symptoms compared with medium dose (75–325 mg/day; OR 1.3, 95% CI 1.1 to 1.5),[11,13] and that medium dose (283 mg/day) aspirin was associated with non-significantly higher odds of upper gastrointestinal upset compared with low dose (30 mg/day; OR 1.1, 95% CI 0.9 to 1.4).[14]

Comment: Among people at high risk of cardiac events, the large absolute reductions in serious vascular events associated with aspirin far outweigh any absolute risks.

OPTION THIENOPYRIDINES (CLOPIDOGREL OR TICLOPIDINE)

One RCT has found that clopidogrel is at least as effective at preventing vascular events and is at least as safe as aspirin in people with a history of cardiovascular disease.

Benefits: **Versus aspirin:** One RCT (19 185 people with a history of myocardial infarction, stroke, or peripheral arterial disease) compared clopidogrel 75 mg daily versus aspirin 325 mg daily.[19] It found that clopidogrel reduced the odds of a serious vascular event by 10% (OR 0.90, 95% CI 0.82 to 0.99). One systematic review found similar, but non-significant results for ticlopidine (a thienopyridine similar to clopidogrel) versus aspirin (search date 1997, 4 RCTs, 3791 high risk people; RR 0.88, 95% CI 0.75 to 1.03).[10] We found one subsequent RCT comparing ticlopidine versus aspirin.[20] It found a non-significant lower risk of a vascular event (OR 0.69, 95% 0.31 to 1.48). A separate systematic review comparing ticlopidine or clopidogrel versus aspirin (search date 1999, 4 RCTs, 22 656 people at high risk of vascular disease, most of whom were included in the trial comparing clopidogrel with aspirin[20]) found that ticlopidine or clopidogrel reduced the odds of a vascular event compared with aspirin (OR 0.91, 95% CI 0.84 to 0.98).[21] However, there was substantial uncertainty about the absolute size of any additional

benefit (average 11 events prevented/1000 people treated for 2 years, 95% CI 2 events prevented/1000 people treated to 19 events prevented/1000 people treated). **Thienopyridines plus aspirin versus aspirin alone:** We found no completed long term trials of the effects of adding clopidogrel to aspirin among people at high risk of occlusive arterial disease but without an acute cardiovascular event. We found one RCT in people with acute coronary syndromes (see comment below).

Harms: One systematic review of randomised trials of the thienopyridine derivatives versus aspirin found that the thienopyridines produced significantly less gastrointestinal haemorrhage and upper gastrointestinal upset than aspirin.[21] However, the odds of skin rash and diarrhoea were doubled with ticlopidine and increased by about a third with clopidogrel. Ticlopidine (but not clopidogrel) increased the odds of neutropenia. Observational studies have also found that ticlopidine is associated with thrombocytopenia and thrombotic thrombocytopenic purpura.[22,23] However, we found no clear evidence of an excess of haematological adverse effects with clopidogrel.[24,25] Three RCTs (about 2700 people undergoing coronary artery stenting) of clopidogrel plus aspirin versus ticlopidine plus aspirin suggested better safety and tolerability with clopidogrel versus ticlopidine.[26–28]

Comment: One RCT (about 12 500 people within 24 hours of onset of an acute coronary syndrome without ST segment elevation) compared clopidogrel plus aspirin versus placebo plus aspirin.[29] After 3–12 months' treatment, it found that adding clopidogrel to aspirin significantly reduced the risk of a major vascular event (RR 0.88, 95% CI 0.72 to 0.90).[29] See antiplatelets under angina (unstable), p 064. The trial found that combined treatment increased risk of major haemorrhages (mainly gastrointestinal) and bleeding at sites of arterial punctures (RR 1.38, 95% CI 1.13 to 1.67), but did not increase intracranial, life-threatening, or fatal haemorrhages compared with aspirin alone.[29] An RCT of the effects of adding clopidogrel to aspirin in people with acute myocardial infarction is underway.[30]

OPTION ORAL GLYCOPROTEIN IIB/IIIA RECEPTOR INHIBITORS

Systematic reviews in people with acute coronary syndromes or undergoing percutaneous coronary interventions have found that oral glycoprotein IIb/IIIa receptor inhibitors (with or without aspirin) increase mortality and bleeding compared with aspirin alone.

Benefits: We found two systematic reviews in people with acute coronary syndrome or undergoing percutaneous coronary intervention (search dates 2000[31] and 2001[32]). Both reviews identified the same four RCTs (33 326 people). They both found that oral glycoprotein IIb/IIIa receptor inhibitors (with or without aspirin) significantly increased mortality. They did not significantly affect the risk of myocardial infarction compared with aspirin alone after 3–10 months (results taken from first review;[31] mortality: pooled OR 1.37, 95% CI 1.13 to 1.66; myocardial infarction: pooled OR 1.04, 95% CI 0.93 to 1.16).

Harms: The first review found that oral glycoprotein IIb/IIIa receptor inhibitors with or without aspirin increased all cause mortality and major bleeding compared with aspirin.[31] One subsequent RCT (9200 people with a recent myocardial infarction, unstable angina, ischaemic stroke/transient ischaemic attack, or peripheral arterial disease) assessing the effects of adding an oral glycoprotein IIb/IIIa receptor inhibitor to aspirin was stopped early because of safety concerns.[33]

Comment: None.

OPTION ORAL ANTICOAGULANTS IN THE ABSENCE OF ANTIPLATELET TREATMENT

One systematic review and subsequent RCTs have found that high or moderate intensity oral anticoagulants given alone reduce the risk of serious vascular events in people with coronary artery disease, but are associated with substantial risks of haemorrhage compared with placebo or no anticoagulants. Oral anticoagulants require regular monitoring for intensity of anticoagulant effect.

Benefits: We found one systematic review (search date 1999) of the effects of oral anticoagulation in people with coronary artery disease.[34] It identified 16 RCTs of high intensity anticoagulation (international normalised ratio [INR — see glossary, p 232] > 2.8) versus control (either no anticoagulation or placebo) in 10 056 people, and four RCTs of moderate intensity anticoagulation (INR 2–3) versus control in 1365 people. Antiplatelet treatment was not routinely given in any of these 20 trials. The review found that high intensity anticoagulation reduced the odds of the combined outcome of mortality, myocardial infarction, or stroke compared with control (OR 0.57, 95% CI 0.51 to 0.63; about 98 events avoided/1000 people treated). Compared with control, moderate intensity anticoagulation was associated with a smaller non-significant reduction.[34] In direct comparisons of high or moderate intensity oral anticoagulation with aspirin, the effects on mortality, myocardial infarction, or stroke were similar (OR 1.04, 95% CI 0.80 to 1.34).[34] One subsequent RCT (3630 people with previous acute myocardial infarction) compared three treatments: warfarin alone (to target INR 2.8–4.2); aspirin 160 mg daily; and warfarin (to target INR 2.0–2.5) plus aspirin 75 mg daily.[35] After 4 years, it found that warfarin alone significantly reduced cardiovascular events (death, myocardial infarction, or cerebral infarction) compared with aspirin alone (cardiovascular event rate 203/1216 [16.7%] with warfarin *v* 241/1206 [20%] with aspirin alone; RR 0.81, 95% CI 0.69 to 0.83). However, warfarin was associated with increased bleeding compared with aspirin (see harms below). A second subsequent RCT (999 people after acute coronary syndrome) similarly compared three treatments: aspirin 80 mg daily; oral anticoagulants (to target INR 3.0–4.0); and aspirin 80 mg daily plus oral anticoagulants (to target INR 2.0–2.5).[36] It found that oral anticoagulants reduced cardiovascular events compared with aspirin, although the result was of borderline significance (17/325 [5%] with anticoagulants *v* 31/336 [9%] with aspirin; HR 0.55, 95% CI 0.30 to 1.00).

Harms: Compared with control, high intensity anticoagulation increased the odds of major (mainly extracranial) haemorrhage about six-fold (OR 6.0, 95% CI 4.4 to 8.2; absolute increase 39 events/1000 people treated), and moderate intensity anticoagulation increased the odds of major haemorrhage about eight-fold (OR 7.7, 95% CI 3.3 to 17.6).[34] Compared with aspirin, high or moderate intensity oral anticoagulation increased the odds of major haemorrhage more than two-fold (OR 2.4, 95% CI 1.6 to 3.6).[34] The first subsequent RCT found that warfarin significantly increased major non-fatal bleeding compared with aspirin (0.68% a year with warfarin *v* 0.17% a year with aspirin; RR 4.00, 95% CI 1.67 to 10.00).[35] The second subsequent RCT found no significant difference in major bleeding between aspirin and combination treatment, although the study may have lacked power to detect a clinically important difference (1% with combination *v* 1% with aspirin; HR 1.03, 95% CI 0.21 to 5.08).[36]

Comment: Oral anticoagulants provide substantial protection against vascular events in the absence of antiplatelet treatment, but the risks of serious haemorrhage are higher than for antiplatelet treatment and regular monitoring is required. Aspirin provides similar protection, but is safer and easier to use (see harms under antiplatelet treatment, p 202).

OPTION ORAL ANTICOAGULANTS IN ADDITION TO ANTIPLATELET TREATMENT

One systematic review found no evidence that the addition of low intensity oral anticoagulation (target international normalised ratio < 1.5) to aspirin reduced mortality, myocardial infarction, and stroke. We found no consistent evidence from RCTs that moderate intensity oral anticoagulation (target international normalised ratio 1.5–3.0) plus aspirin reduced recurrent cardiovascular events or mortality compared with aspirin alone, although we found consistent evidence that it increased the risk of major haemorrhage.

Benefits: We found one systematic review (search date 1999, 6 RCTs, 8915 people with coronary artery disease) of adding an oral anticoagulant regimen to aspirin.[34] Three of these RCTs assessed the addition of a low intensity (target international normalised ratio [INR — see glossary, p 232] < 1.5) regimen to aspirin in a total of 8435 people, and found no significant reduction in the odds of mortality, myocardial infarction, or stroke (OR 0.91, 95% CI 0.79 to 1.06).[34] Trials assessing the addition of a moderate intensity (INR 2–3) oral anticoagulant regimen to aspirin were too small (480 people) to produce reliable estimates of efficacy and safety.[34] We found four subsequent RCTs.[35–38] The first subsequent RCT (3712 people with unstable angina) compared 5 months' oral anticoagulant treatment (target INR 2.0–2.5) plus standard treatment (usually including aspirin) versus standard treatment alone.[37] When this trial was included in a meta-analysis with the previous trials assessing the addition of moderate intensity oral anticoagulation to aspirin, oral anticoagulation was associated with a non-significant reduction in mortality, myocardial infarction, or stroke (OR 0.83, 95% CI 0.66 to

1.03).[34] The second subsequent RCT (5059 people with myocardial infarction in the previous 14 days; unblinded) compared warfarin (target INR 1.5–2.5) plus aspirin 81 mg daily versus aspirin 162 mg daily alone.[38] It found no significant differences between treatments in mortality, recurrent myocardial infarction, or stroke after a median of 2.7 years (mortality 17.6% with warfarin plus aspirin *v* 17.3% with aspirin alone, P = 0.8; AR for recurrent myocardial infarction 13.3% with warfarin plus aspirin *v* 13.1% with aspirin alone, P = 0.8; AR for stroke 3.1% with warfarin plus aspirin *v* 3.5% with aspirin alone, P = 0.5). The third subsequent RCT (3630 people with previous acute myocardial infarction) compared three treatments: warfarin alone (target INR 2.8–4.2); aspirin 160 mg daily; and warfarin (target INR 2.0–2.5) plus aspirin 75 mg daily.[35] After 4 years, it found that warfarin plus aspirin significantly reduced cardiovascular events (death, myocardial infarction, or cerebral infarction) compared with aspirin alone (cardiovascular event rate 181/1208 [15%] with warfarin plus aspirin *v* 241/1206 [20%] with aspirin alone; RR 0.71, 95% CI 0.60 to 0.83). However, warfarin plus aspirin was associated with increased bleeding compared with aspirin alone (see harms below).[35] The fourth subsequent RCT (999 people after acute coronary syndrome) similarly compared three treatments: aspirin 80 mg daily; oral anticoagulants (to target INR 3.0–4.0); and aspirin 80 mg daily plus oral anticoagulants (to target INR 2.0–2.5).[36] It found that combination treatment significantly reduced cardiovascular events compared with aspirin alone (16/332 [5%] with combination *v* 31/336 [9%] with aspirin; HR 0.50, 95% CI 0.27 to 0.92).[36]

Harms: The systematic review found a non-significant excess of major haemorrhage with the addition of low intensity oral anticoagulation to aspirin (OR 1.29, 95% CI 0.96 to 1.75).[34] An updated meta-analysis assessing the addition of moderate intensity oral anticoagulation to aspirin included the RCTs from the systematic review[34] and one subsequent trial[37] (total of 4192 people with coronary artery disease). It found a clear excess of major haemorrhage in people allocated oral anticoagulation (OR 1.95, 95% CI 1.27 to 2.98).[37] The second subsequent RCT (5059 people) examining the addition of moderate intensity anticoagulation to aspirin also found that combined treatment increased risk of major haemorrhage (RR 1.78, 95% CI 1.27 to 2.72).[38] The third subsequent RCT found similar results at 4 years (non-fatal major bleeding: 0.57% a year with warfarin plus aspirin *v* 0.17% a year with aspirin; RR, CI, and significance not stated).[35] The fourth subsequent RCT found no significant difference in major bleeding between aspirin and combination treatment, although the study may have lacked power to detect a clinically important difference (2% with combination *v* 1% with aspirin alone; HR 2.35, 95% CI 0.61 to 9.10).[36]

Comment: The issue of whether adding a moderately intense oral anticoagulant regimen to aspirin provides additional net benefit to people at high risk of ischaemic cardiac events is being assessed in several ongoing RCTs. One RCT (135 people with unstable angina or non-ST segment myocardial infarction, with prior coronary artery bypass grafting) compared three treatments: aspirin 80 mg daily alone plus placebo; warfarin (target INR 2.0–2.5) plus placebo; and aspirin

plus warfarin.[39] It found no significant difference among treatments for rates of primary end point (death or myocardial infarction or unstable angina requiring admission to hospital at 1 year; AR 14.6% with warfarin alone *v* 11.5% with aspirin alone *v* 11.3% with combination, P = 0.76).[39] However, it found no significant difference for major haemorrhage among people taking warfarin compared with those who were not. Event rates were low and the study may have lacked power to detect a clinically important difference for adverse effects.[39]

QUESTION What are the effects of other drug treatments?

Bazian Ltd

OPTION β BLOCKERS

Systematic reviews have found strong evidence that β blockers reduce the risk of all cause mortality, coronary mortality, recurrent non-fatal myocardial infarction, and sudden death in people after myocardial infarction. Most benefit was seen in those at highest risk of mortality after a myocardial infarction (> 50 years old; previous myocardial infarction, angina pectoris, hypertension, or treatment with digitalis; transient mechanical or electrical failure; higher heart rate at study entry). About 25% of people suffered adverse effects.

Benefits:

Survival and reinfarction: One systematic review (search date 1993, 26 RCTs, > 24 000 people) compared oral β blockers versus placebo within days or weeks of an acute myocardial infarction (late intervention trials) and continued for between 6 weeks and 3 years.[40] Most RCTs followed people for 1 year. The review found improved survival in people given β blockers (RR 0.77, 95% CI 0.70 to 0.86).[40] One prior systematic review (search date not stated, 24 RCTs) found that long term use of β blockers versus placebo after myocardial infarction reduced total mortality (RR about 0.80), sudden death (RR about 0.70), and non-fatal reinfarction (RR about 0.75).[41] **Anginal symptoms:** We found no good RCTs assessing the antianginal effects of β blockers in people after myocardial infarction. One trial found atenolol more effective than placebo in people with chronic stable effort angina or silent ischaemia.[42] **Different types of β blockers:** The earlier review found no differences between β blockers with and without cardioselectivity or membrane stabilising properties, but it raised concerns about the lack of efficacy of β blockers with intrinsic sympathomimetic activity in long term management after myocardial infarction.[41] One RCT (607 people after myocardial infarction) found that acebutolol, a β blocker with moderate partial agonist activity, decreased 1 year mortality compared with placebo (AR of death: 11% with placebo *v* 6% with acebutolol; RR 0.52, 95% CI 0.29 to 0.91).[43] **Effects in different subgroups:** One systematic review (search date 1983, 9 RCTs) compared β blockers versus placebo started more than 24 hours after onset of symptoms of acute myocardial infarction and continued for 9–24 months.[44] Pooled analysis of individual data (13 679 people) found that the benefits of β blockers versus placebo on mortality seemed comparable in men and women. The highest absolute benefit from β blockers was found in subgroups

with the highest baseline risks (i.e. those with the highest mortality on placebo), those over 50 years of age; those with a history of previous myocardial infarction, angina pectoris, hypertension, or treatment with digitalis; those with transient signs or symptoms of mechanical or electrical failure in the early phases of myocardial infarction; and those with a higher heart rate at study entry. Low risk subgroups had smaller mean absolute benefit.

Harms: Adverse effects include shortness of breath, bronchospasm, bradycardia, hypotension, heart block, cold hands and feet, diarrhoea, fatigue, reduced sexual activity, depression, nightmares, faintness, insomnia, syncope, and hallucinations. Rates varied among studies. One RCT reported an absolute risk increase for any adverse effect of 24% with propranolol compared with placebo (no CI available). Serious adverse effects were uncommon and only a small proportion of people withdrew from the study as a result.[45] We found one systematic review (search date 2001; 15 RCTs; > 35 000 people) that examined harms of β blockers compared with placebo in people with previous myocardial infarction, heart failure, or hypertension.[46] It found no significant difference between β blockers and placebo in depressive symptoms or sexual dysfunction (depressive symptoms: RR 1.12, 95% CI 0.89 to 1.41; sexual dysfunction 1.10, 95% CI 0.96 to 1.25). However, it found a small but significant increase in fatigue with β blockers compared with placebo (RR 1.15, 95% CI 1.05 to 1.25)

Comment: Continued benefit has been reported from β blockers up to 6 years after myocardial infarction (ARR for mortality: 5.9%, P = 0.003; RR 0.82, CI not available). However, the study was not blinded after 33 months.

OPTION ANGIOTENSIN CONVERTING ENZYME INHIBITORS

One systematic review has found that in people who have had a myocardial infarction and have left ventricular dysfunction, angiotensin converting enzyme inhibitors reduce mortality, admission to hospital for congestive heart failure, and recurrent non-fatal myocardial infarction compared with placebo. One large RCT in people without left ventricular dysfunction found that ramipril versus placebo reduced cardiovascular death, stroke, and myocardial infarction.

Benefits: **In people with left ventricular dysfunction:** One systematic review (search date not stated, 3 RCTs, 5966 people)[47] compared angiotensin converting enzyme (ACE) inhibitors (captopril, ramipril, or trandolapril) versus placebo started 3–16 days after acute myocardial infarction and continued for 15–42 months. It analysed individual data from 5966 people with a recent myocardial infarction and with clinical manifestations of congestive heart failure or moderate left ventricular dysfunction (left ventricular ejection fraction ≥ 35–40%). ACE inhibitors versus placebo significantly reduced mortality (702/2995 [23.4%] with ACE inhibitors *v* 866/2971 [29.1%] with control; OR 0.74, 95% CI 0.66 to 0.83; NNT 17 people treated for about 2 years to prevent 1 death, CI not provided), admission to hospital for congestive heart failure (355/2995 [11.9%] with ACE inhibitors *v* 460/2971 [15.5%] with control; OR 0.73, 95% CI 0.63 to 0.85; NNT 28, CI not available), and

recurrent non-fatal myocardial infarction (324/2995 [10.8%] with ACE inhibitors *v* 391/2971 [13.1%] with control; OR 0.80, 95% CI 0.69 to 0.94; NNT 43, CI not provided). **In people without impaired ventricular function or evidence of congestive heart failure:** We found no systematic review but found one large RCT (9297 people at high risk of cardiovascular events).[48] It found that ramipril 10 mg daily versus placebo reduced the composite primary outcome of cardiovascular death, myocardial infarction, or stroke over an average of 4.7 years (RR for composite outcome 0.78, 95% CI 0.70 to 0.86; NNT 27, 95% CI 20 to 45; RR for cardiovascular death 0.74, 95% CI 0.64 to 0.87; NNT 50, CI not available; RR for myocardial infarction 0.80, 95% CI 0.70 to 0.90; NNT 42, CI not available; RR for stroke 0.68, 95% CI 0.56 to 0.84; NNT 67, CI not available; RR for death from all causes 0.84, 95% CI 0.75 to 0.95; NNT 56, CI not available). The RCT found that ramipril reduced the need for revascularisation procedures and reduced heart failure related outcomes (need for revascularisation: RR 0.85, CI not available; heart failure related outcomes: RR 0.77, CI not available). Ramipril versus placebo produced benefit in all subgroups examined, including women and men; people aged over and under 65 years; those with and without a history of coronary artery disease, hypertension, diabetes, peripheral vascular disease, cerebrovascular disease, and those with and without microalbuminuria at study entry.[48] **In people with diabetes:** See antihypertensive treatment under prevention of cardiovascular events in diabetes, p 777.[49]

Harms: The major adverse effects reported in these trials were cough (ARI 5–10% with ACE inhibitors *v* placebo), dizziness, hypotension (ARI with 5–10% with ACE inhibitors *v* placebo), renal failure (ARI < 3% with ACE inhibitors *v* placebo), hyperkalaemia (ARI < 3% with ACE inhibitors *v* placebo), angina, syncope, diarrhoea (ARI 2% with ACE inhibitors *v* placebo), and, for captopril, alteration in taste (2% of captopril users).[47]

Comment: There are several other ongoing large RCTs assessing ACE inhibitors in people without clinical manifestations of heart failure and with no or with mild impairment in left ventricular systolic function. These include one trial of trandolapril in 8000 people with coronary artery disease, and one trial of perindopril in 10 500 people with stable coronary artery disease.[50]

OPTION CLASS I ANTIARRHYTHMIC AGENTS (QUINIDINE, PROCAINAMIDE, DISOPYRAMIDE, ENCAINIDE, FLECAINIDE, AND MORACIZINE)

One systematic review has found that class I antiarrhythmic agents after myocardial infarction increase the risk of cardiovascular mortality and sudden death.

Benefits: One systematic review has found that class I antiarrhythmics are harmful in people who have had an acute coronary event (see harms below).

Harms: One systematic review (search date 1993, 51 RCTs, 23 229 people) compared class I antiarrhythmic drugs versus placebo given acutely and later in the management of myocardial infarction.[40] The

review found that the antiarrhythmic agents increased mortality (AR of death 5.6% with class I antiarrhythmic *v* 5.0% with placebo; OR 1.14, 95% CI 1.01 to 1.28). One RCT (1498 people with myocardial infarction and asymptomatic or mildly symptomatic ventricular arrhythmia) found that encainide or flecainide versus placebo increased the risk of death or cardiac arrest after 10 months (RR 2.38, 95% CI 1.59 to 3.57; NNH 17).[51]

Comment: The evidence implies that class I antiarrhythmic drugs should not be used in people after myocardial infarction or with significant coronary artery disease.

OPTION CLASS III ANTIARRHYTHMIC AGENTS (AMIODARONE, SOTALOL)

Systematic reviews have found that amiodarone reduces the risk of sudden death and marginally reduces mortality in people at high risk of arrhythmic death after myocardial infarction compared with placebo. One RCT found limited evidence that sotalol increased mortality within 1 year compared with placebo.

Benefits: **Amiodarone:** We found two systematic reviews.[52,53] The first systematic review (search date not stated, individual data from 6553 high risk people in 13 RCTs) compared amiodarone versus control treatments.[52] People were selected with a recent myocardial infarction and a high risk of death from cardiac arrhythmia (based on low left ventricular ejection fraction, frequent ventricular premature depolarisation, or non-sustained ventricular tachycardia, but no history of sustained symptomatic ventricular tachycardia or ventricular fibrillation); 78% of people from eight RCTs had a recent myocardial infarction, and 22% of people from five RCTs had congestive heart failure.[52] Most trials were placebo controlled with a mean follow up of about 1.5 years. The people with congestive heart failure were symptomatic but stable and had not had a recent myocardial infarction, although in most cases the heart failure was ischaemic in origin. All RCTs used a loading dose of amiodarone (400 mg/day for 28 days or 800 mg/day for 14 days) followed by a maintenance dose (200–400 mg/day). Amiodarone significantly reduced total mortality compared with placebo (AR for total mortality: 10.9% a year with amiodarone *v* 12.3% a year with placebo; RR 0.87, 95% CI 0.78 to 0.99) and rates of sudden cardiac death (RR 0.71, 95% CI 0.59 to 0.85). Amiodarone had similar effects in the studies after myocardial infarction and congestive heart failure.[52] The second systematic review (search date 1997, 5864 people with myocardial infarction, congestive heart failure, left ventricular dysfunction, or cardiac arrest) found similar results.[53]
Sotalol: We found one RCT (3121 people with myocardial infarction and left ventricular dysfunction), which found increased mortality with the class III antiarrhythmic agent sotalol versus placebo (AR for death: 5.0% with sotalol *v* 3.1% with placebo; RR 1.65, 95% CI 1.15 to 2.36). The trial was terminated prematurely after less than 1 year.[54]

Harms: Adverse events leading to discontinuation of amiodarone were hypothyroidism (expressed as events per 100 person-years: 7.0 with amiodarone *v* 1.1 with placebo; OR 7.3), hyperthyroidism (1.4

with amiodarone *v* 0.5 with placebo; OR 2.5), peripheral neuropathy (0.5 with amiodarone *v* 0.2 with placebo; OR 2.8), lung infiltrates (1.6 with amiodarone *v* 0.5 with placebo; OR 3.1), bradycardia (2.4 with amiodarone *v* 0.8 with placebo; OR 2.6), and liver dysfunction (1.0 with amiodarone *v* 0.4 with placebo; OR 2.7).[52]

Comment: The conclusions of the review are probably specific to amiodarone.[52,53] The two largest RCTs of amiodarone after myocardial infarction found a favourable interaction between β blockers and amiodarone, with additional reduction in cardiac mortality.[55,56]

OPTION CALCIUM CHANNEL BLOCKERS

One systematic review found no benefit from calcium channel blockers in people after myocardial infarction or with chronic coronary heart disease. Diltiazem and verapamil may reduce rates of reinfarction and refractory angina in people after myocardial infarction who do not have heart failure. The review found non-significantly higher mortality with dihydropyridines compared with placebo.

Benefits: One systematic review (search date 1993, 24 RCTs) compared calcium channel blockers (including dihydropyridines, diltiazem, and verapamil) versus placebo given early or late during the course of acute myocardial infarction or unstable angina and continued in the intermediate or long term.[40] Two of the RCTs used angiographic regression of coronary stenosis as an outcome in people with stable coronary heart disease treated with calcium channel blockers. The review found no significant difference in the absolute risk of death compared with placebo (AR 9.7% with calcium channel blockers *v* 9.3% with placebo; ARI with calcium channel blockers *v* placebo +0.4%, 95% CI −0.4% to +1.2%; OR 1.04, 95% CI 0.95 to 1.14). **Diltiazem and verapamil:** The review found no significant effect compared with placebo (OR 0.95, 95% CI 0.82 to 1.09).[40] Three RCTs comparing diltiazem or verapamil versus placebo found decreased rates of recurrent infarction and refractory angina with active treatment but only for those people without signs or symptoms of heart failure. For those with clinical manifestations of heart failure, the trends were towards harm.[57–59] **Dihydropyridines:** The review found non-significantly higher mortality with dihydropyridines compared with placebo (OR 1.16, 95% CI 0.99 to 1.35). Several individual RCTs of dihydropyridines found increased mortality, particularly when these agents were started early in the course of acute myocardial infarction and in the absence of β blockers.

Harms: Adverse effects reported of verapamil and diltiazem include atrioventricular block, atrial bradycardia, new onset heart failure, hypotension, dizziness, oedema, rash, constipation, and pruritus.

Comment: We found little good evidence on newer generation dihydropyridines, such as amlodipine and felodipine, in people after myocardial infarction but these have been found to be safe in people with heart failure, including heart failure of ischaemic origin.

OPTION HORMONE REPLACEMENT THERAPY

Large RCTs found no significant difference between hormone replacement therapy and placebo in major cardiovascular events in postmenopausal women with established coronary artery disease. Observational studies and one large RCT found that hormone replacement therapy increased risk of breast cancer, venous thromboembolism, and gall bladder disease compared with placebo.

Benefits:

Combined oestrogen and progestins: We found no systematic review. We found two RCTs. The first, and largest RCT (2763 postmenopausal women with coronary heart disease) found that conjugated equine oestrogen 0.625 mg daily plus medroxyprogesterone acetate 2.5 mg daily versus placebo for an average of 4.1 years produced no significant difference in the risk of non-fatal myocardial infarction or deaths caused by coronary heart disease (172/1380 [12.5%] with hormone replacement therapy *v* 176/1383 [12.7%] with placebo; ARR +0.3%, 95% CI −2.2% to +2.7%; RR 0.98, 95% CI 0.80 to 1.19).[60] It also found no significant difference in secondary cardiovascular outcomes (coronary revascularisation, unstable angina, congestive heart failure, resuscitated cardiac arrest, stroke or transient ischaemic attack, and peripheral arterial disease) or in all cause mortality. At the end of the trial, open label treatment was offered to surviving women, according to original treatment allocation.[61] Adherence to hormone replacement therapy was more than 80% for the next 2 years of follow up, but declined to 45% in the final year. Adherence to placebo remained above 90% throughout. Combined analysis of the blinded and open label phases of this RCT found no significant difference between combined hormone replacement therapy and placebo in coronary heart disease events after a mean total follow up of 6.8 years (intention to treat analysis: 36.6 events per 1000 person-years with hormone replacement therapy *v* 36.8 events per 1000 person-years with placebo; HR 0.99, 95% CI 0.84 to 1.17).[61] The second RCT (255 postmenopausal women with congestive heart failure confirmed by angiographic) also compared hormone replacement therapy versus placebo.[62] Women allocated to hormone replacement therapy received oestrogen plus progestin (76 women), except if they had a previous hysterectomy, in which case they received oestrogen alone (58 women). The RCT found no significant difference between hormone replacement therapy and placebo in coronary heart disease events after a mean follow up of about 31 months (composite of death due to heart disease, myocardial infarction, or admission for unstable angina: 15.4 events per 100 person-years with hormone replacement *v* 11.9 events per 100 person-years with placebo; RR 1.29, 95% CI 0.84 to 1.95).[62] **Oestrogen alone:** We found no good RCTs of oestrogen alone in the secondary prevention of coronary heart disease in postmenopausal women. One RCT found that high dose oestrogen (5 mg/day conjugated equine oestrogen) increased the risk of myocardial infarction and thromboembolic events in men with pre-existing coronary heart disease.[63]

Harms: Pooled estimates from observational studies found an increased risk of endometrial cancer (RR > 8) and of breast cancer (RR 1.25–1.46) when oestrogen was used for more than 8 years. In most observational studies, the addition of progestins prevented endometrial cancer but not breast cancer. The risk of venous thromboembolism, including pulmonary embolism and deep vein thrombosis, was three to four times higher with hormone replacement therapy than without. However, because the incidence of venous thromboembolism is low in postmenopausal women, the absolute increase in risk was only about one to two additional cases of venous thromboembolism in 5000 users a year.[64] In one RCT,[60] more women in the HRT group than in the placebo group experienced venous thromboembolism (34/1380 [2.5%] with HRT *v* 12/1383 [0.9%] with placebo; OR 2.65, 95% CI 1.48 to 4.75) and gall bladder disease (84/1380 [6.1%] with HRT *v* 62/1383 [4.5%] with placebo; OR 1.38, 95% CI 0.99 to 1.92). Extended open label follow up of this trial found similar results after a total mean follow up of 6.8 years (combined intention to treat analysis from blind and open label phases; venous thromboembolism: 5.9 events per 1000 person-years with HRT *v* 2.8 events per 1000 person-years with placebo; HR 2.08, 95% CI 1.28 to 3.40; biliary tract surgery: 19.1 events per 1000 person-years with HRT *v* 12.9 events with placebo; HR 1.48, 95% CI 1.12 to 1.95).[65]

Comment: Many observational studies have found reduced rates of clinical events caused by coronary heart disease in postmenopausal women using HRT, especially in women with pre-existing coronary heart disease. Hormone users experienced 35–80% fewer recurrent events than non-users.[66,67] Several RCTs have found that HRT improves cardiovascular risk factors.[68] It is not known whether studies longer than 4 years would show a benefit.

QUESTION What are the effects of cholesterol reduction?

Michael Pignone

OPTION CHOLESTEROL REDUCTION

Systematic reviews and large subsequent RCTs have found that lowering cholesterol in people at high risk of ischaemic coronary events substantially reduces overall mortality, cardiovascular mortality, and non-fatal cardiovascular events. We found good evidence from systematic reviews and subsequent RCTs that statins were the only non-surgical treatment for cholesterol reduction that reduced mortality. One systematic review found that the absolute benefits increase as baseline risk increases, but are not additionally influenced by the person's absolute cholesterol concentration.

Benefits: **All cholesterol treatments:** We found one systematic review (search date 1996, 59 RCTs, 173 160 people), which did not differentiate primary and secondary prevention, and included RCTs of any cholesterol lowering intervention, irrespective of duration, as long as mortality data were reported.[69] It included drug treatments (statins, n-3 fatty acids, fibrates, resins, hormones, or niacin), dietary intervention alone, or surgery (ileal bypass) alone. Overall,

baseline risk was similar among all intervention groups. Among non-surgical treatments, the review found that only statins reduced coronary heart disease mortality, and that only statins and n-3 fatty acids significantly reduced all cause mortality (RR of coronary heart disease mortality: statins *v* control 0.69, 95% CI 0.59 to 0.80; n-3 fatty acids *v* control 0.44, 95% CI 0.18 to 1.07; fibrates *v* control 0.98, 95% CI 0.78 to 1.24; resins *v* control 0.71, 95% CI 0.51 to 0.99; hormones *v* control 1.04, 95% CI 0.93 to 1.17; niacin *v* control 0.95, 95% CI 0.83 to 1.10; diet *v* control 0.91, 95% CI 0.82 to 1.01. RR of all cause mortality: statins *v* control 0.79, 95% CI 0.71 to 0.89; n-3 fatty acids *v* control 0.68, 95% CI 0.53 to 0.88; fibrates *v* control 1.06, 95% CI 0.78 to 1.46; resins *v* control 0.85, 95% CI 0.66 to 1.08; hormone *v* control 1.09, 95% CI 1.00 to 1.20; niacin *v* control 0.96, 95% CI 0.86 to 1.08; diet *v* control 0.97, 95% CI 0.81 to 1.15).[69] **Statins:** We found one systematic review (search date 1998, 5 RCTs, 30 817 people) that compared long term (≥ 4 years) treatment with statins versus placebo.[70] Combining the three secondary prevention trials, the review found that statins reduced coronary heart disease mortality, cardiovascular mortality, and all cause mortality compared with placebo over a mean of 5.4 years (coronary heart disease mortality: OR 0.71, 95% CI 0.63 to 0.80; cardiovascular mortality: OR 0.73, 95% CI 0.66 to 0.82; all cause mortality: OR 0.77, 95% CI 0.70 to 0.85). One subsequent RCT (20 536 adults with total cholesterol > 3.5 mmol/L [an inclusion threshold lower than previous statin trials], including > 5000 women and > 5000 people over 70 years of age) compared simvastatin 40 mg versus placebo. The study included both primary and secondary prevention populations.[71] After a mean of 5.5 years follow up, simvastatin reduced total mortality and major vascular events compared with placebo (all cause mortality: 12.9% with simvastatin *v* 14.7% with placebo, RR 0.87, 95% CI 0.81 to 0.94; major vascular events 19.8% with simvastatin *v* 25.2% with placebo, RR 0.76, 95% CI 0.72 to 0.81). We found one subsequent RCT (1600 people with established coronary heart disease).[72] It found that atorvastatin (10–80 mg/day, titrated to achieve low density lipoprotein cholesterol < 2.6 mM [100 mg/dL]) significantly reduced recurrent coronary events or death, and all cause mortality compared with management not involving statins at 3 years (coronary events or death: 12.0% with atorvastatin *v* 24.5% without statins; RR 0.49, 95% CI 0.27 to 0.73; all cause mortality: 2.9% with atorvastatin *v* 5.0% without statins; RR 0.57, 95% CI 0.39 to 0.78).[72] **Effects of statins in different groups of people:** Combining results from primary and secondary prevention trials, the review found that, compared with placebo, statins reduced coronary events by a similar proportion in men (OR 0.69, 95% CI 0.65 to 0.74; ARR 3.7%, 95% CI 2.9% to 4.4%), in women (OR 0.71, 95% CI 0.64 to 0.76; ARR 3.3%, 95% CI 1.3% to 5.2%), in people under 65 years (OR 0.69, 95% CI 0.64 to 0.76; ARR 3.2%, 95% CI 2.4% to 4.0%), and in people over 65 years (OR 0.68, 95% CI 0.61 to 0.77; ARR 4.4%, 95% CI 3.0% to 5.8%). The reduction of coronary heart disease events in women involved more non-fatal and fewer fatal events than in men. One large RCT found no significant difference in mortality with statins versus placebo for the subgroup

of women, but the confidence interval was wide (28/407 [6.9%] with simvastatin *v* 25/420 [6.0%] with placebo; RR 1.16, 95% CI 0.68 to 1.99).[73] One recent RCT that was not included in the review found that relative risk reductions were similar for people with initial total cholesterol levels of under 5.0 mmol/L compared with people with levels over 5.0 mmol/L and for women and the elderly compared with younger men.[71] One RCT compared early initiation of atorvastatin (80 mg/day started 1–4 days after admission) versus placebo in people with unstable angina or non-Q wave myocardial infarction.[74] After 3 months, it found no significant difference between treatments for coronary event rates, although atorvastatin reduced readmission rate for recurrent ischaemia compared with placebo (AR for readmission for ischaemia: 6.2% with atorvastatin *v* 8.4% with placebo; RR 0.74, 95% CI 0.57 to 0.95). One further RCT compared fluvastatin 80 mg daily versus placebo in 1677 people with total cholesterol 135–270 mg/dL (3.5–7.0 mM) and cardiac ischaemia after percutaneous coronary intervention.[75] It found that fluvastatin significantly reduced major cardiac events (cardiac death, non-fatal myocardial infarction, or reintervention) compared with placebo after 3–4 years (21.4% with fluvastatin *v* 26.7% with placebo; RR 0.78, 95% CI 0.64 to 0.95). **Intensity of statin treatment:** We found one RCT (1351 people with a history of saphenous vein coronary artery bypass grafting) that compared aggressive reduction of cholesterol with lovastatin and, if necessary, cholestyramine (colestyramine) (aiming for target low density lipoprotein cholesterol 1.6–2.2 mmol/L [60–85 mg/dL]) with more moderate reduction (target low density lipoprotein cholesterol 3.4–3.7 mmol/L [130–140 mg/dL]) with the same drugs.[76] The trial found that aggressive treatment reduced the risk of needing repeat revascularisation at 4 years (6.5% with aggressive treatment *v* 9.2% with moderate treatment, P = 0.03). After an additional 3 years, aggressive treatment reduced the risk of revascularisation and cardiovascular death compared with moderate treatment (AR of revascularisation 19% with aggressive treatment *v* 27% with moderate treatment, P = 0.0006; AR for cardiovascular death, 7.4% with aggressive treatment *v* 11.3% with moderate treatment, P = 0.03).[76] **Fibrates:** We found one systematic review (search date not stated, 4 RCTs)[77] and two additional RCTs.[78,79] The systematic review compared fibrates versus placebo in people with known coronary heart disease. The review identified one RCT (2531 men with coronary heart disease and a level of high density lipoprotein cholesterol > 1 mmol/L) that found gemfibrozil versus placebo reduced the composite outcome of non-fatal myocardial infarction plus death from coronary heart disease after a median of 5.1 years (AR 219/1264 [17%] for gemfibrozil *v* 275/1267 [22%] for placebo; ARR 4.4%, 95% CI 1.4% to 7.0%; RR 0.80, 95% CI 0.68 to 0.94; NNT 23, 95% CI 14 to 73). The review identified three trials comparing clofibrate versus placebo, which found no consistent difference between groups. The two additional RCTs[78,79] both compared bezafibrate versus placebo. The larger RCT (3090 people selected with previous myocardial infarction or stable angina, high density lipoprotein cholesterol < 45 mg/dL, and low density lipoprotein cholesterol < 180 mg/dL) found that bezafibrate versus placebo did not significantly reduce all cause mortality or the

composite end point of myocardial infarction plus sudden death (AR for myocardial infarction or sudden death: 13.6% with bezafibrate *v* 15.0% with placebo; cumulative RR 0.91; P = 0.26).[78] The smaller RCT (92 young male survivors of myocardial infarction) found that bezafibrate versus placebo significantly reduced the combined outcome of death, reinfarction, plus revascularisation (3/47 [6%] with bezafibrate *v* 11/45 [24%]; RR 0.26, 95% CI 0.08 to 0.88).[79]

Cholesterol lowering versus angioplasty: We found no systematic review. One RCT found that aggressive lipid lowering treatment was as effective as percutaneous transluminal angioplasty for reducing ischaemic events, although anginal symptoms were reduced more by percutaneous transluminal angioplasty (see percutaneous transluminal angioplasty *v* medical treatment, p 227).

Harms:

Total non-cardiovascular events, total and tissue specific cancers, and accident and violent deaths have been reported in statin trials. However, the systematic review of long term statin trials found no significant difference between statins and placebo in terms of non-cardiovascular mortality, cancer incidence, asymptomatic elevation of creatine kinase (> 10 times upper reference limit), or elevation of transaminases (> 3 times upper reference limit) during a mean of 5.4 years of treatment (OR of event, statin *v* placebo for non-cardiovascular mortality 0.93, 95% CI 0.81 to 1.07; for cancer 0.99, 95% CI 0.90 to 1.08; for creatine kinase increase 1.25, 95% CI 0.83 to 1.89; for transaminase increase 1.13, 95% CI 0.95 to 1.33).[73] We found one meta-analysis of three large RCTs (19 592 people) examining safety of pravastatin compared with placebo in primary or secondary prevention.[80] It found no clinically important difference between pravastatin and placebo for any adverse effects after a mean follow up of 5 years (primary cancer: 9.6% with pravastatin *v* 9.3% with placebo, P = 0.48; musculoskeletal adverse effects: < 0.1% in both groups, P = 0.02; gastrointestinal adverse effects: 1.4% *v* 1.5%, P = 0.48; hepatobiliary adverse effects: ≤ 0.1% in both groups, P = 0.45; dermatological adverse effects: 3.6% with pravastatin *v* 3.4% with placebo, P = 0.31; renal adverse effects: 2.7% with pravastatin *v* 2.5% with placebo, P = 0.42).[80] We found no evidence of additional harm associated with cholesterol lowering in elderly people, or in people after acute myocardial infarction.

Comment:

Multivariate analysis in one systematic review (search date 1996) indicates that in a wide range of clinical contexts the relative risk reduction depends on the percent reduction in total or low density lipoprotein cholesterol and is not otherwise dependent on the method by which cholesterol is lowered. The absolute benefit over several years of lowering cholesterol will therefore be greatest in people with the highest baseline risk of an ischaemic cardiac event. Even if the relative risk reduction attenuates at older age, the absolute risk reduction for ischaemic cardiac events may be higher in elderly people than in younger people. The Women's Health Initiative (48 000 people, completion 2007, diet, up to age 79 years),[81] and the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Disease Trial (10 000 people, completion 2002, pravastatin, no upper age limit) are ongoing.[82] We found no large direct comparisons of cholesterol modifying drugs; it remains

unclear whether any one drug has advantages over others in subgroups of high risk people with particular lipid abnormalities. Because the main aim of treatment is to reduce absolute risk (rather than to reduce the cholesterol to any particular concentration), treatments aimed at lowering cholesterol need assessing for effectiveness in comparison and in combination with other possible risk factor interventions in each individual. People in the large statin trials in both treatment and placebo groups were given dietary advice aimed at lowering cholesterol.

QUESTION What are the effects of blood pressure reduction?

Bazian Ltd

OPTION BLOOD PRESSURE REDUCTION

We found no direct evidence of the effects of blood pressure lowering in people with established coronary heart disease. Observational studies, and extrapolation of primary prevention trials of blood pressure reduction, support the lowering of blood pressure in those at high risk of ischaemic coronary events. The evidence for benefit is strongest for β blockers, although not specifically in people with hypertension. The optimum target blood pressure in people with hypertension is not clear.

Benefits: We found no systematic review and no RCTs designed specifically to examine blood pressure reduction in those with established coronary heart disease. Prospective epidemiological studies have established that blood pressure continues to be a risk factor for cardiovascular events in people who have already experienced myocardial infarction. Prospective follow up of 5362 men who reported prior myocardial infarction during screening for one large RCT found no detectable association between systolic blood pressure and coronary heart disease mortality, and increased coronary heart disease mortality for those with lowest diastolic blood pressure in the first 2 years.[83] After 15 years there were highly significant linear associations between both systolic and diastolic blood pressure and increased risk of coronary heart disease mortality (stronger relation for systolic blood pressure), with apparent benefit for men with blood pressure maintained at levels lower than the arbitrarily defined "normal" levels. Experimental evidence of benefit from lowering of blood pressure in those with coronary heart disease requires extrapolation from primary prevention trials, because trials of antihypertensive treatment in elderly people[84–86] are likely to have included those with preclinical coronary heart disease. Mortality benefit has been established for β blockers after myocardial infarction (see β blockers, p 209), for verapamil and diltiazem after myocardial infarction in those without heart failure (see calcium channel blockers, p 213), and for angiotensin converting enzyme inhibitors after myocardial infarction, especially in those with heart failure (see angiotensin converting enzyme inhibitors, p 210).

Harms: Some observational studies have found increased mortality among those with low diastolic blood pressure.[87] Trials in elderly people of blood pressure lowering for hypertension or while treating heart failure[88] found no evidence of a J-shaped relation between blood pressure and death.

Secondary prevention of ischaemic cardiac events

Comment: Without specific studies comparing different antihypertensive treatments, the available evidence is strongest for a beneficial effect of β blockers when treating survivors of a myocardial infarction who have hypertension. We found no specific evidence about the target level of blood pressure.

QUESTION What are the effects of non-drug treatments?

Bazian Ltd

OPTION DIET

One RCT found that advising people with coronary heart disease to eat more fruit and vegetables, bread, pasta, potatoes, olive oil, and rapeseed margarine (i.e. a Mediterranean diet) may result in a substantial survival benefit. We found no strong evidence from RCTs for a beneficial effect of low fat or high fibre diets on major non-fatal coronary heart disease events or coronary heart disease mortality. One RCT has found that advising people with coronary heart disease to eat more fish (particularly oily fish) significantly reduces mortality at 2 years. A second RCT found that fish oil capsules reduced mortality at 3.5 years.

Benefits:

Low fat diets: One systematic review (search date not stated) found no evidence that allocation to a low fat diet reduced mortality from coronary heart disease in people after myocardial infarction (RR 0.94, 95% CI 0.84 to 1.06).[89] One large RCT included in the review (2033 middle aged men with a recent myocardial infarction) compared three dietary options: fat advice (to eat less fat), fibre advice (to eat more cereal fibre), and fish advice (to eat at least 2 portions of oily fish a week).[90] Advice to reduce fat was complicated and, though fat intake reduced only slightly in the fat advice group, fruit and vegetable intake increased by about 40 g daily.[91] However, there was no significant reduction in mortality (unadjusted RR at 2 years for death from any cause 0.97, 95% CI 0.75 to 1.27). **High fibre diets:** In the RCT, people advised to eat more fibre doubled their intake, but survival was non-significantly worse (unadjusted RR at 2 years for death from any cause 1.23, 95% CI 0.95 to 1.60).[90] **High fish diets:** In the RCT, those advised to eat more fish ate three times as much fish, although about 14% could not tolerate the fish and were given fish oil capsules. Those given fish advice were significantly less likely to die within 2 years (94/1015 [9.3%] with fish advice *v* 130/1018 [12.8%] with no fish advice; NNT 29, 95% CI 17 to 129; RR 0.71, 95% CI 0.54 to 0.93).[90] In a second trial, 11 324 people who had survived a recent myocardial infarction were randomised to receive 1 g daily of n-3 polyunsaturated fatty acids (fish oil) or no fish oil. Those given fish oil were less likely to die within 3.5 years (RR 0.86, 95% CI 0.76 to 0.97).[92] **Mediterranean diet:** One RCT (605 middle aged people with a recent myocardial infarction) compared advice to eat a Mediterranean diet (more bread, fruit and vegetables, fish, and less meat, and to replace butter and cream with rapeseed margarine) versus usual dietary advice.[93] There were several dietary differences between the groups. Fruit intake, for example, was about 50 g daily higher in the intervention group than the control group. After 27 months, the trial was stopped prematurely because of significantly

better outcomes in the intervention group (mortality: 8/302 [2.6%] with intervention *v* 20/303 [6.6%] with usual dietary advice, adjusted RR of death 0.24, 97% CI 0.15 to 0.91 [97% CI to allow for early stopping]; NNT 25, 95% CI 14 to 299 over 27 months).[93]

Harms: No major adverse effects have been reported.

Comment: Diets low in saturated fat and cholesterol can lead to 10–15% reductions in cholesterol concentrations in highly controlled settings, such as in metabolic wards.[94] In people in the community the effects are smaller: 3–5% reductions in cholesterol concentrations in general population studies and 9% reductions in people after myocardial infarction.[89,95–97] Several RCTs of intensive dietary intervention in conjunction with multifactorial risk reduction treatment found decreased progression of anatomic extent of coronary heart disease on angiography.[98] A trial of advice to eat more fruit and vegetables in men with angina is under way (Burr M, personal communication, 2001). **Effect on cardiovascular risk factors:** Other studies have investigated the effects of dietary interventions on cardiovascular risk factors rather than the effect on cardiovascular morbidity and mortality. One systematic review (search date 1992) suggested that garlic may reduce cholesterol by about 10%.[99] Some trials in this review had problems with their methods. More recent reports (published in 1998) found no effects of garlic powder or garlic oil on cholesterol concentrations.[100,101] One systematic review (search date 1991) reported modest reductions in cholesterol levels of 2–5% from oats and psyllium enriched cereals (high fibre diets), although we found no evidence that high fibre diets reduce mortality in people with coronary heart disease.[102] One systematic review (search date 1991) of soy protein also reported modest reductions in cholesterol concentrations.[102]

OPTION ANTIOXIDANT VITAMINS (VITAMIN E, β CAROTENE, VITAMIN C)

We found no consistent evidence from four RCTs about effects of vitamin E versus placebo or other antioxidants in people with high cardiovascular risk. We found insufficient evidence about effects of vitamin C alone. Four large RCTs of β carotene supplementation in primary prevention found no cardiovascular benefits, and two of the RCTs raised concerns about increased mortality.

Benefits: **Vitamin E:** We found four large RCTs of vitamin E in people with coronary artery disease.[92,103–105] The first RCT (2002 people with angiographically proved ischaemic heart disease)[103] used a high dose of vitamin E (400 or 800 IU) and follow up was brief (median 510 days). The RCT found that vitamin E reduced non-fatal coronary events (RR 0.23, 95% CI 0.11 to 0.47), but also found a non-significant increase in coronary death (RR 1.18, 95% CI 0.62 to 2.27) and all cause mortality. The second RCT (29 133 male Finnish smokers) compared β carotene supplements versus vitamin E supplements versus both versus placebo.[104] The dose of vitamin E (50 mg/day) was smaller than that used in the first trial. In the subgroup analysis of data from the 1862 men with prior myocardial infarction, the trial found that vitamin E reduced non-fatal myocardial infarction (RR 0.62, 95% CI 0.41 to 0.96) but

non-significantly increased coronary death (RR 1.33, 95% CI 0.86 to 2.05).[104] The third RCT (11 324 people ≤3 months after myocardial infarction)[102] used a factorial design to compare vitamin E 300 mg daily versus no vitamin E (as well as fish oil *v* no fish oil). After 3.5 years there was a small and non-significant reduction in the risk of cardiovascular death and deaths from all causes in those who received vitamin E compared with those who did not (all cause mortality: RR 0.92, 95% CI 0.82 to 1.04). There was no significant change in the rate of non-fatal coronary events in those who received vitamin E (RR 1.04, 95% CI 0.88 to 1.22).[102] The fourth RCT (9541 people at high cardiovascular risk, 80% with prior clinical coronary artery disease, remainder with other atherosclerotic disease or diabetes with ≥1 additional cardiovascular risk factor) compared natural source vitamin E (D-α tocopherol acetate, 400 IU/day) versus placebo and followed people for an average of 4.7 years.[105] It found no significant differences in any cardiovascular outcomes between vitamin E and placebo (AR for major fatal or non-fatal cardiovascular event 16.2% with vitamin E *v* 15.5% with placebo, P > 0.05; AR for cardiovascular death 7.2% with vitamin E *v* 6.9% with placebo, P > 0.05; AR for non-fatal myocardial infarction 11.2% with vitamin E *v* 11.0% with placebo, P > 0.05; AR for stroke 4.4% with vitamin E *v* 3.8% with placebo, P > 0.05; AR for death from any cause 11.2% with vitamin E *v* 11.2% with placebo, P > 0.05). One additional smaller RCT (196 people on haemodialysis, aged 40–75 years) compared high dose vitamin E (800 IU/day) versus placebo.[106] After a median of 519 days, it found that vitamin E reduced the rate of combined cardiovascular end points but found no significant effect for all cause mortality (cardiovascular end points: vitamin E *v* placebo RR 0.54, 95% CI 0.23 to 0.89; mortality: vitamin E *v* placebo RR 1.09, 95% CI 0.70 to 1.70).[106]
Vitamin C: We found no RCTs examining effects of vitamin C alone in people with coronary heart disease. **β Carotene:** See harms below.

Harms: Two of the trials of vitamin E found non-significant increases in the risk of coronary death (see benefits above).[103,107] **β Carotene:** One systematic review (search date 1996) identified four large RCTs of β carotene supplementation. All were primary prevention studies, and so have not been included in the benefits section above. None found evidence of cardiovascular benefits, although two of the trials suggested that β carotene may increase mortality compared with placebo (cardiovascular death: β carotene *v* placebo RR 1.12, 95% CI 1.04 to 1.22) and cancer rates.[107]

Comment: One systematic review (search date 1996) of epidemiological studies found consistent associations between increased dietary intake, supplemental intake of vitamin E, or both, and lower cardiovascular risk and less consistent associations for β carotene and vitamin C.[107] Most observational studies of antioxidants have excluded people with pre-existing disease.[108,109] The results of the trial in people on haemodialysis raises the possibility that high dose vitamin E supplementation may be beneficial in those at high absolute risk of coronary events.[106] Further trials in such groups are required to confirm or refute this finding. The Heart Protection Study (results not fully published at time of search, 20 536 people aged

40–80 years with prior cardiovascular events or at high risk for vascular disease) compared a combination of antioxidant vitamins (daily doses: vitamin C 250 mg, vitamin E 600 mg, and β carotene 20 mg) versus placebo. After 5.5 years, the antioxidant treatment had no significant effect on total mortality and major cardiovascular events.[110]

OPTION CARDIAC REHABILITATION INCLUDING EXERCISE

One systematic review has found that cardiac rehabilitation including exercise reduces the risk of major cardiac events in people after myocardial infarction. It found that exercise alone reduced the risk of a major cardiac event, and probably reduced mortality. One subsequent RCT found no significant difference in quality of life between standard rehabilitation and early return to normal activities, although the study may have lacked power to detect clinically important differences between groups.

Benefits: We found one systematic review (search date 1998).[111] **Cardiac rehabilitation:** The review identified 42 RCTs of cardiac rehabilitation including exercise versus usual care (7683 people, who have had myocardial infarction, coronary artery bypass grafting [CABG], or percutaneous transluminal coronary angioplasty, or who have angina pectoris or coronary artery disease defined by angiography). It found that cardiac rehabilitation including exercise reduced the composite end point of mortality, non-fatal myocardial infarction, CABG, and percutaneous transluminal angioplasty (636/3863 [16.5%] with cardiac rehabilitation *v* 734/3820 [19.2%] with usual care; RR 0.85, 95% CI 0.77 to 0.93). It found limited evidence of a reduction in mortality but significance was sensitive to the quality of the trials.[111] We found one subsequent RCT.[112] The RCT (142 people with acute myocardial infarction in the previous week) compared 6 weeks of standard rehabilitation versus early return to normal activities.[112] It found no significant difference between groups in quality of life (measured on the cardiovascular extension of the Health Measurement Questionnaire; results presented graphically). However, the trial may have lacked power to exclude clinically important differences between groups.[111] **Exercise alone:** The review identified 12 RCTs of exercise alone versus usual care (2582 people, who have had myocardial infarction, CABG, or percutaneous transluminal angioplasty, or who have angina pectoris or coronary artery disease defined by angiography). It found that exercise significantly reduced mortality (93/1297 [7.2%] with exercise *v* 122/1285 [9.5%] with usual care; RR 0.76, 95% CI 0.59 to 0.98). It was associated with a reduction in the composite end point of mortality, non-fatal myocardial infarction, CABG, and percutaneous transluminal angioplasty, but the difference was not significant (183/1297 [14.1%] with exercise *v* 216/1285 [16.8%] with usual care; RR 0.85, 95% CI 0.71 to 1.01).[111]

Harms: Rates of adverse cardiovascular outcomes (syncope, arrhythmia, myocardial infarction, or sudden death) were low (2–3/100 000 person-hours) in supervised rehabilitation programmes, and rates of fatal cardiac events during or immediately after exercise training, were reported in two older surveys as ranging from 1/116 400 to 1/784 000 person-hours.[113]

Secondary prevention of ischaemic cardiac events

Comment: The review included some RCTs performed before the widespread use of thrombolytic agents and β blockers after myocardial infarction.[113] Most people were white men, without comorbidity, and under 70 years of age. Other interventions aimed at risk factor modification were often provided in the intervention groups (including nutritional education, counselling in behavioural modification, and, in some trials, lipid lowering medications). We found no strong evidence that exercise training and cardiac rehabilitation programmes increased the proportion of people returning to work after myocardial infarction.

OPTION SMOKING CESSATION

We found no RCTs of the effects of smoking cessation on cardiovascular events in people with coronary heart disease. Moderate quality evidence from epidemiological studies indicates that people with coronary heart disease who stop smoking rapidly reduce their risk of recurrent coronary events or death. Treatment with nicotine patches seems safe in people with coronary heart disease.

Benefits: We found no RCTs assessing the effects of smoking cessation on coronary morbidity and mortality. Many observational studies have found that people with coronary heart disease who stop smoking rapidly reduce their risk of cardiac death and myocardial infarction (recurrent coronary events or premature death compared with continuing smokers: RR about 0.50).[114] See smoking cessation under primary prevention for more details, p 163. The studies found that about 50% of the benefits occur in the first year of stopping smoking, followed by a more gradual decrease in risk, reaching the risk of never smokers after several years of abstinence.[114] Among people with peripheral arterial disease and stroke, smoking cessation has been shown in observational studies to be associated with improved exercise tolerance, decreased risk of amputation, improved survival, and reduced risk of recurrent stroke.

Harms: Two recent RCTs found no evidence that nicotine replacement using transdermal patches in people with stable coronary heart disease increased cardiovascular events.[115,116]

Comment: One RCT compared the impact of firm and detailed advice to stop smoking (125 survivors of acute myocardial infarction) versus conventional advice (85 people).[117] Allocation to the intervention or control group was determined by day of admission. At over 1 year after admission, 62% of the intervention group and 28% of the control group were non-smokers. Morbidity and mortality were not reported. (See psychological and stress management, p 224).

OPTION PSYCHOLOGICAL AND STRESS MANAGEMENT

RCTs found limited evidence that psychosocial treatments decreased cardiac events or cardiac death compared with no psychosocial treatment in people with coronary heart disease. Two RCTs found that psychological treatments improved quality of life compared with no psychological treatment.

Benefits: One systematic review (search date not stated, 23 RCTs, 3180 people with coronary artery disease) compared a diverse range of psychosocial treatments (2024 people) versus usual treatment (1156 people).[118] Mortality results were available in only 12 RCTs. Psychosocial interventions versus control interventions significantly reduced mortality (OR survival 1.70, 95% CI 1.09 to 2.64) and non-fatal events in the first 2 years after myocardial infarction (OR for no event 1.84, 95% CI 1.12 to 2.99).[118] We found three subsequent RCTs.[119–121] The first RCT (142 people with newly diagnosed angina managed in primary care) compared a self management plan versus a single nurse-led educational session.[119] The self management plan consisted of a work book and relaxation programme, which was introduced and explained to participants by a primary care nurse. The RCT found that the self management plan significantly improved depression and anxiety scores compared with the educational session at 6 months (measured by Hospital Anxiety and Depression Scale [see glossary, p 231]; change in anxiety score from baseline −1.03 with angina plan *v* 0 with educational session, P = 0.05; change in depression score −0.48 with angina plan *v* 0.41 with educational session, P = 0.01).[119] The second RCT (114 people after acute myocardial infarction) compared usual care versus an individualised cognitive behavioural programme based on national guidelines, which involved discussion of worries, establishing goals, repeated consultation to discuss progress, and a range of written materials and a relaxation tape.[120] The trial found that the individualised cognitive behavioural programme significantly improved health related quality of life compared with usual care (proportion of people with improved Dartmouth COOP score, measured on a scale from 1 [best quality of life] to 5 [worst quality of life]: 59% with intervention *v* 33% with usual care; OR 0.34, 95% CI 0.16 to 0.73; NNT 4, 95% CI 3 to 12).[120] The third RCT (65 people with recent acute myocardial infarction) compared standard care versus a brief in-hospital intervention to alter illness perception, consisting of three 30–40 minute interviews with a psychologist.[121] In these interviews, participants' worries were discussed; participants' causal models of coronary heart disease were discussed and challenged; implications for lifestyle were discussed, and a staged self management plan established and reviewed. At 3 months, the in-hospital intervention significantly reduced angina compared with standard care (self report of angina: 14.3% with intervention *v* 39.3% with standard care, P < 0.05).[121] However, it was not clear whether this difference was due to altered perception of symptoms or because of different rates of genuine ischaemia.[121]

Harms: No specific harms were reported.

Comment: These results should be interpreted with caution because of limits of the methods of the individual RCTs and the diversity of interventions (relaxation, stress management, counselling). The RCTs were generally small, with short follow up, and used non-uniform outcome measures. Methods of concealment allocation were not assessed. The authors of the review acknowledged the strong possibility of publication bias but made no attempt to measure it. The results

were inconsistent across trials.[122] Several observational studies have found that depression and social isolation (lack of social and emotional support) are independent predictors of mortality and non-fatal coronary heart disease events in people after myocardial infarction.[123]

QUESTION What are the effects of surgical treatments?

Charanjit Rihal

OPTION CORONARY ARTERY BYPASS GRAFTING VERSUS MEDICAL TREATMENT ALONE

One systematic review found that coronary artery bypass grafts reduced the risk of death from coronary artery disease at 5 and 10 years compared with medical treatment alone. Greater benefit occurred in people with poor left ventricular function. One subsequent RCT in people with asymptomatic disease found that revascularisation with coronary artery bypass grafting or coronary percutaneous transluminal angioplasty reduced mortality compared with medical treatment alone at 2 years.

Benefits: We found one systematic review comparing coronary artery bypass grafting (CABG) with medical treatment alone[124] and one subsequent RCT in asymptomatic people of revascularisation with CABG or coronary percutaneous transluminal angioplasty versus medical treatment alone.[125] In the systematic review (search date not stated, 7 RCTs, individual results from 2649 people with coronary heart disease) most people were middle aged men with multivessel disease but good left ventricular function who were enrolled from 1972–1984 (97% were male; 82% 41–60 years old; 80% with ejection fraction > 50%; 60% with prior myocardial infarction; and 83% with 2 or 3 vessel disease).[124] People assigned to CABG also received medical treatment, and 40% initially assigned to medical treatment underwent CABG in the following 10 years. The systematic review found that CABG versus medical treatment reduced deaths at 5 and 10 years (death at 5 years: RR 0.61 95% CI 0.48 to 0.77; death at 10 years: RR 0.83, 95% CI 0.70 to 0.98).[124] Most trials did not collect data on recurrent angina or quality of life. **Effects in people with reduced versus normal left ventricular function:** The systematic review found that the relative benefits were similar in people with normal versus reduced left ventricular function (death: OR 0.61, 95% CI 0.46 to 0.81 if left ventricular function was normal; OR 0.59. 95% CI 0.39 to 0.91 if left ventricular function was reduced).[124] The absolute benefit of CABG was greater in people with a reduced left ventricular function because the baseline risk of death was higher. **Effects in people with different numbers of diseased vessels:** The systematic review found lower mortality with CABG versus medical treatment in people with single vessel, two vessel, three vessel, and left main stem disease, but for single vessel and two vessel disease the difference was not statistically significant, possibly because the number of deaths was small (RR with single vessel disease 0.54, 95% CI 0.22 to 1.33; with two vessel disease 0.84, 95% CI 0.54 to 1.32; with three vessel disease 0.58, 95% CI 0.42 to 0.80; with left main stem disease 0.32, 95% CI 0.15 to 0.70).[124] **Effects in**

asymptomatic people: We found one RCT (558 people) of revascularisation with CABG or percutaneous transluminal angioplasty versus symptom guided treatment versus electrocardiogram and symptom guided treatment in people with asymptomatic ischaemia identified by exercise test or ambulatory electrocardiogram.[125] It found that revascularisation versus medical treatment alone reduced death or myocardial infarction at 2 years (death or myocardial infarction: AR 4.7% with revascularisation *v* 8.8% with symptom guided treatment *v* 12.1% with symptom plus electrocardiogram guided treatment; $P < 0.04$).

Harms: In the systematic review, of the 1240 people who underwent CABG, 40 (3.2%) died and 88 (7.1%) had documented non-fatal myocardial infarction within 30 days of the procedure. At 1 year, the estimated incidence of death or myocardial infarction was significantly higher with CABG versus medical treatment (11.6% with CABG *v* 8% with medical treatment; RR 1.45, 95% CI 1.18 to 2.03).[124] The diagnosis of myocardial infarction after CABG is difficult, and true incidence may be higher.

Comment: The results of the systematic review may not be easily generalised to current practice. People were 65 years or younger, but more than 50% of CABG procedures are now performed on people over 65 years of age. Almost all people were male. High risk people, such as those with severe angina and left main coronary artery stenosis, were under-represented. Internal thoracic artery grafts were used in fewer than 5% of people. Lipid lowering agents (particularly statins) and aspirin were used infrequently (aspirin used in 3% of people at enrolment). Only about 50% of people were taking β blockers. The systematic review may underestimate the real benefits of CABG in comparison with medical treatment alone because medical and surgical treatment for coronary artery disease were not mutually exclusive; by 5 years, 25% of people receiving medical treatment had undergone CABG surgery and by 10 years, 41% had undergone CABG surgery. The underestimate of effect would be greatest among people at high risk. People with previous CABG have not been studied in RCTs, although they now represent a growing proportion of those undergoing CABG.

OPTION CORONARY PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY VERSUS MEDICAL TREATMENT ALONE

One systematic review found that coronary percutaneous transluminal angioplasty improved angina compared with medical treatment alone, but was associated with a higher rate of coronary artery bypass grafting. The review found higher mortality and rates of myocardial infarction with percutaneous transluminal angioplasty than with medical treatment but the difference was not significant. RCTs have found that percutaneous transluminal angioplasty was associated with increased risk of emergency coronary artery bypass grafting and myocardial infarction during and soon after the procedure. One RCT found that percutaneous transluminal angioplasty reduced cardiac events and improved angina severity compared with medical treatment alone in people over the age of 75 years.

Secondary prevention of ischaemic cardiac events

Benefits: We found one systematic review (search date 1998, 6 RCTs, 1904 people with stable coronary artery disease) comparing coronary percutaneous transluminal angioplasty (PTA) versus medical treatment alone.[126] Follow up varied from 6–57 months. It found that PTA versus medical treatment alone reduced angina, but increased subsequent coronary artery bypass grafting (CABG) (angina: RR 0.70, 95% CI 0.50 to 0.98; CABG: RR 1.59, 95% CI 1.09 to 2.32). It found higher mortality and myocardial infarction with PTA versus medical treatment alone but the difference was not significant (death: RR 1.32, 95% CI 0.65 to 2.70; myocardial infarction: RR 1.42, 95% CI 0.90 to 2.25). The review found significant heterogeneity between trials. The largest RCT identified by the review (1018 people) found that PTA versus medical treatment improved physical functioning, vitality, and general health at 1 year (proportion of people rating their health "much improved": 33% of people treated with PTA *v* 22% with medical treatment alone; P = 0.008), but found no significant difference at 3 years.[127] The improvements were related to breathlessness, angina, and treadmill tolerance. High transfer (27%) from the medical to PTA group may partly explain the lack of difference between groups at 3 years. **Effects in elderly people:** One RCT (305 people aged > 75 years with chronic refractory angina) compared PTA versus medical treatment alone.[128] It found that PTA reduced all adverse cardiac events and decreased anginal severity compared with medical treatment, but had no significant effect on deaths or non-fatal myocardial infarctions after 6 months (adverse cardiac events: AR 19% with PTA *v* 49% with medical treatment alone, P < 0.0001; change in angina class: –2.0 with PTA *v* –1.6 with medical treatment alone, P < 0.0001; deaths: AR 8.5% with PTA *v* 4.1% with medical treatment alone, P = 0.15; non-fatal infarctions: AR 7.8% with PTA *v* 11.5% with medical treatment alone, P = 0.46). **Effects in people with different angina severity:** One of the RCTs in the systematic review found that antianginal benefit from PTA was limited to people with moderate to severe (grade 2 or worse) angina (20% lower incidence of angina and 1 minute longer treadmill exercise times compared with medical treatment).[129] People with mild symptoms at enrolment derived no significant improvement in symptoms. **Effects in asymptomatic people:** We found one RCT (558 people) of revascularisation with CABG or PTA versus symptom–guided treatment versus electrocardiogram– and symptom–guided treatment in people with asymptomatic ischaemia identified by exercise test or ambulatory electrocardiogram[125] (see benefits of CABG *v* medical treatment alone, p 226).

Harms: Procedural death and myocardial infarction, as well as repeat procedures for restenosis, are the main hazards of PTA. Four RCTs included in the review reported complications of PTA. In the first RCT, two (1.9%) emergency CABG operations and five (4.8%) myocardial infarctions occurred at the time of the procedure. By 6 months, the PTA group had higher rates of CABG surgery (7% with PTA *v* 0% with medical treatment alone) and non-protocol PTA (15.2% with PTA *v* 10.3% with medical treatment alone).[129,130] In the second RCT, the higher mortality or rate of myocardial infarction

with PTA was attributable to one death and seven procedure related myocardial infarctions.[128] The third RCT found a procedure related CABG rate and myocardial infarction rate of 2.8% each, and the fourth found rates of 2.0% for CABG and 3.0% for myocardial infarction.[125]

Comment: We found good evidence that PTA treats the symptoms of angina, but we found no evidence that it reduces the overall incidence of death or myocardial infarction in people with stable angina. This could be because of the risk of complications during and soon after the procedure, and because most PTAs are performed for single vessel disease.

OPTION CORONARY PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY VERSUS CORONARY ARTERY BYPASS GRAFTING

One systematic review has found no significant difference in mortality, risk of myocardial infarction, or quality of life between percutaneous transluminal angioplasty and coronary artery bypass grafting. Percutaneous transluminal angioplasty is less invasive but increased the number of repeat procedures. The relevant RCTs were too small to exclude a 20–30% relative difference in mortality.

Benefits: We found one systematic review (search date not stated, 8 RCTs, 3371 people),[131] one subsequent RCT,[132] one subsequent non-systematic review (including the subsequent RCT),[133] which compared percutaneous transluminal angioplasty (PTA) versus coronary artery bypass grafting (CABG). **Angina:** The systematic review found that the prevalence of moderate to severe angina (grade 2 or worse) was significantly higher after PTA than after CABG at 1 year (RR 1.6, 95% CI 1.3 to 1.9).[131] After 3 years this difference had decreased (RR 1.2, 95% CI 1.0 to 1.5). **Mortality:** The systematic review found that PTA did not reduce deaths compared with CABG after 1 year (RR 1.08, 95% CI 0.79 to 1.50),[131] the subsequent RCT (392 people) found no significant difference in deaths between CABG versus PTA after 8 years, although the trial was too small to exclude a clinically important difference (AR for survival 83% with CABG *v* 79% with PTA; $P = 0.40$).[133] The subsequent non-systematic review found that mortality was not significantly different between PTA versus CABG (OR 1.09, 95% CI 0.88 to 1.35).[132] **Repeat procedures:** The systematic review found that PTA increased subsequent procedures compared with CABG (subsequent CABG: RR 1.59, 95% CI 1.09 to 2.32; subsequent PTA: RR 1.29, 95% CI 0.71 to 3.36).[131] **Quality of life:** Two of the RCTs included in the systematic review found no difference in quality of life between people who had PTA and people who had CABG over 3–5 years.[134,135]

Harms: See harms under percutaneous transluminal angioplasty versus medical treatment, p 228. CABG is more invasive than PTA, but PTA is associated with a greater need for repeat procedures.

Comment: Although no major differences in death or myocardial infarction were observed in the systematic review[131] these trials enrolled people at relatively low risk of cardiac events, so it is premature to

conclude that PTA and CABG are equivalent for people with multivessel disease. Fewer than 20% of people had left ventricular dysfunction, almost 70% had one or two vessel disease, and observed mortality was only 2.6% for the first year and 1.1% for the second year. People enrolled in the largest trial more closely approximated to moderate risk people, but this was caused primarily by the higher proportion of people with diabetes mellitus.[136] Even in that trial nearly 60% of people had two vessel coronary artery disease. The total number of people enrolled in the nine trials so far is not adequate to show anything less than a 20–30% difference in mortality between PTA and CABG. Subgroup analysis of one RCT (1829 people) found that in people with diabetes (353 people) CABG reduced deaths compared with PTA after 7 years[136] (see coronary artery bypass grafting versus percutaneous transluminal angioplasty in prevention of cardiovascular events in diabetes, p 777). This difference was not found in people without diabetes or any other subgroup (deaths in people without diabetes: AR 13.6% with CABG *v* 13.2% with PTA; P = 0.72).[136]

OPTION INTRACORONARY STENTS VERSUS CORONARY PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY ALONE

One systematic review has found that intracoronary stents alone reduce the need for repeat vascularisation compared with coronary percutaneous transluminal angioplasty. It found no significant difference in mortality or myocardial infarction, but crossover rates from angioplasty to stent were high. RCTs found that intracoronary stents improved outcomes after 4–9 months compared with percutaneous transluminal angioplasty in people with previous coronary artery bypass grafting, chronic total occlusions, and for treatment of restenosis after initial percutaneous transluminal angioplasty.

Benefits: We found one systematic review (search date 1999, 11 RCTs with 4–11 months' follow up, 4815 people) of stents versus percutaneous transluminal angioplasty (PTA) alone.[137] It found a significant reduction in cardiac event rates after 4–11 months with stents compared with PTA alone (composite of death, myocardial infarction, or repeat vascularisation; 17.9% with stent *v* 24.1% with PTA; OR 0.68, 95% CI 0.59 to 0.78). Stents reduced repeat vascularisation compared with PTA alone (12.4% with stent *v* 20.6% with PTA alone; OR 0.54, 95% CI 0.45 to 0.65), whereas there was no significant difference in deaths (0.9% with stent *v* 1.3% with PTA alone; OR 0.68, 95% CI 0.40 to 1.14) or myocardial infarctions (4.4% with stent *v* 3.6% with PTA alone; OR 1.23, 95% CI 0.88 to 1.72). Seven RCTs with follow up over 1 year found a significant reduction in cardiac events with stents compared with PTA alone (19.5% with stent *v* 28.1% with PTA alone; OR 0.62, 95% CI 0.52 to 0.74). **In saphenous vein graft lesions in people with prior coronary artery bypass grafting:** We found one RCT (220 people) comparing stents with PTA alone for stenosed saphenous vein grafts.[138] There was no significant difference in rates of restenosis (37% with stent *v* 46% with PTA alone; P = 0.24) after 6 months, but stents compared with PTA alone reduced death, myocardial infarction, coronary artery bypass grafting, or repeat PTA (27% with stent *v* 42% with PTA alone; P = 0.03). **In people with total**

occlusions: We found three RCTs comparing stents with PTA alone in people with chronic totally occluded coronary arteries.[139–141] The first RCT (119 people) found that stent compared with PTA alone reduced angina, angiographic restenosis, and repeat procedures (angina free at 6 months: 57% with stent *v* 24% with PTA alone, $P < 0.001$; > 50% stenosis on follow up angiography: 32% with stent *v* 74% with PTA alone, $P < 0.001$; repeat procedures: 22% with stent *v* 42% with PTA alone, $P = 0.03$).[139] The second RCT (110 people) found that stents compared with PTA alone reduced restenosis and repeat procedures after 9 months (restenosis: 32% with stent *v* 68% with PTA alone, $P < 0.001$; repeat procedures: 5% with stent *v* 22% with PTA alone, $P = 0.04$).[140] The third RCT (110 people) found that stents versus PTA alone reduced restenosis and repeat PTA after 4 months (restenosis: 26% with stent *v* 62% with PTA alone, $P = 0.01$; repeat PTA: 24% with stent *v* 55% with PTA alone, $P = 0.05$). No deaths or coronary artery bypass grafting operations occurred in either group. The incidence of myocardial infarction was low in both groups (0% with stent *v* 2% with PTA alone, $P > 0.05$).[141] **For treatment of restenosis after initial percutaneous transluminal angioplasty:** We found one RCT (383 people) of coronary stent versus PTA alone for treatment of restenosis.[142] It found that stents versus PTA alone reduced restenosis and repeat procedures, and increased survival free of myocardial infarction and repeat revascularisation after 6 months (restenosis: 18% with stent *v* 32% with PTA alone, $P = 0.03$; repeat procedures: 10% with stent *v* 27% with PTA alone, $P = 0.001$; survival free of myocardial infarction or repeat revascularisation: 84% with stent *v* 72% with PTA alone, $P = 0.04$).[142]

Harms: Initially, aggressive combination antithrombotic and anticoagulant regimens were used after stenting because of a high incidence of stent thrombosis and myocardial infarction. These regimens led to a high incidence of arterial access site haemorrhage.[133] More recently, improved stent techniques and use of aspirin and ticlopidine have reduced both stent thrombosis and arterial access site haemorrhage.[138,142] Currently, the risk of stent thrombosis is less than 1%.[143–145] Haemorrhage (particularly femoral artery haemorrhage) was more frequent after stenting than PTA alone,[146] but occurred in less than 3% after stenting when antiplatelet drugs were used without long term anticoagulants.

Comment: It is unclear whether stenting influences the relative benefits and harms of percutaneous procedures compared with coronary artery bypass grafting. Coronary stents are associated with fewer repeat revascularisation procedures and less angiographic restenosis than PTA. Rates of death and myocardial infarction are low in the RCTs and are not significantly different between stents and PTA. However, any potential differences may be masked by the crossover to stents after poor results (such as dissection) immediately after PTA.

GLOSSARY

Hospital anxiety and depression scale (HADS) A self report questionnaire designed to assess anxiety and depression in hospital inpatients. It has subscales for anxiety and depression, each comprising seven questions, which are scored from 0–3.

International normalised ratio (INR) A value derived from a standardised laboratory test that measures the effect of an anticoagulant. The laboratory materials used in the test are calibrated against internationally accepted standard reference preparations, so that variability between laboratories and different reagents is minimised. Normal blood has an INR of 1. Therapeutic anticoagulation often aims to achieve an INR value of 2.0–3.5.

TABLE 1 **Prognostic groups for people who survive the acute stage of myocardial infarction (see text, p 201).**

Baseline risk	1 year mortality	Clinical markers[2–4]
High	10–50%	Older age; history or previous myocardial infarction; reduced exercise tolerance (New York Heart Association functional classes II–IV) before admission; clinical signs of heart failure in the first 2 days (Killip classes IIb, III, and IV) or persistent heart failure on days 3–5 after infarction; early increased heart rate; persistent or early appearance of angina at rest or with minimal exertion; and multiple or complex ventricular arrhythmias during monitoring in hospital.
Moderate	10%	ND
Low	2–5%	Younger age (< 55 years), no previous myocardial infarction, an event free course during the first 5 days after myocardial infarction.[2]

ND, no data.

Secondary prevention of ischaemic cardiac events

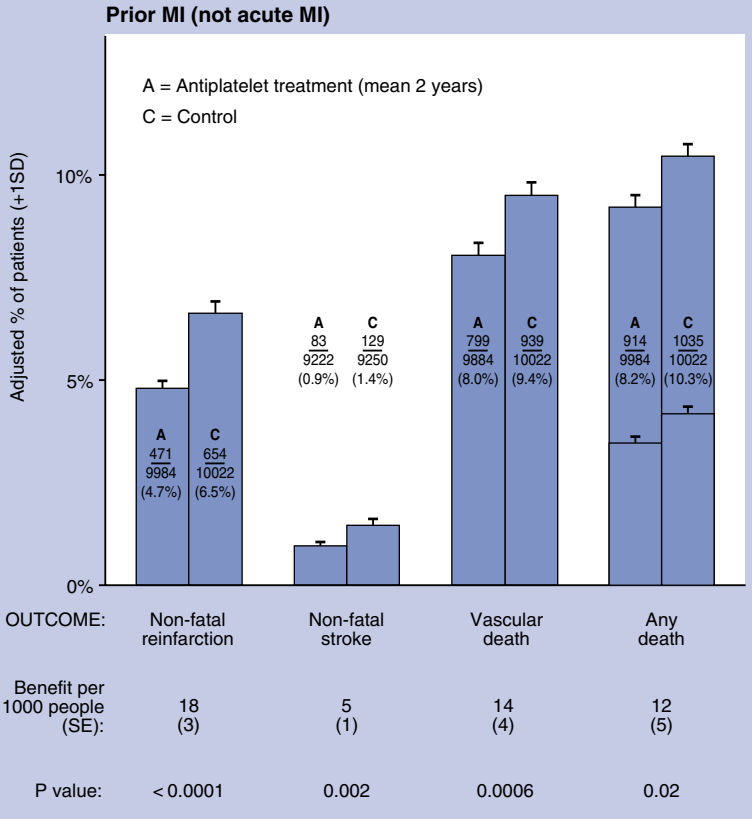

FIGURE 1 **The absolute effects of antiplatelet treatment on various outcomes in people with prior myocardial infarction: results of a systematic review.[10] The columns show the absolute risks over 2 years for each outcome. The error bars represent standard deviations. In the "any death" column, non-vascular deaths are represented by lower horizontal lines (see text, p 202).**

Aspirin daily dose (mg)	No of trials†	Events/patients: Aspirin (%)	Events/patients: Control (%)	Odds ratio (95% CI Random) Aspirin:control	Odds reduction (SD)	2P

QUESTIONS

INTERVENTIONS

ACUTE ISCHAEMIC STROKE

Beneficial

Trade off between benefits and harms

Unlikely to be beneficial

Likely to be ineffective or harmful

INTRACEREBRAL HAEMATOMAS

Unknown effectiveness

To be covered in future updates

Early supported discharge from hospital and other issues pertaining to stroke service organisation

Other treatments for acute ischaemic stroke (corticosteroids, fibrinogen depleting agents, glycerol, haemodilution techniques)

Prevention of deep venous thrombosis/pulmonary embolism in people with stroke

See glossary, p 252

Key Messages

Acute ischaemic stroke

- **Aspirin** One systematic review in people with ischaemic stroke confirmed by computerised tomography scan has found that aspirin within 48 hours of stroke onset reduces death or dependency at 6 months and increases the number of people making a complete recovery compared with placebo**.**
- **Specialised care (specialist stroke rehabilitation)** One systematic review has found that specialist stroke rehabilitation reduces death or dependency after a median follow up of 1 year compared with conventional (less specialised) care. Prospective observational data suggest that these findings may be reproducible in routine clinical settings. A second systematic review found no significant difference between care based on in-hospital care pathways and

standard care in death or dependency rates. However, these results were based on one small RCT, which may have lacked power to detect clinically important effects. One small subsequent pilot study found no significant difference between intensive monitoring and usual stroke unit care in rates of poor outcome at 3 months but found that intensive monitoring significantly reduced mortality.

- **Thrombolysis** One systematic review in people with confirmed ischaemic stroke has found that thrombolysis reduces the risk of the composite outcome of death or dependency after 1–6 months compared with placebo, but increases the risk of death from intracranial haemorrhage in the first 7–10 days and the risk of death after 1–6 months. The excess in deaths is offset by fewer people being alive but dependent 6 months after stroke onset, and the net effect was a reduction in people who were dead or dependent.
- **Neuroprotective agents (calcium channel antagonists, γ-aminobutyric acid agonists, lubeluzole, glycine antagonists, tirilazad, N-methyl-D-aspartate antagonists)** RCTs found no evidence that, compared with placebo, calcium channel antagonists, tirilazad, lubeluzole, γ-aminobutyric acid agonists, glycine antagonists, or N-methyl-D-aspartate antagonists improve clinical outcomes. One systematic review found that lubeluzole was associated with a significant increase in the risk of having Q-T prolongation to more than 450 ms on electrocardiography compared with placebo.
- **Acute reduction in blood pressure** One systematic review in people with acute stroke found insufficient evidence about the effects of lowering blood pressure compared with placebo on clinical outcome, but RCTs have suggested that people treated with antihypertensive agents may have a worse clinical outcome and increased mortality.
- **Immediate systemic anticoagulation** One systematic review comparing systemic anticoagulants (unfractionated heparin, low molecular weight heparin, heparinoids, oral anticoagulants, or specific thrombin inhibitors) with usual care without systemic anticoagulants has found no significant difference in death or dependence after 3–6 months. One systematic review found no significant difference between anticoagulants (unfractionated and low molecular weight heparin) and aspirin in death or dependency at 3–6 months for all people with stroke or for the subset of people who also had atrial fibrillation. Systematic reviews provided evidence that systemic anticoagulation reduces the risk of symptomatic deep venous thrombosis in people with ischaemic stroke, but increases the risk of intracranial haemorrhage or extracranial haemorrhage.

Intracerebral haematomas

- **Evacuation** We found that the balance between benefits and harms has not been clearly established for the evacuation of supratentorial haematomas. We found no evidence from RCTs on the role of evacuation or ventricular shunting in people with infratentorial haematoma whose consciousness level is declining.

DEFINITION Stroke is characterised by rapidly developing clinical symptoms and signs of focal, and at times global, loss of cerebral function lasting more than 24 hours or leading to death, with no apparent cause other than that of vascular origin.[1] Ischaemic stroke is stroke caused by vascular insufficiency (such as cerebrovascular thromboembolism) rather than haemorrhage.

Stroke management

INCIDENCE/ PREVALENCE Stroke is the third most common cause of death in most developed countries.[2] It is a worldwide problem; about 4.5 million people die from stroke each year. Stroke can occur at any age, but half of all strokes occur in people over 70 years old.[3]

AETIOLOGY/ RISK FACTORS About 80% of all acute strokes are ischaemic, usually resulting from thrombotic or embolic occlusion of a cerebral artery.[4] The remainder are caused either by intracerebral or subarachnoid haemorrhage.

PROGNOSIS About 10% of all people with acute ischaemic strokes will die within 30 days of stroke onset.[5] Of those who survive the acute event, about 50% will experience some level of disability after 6 months.[6]

AIMS OF INTERVENTION To minimise impairment, disability, secondary complications, and adverse effects from treatment.

OUTCOMES Risk of death or dependency (generally assessed as the proportion of people dead or requiring physical assistance for transfers, mobility, dressing, feeding, or toileting 3–6 months after stroke onset);[6] quality of life.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION **What are the effects of specialised care in people with stroke?**

OPTION **SPECIALISED CARE**

One systematic review has found that specialist stroke rehabilitation reduces death or dependency after a median follow up of 1 year compared with conventional (less specialised) care. Prospective observational data suggest that these findings may be reproducible in routine clinical settings. A second systematic review found no significant difference between care based on in-hospital care pathways and standard care in death or dependency rates. However, these results were based on one small RCT, which may have lacked power to detect clinically important effects. One small subsequent pilot study found no significant difference between intensive monitoring and usual stroke unit care in rates of poor outcome at 3 months but found that intensive monitoring significantly reduced mortality.

Benefits: We found one systematic review comparing specialised stroke rehabilitation versus conventional care, one systematic review comparing integrated care pathway (see glossary, p 252) versus conventional multidisciplinary care in hospital, and one subsequent RCT comparing intensive monitoring versus conventional stroke unit care.[7–9] In most RCTs in the first review (search date 2001, 23 RCTs, 4911 people with stroke), the specialised stroke rehabilitation unit consisted of a designated area or ward, although some trials used a mobile "stroke team". People in these trials were usually transferred to stroke unit care within the first or second week after stroke onset. It found that stroke rehabilitation units significantly reduced death or dependency after a median follow up of 1 year compared with alternative, less organised care (AR 60.5% without stroke unit *v* 55.8% with stroke unit; ARR 4.7%, 95% CI 1.6% to 7.8%; NNT 21, 95% CI 13 to 63; OR 0.78, 95% CI 0.68 to 0.89; see figure 1, p 256).[7] The duration of stay was calculated

differently for many of the trials, so heterogeneity among results limits generalisability. However, overall, duration of stay in the stroke unit was about 6 days (95% CI 2 to 10 days) shorter than duration of stay in a non-stroke unit setting. Two RCTs included in the review extended follow up to 5 years post stroke. The review found that organised stroke unit care significantly reduced death or dependency at 5 years compared with alternative care (2 RCTs; 223/286 [78%] with organised stroke unit care *v* 214/249 [86%] with alternative care; RR 0.91, 95% CI 0.84 to 0.99).[7] One RCT (220 people) included in the review found that care in a combined acute and rehabilitation unit increased the proportion of people able to live at home 10 years after their stroke compared with care in general wards (ARI 11%, 95% CI 1.9% to 20%; NNT 9, 95% CI 5 to 52).[10] The second systematic review (search date 2001, 3 RCTs, 340 people) compared care based on in-hospital care pathways versus standard care.[8] It found no significant difference in the combined outcome of death or dependency or death alone at 6 months (death or dependency: 1 RCT, 76 people; OR 1.36, 95% CI 0.68 to 2.72; death: 1 RCT, 76 people; OR 1.77, 95% CI 0.61 to 5.14). However, the meta-analysis may have lacked power to detect clinically important differences in effect. The subsequent RCT (54 people with acute ischaemic stroke) was a small pilot study that compared care in a stroke care monitoring unit (intensive monitoring of temperature, oxygen saturation, blood pressure, and electrocardiogram) versus conventional stroke unit care.[9] It found no significant difference between treatments in rates of "poor outcome" at 3 months but found that monitoring significantly reduced mortality (poor outcome defined as modified Rankin score ≥ 4 or Barthel Index < 60 or need for institutionalised care: 7/27 [25.9%] with monitoring *v* 13/27 [48.1%] with conventional care, $P = 0.16$; mortality: 1/27 [3.7%] with monitoring *v* 7/27 [25.9%] with conventional care; OR 0.11, 95% CI 0.02 to 0.96). The RCT may not have been large enough to detect clinically important differences in function.

Harms: No detrimental effects attributable to stroke units were reported.[7–9]

Comment: Although the proportional reduction in death or dependency seems larger with thrombolysis (see thrombolysis option, p 244), stroke unit care is applicable to most people with stroke, whereas thrombolysis is applicable only to a small proportion. The systematic review did not provide evidence about which aspects of the multidisciplinary approach led to improved outcome,[7] although one limited retrospective analysis of one of the RCTs found that several factors, including early mobilisation, increased use of oxygen, intravenous saline solutions, and antipyretics, might have been responsible.[11] Most RCTs excluded the most mild and severe strokes. Since publication of the systematic review,[7] prospective observational data have been collected in one large series of over 14 000 people in 80 Swedish hospitals.[12] In this series, people admitted to stroke units had reduced dependence at 3 months (RRR 6%, 95% CI 1% to 11%). Although biases are inherent in such observational data, the findings suggest that the results of the meta-analysis may be reproducible in routine clinical settings. One review examined the characteristics of 11 controlled trials identified

by the first systematic review,[7] which found benefit from stroke units.[13] It found that most effective units described similar management in terms of: medical, nursing, and therapy assessment; early mobilisation, treatment of hypoxia, hyperglycaemia, and suspected infection; and coordinated goal directed rehabilitation policies.[13] The authors of the review suggested that these elements might form the benchmark for general stroke unit care and future studies.

QUESTION What are the effects of medical treatment in acute ischaemic stroke?

OPTION THROMBOLYSIS

One systematic review in people with confirmed ischaemic stroke has found that thrombolysis reduces the risk of the composite outcome of death or dependency after 1–6 months compared with placebo, but increases the risk of death from intracranial haemorrhage measured in the first 7–10 days and risk of death after 1–6 months. The excess in deaths was offset by fewer people being alive but dependent 6 months after stroke onset, and the net effect was a reduction in people who were dead or dependent.

Benefits: We found one systematic review (search date 1999, 17 RCTs, 5216 highly selected people[14]) comparing intravenous or intra-arterial thrombolysis versus placebo given soon after the onset of stroke. In the systematic review, all trials used computerised tomography or magnetic resonance imaging before randomisation to exclude intracranial haemorrhage or other non-stroke disorders. Results for three different thrombolytic agents (streptokinase, urokinase, and recombinant tissue plasminogen activator) were included, but direct comparison of different thrombolytic drugs was not possible. Two RCTs used intra-arterial administration and the rest used the intravenous route. Thrombolysis significantly reduced the composite risk of death or dependency at the end of the studies (1–6 months: ARR 4.2%, 95% CI 1.2% to 7.2%; NNT 24, 95% CI 14 to 83) (see figure 1, p 256 and figure 2, p 256).[14] In the subset of trials that assessed intravenous recombinant tissue plasminogen activator, the findings for death or dependency were similar (ARR 5.7%, 95% CI 2.0% to 9.4%; RR 0.90; 95% CI 0.84 to 0.96; NNT 18, 95% CI 11 to 50). One meta-analysis (4 RCTs, individual results of 1292 people with acute ischaemic stroke treated with streptokinase or placebo) found no significant difference between streptokinase and placebo in the proportion of people who were dead or dependent at 3 months (RR 0.99, 95% CI 0.92 to 1.06).[15] However, streptokinase increased mortality compared with placebo after 3 months (RR 1.46, 95% CI 1.24 to 1.73). The combination of aspirin plus streptokinase significantly increased mortality at 3 months ($P = 0.005$), but this did not affect the combined risk of death or severe disability (CI not reported; $P = 0.28$).

Harms: **Fatal intracranial haemorrhage:** In the systematic review, thrombolysis increased fatal intracranial haemorrhage compared with placebo measured in the first 7–10 days (ARI 4.4%, 95% CI 3.4% to

5.4%; RRI 396%, 95% CI 220% to 668%; NNH 23, 95% CI 19 to 29).[14] In the subset of trials that assessed intravenous recombinant tissue plasminogen activator, the findings were similar (ARI 2.9%, 95% CI 1.7% to 4.1%; RRI 259%, 95% CI 102% to 536%; NNH 34, 95% CI 24 to 59). **Death:** In the systematic review, thrombolysis compared with placebo increased the risk of death by the end of the follow up (1–6 months: ARI 3.3%, 95% CI 1.2% to 5.4%; RRI 23%, 95% CI 10% to 38%; NNH 30, 95% CI 19 to 83).[14] This excess of deaths was offset by fewer people being alive but dependent 6 months after stroke onset. The net effect was a reduction in the number of people who were dead or dependent.

Comment: In the first systematic review, there was no significant heterogeneity of treatment effect overall, but heterogeneity of results was noted for the outcomes of death, and death or dependency at final follow up among the eight trials of intravenous recombinant tissue plasminogen activator.[14] Explanations may include the combined use of antithrombotic agents (aspirin or heparin within the first 24 hours of thrombolysis), stroke severity, the presence of early ischaemic changes on computerised tomography scan, and the time from stroke onset to randomisation. Most trials reported outcomes at 3 months; only one trial reported 1 year outcome data.[16] We found little evidence about which people are most and least likely to benefit from thrombolysis. A subgroup analysis suggested that thrombolysis may be more beneficial if given within 3 hours of symptom onset, but the duration of the "therapeutic time window" could not be determined reliably. A recent preliminary pooling of three RCTs (1734 people) suggested that recombinant tissue plasminogen activator given between 3 and 6 hours may reduce death or dependency in some people compared with placebo.[17] However, there is currently no consensus about giving thrombolysis after 3 hours. Newer magnetic resonance imaging techniques, such as diffusion/perfusion weighted imaging, may be helpful in patient selection, but studies using these techniques have so far been small.[18] A number of trials of different thrombolytic regimens are under way.[19] In addition, preliminary information from a meta-analysis of individual patient data from the recombinant tissue plasminogen activator trials by the ECASS, NINDS, and ATLANTIS investigators was recently reported at the 27th International Stroke Conference; when published, data will be presented in future *Clinical Evidence* updates (Thomas B, personal communication, 2002).

OPTION ASPIRIN

One systematic review in people with definite or presumed ischaemic stroke confirmed by computerised tomography scan has found that aspirin within 48 hours of stroke onset reduces death or dependency at 6 months and increases the rates of complete recovery compared with placebo.

Benefits: **Early use of aspirin:** We found one systematic review (search date 1999, 8 RCTs, 41 325 people with definite or presumed ischaemic stroke), which compared antiplatelet treatment started within 14 days of the stroke with placebo.[20] Most (98%) of the data in the

systematic review came from two large RCTs of aspirin (160–300 mg daily) started within 48 hours of stroke onset.[21,22] Most people had an ischaemic stroke confirmed by computerised tomography scan before randomisation, but people who were conscious could be randomised before computerised tomography scan if the stroke was very likely to be ischaemic on clinical grounds. Treatment duration varied from 10–28 days. Aspirin started within the first 48 hours of acute ischaemic stroke reduced death or dependency at 6 months' follow up and increased the proportion of people making a complete recovery (death or dependency: RRR 3%, 95% CI 1% to 5%; NNT 77, 95% CI 43 to 333 (see figure 1, p 256); complete recovery: NNT 91, 95% CI 50 to 500). A prospective combined analysis[23] of the two large RCTs[21,22] found that aspirin significantly reduced further stroke or death compared with placebo (ARR 0.9%, 95% CI 0.75% to 1.85%; NNT 111, 95% CI 54 to 133). The effect was similar across subgroups (older *v* younger; male *v* female; impaired consciousness or not; atrial fibrillation or not; blood pressure; stroke subtype; timing of computerised tomography scanning). **Long term treatment:** See aspirin under stroke prevention, p 257.

Harms: Aspirin caused an excess of about two intracranial and four extracranial haemorrhages per 1000 people treated, but these small risks were more than offset by the reductions in death and disability from other causes both in the short term[20] and in the long term.[24] Common adverse effects of aspirin (such as dyspepsia and constipation) were dose related.[25]

Comment: We found no clear evidence that any one dose of aspirin is more effective than any other in the treatment of acute ischaemic stroke. One recent meta-regression analysis of the dose–response effect of aspirin on stroke found a uniform effect of aspirin in a range of doses from 50–1500 mg daily.[26] People unable to swallow safely after a stroke may be given aspirin as a suppository.

OPTION IMMEDIATE SYSTEMIC ANTICOAGULATION

One systematic review comparing systemic anticoagulants (unfractionated heparin, low molecular weight heparin, heparinoids, oral anticoagulants, or specific thrombin inhibitors) with usual care without systemic anticoagulants has found no significant difference in death or dependence after 3–6 months. One systematic review found no significant difference between anticoagulants (unfractionated and low molecular weight heparin) and aspirin in death or dependency at 3–6 months for all people with stroke or for the subset of people who also had atrial fibrillation. Systematic reviews provided evidence that systemic anticoagulation reduces the risk of symptomatic deep venous thrombosis in people with ischaemic stroke, but increases the risk of intracranial haemorrhage or extracranial haemorrhage.

Benefits: **Death or dependency:** We found one systematic review (search date 1999, 21 RCTs, 23 427 people)[27] comparing anticoagulants with usual care, one systematic review (search date 2000, 4 RCTs, 16 558 people)[28] comparing anticoagulants with aspirin, and one subsequent RCT.[29] The first systematic review compared unfractionated heparin, low molecular weight heparin, heparinoids, oral

anticoagulants, or specific thrombin inhibitors with usual care without systemic anticoagulants.[27] Over 80% of the data came from one trial, which randomised people with any severity of stroke to either subcutaneous heparin or placebo, usually after exclusion of haemorrhage by computerised tomography scan.[22] The systematic review found no significant difference in the proportion of people dead or dependent in the treatment and control groups at the end of follow up (3–6 months after the stroke: ARR +0.4%, 95% CI −0.9% to +1.7%; RRR 0%, 95% CI −2% to +3%).[27] There was no clear short or long term benefit of anticoagulants in any prespecified subgroups (stroke of presumed cardioembolic origin *v* others; different anticoagulants). The second systematic review (search date 2000, 4 RCTs, 16 558 people treated within 14 days of acute ischaemic stroke) found no significant difference in death or dependency at 3–6 months between anticoagulants (unfractionated and low molecular weight heparin) and aspirin (OR 1.07, 95% CI 0.99 to 1.15).[28] Results were similar in the subgroup of people with atrial fibrillation (OR 1.10, 95% CI 0.90 to 1.35). The review found no significant difference in death or dependency between unfractionated heparin plus aspirin and aspirin alone, either for all people or for the subgroup of people with atrial fibrillation (1 RCT, all people: OR 1.00, 95% CI 0.92 to 1.09; people with atrial fibrillation: OR 1.00, 95% CI 0.92 to 1.09).The subsequent RCT randomised 404 people to one of four different doses of certoparin (a low molecular weight heparin) within 12 hours of stroke onset.[29] It found no difference in neurological outcome between the four groups 3 months after treatment. **Deep venous thrombosis and pulmonary embolism:** We found four systematic reviews.[27,28,30,31] The first systematic review (search date 1999, 10 small heterogeneous RCTs, 22 000 people), which assessed anticoagulants in 916 people at high risk of deep venous thrombosis after their stroke.[27] Anticoagulation reduced deep vein thrombosis and reduced symptomatic pulmonary emboli compared with control (deep venous thrombosis: ARR 29%, 95% CI 24% to 35%; RRR 64%, 95% CI 54% to 71%; NNT 3, 95% CI 2 to 4; pulmonary embolism: ARR 0.3%, 95% CI 0.1% to 0.6%; RRR 38%, 95% CI 16% to 54%; NNT 333, 95% CI 167 to 1000). No RCT performed investigations in all people to rule out silent events. The frequency of reported pulmonary emboli was low and varied among RCTs, so there may have been under ascertainment. Two other systematic reviews (search dates 1999[31] and 2001,[30] same 5 RCTs in each review, 705 people with acute ischaemic stroke) found that low molecular weight heparins or heparinoids significantly reduced deep venous thrombosis compared with unfractionated heparin (AR 13% with low molecular weight heparins or heparinoids *v* 22% with unfractionated heparin; ARR 9%, 95% CI 4.5% to 16%). The number of events was too small to compare the effects of low molecular weight heparins or heparinoids with unfractionated heparin on death, intracranial haemorrhage, or functional outcome in survivors. The fourth systematic review (search date 2000, 2 RCTs) found that anticoagulants (unfractionated and low molecular

weight heparin) significantly reduced symptomatic deep vein thrombosis during the treatment period compared with aspirin but found no significant difference in symptomatic pulmonary embolism (deep vein thrombosis: OR 0.19, 95% CI 0.07 to 0.58; pulmonary embolism: OR 0.85, 95% CI 0.55 to 1.32).[28]

Harms: One systematic review found that anticoagulation slightly increased symptomatic intracranial haemorrhages within 14 days of starting treatment compared with control (ARI 0.93%, 95% CI 0.68% to 1.18%; RRI 163%, 95% CI 95% to 255%; NNH 108, 95% CI 85 to 147).[27] The large trial of subcutaneous heparin found that this effect was dose dependent (symptomatic intracranial haemorrhage by using medium dose compared with low dose heparin for 14 days: RRI 143%, 95% CI 82% to 204%; NNH 97, 95% CI 68 to 169).[22] The review also found a dose dependent increase in major extracranial haemorrhages after 14 days of treatment with anticoagulants (ARI 0.91%, 95% CI 0.67% to 1.15%; RRI 231%, 95% CI 136% to 365%; NNH 109, 95% CI 87 to 149).[27] One systematic review (search date 2000, 4 RCTs) found that anticoagulants (unfractionated and low molecular weight heparin) significantly increased symptomatic intracranial haemorrhage compared with aspirin (OR 2.27, 95% CI 1.49 to 3.46).[28] It found that the increase was greater with higher dose compared with lower dose anticoagulants (high dose: OR 3.24, 95% CI 2.09 to 5.04; low dose: OR 1.29, 95% CI 0.72 to 2.32).One RCT identified by this systematic review[28] found no difference between dalteparin and aspirin for people with acute stroke and atrial fibrillation in adverse events, including symptomatic or asymptomatic intracerebral haemorrhage, progression of symptoms, or early or late death.[32] As in the systematic review,[27] the RCT comparing different doses of certoparin found that intracranial haemorrhage occurred more often in those receiving a higher dose of anticoagulant.[29] However, the overall number of people experiencing haemorrhagic complications in the RCT may have been artificially lowered because the study protocol was changed during the trial period so as to exclude people with early ischaemic changes on computerised tomography scan.

Comment: Alternative treatments to prevent deep venous thrombosis and pulmonary embolism after acute ischaemic stroke include aspirin and compression stockings. The evidence relating to these will be reviewed in future *Clinical Evidence* updates.

OPTION BLOOD PRESSURE REDUCTION

One systematic review in people with acute stroke found insufficient evidence about the effects of lowering blood pressure compared with placebo on clinical outcome, but RCTs have suggested that people treated with antihypertensive agents may have a worse clinical outcome and increased mortality.

Benefits: We found one systematic review (search date 2000, 5 RCTs, 281 people with acute stroke) comparing blood pressure lowering treatment with placebo.[33] Several different antihypertensive agents were used. The trials collected insufficient clinical data to allow an analysis of the relation between changes in blood pressure and clinical outcome to be carried out.

Harms: Two placebo controlled RCTs have suggested that people treated with antihypertensive agents may have a worse clinical outcome and increased mortality.[34,35] The first RCT (295 people with acute ischaemic stroke) compared nimodipine (a calcium channel antagonist) versus placebo.[34] The RCT was stopped prematurely because of an excess in unfavourable neurological outcomes in the nimodipine treated group. Exploratory analyses confirmed that this negative correlation was related to reductions in mean arterial blood pressure (CI not reported; P = 0.02) and diastolic blood pressure (P = 0.0005). The second RCT (302 people with acute ischaemic stroke) assessed β blockers (atenolol or propranolol).[35] There was a non-significant increase in death for people taking β blockers, and no difference in the proportion of people achieving a good outcome. One systematic review (search date 1994, 9 RCTs, 3719 people with acute stroke) compared nimodipine versus placebo; no net benefit was found.[36] A second review (24 RCTs, 6894 people) found a non-significant increase in the risk of death with calcium channel antagonists versus placebo (RRI 8%, 95% CI 1% reduction to 18% increase).[37] Although treatment with calcium channel antagonists in these trials was intended for neuroprotection, blood pressure was lower in the treatment group in several trials.

Comment: Population based studies suggest a direct and continuous association between blood pressure and the risk of recurrent stroke.[38] However, acute blood pressure lowering in acute ischaemic stroke may lead to increased cerebral ischaemia. The systematic review[33] identified several ongoing RCTs. We identified one additional ongoing RCT not included in the review.[39]

OPTION NEUROPROTECTIVE AGENTS

RCTs found no evidence that calcium channel antagonists, lubeluzole, γ-aminobutyric acid agonists, tirilazad, glycine antagonists, or N-methyl-D-aspartate antagonists significantly improved clinical outcomes compared with placebo. One systematic review found that lubeluzole increased the risk of having Q-T prolongation to more than 450 ms on electrocardiography compared with placebo.

Benefits: We found no systematic reviews assessing the general effectiveness of neuroprotective agents in acute ischaemic stroke. **Calcium channel antagonists:** We found two systematic reviews comparing calcium channel antagonists with placebo.[40,41] The first review (search date 1999, 28 RCTs, 7521 people with acute ischaemic stroke) found that calcium channel antagonists did not significantly reduce the risk of poor outcome (including death) at the end of the follow up period compared with placebo (ARI of poor outcome +4.9%, 95% CI −2.5% to +7.3%; RRI +4%, 95% CI −2% to +9%).[40] The second review (search date 1999)[41] included one additional RCT (454 people)[42] that was stopped prematurely because of publication of the first review.[40] Inclusion of its data did not change the results of the first review. **γ-Aminobutyric acid agonists:** We found one systematic review (search date not stated, 3 RCTs, 1002 people with acute ischaemic stroke) and two subsequent RCTs.[43–45] The systematic review found no significant difference between piracetam (a γ-aminobutyric acid agonist) and control in the proportion of people dead or dependent at the end of

follow up (ARI +0.2%, 95% CI –6.0% to +6.4%; RRI 0%, 95% CI –11% to +9%).[43] Similar results were found in the two subsequent RCTs.[44,45] The first subsequent RCT (1360 people with acute stroke) found no significant difference between clomethiazole (a γ-aminobutyric acid agonist) and placebo in functional independence (ARR +1.5%, 95% CI –4.0% to +6.6%; RRR +3.0%, 95% CI –7% to +13%).[44] The second subsequent RCT (1198 people with major acute ischaemic stroke treated within 12 hours) found no significant difference between clomethiazole and placebo in neurological recovery at 3 months (Barthel index ≥ 60: 42/586 [7.1%] with clomethiazole *v* 46/583 [7.9%] with placebo; OR 0.81, 95% CI 0.62 to 1.05).[45] **Lubeluzole:** We found one systematic review (search date 2001, 5 RCTs, 3510 people) that compared lubeluzole (5, 10, or 20 mg daily for 5 days) with placebo.[46] It found no significant difference between any dose of lubeluzole and placebo in death or dependency at the end of follow up (after 4–12 weeks' follow up: AR 54.6% with lubeluzole *v* 53.4% with placebo; ARI +1.2%, 95% CI –2.5% to +6.2%). **Glycine antagonists:** We found two RCTs.[47,48] One RCT (1804 conscious people with limb weakness assessed within 6 hours of stroke onset) found no significant difference between gavestinel (a glycine antagonist) and placebo in survival and outcome at 3 months, as measured using the Barthel index (ARR +1.0%, 95% CI –3.5% to +6.0%).[47] The second RCT (1367 people with predefined level of limb weakness and functional independence before stroke) also found no significant difference in survival and outcome at 3 months, measured using the Barthel index (ARI +1.9%, 95% CI –3.8% to +6.4%).[48] **N-methyl-D-aspartate antagonists:** Two recent RCTs assessing the N-methyl-D-aspartate antagonist (see glossary, p 252) selfotel found no significant difference in the proportion of people with a Barthel index over 60, but data were limited as the trials were terminated because of adverse outcomes after only 31% of the total planned patient enrolment.[49] Similarly, an RCT comparing the N-methyl-D-aspartate antagonist aptiganel with placebo was terminated early because of lack of efficacy and a potential imbalance in mortality.[50] The RCT found a larger proportion of people with favourable outcomes in the placebo group and a non-significant trend favouring placebo in mortality rates.[50] **Tirilazad:** We found one systematic review (search date 2001, 6 RCTs, 1757 people with acute ischaemic stroke) comparing tirilazad (a steroid derivative) with placebo.[51] Tirilazad increased death and disability at 3 months' follow up when measured using the expanded Barthel index (ARI +3.9%, 95% CI –0.8% to +8.6%).[51]

Harms:

Calcium channel antagonists: In the systematic review of calcium channel antagonists, indirect and limited comparisons of intravenous versus oral administration found no significant difference in adverse events (ARI of adverse events, iv *v* oral, +2.3%, 95% CI –0.9% to +3.7%; RRI +17%, 95% CI –3% to +41%).[40] **γ-Aminobutyric acid agonists**: In the systematic review of piracetam, there was a non-significant increase in death with piracetam compared with placebo, which was no longer apparent after correction for imbalance in stroke severity.[43] The second subsequent RCT (1198 people) found that clomethiazole significantly increased somnolence and rhinitis compared with placebo (somnolence:

50.6% with clomethiazole *v* 12.7% with placebo; rhinitis: 6.3% with clomethiazole *v* 1.9% with placebo, P not reported).[45] **Lubeluzole:** The systematic review of lubeluzole found that, at any dose, lubeluzole was associated with a significant increase in the risk of having a heart conduction disorder (Q-T prolongation to more than 450 ms on electrocardiography) at the end of follow up (AR with lubeluzole 11.9% *v* 9.74% with control; ARI 2.2%, 95% CI 0.1% to 4.2%; NNH 45, 95% CI 23 to 1000).[46] Lubeluzole did not significantly increase heart rhythm disorders (atrial fibrillation, ventricular tachycardia or fibrillation, torsade de pointes) at the end of the scheduled follow up (OR 1.28, 95% CI 0.97 to 1.69). **N-methyl-D-aspartate antagonists:** The trials of selfotel were terminated after enrolling 567 people because of greater early mortality in the selfotel groups.[49] **Tirilazad:** The systematic review of tirilazad found an increased risk of injection site phlebitis compared with placebo (ARI 12.2%, 95% CI 8.7% to 15.7%).[51]

Comment: The effects of the cell membrane precursor citicholine have been assessed in small trials, and a systematic review is in progress.[52] Systematic reviews are being developed for antioxidants and for excitatory amino acid modulators.[53] Several RCTs are ongoing, including one of intravenous magnesium sulphate[54] and another of diazepam (a γ-aminobutyric acid agonist).[55]

QUESTION What are the effects of surgical treatment for intracerebral haematomas?

OPTION EVACUATION

We found that the balance between benefits and harms has not been clearly established for the evacuation of supratentorial haematomas. We found no evidence from RCTs on the role of evacuation or ventricular shunting in people with infratentorial haematoma whose consciousness level is declining.

Benefits: **For supratentorial haematomas:** We found three systematic reviews.[56–58] The first review (search date 1998)[56] and second review (search date 1997)[57] both assessed the same four RCTs comparing surgery (craniotomy in 3 trials and endoscopy in 1 trial) with best medical treatment in 354 people with primary supratentorial intracerebral haemorrhage. The second review also assessed information from case series.[57] Overall, neither review found significant short or long term differences between surgical and medical treatment for death or disability (ARI +3.3%, 95% CI –5.9% to +12.5%; RRI +5%, 95% CI –7% to +19%). The third review (search date 1999)[58] included several analyses. The first analysis included results from seven RCTs (530 people), including two RCTs not included in either of the first two systematic reviews. The overall results are similar to those of the first two systematic reviews, with no significant difference in death or disability for surgically treated people (ARI +3.5%, 95% CI –4.4% to +11.4%). A further analysis of results from only recent, post-computerised tomography, well

constructed, balanced trials (5 trials, 224 people in total) did not find a significant difference between the two groups (ARR +9.3%, 95% CI –2.6% to +21.2%). **For infratentorial haematomas:** We found no evidence from systematic reviews or RCTs on the role of surgical evacuation or ventricular shunting.[59]

Harms: The two earlier reviews undertook subgroup analyses separating results for craniotomy and endoscopy. They found that for the 254 people randomised to craniotomy rather than best medical treatment, there was increased death and disability (ARI 12%, 95% CI 1.8% to 22%; RRI 17%, 95% CI 2% to 34%; NNH 8, 95% CI 5 to 56).[56,57] For the 100 people randomised to endoscopy rather than best medical practice, there was no significant effect on death and disability (RRR 24%, 95% CI –2% to +44%). The third systematic review did not evaluate these adverse outcomes.[58]

Comment: Current practice is based on the consensus that people with infratentorial (cerebellar) haematomas whose consciousness level is declining probably benefit from evacuation of the haematoma. We identified one ongoing multicentre trial comparing a policy of "early surgical evacuation" of haematoma versus "initial conservative treatment" in people with spontaneous intracerebral haemorrhage.[60]

GLOSSARY

Integrated care pathway A model of care that includes definition of therapeutic goals and specification of a timed plan designed to promote multidisciplinary care, improve discharge planning, and reduce the duration of hospital stay.

N-methyl-D-aspartate antagonist Glutamate can bind to N-methyl-D-aspartate receptors on cell surfaces. One hypothesis proposed that glutamate released during a stroke can cause further harm to neurones by stimulating the N-methyl-D-aspartate receptors. N-methyl-D-aspartate antagonists block these receptors.

Substantive changes

Specialised care One RCT added;[9] categorisation unchanged.

Anticoagulants One systematic review added;[28] categorisation unchanged.

INTERVENTIONS

See glossary, p 277

Stroke prevention

Key Messages

In people with a prior stroke or transient ischaemic attack

- **Antiplatelet treatment** One systematic review has found that antiplatelet treatment reduces the risk of serious vascular events in people with prior stroke or transient ischaemic attack compared with placebo or no antiplatelet treatment.
- **Blood pressure reduction** One systematic review and one subsequent RCT found that antihypertensive treatment reduced stroke among people with a prior stroke or transient ischaemic attack, whether or not they were hypertensive.
- **Carotid endarterectomy in people with moderately severe (50–69%) symptomatic carotid artery stenosis** Evidence from a pooled analysis of individual patient data from three RCTs found that carotid endarterectomy reduced stroke and death compared with no endarterectomy in symptomatic people with 50–69% carotid stenosis.
- **Carotid endarterectomy in people with severe (> 70%) symptomatic carotid artery stenosis** Evidence from three RCTs has found that carotid endarterectomy reduces stroke and death compared with no endarterectomy in symptomatic people with more than 70% carotid stenosis, although no benefit was found in people with near-occlusion. Benefit in symptomatic people with more than 70% stenosis is greater than in people with lower grade stenosis.
- **Cholesterol reduction** One large RCT has found that, compared with placebo, simvastatin reduced major vascular events, including stroke, in people with prior stroke or transient ischaemic attack. RCTs found no evidence that non-statin treatments reduced stroke compared with placebo or no treatment.
- **Carotid endarterectomy in people with asymptomatic but severe carotid artery stenosis** Two systematic reviews found that carotid endarterectomy reduced perioperative stroke, death, and subsequent ipsilateral stroke in people with asymptomatic but severe stenosis. However, because the risk of stroke without surgery in asymptomatic people is relatively low, the benefit from surgery is small.
- **Carotid or vertebral angioplasty** We found insufficient evidence about the effects of carotid or vertebral percutaneous transluminal angioplasty or stenting compared with medical treatment or carotid endarterectomy in people with a recent carotid or vertebral territory transient ischaemic attack or non-disabling ischaemic stroke who have severe stenosis of the ipsilateral carotid or vertebral artery.
- **Different blood pressure lowering regimens (no evidence that any regimen more or less effective than any other)** Systematic reviews found no clear evidence of a difference in effectiveness between different antihypertensive drugs. One systematic review found that more intensive treatment reduced stroke and major cardiovascular events, but not mortality, compared with less intensive treatment.
- **Alternative antiplatelet agents to aspirin (no evidence that any more or less effective than aspirin)** Systematic reviews have found no good evidence that any antiplatelet treatment is superior to aspirin for long term secondary prevention of serious vascular events.
- **Carotid endarterectomy in people with moderate (30–49%) symptomatic carotid artery stenosis** Evidence from a pooled analysis of individual patient data from three RCTs suggests that carotid endarterectomy is of no benefit in symptomatic people with 30–49% stenosis.

- **Carotid endarterectomy in people with symptomatic near-occlusion of the carotid artery** We found limited evidence from three RCTs that carotid endarterectomy increases the risk of stroke or death due to surgery in symptomatic people with near occlusion of the ipsilateral carotid artery.
- **High dose versus low dose aspirin (no additional benefit but may increase harms)** One systematic review and one subsequent RCT have found that low dose aspirin (75–150 mg/day) is as effective as higher doses for preventing serious vascular events. It found insufficient evidence that doses lower than 75 mg daily are as effective. Systematic reviews found no evidence of an association between aspirin dose and risk of intracranial, major extracranial, or gastrointestinal haemorrhage. RCTs found that high dose aspirin (500–1500 mg/day) increased the risk of upper gastrointestinal upset compared with medium dose aspirin (75–325 mg/day).
- **Carotid endarterectomy in people with less than 30% symptomatic carotid artery stenosis** Evidence from a pooled analysis of individual patient data from three RCTs suggests that carotid endarterectomy increases the risk of stroke or death due to surgery in symptomatic people with less than 30% carotid stenosis.
- **Oral anticoagulation in people with prior cerebrovascular ischaemia and sinus rhythm** Systematic reviews found no significant difference between anticoagulation and placebo or antiplatelet treatment for preventing recurrent stroke after presumed ischaemic stroke in people in normal sinus rhythm. Anticoagulants increased the risk of fatal intracranial and extracranial haemorrhage compared with placebo. High intensity anticoagulation increased the risk of major bleeding compared with antiplatelet treatment.

In people with atrial fibrillation and a prior stroke or transient ischaemic attack

- **Aspirin in people with contraindications to anticoagulants** Systematic reviews have found that aspirin reduces the risk of stroke compared with placebo, but found that aspirin is less effective than anticoagulants. These findings support the use of aspirin in people with atrial fibrillation and contraindications to anticoagulants.
- **Oral anticoagulation** Systematic reviews have found that adjusted dose warfarin reduces the risk of stroke compared with placebo. Systematic reviews have also found that warfarin reduces the risk of stroke in people with previous stroke or transient ischaemic attack compared with aspirin.

In people with atrial fibrillation but no other major risk factors for stroke

- **Aspirin in people with contraindications to anticoagulants** One systematic review has found that aspirin reduces the risk of stroke compared with placebo, but another review found no significant difference. These findings support the use of aspirin in people with atrial fibrillation and contraindications to anticoagulants.
- **Oral anticoagulation** One systematic review has found that warfarin reduces fatal and non-fatal ischaemic stroke compared with placebo, provided there is a low risk of bleeding and careful monitoring. The people in the review had a mean age of 69 years. One overview in people less than 65 years old has found no significant difference in the annual stroke rate between warfarin and placebo.

DEFINITION Prevention in this context is the long term management of people with a prior stroke or transient ischaemic attack, and of people at high risk of stroke (see glossary, p 277) for other reasons such as

atrial fibrillation. **Stroke:** See definition under stroke management, p 240. **Transient ischaemic attack:** This is similar to a mild ischaemic stroke except that symptoms last for less than 24 hours.[1]

INCIDENCE/ PREVALENCE See incidence/prevalence under stroke management, p 240.

AETIOLOGY/ RISK FACTORS See aetiology under stroke management, p 240. Risk factors for stroke include prior stroke or transient ischaemic attack, increasing age, hypertension, diabetes, cigarette smoking, and emboli associated with atrial fibrillation, artificial heart valves, or myocardial infarction. The relation with cholesterol is less clear. One overview of prospective studies among healthy middle aged people found no association between total cholesterol and overall stroke risk.[2] However, one review of prospective observational studies in eastern Asian people found that cholesterol was positively associated with ischaemic stroke but negatively associated with haemorrhagic stroke.[3]

PROGNOSIS People with a history of stroke or transient ischaemic attack are at high risk of all vascular events, such as myocardial infarction, but are at particular risk of subsequent stroke (about 10% in the first year and about 5% each year thereafter); see figure 1, p 283, and figure 1 in secondary prevention of ischaemic cardiac events, p 197.[4,5] People with intermittent atrial fibrillation treated with aspirin should be considered at similar risk of stroke, compared with people with sustained atrial fibrillation treated with aspirin (rate of ischaemic stroke/year: 3.2% with intermittent *v* 3.3% with sustained).[6]

AIMS OF INTERVENTION To prevent death or disabling stroke, as well as other serious non-fatal outcomes, especially myocardial infarction, with minimal adverse effects from treatment.

OUTCOMES Stroke, myocardial infarction; mortality, and dependency.

METHODS *Clinical Evidence* search and appraisal January 2003. Options authored by Cathie Sudlow were searched May 2002 (including hand searches of vascular, neurology, and general medical journals). The six journals that contained the largest number of relevant papers were hand searched (search dates 1994–2000).

QUESTION What are the effects of interventions in people with prior stroke or transient ischaemic attack?

OPTION BLOOD PRESSURE REDUCTION VERSUS NO BLOOD PRESSURE REDUCTION

Cathie Sudlow

One systematic review and one subsequent RCT found that antihypertensive treatment reduced stroke in people with a prior stroke or transient ischaemic attack, whether or not they were hypertensive.

Benefits: We found one systematic review[7] and one subsequent RCT[8] comparing antihypertensive treatment versus placebo, no treatment, or usual care in people with a prior stroke or transient ischaemic attack. The systematic review (search date not stated, 9 RCTs,

6753 people with a prior stroke or transient ischaemic attack) found that antihypertensive treatment significantly reduced stroke and major cardiovascular events compared with placebo, no treatment, or usual care over 2–7 years (stroke: RR 0.72, 95% CI 0.61 to 0.85; major cardiovascular events: RR 0.79, 95% CI 0.68 to 0.91).[7] Over 80% of people in the review were included in a single large RCT, the results of which have only been published in preliminary form.[9] The subsequent RCT (6105 people with a prior stroke or transient ischaemic attack with and without hypertension) compared the angiotensin converting enzyme inhibitor perindopril plus indapamide (added at the discretion of the physician) versus placebo.[8] It found that active treatment reduced stroke compared with placebo but found no significant difference in mortality after about 4 years (stroke: AR 10% with treatment *v* 14% with placebo; RR 0.72, 95% CI 0.62 to 0.83; deaths: AR 10% with treatment *v* 10% with placebo; RR 0.96, 95% CI 0.82 to 1.12). Relative risks were similar in people with and in those without hypertension.

Harms: In people with a history of stroke, reports of an apparently J-shaped relationship between blood pressure and subsequent stroke have led to concerns that blood pressure reduction may increase the risk of recurrent stroke, perhaps because of reduced cerebral perfusion, particularly among people with extracranial carotid or vertebral artery stenosis.[10] However, observational studies found no evidence of a threshold of diastolic blood pressure below which there was no reduction in stroke.[10,11]

Comment: The systematic review found that the effects of blood pressure lowering were similar in people with and without a history of stroke or transient ischaemic attack.[7]

OPTION DIFFERENT BLOOD PRESSURE LOWERING REGIMENS

Cathie Sudlow

Systematic reviews found no clear evidence of a difference in effectiveness between different antihypertensive drugs. One systematic review found that more intensive treatment reduced stroke and major cardiovascular events, but not mortality, compared with less intensive treatment.

Benefits: We found no RCTs comparing different antihypertensive regimens specifically among people with a prior stroke or transient ischaemic attack. We found three systematic reviews[12–14] and one subsequent RCT[15] that compared the effects of different antihypertensive treatments on stroke and other vascular outcomes in people with hypertension. One systematic review (search date 1997, 5 RCTs, about 18 000 people) found no significant difference between diuretics and β blockers in death, stroke, or coronary artery disease.[12] The second systematic review (search date not stated, 15 RCTs) compared more intensive versus less intensive treatment (3 RCTs, about 20 000 people), angiotensin converting enzyme inhibitors versus diuretics or β blockers (3 RCTs, about 16 000 people), calcium channel blockers versus diuretics or β blockers (5 RCTs, about 23 000 people), and angiotensin converting enzyme inhibitors versus calcium channel blockers (2 RCTs, about 5000 people).[13] It found that more intensive treatment (target diastolic blood

pressure 75–85 mm Hg) significantly reduced stroke and major cardiovascular events but not death compared with less intensive treatment (target diastolic blood pressure 85–105 mm Hg) (stroke: RR 0.80, 95% CI 0.65 to 0.98; major cardiovascular events: RR 0.85, 95% CI 0.76 to 0.96; death: RR 0.97, 95% CI 0.85 to 1.11). It found no significant difference between angiotensin converting enzyme inhibitors and diuretics or β blockers in stroke, other vascular outcomes, or death (stroke: RR 1.05, 95% CI 0.92 to 1.19; death: RR 1.03, 95% CI 0.93 to 1.14). Calcium channel blockers reduced stroke compared with diuretics or β blockers, but they slightly increased coronary heart disease and had no significant effect on death or other vascular outcomes (stroke: RR 0.87, 95% CI 0.77 to 0.98; coronary heart disease: RR 0.81, 95% CI 0.68 to 0.97; death: RR 1.01, 95% CI 0.92 to 1.11). Angiotensin converting enzyme inhibitors reduced coronary heart disease compared with calcium channel blockers, but they had no significant effect on stroke or death (coronary heart disease: RR 0.81, 95% CI 0.68 to 0.97; stroke: RR 1.02, 95% CI 0.85 to 1.21; death: RR 1.03, 95% CI 0.91 to 1.18). However, the RCTs included in this comparison were statistically heterogeneous, and so the results of the analysis should be treated with caution. The third systematic review (search date not stated) found similar results to those of the second review.[14] It suggested that results for different antihypertensive drugs could be explained by the blood pressure differences between randomised groups. The subsequent RCT (9193 people with hypertension, 728 of whom had a history of cerebrovascular disease) compared an angiotensin II receptor blocker (losartan) versus a β blocker (atenolol).[15] It found that losartan significantly reduced the combined outcome of cardiovascular death, myocardial infarction, and stroke after 5 years compared with atenolol (AR 14% with atenolol *v* 12% with losartan; HR 0.85, 95% CI 0.76 to 0.96). Blood pressure reduction was similar in both treatment groups (systolic/diastolic: about 30/17 mm Hg).

Harms: See harms under blood pressure reduction, p 261.

Comment: It has been suggested that both angiotensin converting enzyme inhibitors and angiotensin II receptor blockers produce reductions in vascular outcomes beyond what might be expected from their effects on blood pressure.[15,16]

OPTION CHOLESTEROL REDUCTION

Cathie Sudlow

One large RCT has found that, compared with placebo, simvastatin reduced major vascular events, including stroke, in people with prior stroke or transient ischaemic attack. RCTs have found no evidence that non-statin treatments reduced stroke compared with placebo or no treatment.

Benefits: **Statins:** We found several systematic reviews (about 38 000 people with and without a history of coronary heart disease) that assessed the effects of reducing cholesterol with a statin on coronary heart disease and that reported on stroke as an outcome.

The RCTs included did not specifically aim to include people with a prior stroke or transient ischaemic attack (TIA). One systematic review (search date 1995, 14 RCTs)[17] and one additional RCT[18] included all of the relevant results, which are summarised in table 1, p 282. The review found that reducing mean total cholesterol with a statin by 21% over an average of 4 years reduced the relative odds of stroke by 24% (see table 1, p 282). We found one subsequent RCT (20 536 people with coronary heart disease, other occlusive vascular disease, or diabetes, 3280 of whom had a history of cerebrovascular disease and over 4000 of whom had a pretreatment cholesterol of < 5.0 mmol/L) that compared simvastatin 40 mg daily versus placebo (see table 1, p 282).[19] It found that simvastatin reduced mean total cholesterol by 24%, and reduced stroke, major vascular events (major coronary events, strokes, and coronary or non-coronary revascularisations), and deaths over 5 years compared with placebo (stroke: AR 4% with simvastatin *v* 6% with placebo; RR 0.75, 95% CI 0.66 to 0.85; major vascular events: AR 20% with simvastatin *v* 25% with placebo; RR 0.76, 95% CI 0.72 to 0.81; deaths: AR 13% with simvastatin *v* 15% with placebo; RR 0.87, 95% CI 0.81 to 0.94). The relative risk of major vascular events was similar and separately significant in people with and without a history of coronary artery disease, among those with a history of ischaemic stroke or TIA, peripheral vascular disease, and diabetes, and among those with different pretreatment concentrations of cholesterol and triglycerides. **Non-statin treatments:** We found one overview,[20] one subsequent RCT,[21] and one additional RCT[22] that assessed the outcome of stroke. The overview (11 RCTs) compared reducing cholesterol with a non-statin treatment (fibrate, resin, or diet) versus placebo or no treatment.[20] It found no significant difference between a non-statin treatment and placebo in the risk of stroke (OR 0.99, 95% CI 0.82 to 1.21). Results for people with previous stroke or TIA were not reported separately. The subsequent RCT (2531 men with coronary heart disease) found no significant difference between gemfibrozil and placebo in the risk of stroke (AR 5% with gemfibrozil *v* 6% with placebo; RRR +25%, 95% CI −6% to +47%).[21] Results for people with previous stroke or TIA were not reported separately. The additional RCT (532 men who had a previous stroke or TIA) found no significant difference between clofibrate and placebo in death after 3.5 years (AR 13% with clofibrate *v* 19% with placebo; P value not reported).[22]

Harms: Although it has been suggested that statins may increase haemorrhagic stroke,[3,17] the subsequent RCT found that simvastatin did not increase haemorrhagic stroke.[19]

Comment: An RCT comparing atorvastatin versus placebo in 4200 people with minor stroke or TIA is in progress.[23] A planned overview of individual participant data from all RCTs of cholesterol reduction aims to summarise the effects of reducing cholesterol in different groups of people, including those with a prior stroke or TIA.[24]

OPTION ANTIPLATELET TREATMENT VERSUS NO ANTIPLATELET TREATMENT

Cathie Sudlow

One systematic review has found that prolonged antiplatelet treatment reduces the risk of serious vascular events in people with prior stroke or transient ischaemic attack compared with placebo or no antiplatelet treatment.

Benefits: We found one systematic review (search date 1997, 195 RCTs, about 135 640 people at high risk of vascular disease: previous stroke or transient ischaemic attack [TIA], acute stroke, ischaemic heart disease, heart failure, cardiac valve disease, atrial fibrillation, peripheral arterial disease, diabetes, and haemodialysis) comparing antiplatelet treatment (mostly aspirin) versus placebo or no antiplatelet treatment.[25] It found that in people with prior stroke or TIA (21 RCTs, 18 270 people) antiplatelet treatment reduced serious vascular events (stroke, myocardial infarction, or vascular death) compared with placebo or no antiplatelet treatment after 3 years (AR 18% with antiplatelet *v* 21% with placebo or no antiplatelet treatment; OR 0.78, 95% CI 0.73 to 0.85). Antiplatelet treatment also reduced the separate outcomes of stroke, myocardial infarction, vascular death, and death (see figure 1, p 283). For every 1000 people with a prior stroke or TIA treated for about 3 years, antiplatelet treatment prevented 25 non-fatal strokes, six non-fatal myocardial infarctions, and 15 deaths.[25]

Harms: The systematic review found that antiplatelet treatment in people with prior stroke or TIA increased major extracranial haemorrhage (haemorrhages requiring hospital admission or blood transfusion) and intracranial haemorrhage compared with no antiplatelet treatment (intracranial haemorrhage: AR 0.64% with antiplatelet *v* 0.56% with no antiplatelet; OR 1.2, CI not reported; major extracranial haemorrhage: AR 0.97% with antiplatelet *v* 0.47% with no antiplatelet; OR 2.0, CI not reported).[25] We found one systematic review (search date 1999, 24 RCTs) that assessed the effects of aspirin on gastrointestinal bleeding.[26] It found that aspirin increased gastrointestinal bleeding compared with placebo or no aspirin (OR 1.68, 95% CI 1.51 to 1.88). Another systematic review (search date 1997, 16 RCTs, 55 462 people) found that aspirin increased intracranial haemorrhage by about one event per 1000 people treated for 3 years.[27]

Comment: In people at high risk of vascular disease, including those with a prior ischaemic stroke or TIA, the large absolute reductions in serious vascular events produced by antiplatelet treatment far outweighed any absolute hazards.

OPTION HIGH DOSE VERSUS LOW DOSE ASPIRIN

Cathie Sudlow

One systematic review and one subsequent RCT have found that low dose aspirin (75–150 mg/day) is as effective as higher doses for preventing serious vascular events. It found insufficient evidence that doses lower than 75 mg daily are as effective. Systematic reviews found no evidence

of an association between aspirin dose and risk of intracranial, major extracranial, or gastrointestinal haemorrhage. RCTs found that high dose aspirin (500–1500 mg/day) increased the risk of upper gastrointestinal upset compared with medium dose aspririn (75–325 mg/day).

Benefits: We found one systematic review (search date 1997; 7225 people at high risk of vascular disease in RCTs comparing different doses of aspirin; about 60 000 people at high risk of vascular disease, excluding those with acute stroke, in RCTs comparing different doses of aspirin versus placebo or no aspirin) that compared the effects of higher versus lower dose aspirin on stroke.[25] The results in people with prior stroke or transient ischaemic attack were not presented separately. The systematic review found no significant difference between aspirin 500–1500 mg daily and 75–325 mg daily in serious vascular events (stroke, myocardial infarction, or vascular death; OR 0.97, 95% CI 0.79 to 1.19). It also found that doses of 75 mg or more did not reduce serious vascular events compared with doses lower than 75 mg (OR 1.08, 95% CI 0.90 to 1.31). However, the comparison lacked power to exclude a clinically important difference. The systematic review also found that different aspirin doses compared with placebo or no antiplatelet treatment reduced serious vascular events by similar amounts for the higher daily doses (500–1500 mg/day *v* placebo or no antiplatelet treatment: OR 0.81, 95% CI 0.75 to 0.87; 160–325 mg/day *v* placebo or no antiplatelet treatment: OR 0.74, 95% CI 0.69 to 0.80; 75–150 mg/day *v* placebo or no antiplatelet treatment: OR 0.68, 95% CI 0.59 to 0.79) but by a smaller amount for lower doses (< 75 mg/day *v* placebo or no antiplatelet treatment: OR 0.87, 95% CI 0.74 to 1.03). See figure 2 in secondary prevention of ischaemic cardiac events, p 197. People with acute stroke were excluded from these analyses.

Harms: **Extracranial haemorrhage:** The systematic review found that the proportional increase in risk of major extracranial haemorrhage was similar with all daily aspirin doses. In direct comparisons, 75–325 mg aspirin did not increase major extracranial haemorrhage compared with doses lower than 75 mg (AR 2.5% with 75–325 mg/day *v* 1.8% with < 75 mg/day; $P > 0.05$).[25] We found one systematic review (search date 1999, 24 RCTs) of the effects of aspirin on gastrointestinal bleeding.[26] Indirect comparisons in a meta-regression analysis found no association between dose of aspirin and risk of gastrointestinal bleeds. RCTs directly comparing different daily doses of aspirin have found a trend toward more gastrointestinal haemorrhage and a significant increase in upper gastrointestinal symptoms with high (500–1500 mg) than with medium (75–325 mg) doses (upper gastrointestinal symptoms: OR 1.3, 95% CI 1.1 to 1.5), but no significant difference in these outcomes between 283 mg and 30 mg daily.[28–30] We found one systematic review of observational studies (search date 2001, 5 studies) of the effects of different doses of aspirin on the risk of upper gastrointestinal complications (bleeding, perforation, or upper gastrointestinal event leading to hospital admission or visit to specialist).[31] It found greater risks of upper gastrointestinal complications with doses of aspirin greater than 300 mg daily. **Intracranial haemorrhage:** We found one systematic review

(search date 1997, 16 RCTs, 55 462 people) of the effects of aspirin on intracranial haemorrhage.[27] It found no clear variation in risk with the dose of aspirin used. Three RCTs directly compared different daily doses of aspirin and found no significant differences in the risk of intracranial haemorrhage, but they lacked power to detect clinically important differences.[28–30]

Comment: None.

OPTION ALTERNATIVE ANTIPLATELET AGENTS TO ASPIRIN

Cathie Sudlow

Systematic reviews have found no good evidence that any antiplatelet regimen is superior to aspirin for long term secondary prevention of serious vascular events.

Benefits: **Thienopyridines (clopidogrel and ticlopidine) versus aspirin:** We found two systematic reviews (search dates 1997[25] and 1999[32]) that compared thienopyridines versus aspirin. The first systematic review (4 RCTs, 3791 people at high risk of vascular disease) found no significant difference between ticlopidine and aspirin in serious vascular events (stroke, myocardial infarction, or vascular death: AR 21% with ticlopidine *v* 23% with aspirin; OR presented graphically; P value not reported).[25] It also found that the risk of serious vascular events was similar with clopidogrel and aspirin (1 RCT, 19 185 people: AR 10% with clopidogrel *v* 11% with aspirin; OR 0.90, 95% CI 0.82 to 0.99). The second systematic review (4 RCTs) found that ticlopidine or clopidogrel marginally reduced vascular events after about 2 years compared with aspirin (OR 0.91, 95% CI 0.84 to 0.98; ARR 1.1%, 95% CI 0.2% to 1.9%).[32] **Dipyridamole plus aspirin:** We found one systematic review (search date 1997, 25 relevant RCTs, 10 404 people) comparing dipyridamole plus aspirin versus aspirin alone.[25] It found no significant difference in serious vascular events (stroke, myocardial infarction, or vascular death) between dipyridamole plus aspirin and aspirin alone (AR 11.8% with combination treatment *v* 12.4% with aspirin alone; OR 0.94, 95% CI 0.83 to 1.06).

Harms: **Thienopyridines (clopidogrel and ticlopidine):** The second systematic review comparing thienopyridines versus aspirin found that the thienopyridines reduced gastrointestinal haemorrhage and upper gastrointestinal symptoms compared with aspirin (gastrointestinal haemorrhage: OR 0.71, 95% CI 0.59 to 0.86; indigestion, nausea, or vomiting: OR 0.84, 95% CI 0.78 to 0.90).[32] However, thienopyridines increased the incidence of skin rash and diarrhoea compared with aspirin (skin rash: clopidogrel *v* aspirin OR 1.3, 95% CI 1.2 to 1.5; ticlopidine *v* aspirin OR 2.2, 95% CI 1.7 to 2.9; diarrhoea: clopidogrel *v* aspirin OR 1.3, 95% CI 1.2 to 1.6; ticlopidine *v* aspirin OR 2.3, 95% CI 1.9 to 2.8). Ticlopidine (but not clopidogrel) increased neutropenia compared with aspirin (OR 2.7, 95% CI 1.5 to 4.8). Observational studies have found ticlopidine to be associated with thrombocytopenia and thrombotic thrombocytopenic purpura.[33,34] **Dipyridamole:** One RCT found that combination treatment with dipyridamole plus aspirin was discontinued more frequently for adverse effects than was aspirin alone.[35]

Comment: One large RCT has assessed effects of adding clopidogrel to aspirin among people with unstable angina (see benefits of antiplatelet treatments in angina [unstable], p 064).[36] A further large RCT is currently assessing the effects of alternative antiplatelet regimens among people with acute myocardial infarction.[37] One ongoing RCT is comparing effects of oral anticoagulation, aspirin plus dipyridamole, and aspirin alone among 4500 people with a prior transient ischaemic attack or minor ischaemic stroke.[38]

OPTION LONG TERM ORAL ANTICOAGULATION IN PEOPLE WITH RECENT CEREBRAL ISCHAEMIA AND IN SINUS RHYTHM

Systematic reviews have found no significant difference between anticoagulation and placebo or antiplatelet treatment for preventing recurrent stroke after presumed ischaemic stroke in people in normal sinus rhythm. Anticoagulants increased the risk of fatal intracranial and extracranial haemorrhage compared with placebo. High intensity anticoagulation increased the risk of major bleeding compared with antiplatelet treatment.

Benefits: **Versus placebo:** We found one systematic review (search date not stated, 9 small RCTs, 1214 people in sinus rhythm with previous non-embolic presumed ischaemic stroke or transient ischaemic attack, mean duration 1.8 years).[39] It found no clear benefit of oral anticoagulants (warfarin, dicoumarol, or phenindione) on death or dependency compared with placebo, or on mortality or recurrent stroke (death or dependency: ARR +4%, 95% CI –6% to +14%; RRR +5%, 95% CI –9% to +18%). **Versus antiplatelet treatment:** We found one systematic review (search date 2001, 4 RCTs, 1870 people) comparing long term (> 6 months) treatment with oral anticoagulants (warfarin, phenprocoumarin, or acenocoumarol [nicoumalone]) versus antiplatelet treatment in people with a history of transient ischaemic attack or minor stroke of presumed arterial (non-cardiac) origin in the past 6 months.[40] It found no significant difference between high intensity (international normalised ratio [INR — see glossary, p 277] 3.0–4.5) or low intensity (INR 2.1–3.5) anticoagulation compared with antiplatelet treatment for preventing recurrent stroke (low intensity anticoagulation *v* antiplatelet treatment: ARR +0.2%, 95% CI –4.0% to +4.3%; RR 0.96, 95% CI 0.38 to 2.42; high intensity anticoagulation *v* antiplatelet treatment: ARR –0.1%, 95% CI –1.7% to +1.5%; RR 1.02, 95% CI 0.49 to 2.13).

Harms: **Versus placebo:** The first review found that anticoagulants increased the risk of fatal intracranial haemorrhage (ARI 2.0%, 95% CI 0.4% to 3.6%; RR 2.51, 95% CI 1.12 to 5.60; NNH 49 people treated with anticoagulants over 1.8 years for 1 additional non-fatal extracranial haemorrhage, 95% CI 27 to 240).[39] The risk of fatal and non-fatal extracranial haemorrhage was also increased by anticoagulants compared with placebo (ARI 5.1%, 95% CI 3.0% to 7.2%; RR 5.86, 95% CI 2.39 to 14.3; NNH 20, 95% CI 14 to 33). **Versus antiplatelet treatment:** The review comparing anticoagulants versus antiplatelet treatment found no significant difference in risk of major intracranial or extracranial bleeding between low

intensity anticoagulation (INR 2.1–3.6) and antiplatelet treatment (RR 1.19, 95% CI 0.59 to 2.41).[40] However, high intensity anticoagulation (INR 3.0–4.5) significantly increased the risk of major intracranial or extracranial bleeding (RR 1.08, 95% CI 1.03 to 1.20).

Comment: **Versus placebo:** The trials in the systematic review all had major problems with their methods, including poor monitoring of anticoagulation.[39] All were completed before introducing routine computerised tomography scanning, which means that people with primary haemorrhagic strokes could have been included. The systematic review could not therefore provide a reliable and precise overall estimate of the balance of risk and benefit regarding death or dependency. Most people in the trial comparing warfarin and aspirin did have a computerised tomography scan, but an adverse outcome was still seen with anticoagulants. Two further RCTs are in progress: one is comparing a lower intensity of adjusted dose warfarin (to maintain an INR of 1.4–2.8) versus aspirin 325 mg four times daily within 30 days after stroke and treated for at least 2 years;[41] whereas the other is comparing warfarin (to maintain an INR of 2.0–3.0) versus aspirin (any dose between 30–325 mg/day) versus aspirin plus dipyridamole (400 mg/day).[42]

OPTION CAROTID ENDARTERECTOMY FOR PEOPLE WITH RECENT CAROTID TERRITORY ISCHAEMIA

Peter Rothwell

Evidence from a pooled analysis of individual patient data from three RCTs in people with symptomatic carotid artery stenosis suggests that carotid endarterectomy increases the risk of stroke or death due to surgery in people with less than 30% stenosis, is of no benefit in people with 30–49% stenosis, and is of increasing benefit in people with higher grade stenosis. The RCTs found that carotid endarterectomy is of greatest benefit in people with less than 70% stenosis, although it may be ineffective in people with near-occlusion. Two systematic reviews found that carotid endarterectomy reduced perioperative stroke, death, and subsequent ipsilateral stroke in people with asymptomatic but severe stenosis. However, benefit from surgery is small because the absolute risk of stroke in asymptomatic people is low. One systematic review found no evidence that eversion carotid endarterectomy is more beneficial than conventional carotid endarterectomy.

Benefits: **People with symptomatic stenosis:** We found one pooled analysis[43] of individual patient data from the three large RCTs (4 publications) that examined the effects of endarectomy in people with symptomatic carotid stenosis.[44–47] The RCTs used different methods to measure the degree of carotid stenosis, studied different populations, and used different definitions of outcome events. However, the pooled analysis adjusted for these differences. The pooled analysis (3 RCTs, 6092 people, 35 000 person years of follow up) found that surgery increased the 5 year risk of any stroke or surgical death in people with less than 30% stenosis, had no significant effect in patients with 30–49% stenosis, was of some benefit in patients with 50–69% stenosis, and was highly beneficial in patients with 70% or more stenosis without near-occlusion

(< 30% stenosis, 1746 people: RR 1.17, 95% CI 0.90 to 1.43; 30–49% stenosis, 1429 people: RR 0.90, 95% CI 0.75 to 1.04; 50–69% stenosis, 1549 people: RR 0.72, 95% CI 0.58 to 0.86; ≥ 70% stenosis without near-occlusion, 1095 people: RR 0.52, 95% CI 0.40 to 0.64).[43] However, there was no evidence of benefit in people with the most severe disease (near-occlusion of ipsilateral carotid artery, 262 people: RR compared with control 0.98, 95% CI 0.61 to 1.59). **People with asymptomatic stenosis:** We found two systematic reviews (search dates 1998) assessing carotid endarterectomy for asymptomatic carotid stenosis (no carotid territory transient ischaemic attack or minor stroke within the past few months).[48,49] One review included results from five RCTs (2440 people).[48] The other review included results from 2203 people from four of these five RCTs, after excluding the fifth RCT because of weak methods.[49] Both reviews found similar results. Carotid endarterectomy reduced the risk of perioperative stroke, death, or subsequent ipsilateral stroke (for the review of 4 RCTs:[49] AR 4.9% over 3 years in the surgical group *v* 6.8% in the medical group; ARR 1.9%, 95% CI 0.1% to 3.9%; NNT 52, 95% CI 26 to 1000; for the review of 5 RCTs:[48] 4.7% over 3 years in the surgical group *v* 7.4% in the medical group; ARR 2.7%, 95% CI 0.8% to 4.6%; NNT 37, 95% CI 22 to 125). Although the risk of perioperative stroke or death from carotid surgery for people with asymptomatic stenosis appears to be lower than in people with symptomatic stenosis, the risk of stroke or death without surgery in asymptomatic people is low and so the absolute benefit from surgery is small, and for most people the balance of risk and benefit from surgery remains unclear.[48,49]

Eversion carotid endarterectomy versus conventional carotid endarterectomy: We found one systematic review (search date 1999, 5 RCTs, 2645 people, 2590 carotid arteries) that compared eversion carotid endarterectomy versus conventional carotid endarterectomy (see glossary, p 277) performed either with primary closure or patch angioplasty.[50] Overall, the review found no significant differences in the rate of perioperative stroke, stroke or death, local complication rate, and rate of neurological events (for stroke or death: AR 1.7% with eversion *v* 2.6% with conventional; ARR +0.9%, 95% CI –0.3% to +2.1%; for stroke: AR 1.4% with eversion *v* 1.7% with conventional, ARR +0.3%, 95% CI –0.7% to +1.3%).

Harms:

People with symptomatic stenosis: The pooled analysis (3248 people randomised to surgery a median of 6 days after randomisation) reported 229 strokes or deaths within 30 days of surgery (7.1%, 95% CI 6.3 to 8.1).[43] Operative risk was not related to the degree of stenosis. The risk of death within 30 days of endarterectomy was 1.1% (36/3248; 95% CI 0.8% to 1.5%), and among 209 people who had an operative stroke 20 people (9.6%) died (95% CI 5.9% to 14.4%). One earlier systematic review (search date 1996, 36 studies) identified several risk factors for operative stroke and death from carotid endarterectomy, including female sex, occlusion of the contralateral internal carotid artery, stenosis of the ipsilateral external carotid artery, and systolic blood pressure greater than 180 mm Hg.[51] Endarterectomy is also associated with other postoperative complications, including wound infection (3%),

wound haematoma (5%), and lower cranial nerve injury (5–7%). **People with asymptomatic stenosis:** Given the low prevalence of severe carotid stenosis in the general population, there is concern that screening and surgical intervention in asymptomatic people may result in more strokes than it prevents.[52]

Comment: **People with symptomatic stenosis**: The RCTs included in the pooled analysis found different results.[44–47] This may be partly due to differences in the methods of measurement of the degree of carotid stenosis on the pre-randomisation catheter angiograms; the method used in one RCT[44] produced higher values than the method used in the other trials.[45,46,53] There were also other differences, such as in the definitions of outcome events. Meta-analyses of the overall trial results have been reported but these took no account of the differences between the trials.[54,55] The subsequent meta-analysis reported here analysed individual participant data and was designed to determine the effectiveness and durability of endarterectomy according to degree of carotid stenosis.[43] The degree of carotid stenosis is the single most important factor influencing effects of endarterectomy.[44] A preliminary report based on subgroup analyses of the three RCTs[44–47] suggested that benefits of carotid endarterectomy were greatest within 2 weeks of an ischaemic event and that benefits reduced if surgery was delayed (interaction; P=0.009).[56] There was also evidence of reduced benefit in women (interaction; P=0.003) and trend towards increasing benefit with age (P=0.03). These observations were consistent across the individual trials. **People with asymptomatic stenosis:** A large scale trial is ongoing and is due to report initial results in 2003.[57]

OPTION CAROTID AND VERTEBRAL PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Peter Rothwell

We found insufficient evidence about effects of carotid or vertebral percutaneous transluminal angioplasty or stenting compared with medical treatment or carotid endarterectomy in people with a recent carotid or vertebral territory transient ischaemic attack or non-disabling ischaemic stroke who have severe stenosis of the ipsilateral carotid or vertebral artery.

Benefits: **Carotid percutaneous transluminal angioplasty versus medical treatment:** We found one RCT.[58] The RCT (504 people with a recent carotid territory transient ischaemic attack or non-disabling ischaemic stroke with stenosis of the ipsilateral carotid artery) compared "best medical treatment" plus carotid percutaneous transluminal angioplasty (PTA) versus "best medical treatment" plus carotid endarterectomy.[58] It found no significant difference between endovascular treatment and surgery for disabling stroke or death within 30 days of first treatment (AR for disabling stroke or death 6.4% with PTA *v* 5.9% with surgery; AR for stroke lasting more than 7 days or death 10.0% with PTA *v* 9.9% with surgery). The trial found no significant difference between treatments for ipsilateral stroke rate up to 3 years after randomisation (adjusted HR 1.04, 95% CI 0.63 to 1.70; P = 0.9). **Carotid angioplasty plus stenting versus endarterectomy:** We found two RCTs in symptomatic people.[59,60] The first RCT (219 people with carotid stenosis of

60–90%) found that carotid stenting significantly increased the combined outcome of ipsilateral stroke, procedure related death, or vasular death at 1 year compared with carotid endarterectomy (12.1% with stent *v* 3.6% with endarterectomy, P = 0.022).[59] The second RCT (104 people with > 70% carotid stenosis) found no significant difference between carotid angioplasty plus stenting and carotid endarterectomy for death or cerebral ischaemia (1 transient ischaemic attack with angioplasty *v* 1 death for endarterectomy; P not reported).[60] **Vertebral artery angioplasty:** The RCT also compared vertebral angioplasty versus "best medical treatment" in 16 people, but did not provide enough data for reliable estimates of efficacy to be made.[58]

Harms: The RCT comparing carotid angioplasty versus medical treatment found that cranial neuropathy was more common with surgery (22 people [8.7%] undergoing surgery *v* 0 people after endovascular treatment; P < 0.0001).[58] Major groin or neck haematoma occurred less often after endovascular treatment than after surgery (3 people with endovascular treatment [1.2%] *v* 17 people with surgery [6.7%]; P < 0.0015).[58] Harms data are not yet available from the other trial, which is still to be published in full.[59]

Comment: The RCTs comparing endovascular treatment versus surgery had low power, and results lacked precision.[58] Several ongoing RCTs are comparing carotid endarterectomy versus primary stenting in people with recently symptomatic severe carotid stenosis. **Carotid percutaneous transluminal angioplasty:** The two RCTs comparing angioplasty (with or without stenting) and endarterectomy suggest that angioplasty with or without stenting is associated with a higher procedural risk than endarterectomy, and a higher rate of restenosis during follow up.[59,60] However, improvements in cerebral protection devices may reduce the procedural risks,[61] and several other RCTs comparing angioplasty plus stenting with cerebral protection versus endarterectomy are currently ongoing. The use of angioplasty is likely to increase in future, but trial results will help to decide whether increased use will be confined to people in whom endarterectomy is technically difficult.

QUESTION What are the effects of anticoagulant and antiplatelet treatment in people with atrial fibrillation?

Gregory YH Lip and Bethan Freestone

OPTION ANTICOAGULANT AND ANTIPLATELET TREATMENT IN PEOPLE WITH ATRIAL FIBRILLATION

Systematic reviews have found that people with atrial fibrillation at high risk of stroke and with no contraindications are likely to benefit from anticoagulation. However, one recent systematic review has questioned the quality of existing RCTs and reviews, and suggested that more trials are needed to establish the effects of anticoagulation. Antiplatelet agents are less effective than warfarin, but they are associated with a lower bleeding risk and are a reasonable alternative if warfarin is contraindicated. The best time to begin anticoagulation after an ischaemic stroke is unclear.

Benefits:

Adjusted dose warfarin versus placebo in people with atrial fibrillation and high risk of stroke: We found two systematic reviews examining the effect of warfarin in different groups of people with atrial fibrillation at high risk of stroke (see glossary, p 277).[62,63] The first systematic review (search date 1999, 16 RCTs, 9874 people) included six RCTs (2900 people) of adjusted dose warfarin versus placebo (5 RCTs) or versus control (1 RCT) in high risk people (45% had hypertension, 20% had experienced a previous stroke or transient ischaemic attack [TIA]).[62] These six RCTs included five trials in people without prior cerebral ischaemia (primary prevention trials) and one RCT in people with prior cerebral ischaemia (secondary prevention trial).[64] Target international normalised ratio (INR) (see glossary, p 277) varied among RCTs (2.0–2.6 in primary prevention RCTs and 2.9 in the secondary prevention RCT). The results of this systematic review were similar to the others. The meta-analysis found that adjusted dose warfarin reduced the risk of stroke (5 primary prevention RCTs: ARR 4.0%, 95% CI 2.3% to 5.7%; NNT 25, 95% CI 18 to 43; 1 secondary prevention RCT: ARR 14.5%, 95% CI 7.7% to 21.3%; NNT 7, 95% CI 5 to 13; combined primary and secondary prevention RCTs: ARR 5.5%, 95% CI 3.7% to 7.3%; NNT 18, 95% CI 14 to 27). The second systematic review (search date 1999, 14 RCTs) identified the same trials of warfarin compared with placebo and found similar results.[63]

Adjusted dose warfarin versus minidose warfarin in people with atrial fibrillation and high risk of stroke: We found no systematic review or RCTs of low dose warfarin regimens in people with atrial fibrillation and a recent TIA or acute stroke. We found one RCT that compared low, fixed dose warfarin plus aspirin versus standard adjusted dose warfarin;[65] three RCTs that compared adjusted dose warfarin versus low dose warfarin plus aspirin;[66–68] and one RCT that compared conventional intensity warfarin versus low intensity warfarin.[69] The first RCT (1044 people with atrial fibrillation at high risk of stroke) found that adjusted dose warfarin (target 1.2–1.5) significantly reduced the combined rate of ischaemic stroke or systemic embolism, and reduced disabling or fatal stroke compared with low, fixed dose warfarin (target INR 1.2–1.5) plus aspirin (325 mg/day) (stroke or embolism: ARR 6.0%, 95% CI 3.4% to 8.6%; NNT 17, 95% CI 12 to 29; disabling or fatal stroke: ARR 3.9%, 95% CI 1.6% to 6.1%; NNT 26, 95% CI 16 to 63).[65] The three RCTs comparing adjusted dose warfarin versus low dose warfarin plus aspirin[66–68] were stopped prematurely when the results of the earlier trial[65] were published. Analyses of the optimal anticoagulation intensity for stroke prevention in atrial fibrillation found that stroke risk was substantially increased at INR levels below 2.[64,70] The fourth RCT (115 people with ischaemic stroke in the previous 1–6 months) found no significant difference between conventional (target INR 2.2–3.5) and low intensity (target INR 1.5–2.1) warfarin in ischaemic stroke rate after mean follow up of around 1 year (AR 1/55 [1.1%] with conventional intensity *v* 2/60 [1.7%] with low intensity warfarin).[69] The RCT was terminated prematurely because of significantly more bleeding complications with conventional intensity warfarin (see harms and comment, below). **Adjusted dose warfarin versus aspirin in people with**

atrial fibrillation and high risk of stroke: We found one systematic review comparing warfarin versus different antiplatelet regimens in people at high risk of stroke[62] and one subsequent individual patient meta-analysis.[71] The systematic review (search date 1999, 16 RCTs, 9874 people) included five RCTs (4 primary prevention and 1 secondary prevention RCTs; 2837 people) of adjusted dose warfarin versus aspirin in high risk people (45% had hypertension, 20% had experienced a previous stroke or TIA).[62] Target INR varied among RCTs (2.0–4.5 in primary prevention RCTs; 2.5–4.0 in the secondary prevention RCT). Adjusted dose warfarin reduced the overall risk of stroke compared with aspirin (ARR 2.9%, 95% CI 0.9% to 4.8%; NNT 34, 95% CI 21 to 111). The effect varied widely among the five RCTs, none of which were blinded. The recent individual patient meta-analysis (5 RCTs of primary and secondary prevention, 2633 people at high risk of ischaemic stroke) compared full dose oral anticoagulation (largely coumarin derivatives) versus aspirin (75–325 mg).[71] It found that anticoagulation significantly decreased strokes compared with aspirin in people at high risk of ischaemic stroke (ARR 3.3% per year). **Adjusted dose warfarin versus other antiplatelet treatment in people with atrial fibrillation and high risk of stroke:** One systematic review (search date 1999) compared adjusted dose warfarin versus other antiplatelet agents such as indobufen.[62] One RCT included in the review (916 people within 15 days of stroke onset) compared warfarin (target INR 2.0–3.5) versus indobufen.[72] It found no significant difference in the rate of recurrent stroke between the two groups (5% for indobufen *v* 4% for warfarin; ARR +1.0%, 95% CI −1.7% to +3.7%). **Oral anticoagulant versus oral anticoagulant plus aspirin in people with atrial fibrillation and high risk of stroke:** We found one RCT (157 people at high risk) that compared oral fluindione (active dose 5–25 mg) versus fluindione plus aspirin (100 mg).[73] It found no significant difference between fluindione alone and fluindione plus aspirin for a combined outcome of stroke, myocardial infarction, systemic arterial embolism, vascular death, or haemorrhagic complications after mean follow up of 8 months (2/81 [2.5%] with fluindione *v* 5/76 [6.6%] with fluindione plus aspirin; P = 0.21). The study was insufficiently powered to detect clinically important differences between treatments. **Aspirin versus placebo in people with atrial fibrillation and high risk of stroke:** We found one systematic review (search date 1999, 4 RCTs, 2769 people with atrial fibrillation and prior stroke or TIA).[63] It found no significant difference between aspirin and placebo for stroke or death (stroke: OR 0.68, 95% CI 0.29 to 1.57; death: OR 0.87, 95% CI 0.68 to 1.12). **In people with atrial fibrillation at moderate risk of stroke:** See glossary, p 277. We found no RCT that considered this group specifically. **Anticoagulants in people with atrial fibrillation at low risk of stroke:** See glossary, p 277. We found one systematic review[74] and one overview[75] comparing warfarin versus placebo in people with atrial fibrillation and a variety of stroke risks. Both reviews included the same five RCTs. The overview (2461 people) found that, for people younger than 65 years with atrial fibrillation (but no history of hypertension, stroke, TIA, or diabetes), the annual stroke rate was the same with warfarin or placebo (subgroup analysis among 17%

of people on warfarin and 15% on placebo; stroke rate 1% per year in each group).[75] The systematic review (search date 1999, 2313 people, mean age 69 years, 20% aged > 75 years; 45% had hypertension, 15% diabetes, and 15% a prior history of myocardial infarction) found that warfarin (INR 2.0–2.6) reduced fatal and non-fatal ischaemic stroke, reduced all ischaemic strokes or intracranial haemorrhage, and reduced the combined outcome of disabling or fatal ischaemic stroke or intracranial haemorrhage compared with placebo after mean follow up of 1.7 years (fatal and non-fatal ischaemic stroke: ARR 4.0%, 95% CI 2.4% to 5.6%; NNT 25, 95% CI 18 to 42; all ischaemic strokes or intracranial haemorrhage: ARR 4.5%, 95% CI 2.8% to 6.2%; NNT 22, 95% CI 16 to 36; combined outcome: ARR 1.8%, 95% CI 0.5% to 3.1%; NNT 56, 95% CI 32 to 200).[74] **Antiplatelet treatment in people with atrial fibrillation and low risk of stroke:** We found two systematic reviews in people with atrial fibrillation at low risk of stroke.[62,76] The first review (search date 1999, 2 RCTs, 1680 people with either paroxysmal or sustained non-valvular atrial fibrillation confirmed by electrocardiogram but without previous stroke or TIA, 30% aged > 75 years) compared aspirin versus placebo.[76] In primary prevention, aspirin did not significantly reduce ischaemic stroke, all stroke, all disabling or fatal stroke, or the composite end point of stroke, myocardial infarction, or vascular death after mean follow up of 1.3 years (ischaemic stroke: OR 0.71, 95% CI 0.46 to 1.10; ARR +1.6%, 95% CI –0.5% to +3.7%; all stroke: OR 0.70, 95% CI 0.45 to 1.08; ARR +1.8%, 95% CI –0.5% to +3.9%; all disabling or fatal stroke: OR 0.88, 95% CI 0.48 to 1.58; ARR +0.4%, 95% CI –1.2% to +2.0%; composite end point: OR 0.76, 95% CI 0.54 to 1.05; ARR +2.3%, 95% CI –0.4% to +5.0%). The second systematic review (search date 1999) included three RCTs of primary prevention.[62] The average rate of stroke among people taking placebo was 5.2%. Meta-analysis of the three RCTs found that antiplatelet treatment reduced the risk of stroke compared with placebo after mean follow up from 1.2–2.3 years (ARR 2.2%, 95% CI 0.3% to 4.1%; NNT 45, 95% CI 24 to 333).

Harms: The major risk associated with anticoagulants and antiplatelet agents was haemorrhage. In the overview assessing elderly people with variable risk factors for stroke, the absolute risk of major bleeding was 1% for placebo, 1% for aspirin, and 1.3% for warfarin.[75] Another systematic review found the absolute risk of intracranial haemorrhage increased from 0.1% a year with control to 0.3% a year with warfarin, but the difference was not significant.[62] The absolute risks were three times higher in people who had bled previously. Both bleeding and haemorrhagic stroke were more common in people aged over 75 years. The risk of death after a major bleed was 13–33%, and risk of subsequent morbidity in those who survived a major bleed was 15%. The risk of bleeding was associated with an INR greater than 3, fluctuating INRs, and uncontrolled hypertension. In a systematic review (search date not stated, 2 RCTs) major extracranial bleeding was more frequent with anticoagulation treatment than with placebo (ARI 4.9%, 95% CI 1.6% to 8.2%; RR 6.2, 95% CI 1.4 to 27.1; NNH 20, 95% CI 12 to 63).[77] The studies were too small to define the rate of intracranial haemorrhage (none occurred). In a systematic review (search date

not stated) comparing anticoagulants versus antiplatelet treatment, major extracranial bleeding was more frequent with anticoagulation (ARI 4.9%, 95% CI 1.6% to 8.2%; RR 6.4, 95% CI 1.5 to 28.1; NNH 20, 95% CI 12 to 63).[78] The studies were too small to define the rate of intracranial haemorrhage (in 1 RCT, none of the people on anticoagulant and 1 person on aspirin had an intracranial bleed). In the systematic review of oral anticoagulants versus placebo in low risk people, the number of intracranial haemorrhages was small, with a non-significant increase in the treatment group (5 in the treatment group and 2 in the control group).[74] Likewise, in the systematic review assessing antiplatelet treatment in low risk people with atrial fibrillation, too few haemorrhages occurred to characterise the effects of aspirin.[76] One more recent systematic review found no evidence that warfarin significantly increased the risk of major haemorrhage compared with placebo among people with no prior TIA or stroke (5 RCTs, 2415 people: ARI for major haemorrhage warfarin *v* placebo +0.8%, 95% CI −1.3% to +2.9%).[63] However, if people with prior stroke or TIA were included then warfarin significantly increased major haemorrhage (6 RCTs: ARI warfarin *v* placebo 1.3%, 95% CI 0.4% to 2.2%; NNH 77, 95% CI 45 to 250). The systematic review found no evidence of a difference in major haemorrhage between warfarin and aspirin; warfarin and any antiplatelet agent; warfarin and low dose warfarin plus aspirin; and low molecular weight heparin and placebo. However, the review may have lacked power to detect a clinically important difference.[63] One small RCT (157 people) found that full dose anticoagulation (target INR 2–2.6) plus aspirin significantly increased haemorrhagic complications compared with aspirin alone (13/76 [17%] with fluindione plus aspirin *v* 2/81[2.5%] with fluindione alone; P = 0.0021).[73] **Adjusted dose warfarin versus minidose warfarin in people with atrial fibrillation and high risk of stroke:** One RCT (115 people) found that conventional intensity warfarin significantly increased major haemorrhagic complications compared with low intensity warfarin after about 1 year (6/55 [10.9%] with conventional v 0/60 [0%] with low intensity; P = 0.01).[69]

Comment: The three risk strata used above have been identified based on evidence derived from one overview of five RCTs[75] and one subsequent RCT.[65] Most reviews have stratified effects of treatment in terms of these risk categories. However, one recent systematic review (search date 1999), which did not stratify for perceived risk, has suggested that RCTs may be too heterogeneous to determine effects of long term oral anticoagulation compared with placebo among people with non-rheumatic atrial fibrillation (see comment below).[79] The review (search date 1999, 5 RCTs, 3298 people) has found results that conflict with those of previous reviews.[79] The review questions the methods and highlights the heterogeneity of RCTs of oral anticoagulation in people with non-rheumatic atrial fibrillation. People in the RCTs were highly selected (< 10%, range 3–40% of eligible people were randomised); many were excluded after assessments for the absence of contraindications and physicians' refusal to enter them into the study. Many of the studies were not double blinded, and in some studies there was poor agreement between raters for "soft" neurological end points. The frequent

monitoring of warfarin treatment under trial conditions and motivation of people/investigators was probably more than that seen in usual clinical practice. The review has suggested that considerable uncertainty remains about benefits of long term anticoagulation in people with non-rheumatic atrial fibrillation. The review has different inclusion and exclusion criteria than previously published reviews, having excluded data from two RCTs and including a trial not included in previous reviews.[65] Unlike previous reviews, the recent systematic review did not stratify people for perceived stroke risk and identified no significant difference between anticoagulant and placebo with either a fixed effects model or a random effects model, which was employed to account for heterogeneity of underlying trials (fixed effects: OR 0.74, 95% CI 0.39 to 1.40 for stroke deaths; OR 0.86, 95% CI 0.16 to 1.17 for vascular deaths; random effects: OR 0.79, 95% CI 0.61 to 1.02 for combined fatal and non-fatal events).[79] The publication of this review has led to debate and uncertainty about clinical effectiveness of long term anticoagulation in people with non-rheumatic atrial fibrillation. Decisions to treat should be informed by considering trade offs between benefits and harms, and each person's treatment preferences.[80–85] We found net benefit of anticoagulation for people in atrial fibrillation who have had a TIA or stroke, or who are over 75 years of age and at a high risk of stroke. We found less clear cut evidence for those aged 65–75 years at high risk, and for those with moderate risk (i.e. > 65 years and not in a high risk group or < 65 years with clinical risk factors) or for those at low risk (< 65 years with no other risk factors). The benefits of warfarin in the RCTs may not translate into effectiveness in clinical practice.[79,86,87] In the RCTs, most strokes in people randomised to warfarin occurred while they were not in fact taking warfarin, or were significantly underanticoagulated at the time of the event. A recent systematic review (search date not stated, 410 people) identified three trials comparing the outcomes of people treated with anticoagulants in the community versus the pooled results of the RCTs.[88] The authors confirmed that people who undergo anticoagulation for atrial fibrillation in actual clinical practice are generally older and have more comorbid conditions than people enrolled in RCTs. However, both groups had similar rates of stroke and major bleeding. This risk of minor bleeding was higher in the community group, and it was suggested that these people may require more intensive monitoring in routine practice.

Adjusted dose warfarin versus minidose warfarin in people with atrial fibrillation and high risk of stroke: The RCT comparing conventional versus low intensity warfarin found no significant difference between treatments.[69] This may be due to insufficient power; premature termination of the trial because of significantly more bleeding complications in the conventional intensity anticoagulation group; the low rate of ischaemic stroke observed in both groups in this population, possibly contributed to by different ethnicity from original anticoagulation trial cohorts; or the similar anticoagulation range reached in the two groups (1.9 with low intensity *v* 2.2 with conventional).[69] **Timing of anticoagulation:**

The best time to start anticoagulation after an ischaemic stroke is unclear, but aspirin reduces the risk of recurrent stroke in such people with or without atrial fibrillation, suggesting that it is reasonable to use aspirin until it is considered safe to start oral anticoagulants.[89]

GLOSSARY

Conventional carotid endarterectomy This is more commonly employed and involves a longitudinal arteriotomy of the carotid artery.

Eversion carotid endarterectomy This involves a transverse arteriotomy and reimplantation of the carotid artery.

International normalised ratio (INR) A value derived from a standardised laboratory test that measures the effect of an anticoagulant such as warfarin. The laboratory materials used in the test are calibrated against internationally accepted standard reference preparations, so that variability between laboratories and different reagents is minimised. Normal blood has an INR of 1. Therapeutic anticoagulation often aims to achieve an INR value of 2.0–3.5.

People at high risk of stroke People of any age with a previous transient ischaemic attack or stroke or a history of rheumatic vascular disease, coronary artery disease, congestive heart failure, and impaired left ventricular function or echocardiography; and people aged 75 years and over with hypertension, diabetes, or both.

People at moderate risk of stroke People aged over 65 years who are not in the high risk group; and people aged under 65 years with clinical risk factors, including diabetes, hypertension, peripheral arterial disease, and ischaemic heart disease.

People at low risk of stroke All other people aged less than 65 years with no history of stroke, transient ischaemic attack, embolism, hypertension, diabetes, or other clinical risk factors.

QUESTIONS

INTERVENTIONS

See glossary, p 297

Key Messages

Proximal deep vein thrombosis

- **Unfractionated and low molecular weight heparin** Systematic reviews have found that low molecular weight heparin reduces the incidence of recurrent thromboembolic disease and decreases the risk of major haemorrhage compared with unfractionated heparin. One systematic review found no significant difference between long term low molecular weight heparin and oral anticoagulation in recurrent thromboembolism, major haemorrhage, or mortality. One systematic review of RCTs found no significant difference in recurrence of thromboembolism between heparin treatment at home and in hospital.
- **Warfarin** We found no RCTs comparing warfarin versus placebo. One RCT found that fewer people had recurrence of proximal deep vein thrombosis within 6 months with combined acenocoumarol (nicoumalone) plus intravenous unfractionated heparin than with acenocoumarol alone; as a result, the trial was stopped. Systematic reviews have found that longer duration of anticoagulation reduces recurrence of deep vein thrombosis compared with

shorter duration of anticoagulation. One non-systematic review found limited evidence that longer compared with shorter duration of warfarin was associated with an increased risk of major haemorrhage, but another non-systematic review found no significant difference in major haemorrhage. The absolute risk of recurrent venous thromboembolism decreases with time, but the relative risk reduction with treatment remains constant. Harms of treatment, including major haemorrhage, continue during prolonged treatment. Individuals have different risk profiles and it is likely that the optimal duration of anticoagulation will vary.

- **Compression stockings** We found no RCTs of standard compression stockings for treating people with proximal deep vein thrombosis. One RCT found that made to measure knee length graduated compression stockings reduced post-thrombotic syndrome over 5–8 years compared with no stockings.

Isolated calf vein thrombosis

- **Warfarin plus heparin** One unblinded RCT found no significant difference in recurrent thromboembolism or rates of major haemorrhage between 6 and 12 weeks of anticoagulation. One RCT found that warfarin plus intravenous unfractionated heparin (international normalised ratio 2.5–4.2) reduced the rate of proximal extension compared with heparin alone.

Pulmonary embolism

- **Oral anticoagulants** We found no direct evidence about the optimum intensity and duration of anticoagulation in people with pulmonary embolism. The best available evidence requires extrapolation of results from studies of people with proximal deep vein thrombosis (see above).
- **Unfractionated and low molecular weight heparin** One small RCT in people with pulmonary embolism found that heparin plus warfarin reduced mortality compared with no anticoagulation at 1 year. One RCT in people with symptomatic pulmonary embolism who did not receive thrombolysis or embolectomy found no significant difference between low molecular weight heparin and unfractionated heparin in mortality or new episodes of thromboembolism. Another RCT in people with proximal deep vein thrombosis without clinical signs or symptoms of pulmonary embolism but with high probability lung scan findings found that fixed dose low molecular weight heparin reduced the proportion of people with new episodes of venous thromboembolism compared with intravenous heparin.
- **Thrombolysis** RCTs identified by one systematic review found no significant difference in mortality between thrombolysis plus heparin and heparin alone, and found that thrombolysis may increase the incidence of intracranial haemorrhage. One small RCT identified by the review found limited evidence that adding thrombolysis to heparin may reduce mortality in people with shock due to massive pulmonary embolism.

Computerised decision support

- **Computerised decision support in oral anticoagulation** We found no RCTs comparing computerised decision support versus usual management of oral anticoagulation that used clinically important outcomes (major haemorrhage or death).
- One systematic review and three subsequent RCTs have found that, compared with usual care, computerised decision support in oral anticoagulation increases time spent in the target international normalised ratio range. Another subsequent RCT found no significant difference between computerised decision support and standard manual support in the time spent in the target

international normalised ratio range. A subsequent RCT of initiation of warfarin found that computerised decision support reduced the mean time taken to reach therapeutic levels of anticoagulation compared with usual care. Most RCTs were small and brief.

DEFINITION

Venous thromboembolism is any thromboembolic event occurring within the venous system, including deep vein thrombosis and pulmonary embolism. **Deep vein thrombosis** is a radiologically confirmed partial or total thrombotic occlusion of the deep venous system of the legs sufficient to produce symptoms of pain or swelling. **Proximal deep vein thrombosis** affects the veins above the knee (popliteal, superficial femoral, common femoral, and iliac veins). **Isolated calf vein thrombosis** is confined to the deep veins of the calf and does not affect the veins above the knee. **Pulmonary embolism** is radiologically confirmed partial or total thromboembolic occlusion of pulmonary arteries, sufficient to cause symptoms of breathlessness, chest pain, or both. **Post-thrombotic syndrome** is oedema, ulceration, and impaired viability of the subcutaneous tissues of the leg occurring after deep vein thrombosis. **Recurrence** refers to symptomatic deterioration owing to a further (radiologically confirmed) thrombosis, after a previously confirmed thromboembolic event, where there had been an initial partial or total symptomatic improvement. **Extension** refers to a radiologically confirmed new, constant, symptomatic intraluminal filling defect extending from an existing thrombosis.

INCIDENCE/ PREVALENCE

We found no reliable study of the incidence/prevalence of deep vein thrombosis or pulmonary embolism in the UK. A prospective Scandinavian study found an annual incidence of 1.6–1.8/1000 people in the general population.[1,2] One postmortem study estimated that 600 000 people develop pulmonary embolism each year in the USA, of whom 60 000 die as a result.[3]

AETIOLOGY/ RISK FACTORS

Risk factors for deep vein thrombosis include immobility, surgery (particularly orthopaedic), malignancy, smoking, pregnancy, older age, and inherited or acquired prothrombotic clotting disorders.[4] The oral contraceptive pill is associated with increased risk of death due to venous thromboembolism (ARI with any combined oral contraception: 1–3/million women a year).[5] The principal cause of pulmonary embolism is a deep vein thrombosis.[4]

PROGNOSIS

The annual recurrence rate of symptomatic calf vein thrombosis in people without recent surgery is over 25%.[6,7] Proximal extension develops in 40–50% of people with symptomatic calf vein thrombosis.[8] Proximal deep vein thrombosis may cause fatal or non-fatal pulmonary embolism, recurrent venous thrombosis, and the post-thrombotic syndrome. One case series (462 people) published in 1946 found 5.8% mortality from pulmonary emboli in people in a maternity hospital with untreated deep vein thrombosis.[9] One non-systematic review of observational studies found that, in people after recent surgery who have an asymptomatic deep calf vein thrombosis, the rate of fatal pulmonary embolism was 13–15%.[10] The incidence of other complications without treatment is not known. The risk of recurrent venous thrombosis and complications is increased by thrombotic risk factors.[11]

AIMS OF INTERVENTION To reduce acute symptoms of deep vein thrombosis and to prevent morbidity and mortality associated with thrombus extension, post-thrombotic syndrome, and pulmonary embolisation; to reduce recurrence; to minimise any adverse effects of treatment.

OUTCOMES Rates of symptomatic recurrence, post-thrombotic syndrome, symptomatic pulmonary embolism, and death. Proxy outcomes include radiological evidence of clot extension or pulmonary embolism.

METHODS *Clinical Evidence* search and appraisal November 2002. Observational studies were used for estimating incidence, prevalence, and adverse event rates. RCTs were included only if participants were included and outcomes defined on the basis of objective tests, and if the trial provided dose ranges (with adjusted dosing schedules for oral anticoagulation and unfractionated heparin) and independent, blinded outcome assessment.

QUESTION What are the effects of treatments for proximal deep vein thrombosis?

OPTION WARFARIN

We found no RCTs comparing warfarin versus placebo. One RCT found that fewer people had recurrence of proximal deep vein thrombosis within 6 months with acenocoumarol (nicoumalone) plus intravenous unfractionated heparin as initial treatment than with acenocoumarol alone; as a result, the trial was stopped. Systematic reviews have found fewer deep vein thrombosis recurrences with longer versus shorter duration of anticoagulation. One non-systematic review found limited evidence that prolonged compared with shorter anticoagulation significantly increased major haemorrhage, but another non-systematic review found no significant difference in major haemorrhage.

Benefits:

Versus placebo: We found no systematic review and no RCTs.

Acenocoumarol (nicoumalone) plus intravenous unfractionated heparin versus acenocoumarol alone for initial treatment: We found no systematic review. One RCT (120 people with proximal deep vein thrombosis) found that fewer people had recurrence at interim analysis at 6 months with combined intravenous unfractionated heparin plus acenocoumarol than with acenocoumarol alone; as a result, the trial was stopped. The difference in recurrence did not quite reach significance (4/60 [7%] with combined treatment *v* 12/60 [20%] with warfarin alone; P = 0.058).[12]

Longer versus shorter duration of anticoagulation: We found two systematic reviews[13,14] and two subsequent open label RCTs.[15,16] The first systematic review (search date 2000, 4 RCTs, 1500 people) included two RCTs of people with a first episode of venous thromboembolism, one RCT in people with a second episode of venous thromboembolism, and one RCT in people with acute proximal deep vein thrombosis.[13] The periods of treatment compared were different in all four RCTs: 4 weeks versus 3 months, 6 weeks versus 6 months, 3 months

versus 27 months, and 6 months versus 4 years. In all RCTs, warfarin doses were adjusted to achieve an international normalised ratio (see glossary, p 297) of 2.0–3.0. The review found that prolonged compared with shorter warfarin treatment significantly reduced thromboembolic complications (AR 7/758 [0.9%] in the long arm *v* 91/742 [12.3%] in the short arm; RR 0.08, 95% CI 0.04 to 0.16; NNT 9, 95% CI 8 to 12). However, it found no significant reduction in mortality between prolonged and shorter treatment (AR 37/758 [4.9%] in the long arm *v* 50/742 [6.7%] in the short arm; RR 0.72, 95% CI 0.48 to 1.08).[13] The second systematic review (search date not stated, 7 RCTs, 2304 people) included three of the same RCTs as the first systematic review plus four RCTs that had been excluded from the first systematic review on methodological grounds (either because of problems with blinding of outcomes or lack of an objective test to confirm thromboembolism).[14] There was wide variation in the duration of short term (3–12 weeks) and longer term (12 weeks to 2 years) RCTs. This review also found that longer compared with shorter duration of warfarin reduced the risk of recurrent thromboembolism (74/1156 [6.4%] events per person with longer duration *v* 127/1148 [11.1%] with shorter duration; RR 0.60, 95% CI 0.45 to 0.79; NNT 22, 95% CI 15 to 43). The first subsequent RCT (736 people, including 539 with proximal deep vein thrombosis, pulmonary embolism, or both; open label) comparing fluindione for 3 months versus 6 months found no significant difference in the risk of recurrent thromboembolism, although the confidence interval was wide (AR 21/270 [7.8%] with 3 months *v* 23/269 [8.6%] with 6 months; ARR +0.8%, 95% CI –3.9% to +5.4%; RR 0.93, 95% CI 0.53 to 1.65).[15] The second subsequent RCT (267 people with a first episode of symptomatic proximal deep vein thrombosis; open label) compared warfarin or acenocoumarol treatment for 3 months versus 12 months.[16] It found no significant difference in recurrence of venous thromboembolism over a mean of 3 years between longer and shorter treatment (21/134 [15.7%] with 12 months *v* 21/133 [15.8%] with 3 months; RR 0.99, 95% CI 0.57 to 1.73). However, it found that mean time to recurrence was shorter with 3 months' than with 12 months' treatment (11.2 months with 3 months *v* 16 months with 12 months; no further data reported).[16] **Intensity of anticoagulation:** We found one RCT (96 people with a first episode of idiopathic venous thromboembolism) comparing international normalised ratio targets of 2.0–3.0 versus 3.0–4.5 over 12 weeks' treatment with warfarin after an initial course of intravenous heparin.[17] It found similar recurrence rates at 10 months for both international normalised ratio target ranges (1/47 [2.1%] with lower range *v* 1/49 [2.0%] with higher range; $P > 0.05$), but found significantly fewer haemorrhagic events with the lower target range (2/47 [4.3%] with lower range *v* 11/49 [22.4%] with higher range; ARR 18%, 95% CI 5% to 32%; RR 0.19, 95% CI 0.04 to 0.81; NNT 6, 95% CI 4 to 23).[17] **Abrupt versus gradual discontinuation of anticoagulation:** One RCT (41 people with deep vein thrombosis who had received iv heparin for 3–5 days followed by warfarin for 3–6 months) compared abrupt withdrawal

of warfarin versus an additional month of warfarin at a fixed low dose of 1.25 mg daily.[18] It found similar recurrence with abrupt compared with gradual discontinuation (3 people with abrupt withdrawal *v* 1 person with gradual withdrawal; CI not reported).[18]

Harms: **Warfarin:** Two non-systematic reviews of RCTs and cohort studies found annual bleeding rates of 0–5% (fatal bleeding) and 2–8% (major bleeds).[19,20] Rates depended on how bleeding was defined and the intensity of anticoagulation. **Acenocoumarol plus intravenous unfractionated heparin versus acenocoumarol alone for initial treatment:** In the RCT comparing acenocoumarol plus heparin versus acenocoumarol alone, one person in the combined treatment group committed suicide at 6 months.[12] There were two cancer related deaths, confirmed by postmortem examination, in the group treated with warfarin alone: one in week 11 and the other in week 12. **Longer versus shorter duration of anticoagulation:** No individual RCT in either review comparing length of anticoagulation found a significant increase in bleeding complications during prolonged compared with shorter treatment for venous thromboembolism.[13,14] Both reviews included studies with different periods of treatment and the populations studied had different types of venous thromboembolism (see benefits above). The first review found that prolonged compared with shorter anticoagulation significantly increased the risk of major haemorrhage (see glossary, p 298) (19/758 [2.5%] with prolonged anticoagulation *v* 4/742 [0.5%] with shorter anticoagulation; OR 3.75, 95% CI 1.63 to 8.62).[13] The second review found a greater risk of major haemorrhage with prolonged compared with shorter anticoagulation, but the difference was not significant (10/917 [1.1%] with prolonged anticoagulation *v* 6/906 [0.7%] with shorter anticoagulation; RR 1.43, 95% CI 0.51 to 4.01).[14]

Comment: **Studies assessing harm:** These varied in regard to diagnostic criteria, definitions of adverse events, and intensity of anticoagulation, making interpretation difficult.[13,14] **Duration of anticoagulation:** The absolute risk of recurrent venous thromboembolism decreases with time, whereas the relative risk reduction with treatment remains constant. Observed recurrence of venous thromboembolism is therefore dependent on length of follow up. Harms of treatment, including major haemorrhage, continue during prolonged treatment. Individuals have different risk profiles and it is likely that the optimal duration of anticoagulation will vary.

OPTION UNFRACTIONATED AND LOW MOLECULAR WEIGHT HEPARIN

Systematic reviews have found that low molecular weight heparin reduces the incidence of recurrent thromboembolic disease and decreases the risk of major haemorrhage compared with unfractionated heparin. One systematic review found no significant difference between long term low molecular weight heparin and oral anticoagulation in recurrent thromboembolism, major haemorrhage, or mortality. One systematic review of weak RCTs found no significant difference in recurrence of thromboembolism between heparin treatment at home and in hospital.

Benefits:

Low molecular weight heparin versus unfractionated heparin in people with proximal deep vein thrombosis: We found one systematic review[21] and one subsequent RCT[22] in people with symptomatic proximal deep vein thrombosis, and one systematic review[23] in people with symptomatic venous thromboembolism that included two RCTs in people with proximal deep vein thrombosis. The first review (search date 1994, 10 RCTs, 1424 people) found that low molecular weight heparin (LMWH) (see glossary, p 298) significantly reduced symptomatic thromboembolic complications compared with unfractionated heparin (5 RCTs: 17/540 [3%] with LMWH *v* 36/546 [7%] with unfractionated heparin; RR 0.47, 95% CI 0.27 to 0.82) and mortality (21/540 [4%] with LMWH *v* 39/546 [7%] with unfractionated heparin; RR 0.53, 95% CI 0.31 to 0.90).[21] The second review[23] (search date not stated, 16 unblinded and blinded RCTs, 6042 people with symptomatic venous thromboembolism) included two RCTs[24,25] in people with proximal deep vein thrombosis published after the search date of the first review. Results for people with proximal deep vein thrombosis alone were not analysed separately.[23] The first RCT included in the review (961 people, unblinded) compared LMWH twice daily for 1 week versus LMWH once daily for 4 weeks versus intravenous unfractionated heparin.[24] It found that both LMWH regimens significantly increased thrombus regression at 21 days compared with unfractionated heparin (167/312 [53.5%] with once daily LMWH *v* 129/321 [40.2%] with unfractionated heparin; RR 1.29, 97.5% CI 1.08 to 1.53; 175/328 [53.4%] with twice daily LMWH *v* 129/321 [40.2%] with unfractionated heparin; RR 1.28, 97.5% CI 1.08 to 1.52). It found that twice daily LMWH significantly reduced recurrent thromboembolism at 90 days compared with unfractionated heparin (7/388 [1.8%] with twice daily LMWH *v* 24/375 [6.4%] with unfractionated heparin; RR 0.28, 97.5% CI 0.11 to 0.74), but found no significant difference between once daily LMWH and unfractionated heparin (13/374 [3.5%] with once daily LMWH *v* 24/375 [6.4%] with unfractionated heparin; RR 0.55, 97.5% CI 0.24 to 1.16). The second RCT included in the review (538 people, unblinded) compared fixed dose LMWH versus adjusted dose unfractionated heparin for 12 days.[25] It found no significant difference in thrombus regression at 7–15 days between LMWH and unfractionated heparin (RR 0.93, 95% CI 0.82 to 1.05). It found that LMWH significantly reduced recurrent venous thromboembolism compared with unfractionated heparin (ARs not provided; OR 0.66, 95% CI 0.51 to 0.86).[25] The subsequent RCT (294 people with acute proximal deep vein thrombosis, unblinded) compared intravenous unfractionated heparin in hospital versus LMWH twice daily given mainly at home (outpatients) or alternatively in hospital versus subcutaneous heparin calcium given at home.[22] It found no significant difference in recurrent deep vein thrombosis (6/98 [6%] with unfractionated heparin *v* 6/97 [6%] with LMWH *v* 7/99 [7%] with subcutaneous heparin calcium).[22] See systematic anticoagulation under stroke management, p 240.

Once daily versus twice daily LMWH: We found one systematic review (search date 1999, 5 RCTs, 1522 people with symptomatic proximal deep vein thrombosis) comparing once versus twice daily LMWH for 5–10 days.[26] It found no significant difference in the

proportion of people with symptomatic or asymptomatic venous thromboembolism at 10 days or 3 months between once and twice daily LMWH (symptomatic venous thromboembolism at 10 days: 5 RCTs, OR 0.82, 95% CI 0.26 to 2.49; at 3 months: 3 RCTs, OR 0.85, 95% CI 0.48 to 1.49). **Long term low molecular weight heparin versus oral anticoagulation:** We found one systematic review (search date 2001, 7 RCTs, 1137 people with proximal deep vein thrombosis treated initially with LMWH or unfractionated heparin for 5–10 days) comparing long term oral anticoagulation versus long term LMWH.[27] It found no significant difference between LMWH and oral anticoagulation in recurrent symptomatic thromboembolism (27/568 [4.8%] *v* 38/569 [6.7%]; OR 0.70, 95% CI 0.42 to 1.16) or mortality (21/568 [3.7%] *v* 14/569 [2.5%]; OR 1.51, 95% CI 0.77 to 2.97).[27] **Home versus hospital treatment with short term heparin:** We found one systematic review (search date 2000, 3 RCTs, 1104 people).[28] Two of the RCTs in the systematic review compared LMWH at home versus unfractionated heparin in hospital, and the other RCT compared LMWH both at home and in hospital. The RCTs had methodological problems, including high exclusion rates and partial hospital treatment in the home treatment arms. The systematic review found no significant difference between treatments in recurrence of thromboembolism, minor bleeding, major haemorrhage (see glossary, p 298), or mortality.[28]

Harms:

Haemorrhage and mortality with low molecular weight heparin versus unfractionated heparin: We found two systematic reviews.[21,23] The first review found that unfractionated heparin was associated with significantly higher rates of clinically important bleeding compared with LMWH (21/759 [3%] with unfractionated heparin *v* 6/753 [0.8%] with LMWH; RR 3.47, 95% CI 1.41 to 8.55).[21] One RCT (538 people with proximal deep vein thrombosis) included in the second review[23] found that LMWH significantly reduced the composite end point of death, recurrent venous thromboembolism, or major bleeding at 6 months compared with unfractionated heparin (18/265 [7%] with LMWH *v* 35/273 [13%] with unfractionated heparin; RR 0.53, 95% CI 0.31 to 0.90).[25] **Thrombocytopenia with low molecular weight heparin versus unfractionated heparin:** We found one systematic review[29] and one subsequent RCT.[30] The review (3306 people treated for at least 5 days) found no significant difference between LMWH and unfractionated heparin in the risk of thrombocytopenia (RR 0.85, 95% CI 0.45 to 1.62).[29] The subsequent RCT (1137 people with symptomatic venous thromboembolism, unblinded) assessed the risk of thrombocytopenia with three treatments: LMWH for 5–7 days; LMWH for 26–30 days; or unadjusted dose unfractionated heparin for 5–7 days.[30] It found that short term LMWH was associated with less thrombocytopenia compared with long term LMWH or unfractionated heparin (0/388 [0%] with short term LMWH *v* 2/374 [0.53%] with long term LMWH *v* 2/375 [0.53%] with unfractionated heparin). The RCT did not assess the significance of the difference between groups. **Long term low molecular weight heparin versus anticoagulation:** One systematic review found that long term anticoagulation significantly reduced major haemorrhage compared with long term LMWH (7 RCTs; 5/568 [0.9%] *v* 14/569

[2.5%]; OR 0.38, 95% CI 0.15 to 0.94) but, when only high quality RCTs were included, it found no significant difference in major haemorrhage between long term LMWH and anticoagulation (3 RCTs; 4/236 [1.7%] with long term LMWH *v* 5/241 [2.1%] with anticoagulation; OR 0.80, 95% CI 0.21 to 3.00).[27]

Comment: **Studies assessing harm:** These varied in their diagnostic criteria and definitions of adverse events, making interpretation difficult.

OPTION COMPRESSION STOCKINGS

We found no RCTs of standard compression stockings for treating people with proximal deep vein thrombosis. One RCT found that made to measure knee length graduated compression stockings significantly reduced post-thrombotic syndrome over 5–8 years compared with no stockings.

Benefits: We found no systematic review but found one RCT (194 people with a first episode of venogram proven proximal deep vein thrombosis) comparing made to measure knee length graduated compression stockings (see comment below) versus no stockings for 2 years.[31] Median follow up was 76 months (range 60–96 months). It found that, compared with no stockings, compression stockings significantly reduced mild to moderate post-thrombotic syndrome (19/94 [20%] with compression stockings *v* 46/94 [47%] with no stockings; $P < 0.001$) and severe post-thrombotic syndrome (11/100 [11%] with stockings *v* 23/100 [23%] with no stockings; $P < 0.001$).[31]

Harms: The RCT gave no information on harms.[31]

Comment: The compression stockings evaluated in the RCT were made to measure rather than the standard sized stockings generally used in clinical practice.[31]

QUESTION What are the effects of treatment for isolated calf vein thrombosis?

OPTION WARFARIN

We found no RCTs comparing warfarin versus placebo. One RCT found that warfarin plus intravenous unfractionated heparin reduced rates of proximal extension compared with heparin alone. One unblinded RCT found no significant difference in recurrent thromboembolism or rates of major haemorrhage between 6 and 12 weeks of warfarin.

Benefits: **Versus placebo:** We found no systematic review and no RCTs. **Plus heparin versus warfarin alone:** We found no systematic review. We found one RCT that compared intravenous unfractionated heparin (international normalised ratio [see glossary, p 297] 2.5–4.2) for at least 5 days with or without 3 months of warfarin. It found that heparin plus warfarin significantly reduced proximal extension of clot at 1 year compared with heparin alone (1/23 [4%] people with heparin plus warfarin *v* 9/28 [32%] people with heparin alone; ARR 28%, 95% CI 9% to 47%).[6] **Duration of anticoagulation:** We found one unblinded RCT (736 people,

including 197 with isolated calf vein thrombosis) comparing 6 weeks versus 12 weeks of warfarin, which found no significant difference in recurrence of venous thromboembolism (AR 2/105 [1.9%] with 6 weeks *v* 3/92 [3.3%] with 12 weeks; RR 0.58, 95% CI 0.10 to 3.36).[15]

Harms: See harms of anticoagulation under treatments for proximal deep vein thrombosis, p 289. **Duration of anticoagulation:** One RCT (197 people) found no significant difference in rate of haemorrhage between 6 weeks and 12 weeks of warfarin (AR 13/105 [12.4%] with 6 weeks *v* 19/92 [20.6%] with 12 weeks; RR 0.59, 95% CI 0.31 to 1.26).[15]

Comment: Many reported cases of isolated calf vein thrombosis are asymptomatic but detected radiologically for research purposes. We found limited evidence about the clinical importance of asymptomatic calf vein thrombosis. Similarly, studies into the incidence of pulmonary embolism associated with isolated calf vein thrombosis detected asymptomatic embolism by ventilation–perfusion scanning, and the clinical relevance of these findings is unclear.

QUESTION What are the effects of treatments for pulmonary embolism?

OPTION ANTICOAGULATION

We found no direct evidence in people with pulmonary embolism about the optimum intensity and duration of anticoagulation. Evidence for intensity and duration of treatment has been extrapolated from RCTs in people with proximal deep vein thrombosis and any venous thromboembolism. One small RCT found that heparin plus warfarin significantly reduced mortality in people with pulmonary embolism compared with no anticoagulation. One RCT in people with symptomatic pulmonary embolism who did not receive thrombolysis or embolectomy found no significant difference between low molecular weight heparin and unfractionated heparin in mortality or new episodes of thromboembolism. Another RCT in people with proximal deep vein thrombosis without clinical signs or symptoms of pulmonary embolism but with high probability lung scan findings found that low molecular weight heparin reduced the proportion of people with new episodes of venous thromboembolism compared with intravenous heparin.

Benefits: We found no RCTs comparing heparin versus placebo, warfarin versus placebo, or heparin plus warfarin versus heparin alone or versus warfarin alone. **Heparin plus warfarin versus no anticoagulation:** We found no systematic review. We found one RCT (published 1960; 35 people with pulmonary embolism) comparing heparin plus warfarin versus no anticoagulation.[32] It found that anticoagulation significantly reduced mortality at 1 year compared with no anticoagulation (0/16 [0%] deaths with anticoagulation *v* 5/19 [26%] deaths with no anticoagulation; NNT 4, 95% CI 2 to 16).[32] **Duration and intensity of anticoagulation:** We found no direct evidence in people with pulmonary embolism. Evidence for intensity and duration of treatment has been extrapolated from RCTs in people with proximal deep vein thrombosis and any venous

thromboembolism. These trials found that bleeding rates were increased by higher international normalised ratio (see glossary, p 297) target ranges (international normalised ratio 3.0–4.5), but recurrence rates were not significantly different compared with a lower range (international normalised ratio 2.0–3.0), and that longer courses of anticoagulation reduced recurrence compared with shorter courses (see benefits of anticoagulation under treatments for proximal deep vein thrombosis, p 287). **Low molecular weight heparin versus unfractionated heparin:** We found no systematic review but found two RCTs.[33,34] The first RCT (612 people with symptomatic pulmonary embolism who did not receive thrombolysis or embolectomy) found no significant difference in mortality between low molecular weight heparin (LMWH — tinzaparin) and intravenous heparin (AR 12/304 [3.9%] with tinzaparin *v* 14/308 [4.5%] with heparin; P = 0.7) or recurrent thromboembolism (5/304 [1.6%] with tinzaparin *v* 6/308 [1.9%] with heparin; P = 0.8).[33] The second RCT (200 people with proximal deep vein thrombosis without clinical signs or symptoms of pulmonary embolism but with high probability lung scan findings) found that fixed dose LMWH (see glossary, p 298) given once daily significantly reduced the proportion of people with new episodes of venous thromboembolism compared with dose adjusted intravenous heparin (AR 0/97 [0%] with LMWH *v* 7/103 [6.8%] with iv heparin; P = 0.01).[34]

Harms: The first RCT comparing LMWH versus unfractionated heparin found no significant difference in the rate of major haemorrhage (see glossary, p 298) (3/304 [1.0%] with LMWH *v* 5/308 [1.6%] with unfractionated heparin; P = 0.5).[33] The second RCT also found no significant difference in the risk of major haemorrhage (1/97 [1%] with LMWH *v* 2/103 [2%] with iv heparin; P = 0.6).[34] See harms of anticoagulation under treatments for proximal deep vein thrombosis, p 289. However, in both RCTs, the incidence of major haemorrhage was low and the number of people is likely to have been too small to detect a clinically important difference.[33,34]

Comment: None.

OPTION THROMBOLYSIS

RCTs identified by a systematic review found no significant difference in mortality between thrombolysis plus heparin and heparin alone, and found that thrombolysis may increase the incidence of intracranial haemorrhage. One small RCT identified by the review found limited evidence that adding thrombolysis to heparin may reduce mortality in people with shock owing to massive pulmonary embolism.

Benefits: We found one systematic review,[35] one subsequent RCT,[36] and one large, non-randomised trial (see comment below).[37] **Plus heparin versus heparin alone:** One systematic review (search date 1998) identified nine RCTs comparing various thrombolytic agents versus heparin.[35] The review did not perform a meta-analysis. The largest RCT (160 people with angiographically documented pulmonary embolism) identified by the review compared a 12 hour infusion of urokinase followed by heparin versus heparin alone. It found no

significant difference between treatments in mortality (6/82 [7%] with combined treatment *v* 7/78 [9%] with heparin alone; RR 1.23, 95% CI 0.43 to 3.49) or recurrent pulmonary embolism at 12 months (12/82 [15%] with combined treatment *v* 15/78 [19%] with heparin alone; RR 1.31, 95% CI 0.66 to 2.63).[35] Seven short term RCTs identified by the review compared urokinase, streptokinase, or recombinant tissue-type plasminogen activator followed by heparin versus heparin alone, where heparin was adjusted to maintain a therapeutic partial thromboplastin time. They found no significant difference in mortality or recurrent embolism at 24 hours to 30 days. One small RCT identified by the review (8 people with shock related to pulmonary embolism) comparing bolus streptokinase versus heparin found limited evidence that streptokinase may reduce mortality (0/4 [0%] with streptokinase *v* 4/4 [100%] with heparin).[35] However, these results should be interpreted with caution as people receiving heparin alone had a much longer delay between onset of symptoms and initiation of treatment than people receiving streptokinase. One subsequent RCT (256 people) comparing alteplase plus heparin versus placebo plus heparin for 2 days found no significant difference in in-hospital mortality over a mean 16.7 days (4/118 [3.4%] with alteplase plus heparin *v* 3/118 [2.2%] with heparin alone; P = 0.71).[36] However, it also found that people given heparin alone compared with heparin plus alteplase were significantly more likely to receive rescue thrombolysis (P = 0.004). This makes the results difficult to interpret.[36] **Versus each other:** The systematic review identified six RCTs (491 people) comparing different thrombolytic agents versus each other.[35] It found no significant difference in mortality or recurrent pulmonary embolism with different thrombolytics.

Harms:

One systematic review (search date not stated)[38] assessing haemorrhagic complications of anticoagulation identified the same 16 RCTs as the review above.[35] It found a similar range of major bleeding event rates with thrombolysis compared with thrombolytics plus heparin or heparin alone (0–48% with thrombolytics *v* 0–45% with thrombolytics plus heparin *v* 0–27% with heparin alone).[38] It also found similar rates of major bleeding events with different thrombolytics (9–14%). It found that intravenous thrombolytics increased the proportion of people who had an intracranial haemorrhage compared with heparin (896 people; 1.2% with thrombolytics [half of which were fatal] *v* 0% with heparin alone).[38]

Comment:

Versus heparin: One additional, non-randomised trial (719 people), which excluded people with shock, found limited evidence that thrombolytics reduced overall mortality (8/169 [5%] with thrombolytics *v* 61/550 [11%] with heparin; RR 0.43, 95% CI 0.21 to 0.87) and recurrent pulmonary embolism over 30 days compared with heparin (13/169 [8%] with thrombolytics *v* 103/550 [19%] with heparin; RR 0.25, 95% CI 0.13 to 0.51).[37] However, these results should be interpreted with caution as people receiving heparin were older and more likely to have underlying cardiac or pulmonary disease than those receiving thrombolytics.

QUESTION What are the effects of computerised decision support on oral anticoagulation management?

OPTION COMPUTERISED DECISION SUPPORT FOR ORAL ANTICOAGULATION MANAGEMENT

We found no RCTs comparing computerised decision support versus usual management of oral anticoagulation that used clinically important outcomes (major haemorrhage or death). One systematic review and three subsequent RCTs have found that, compared with usual care, computerised decision support in oral anticoagulation significantly increases time spent in the target international normalised ratio range. Another subsequent RCT found no significant difference between computerised decision support and standard manual support in the time spent in the target international normalised ratio range. A subsequent RCT of initiation of warfarin found that computerised decision support significantly reduced the mean time taken to reach therapeutic levels of anticoagulation compared with usual care. Most RCTs were small and brief.

Benefits:

Clinical outcomes: We found no systematic review and no RCTs.
Laboratory outcomes: We found one systematic review[39] and five subsequent RCTs.[40–44] The review (search date 1997, 9 RCTs, 1336 people) included eight RCTs using warfarin and one using heparin.[39] The computer systems advised the doses for initiation of anticoagulation (2 RCTs) and for maintenance of anticoagulation (6 RCTs). Follow up was short (15 days to 12 months). Indications for treatment included cardiac diseases and venous thrombosis. The outcome reported by 7/9 RCTs (693 people) in the systematic review was the proportion of days within the target range of anticoagulation. The review found that computerised decision support (see glossary, p 297) increased the time that the international normalised ratio (see glossary, p 297) was in the target range compared with usual care (OR 1.29, 95% CI 1.12 to 1.49). Reanalysis excluding one trial that introduced significant heterogeneity found similar results (OR for remaining RCTs 1.25, 95% CI 1.08 to 1.45). The first subsequent RCT (285 people) compared a computerised decision support dosing system versus physician adjusted dosing in five hospitals.[40] People who were taking warfarin for at least 6 days were selected and followed for at least 3 months (results from 254 people [89%] were analysed). People managed by computerised decision support spent significantly more time with their international normalised ratio in the target range than people managed conventionally (63% with computerised decision support *v* 53% with conventional management; $P < 0.05$).[40] The second subsequent RCT (244 people) compared a package of care that included computerised decision support versus traditional hospital outpatient management.[41] The intervention was based in primary care: a practice nurse clinic that included near patient international normalised ratio testing and computerised decision support. It found significantly more time spent in the target range after 12 months with packaged care versus traditional outpatient management (69% with packaged care *v* 57% with traditional care; $P < 0.001$), but found no significant difference in the proportion of tests in range (61% with packaged care *v* 51% with traditional care;

reported as non-significant, no further data provided) or in the point prevalence of tests in range (71% with packaged care *v* 62% with traditional care; reported as non-significant, no further data provided).[41] The third subsequent RCT (101 people receiving oral anticoagulation after heart valve replacement) compared a computerised decision support system versus standard manual monitoring of international normalised ratio over 315 days.[42] It found no significant difference in the proportion of international normalised ratios in the target range or time spent in the target range (no further data and no mean follow up time provided). It found that people had significantly fewer dose changes with computerised than with standard manual monitoring (31% with computerised *v* 47% with manual; $P = 0.02$). The fourth subsequent RCT (335 people receiving initiation, 916 people receiving maintenance anticoagulation treatment for a variety of indications) compared a computerised decision support system for both dosing and appointment scheduling versus standard manual monitoring by "expert physicians".[43] It found that significantly more people managed by computerised decision support compared with standard monitoring achieved a stable international normalised ratio in the first month (39% with computerised decision support *v* 27% with standard monitoring; $P < 0.01$) and spent more time with their international normalised ratio in the target range over 3 months (71% with computerised decision support *v* 68% with standard monitoring; $P < 0.001$). The fifth subsequent RCT (122 people on warfarin after hip replacement) compared usual care versus computerised decision support.[44] Only initiation of warfarin was studied. It found that computerised decision support significantly reduced the mean time taken to reach therapeutic levels of anticoagulation compared with usual care (2.8 days with computerised decision support *v* 4.7 days with usual care; $P = 0.002$).[44]

Harms: One systematic review (search date 1997, 9 RCTs, 1336 people) found major haemorrhages (see glossary, p 298) in 14/700 (2%) people with computerised decision support compared with 25/636 (4%) in the standard monitoring group.[39] Most of the events occurred in one study, making meta-analysis inappropriate. One RCT found no significant difference in overall mortality or serious adverse events with computerised decision support versus usual care.[40]

Comment: We found limited evidence (from small trials with short follow up of proxy outcomes) on the use of computerised decision support in oral anticoagulation management. Computerised decision support for oral anticoagulation seems to be at least as effective as human performance in terms of time spent in the target international normalised ratio range. It is not clear if this will translate to improved clinical outcomes. Larger and longer trials that measure clinical outcomes (particularly harms) are needed.

GLOSSARY

Computerised decision support system A computer program that provides advice on the significance and implications of clinical findings or laboratory results.

International normalised ratio (INR) A value derived from a standardised laboratory test that measures the effect of an anticoagulant. The laboratory materials used in the test are calibrated against internationally accepted standard

reference preparations, so that variability between laboratories and different reagents is minimised. Normal blood has an international normalised ratio of 1. Therapeutic anticoagulation often aims to achieve an international normalised ratio value of 2.0–3.5.

Low molecular weight heparin (LMWH) is made from heparin using chemical or enzymatic methods. The various formulations of LMWH differ in mean molecular weight, composition, and anticoagulant activity. As a group, LMWHs have distinct properties and it is not yet clear if one LMWH will behave exactly like another. Some LMWHs given subcutaneously do not require monitoring.

Major haemorrhage Exact definitions vary between studies but usually a major haemorrhage is one involving intracranial, retroperitoneal, joint, or muscle bleeding leading directly to death or requiring admission to hospital to stop the bleeding or provide a blood transfusion. All other haemorrhages are classified as minor.

Key Messages

- **Surgery** We found no RCTs comparing surgery versus no treatment or compression stockings. RCTs have found that surgery reduced varicose vein recurrence and incidence of new varicose veins at 1 to 10 years compared with injection sclerotherapy.
- **Compression stockings** One crossover RCT found no significant difference in symptoms between compression stockings for 4 weeks and no treatment in people with varicose veins. However, the study may have lacked power to detect clinically important effects.
- **Injection sclerotherapy** One RCT found no significant difference between polidocanol and sodium tetradecyl sulphate for improving the appearance of varicose veins at 16 weeks. One RCT reported a similar incidence of new varicose veins at 5 or 10 years with standard dose sclerotherapy, high dose sclerotherapy, and foam sclerotherapy.

DEFINITION Although we found no consistent definition of varicose veins,[1] the term is commonly taken to mean veins that are distended and tortuous. Any vein may become varicose, but the term "varicose veins" conventionally applies to varices of the superficial leg veins. The condition is caused by poorly functioning valves within the lumen of the veins. Blood flows from the deep to the superficial venous systems through these incompetent valves, causing persistent superficial venous hypertension, which leads to varicosity of the superficial veins. Common sites of valvular incompetence include the saphenofemoral and saphenopopliteal junctions and perforating veins connecting the deep and superficial venous systems along the length of the leg. Sites of venous incompetence are determined by clinical examination, handheld Doppler, or by duplex ultrasound. Symptoms of varicose veins include distress about cosmetic appearance, pain, itch, limb heaviness, and cramps. This review focuses on uncomplicated, symptomatic varicose veins. We have excluded treatments for chronic venous ulceration and other complications. We have also excluded studies that solely examine treatments for small, dilated veins in the skin of the leg, known as thread veins, spider veins, or superficial telangiectasia.

INCIDENCE/ PREVALENCE One large US cohort study found the biannual incidence of varicose veins to be 2.6% in women and 2.0% in men.[2] Incidence was constant over the age of 40 years. The prevalence of varicose veins in Western populations has been estimated in one study to be about 25–30% among women and 10–20% in men.[3] A recent Scottish cohort study has, however, found a higher prevalence of varices of the saphenous trunks and their main branches in men than in women (40% men and 32% women).[4]

AETIOLOGY/ RISK FACTORS One large case control study found that women with two or more pregnancies were at increased risk of varicose veins compared with women with fewer than two pregnancies (RR about 1.2–1.3 after adjustment for age, height, and weight).[2] It found that obesity was also a risk factor, although only among women (RR about 1.3). One narrative systematic review found insufficient evidence on the effects of other suggested risk factors, including genetic predisposition; prolonged sitting or standing; tight undergarments; low fibre diet; constipation; deep vein thrombosis, and smoking.[3]

PROGNOSIS We found no reliable data on prognosis, nor on the frequency of complications, which include chronic inflammation of affected veins (phlebitis), venous ulceration, and rupture of varices.

AIMS OF INTERVENTION Treating varicose veins aims to reduce symptoms, improve appearance, and prevent recurrence and complications, with minimal adverse effects.

OUTCOMES Symptoms, including pain, ache, itch, heaviness, cramps, and cosmetic distress or cosmetic appearance (self or physician rated); quality of life; recurrence rates; complications of treatment, including haematoma formation; pigmentation; ulceration; superficial thrombophlebitis, and deep venous and pulmonary thromboembolism. Retreatment rates were only considered if other outcomes were unavailable, and are described only in comments.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION **What are the effects of treatments in adults with varicose veins?**

OPTION COMPRESSION STOCKINGS

One crossover RCT found no significant difference in symptoms between compression stockings for 4 weeks and no treatment in people with varicose veins. However, the study may have lacked power to detect clinically important effects.

Benefits: **Versus no treatment:** We found one crossover RCT (72 people aged < 65 years with ≥ 2 of the following symptoms: pain, heaviness, itch, night cramps, swelling, or cosmetic distress).[5] People with a history of deep vein thrombosis were excluded. The study did not specify the sites of venous incompetence. It compared four treatments: a pharmacological agent (O-[beta-hydroxyethyl]-rutoside, 1 g/day orally), placebo alone, stockings plus placebo, and stockings plus the drug. Stockings were fitted to apply a pressure of 30–40 mm Hg to each ankle. Each treatment was given for 4 weeks before crossover to another treatment. The trial found no significant difference between stockings plus placebo and placebo alone for any symptom scores after each treatment (analysis not by intention to treat; 6 people excluded from analysis; symptom scores measured on 100 point visual analogue scale [high score = more severe]; pain: mean score 35 with stockings *v* 38 with placebo, P = 0.06; heaviness: 34 with stockings *v* 36 with placebo, P = 0.39; itch: 32 with stockings *v* 31 with placebo, P = 0.56; swelling: 28 with stockings *v* 35 with placebo, P = 0.13; night cramps: 22 with stockings *v* 25 with placebo, P = 0.24; cosmetic distress: 43 with stockings *v* 41 with placebo, P = 0.43). The RCT may have lacked power to detect clinically important effects. **Versus injection sclerotherapy:** See benefits of injection sclerotherapy, p 302. **Versus surgery:** See benefits of surgery, p 304.

Harms: The RCT did not report on harms of compression stockings.

Comment: **Versus no treatment:** The RCT did not report whether investigators were blinded to treatment allocation.[5] Reliability of results could be reduced because previous treatments might continue to have effects even after crossover. The study did not report the duration of any washout period, which may have reduced such an effect between treatment periods.

OPTION INJECTION SCLEROTHERAPY

One RCT found no significant difference between polidocanol and sodium tetradecyl sulphate for improving the appearance of varicose veins at 16 weeks. One RCT reported a similar incidence of new varicose veins at 5 or 10 years with standard dose conventional sclerotherapy, high dose conventional sclerotherapy, and foam sclerotherapy.

Benefits: **Versus no treatment:** One systematic review (search date 2001) found no RCTs.[1] **Versus compression stockings:** One systematic review (search date 2001) found no RCTs.[1] **Different types of sclerosant:** See glossary, p 306. One systematic review (search

date 2001) found no RCTs reporting clinical outcomes in people with varicose veins.[1] We found one subsequent RCT.[6] The RCT (129 people with a total of 169 varicose veins: 58 veins < 1 mm diameter; 55 veins 1–3 mm diameter; 54 veins 3–6 mm diameter) excluded people with saphenofemoral or saphenopopliteal incompetence.[6] Each vein, rather than each person, was randomly allocated to injection sclerotherapy with either polidocanol or sodium tetradecyl sulphate. The strength of solution depended on the size of vein being treated (veins < 1 mm diameter: polidocanol 0.5% or sodium tetradecyl sulphate 0.5%; veins 1–3 mm diameter: polidocanol 1% or sodium tetradecyl sulphate 0.5%; veins 3–6 mm diameter: polidocanol 3% or sodium tetradecyl sulphate 1.5%). The study found no significant difference between polidocanol and sodium tetradecyl sulphate in change in photographic appearance of veins 16 weeks after treatment (scale of 1 to 5 [1 = worse than pretreatment photograph; 5 = complete disappearance]; mean score 4.5 with both treatments; P = 0.12). **Foam sclerotherapy versus conventional sclerotherpy:** See glossary, p 305. We found one RCT in 887 people with uncomplicated varicose veins and long saphenous incompetence, with or without perforator incompetence.[7] It compared six treatment arms: standard dose conventional sclerotherapy (1–2 mL 2% or 3% sodium tetradecyl sulphate according to vein calibre, with 2 to 3 weeks' compression after sclerotherapy); high dose conventional sclerotherapy (3–6 mL 3% sodium tetradecyl sulphate, with 1 to 2 weeks' compression); foam sclerotherapy (foaming agent plus 3% sodium tetradecyl sulphate); ligation (see glossary, p 306); stab avulsion (see glossary, p 305); and ligation plus sclerotherapy.[7] The RCT found that the incidence of new veins was similar with foam sclerotherapy, standard dose conventional sclerotherapy, and high dose conventional sclerotherapy at 5 and 10 years (AR for new veins at 5 years: 48% with standard dose sclerotherapy v 41% with high dose sclerotherapy v 44% with foam sclerotherapy; AR for new veins at 10 years: 56% with standard dose sclerotherapy v 49% with high dose sclerotherapy v 51% with foam sclerotherapy; significance not reported). **Versus surgery:** See benefits of surgery, p 304.

Harms: **Different types of sclerosant:** The RCT only reported local reactions.[6] It found that both treatments were associated with similar rates of ecchymosis (70% of veins treated with sodium tetradecyl sulphate *v* 58% with polidocanol), hyperpigmentation (64% with sodium tetradecyl sulphate *v* 53% with polidocanol), and thrombosis (46% with sodium tetradecyl sulphate *v* 42% with polidocanol; significance not stated for any comparison). Polidocanol reduced local urticaria and skin necrosis compared with sodium tetradecyl sulphate (skin necrosis 7% with sodium tetradecyl sulphate *v* 0% with polidocanol; urticaria 36% with sodium tetradecyl sulphate *v* 23% with polidocanol; significance not reported). **Foam sclerotherapy versus conventional sclerotherapy:** The RCT did not discuss harms.[7] **Versus surgery:** See harms of surgery, p 304.

Comment: **Versus surgery:** See comment under surgery, p 304.

OPTION **SURGERY VERSUS NON-SURGICAL TREATMENT**

We found no RCTs comparing surgery versus no treatment or compression stockings. RCTs have found that surgery reduced varicose vein recurrence and incidence of new varicose veins at 1 to 10 years compared with injection sclerotherapy.

Benefits:

Versus no treatment: We found no RCTs. **Versus compression stockings**: We found no RCTs. **Versus injection sclerotherapy**: We found four RCTs comparing surgical versus non-surgical treatments for varicose veins.[7–10] The first RCT (164 people with symptomatic primary varicose veins, aged 21–65 years) compared surgery versus injection sclerotherapy (polidocanol 30 mg/mL; 0.5–0.75 mL injected into each varicosity, repeated after 1–2 weeks if required).[8] People were allocated to treatments without regard for site of venous incompetence (53 legs with saphenofemoral or saphenopopliteal incompetence alone; 97 legs with saphenofemoral or saphenopopliteal incompetence combined with perforator incompetence; 17 legs with perforator incompetence only). Among people allocated to surgery, the surgical technique depended on the site of venous incompetence (see comment below). It found that surgery increased the proportion of people who were free of varicose veins at 5 years compared with injection sclerotherapy (AR for freedom from varicose vein at 5 years: 55% with surgery v 3% with sclerotherapy; significance not reported; see comment below). The second RCT (249 people with varicose veins but no prior treatment, aged 15–64 years) compared surgery versus injection sclerotherapy.[9] The study did not specify the proportions of people with saphenofemoral, saphenopopliteal, or perforator incompetence. The extent and type of surgery depended on the site of venous incompetence (see comment below). The trial did not report on symptoms, quality of life, or recurrence (see comment below). The third RCT (82 people aged over 18 years) compared sclerotherapy (3% polidocanol; repeat treatments at 2 and/or 4 weeks as necessary) versus avulsion (see glossary, p 305) under local anaesthetic.[10] People with saphenofemoral or deep venous incompetence were excluded. Sclerotherapy significantly increased recurrence at 1 and 2 years compared with avulsion (AR for recurrence at 1 year: 25% with sclerotherapy *v* 2.1% with avulsion; RR 12, 95% CI 1.62 to 88.7; AR for recurrence at 2 years: 37.5% with sclerotherapy *v* 2.1% with avulsion; RR 18, 95% CI 2.5 to 129.5). The fourth RCT, in 887 people with long saphenous incompetence, with or without perforator incompetence, compared six treatments: standard dose conventional sclerotherapy (148 people); high dose conventional sclerotherapy (136 people); foam sclerotherapy (see glossary, p 305) (150 people); ligation (see glossary, p 306) (155 people); stab avulsion (144 people); and combined ligation and high dose conventional sclerotherapy (154 people).[7] Avulsion or ligation with or without sclerotherapy reduced the incidence of new varicose veins at 5 and 10 years compared with sclerotherapy alone, although it was not clear whether differences were significant (AR for new veins at 5 years: 48% with standard dose sclerotherapy *v* 41% with high dose sclerotherapy *v* 44% with foam sclerotherapy *v* 34% with ligation *v* 40% with stab

avulsion *v* 37% with ligation plus sclerotherapy; AR for new veins at 10 years: 56% standard dose sclerotherapy *v* 49% high dose sclerotherapy *v* 51% foam sclerotherapy *v* 38% ligation *v* 41% stab avulsion *v* 37% ligation plus sclerotherapy; no significance tests reported).

Harms:

Versus injection sclerotherapy: The first RCT reported postoperative wound infection in 6% and symptoms of sural or saphenous nerve injury in 10% of surgically treated patients (rates not reported in sclerotherapy group).[8] Five people (proportion not stated) in the sclerotherapy group had migratory thrombophlebitis and 28% developed haematoma (rates not reported in surgical group). Duration of sick leave was greater with surgery than with sclerotherapy (mean duration 20 days with surgery *v* 1 day with sclerotherapy; significance not reported). One person in the surgical arm had a symptomatic pulmonary embolism that resolved without complications. No thromboembolic events occurred in the sclerotherapy group. The second RCT reported that one person in the surgically treated group had severe bronchospasm under anaesthetic.[9] The 5 year follow up to this study reported that during surgery one person had a myocardial infarction and one person had a pulmonary embolus.[11] The third RCT found no significant difference in phlebitis between avulsion and sclerotherapy at 2 weeks (12% with avulsion *v* 27% with sclerotherapy; $P = 0.07$).[10] Sclerotherapy reduced telangiectasia (thread veins) at 2 years compared with avulsion (6.2% with avulsion *v* 0% with sclerotherapy; $P = 0.039$). The fourth RCT did not discuss harms.[7]

Comment:

Versus injection sclerotherapy: The effects of surgery versus injection sclerotherapy or other treatments may vary according to the sites of venous incompetence. However, none of the identified RCTs reported relative effects with regard to sites of venous incompetence. In the surgical groups of the first two RCTs, varicose veins from saphenofemoral or saphenopopliteal incompetence were treated by ligation and stripping (see glossary, p 306), while incompetent perforator veins were treated by avulsion.[8,9] The first RCT did not report whether the investigators were blinded to treatment allocation.[8] It was not clear whether analysis was by intention to treat. The follow up rate at 5 years was about 77%. The second RCT found that surgery reduced retreatment rates compared with sclerotherapy at 3 years (14% with surgery *v* 22% with sclerotherapy; significance not reported).[9] The 5 year follow up of the same RCT also found that surgery reduced retreatment rates (24.2% with surgery *v* 40% with sclerotherapy; significance not reported; no blinding of assessors).[11]

GLOSSARY

Avulsion Used to treat multiple varicosities after saphenofemoral or saphenopopliteal ligation or in patients with perforator incompetence. Small incisions are made in the skin overlying each varicosity and the affected vein interrupted or excised.

Foam sclerotherapy A new technique in which a standard sclerosant is mixed with air to create a foam. This is then injected into the varicosities under ultrasound guidance.

Ligation Involves tying off a vein close to the site of incompetence to prevent blood flowing from the deep to the superficial system.

Sclerosant An injected solution which displaces blood from the vein, causing inflammation of the vein wall and occlusion. Commonly used sclerosants include sodium tetradecyl sulphate (sotradecol) and polidocanol (also called aetoxysclerol; aethoxysclerol; aethoxyskerol, or hydroxypolyaethoxydodecan).

Stripping A wire, plastic, or metal rod is passed through the lumen of the saphenous vein and is used to strip the entire vein out of the leg. This disconnects any superficial veins from the deep venous system.

Substantive changes

Injection sclerotherapy One RCT added;[7] conclusions unchanged.

Surgery versus non-surgical treatment Two RCTs added;[7,10] conclusions unchanged.

QUESTIONS

INTERVENTIONS

Trade off between benefits and harms

Unknown effectiveness

To be covered in future updates

Atypical absence seizures
Clonazepam

*We found no RCT evidence for valproate or ethosuximide versus placebo but there is consensus belief that valproate and ethosuximide are beneficial in typical absence seizures

See glossary, p 312

Key Messages

- **Ethosuximide** We found one systematic review. It found no RCTs comparing ethosuximide versus placebo. There is, however, consensus that ethosuximide is beneficial, although it is associated with rare but serious adverse effects, including aplastic anaemia, skin reactions, and renal and hepatic impairment. The review found three small RCTs comparing ethosuximide versus valproate. It found no significant difference between ethosuximide and valproate in clinical response (as determined by either electroencephalogram or telemetry recordings, or observer reports of seizure frequency). The review found no RCTs comparing ethosuximide versus other anticonvulsants.
- **Lamotrigine** One RCT in children and adolescents who had previously benefited from lamotrigine found that lamotrigine increased the proportion of children who remained seizure free compared with placebo. However, lamotrigine is associated with serious skin reactions. We found no RCTs comparing lamotrigine versus other anticonvulsants.
- **Valproate** We found one systematic review. It found no RCTs comparing valproate versus placebo. There is, however, consensus that valproate (sodium valproate or valproic acid) is beneficial, although it is associated with rare but serious adverse effects, including behavioural and cognitive abnormalities, liver necrosis, and pancreatitis. The review found three small RCTs comparing valproate versus ethosuximide. It found no significant difference between valproate and ethosuximide in clinical response (as determined by either electroencephalogram or telemetry recordings, or observer reports of seizure frequency). The review found no RCTs comparing valproate versus other anticonvulsants.
- **Gabapentin** One small RCT found no significant difference between gabapentin versus placebo in the frequency of typical absence seizures. However, the study may have lacked power to detect clinically important effects.

Absence seizures in children

DEFINITION Absence seizures are sudden, frequent episodes of unconsciousness lasting a few seconds and are often accompanied by simple automatisms. Typical absence seizures display a characteristic electroencephalogram showing regular symmetrical generalised spike and wave complexes with a frequency of 3 Hz. Typical absence seizures should not be confused with atypical absence seizures, which differ markedly in electroencephalogram findings and ictal behaviour, and usually present with other seizure types in a child with a background of learning disability and severe epilepsy.[1] Childhood absence epilepsy is an epileptic syndrome (see glossary, p 312) whereby typical absence seizures are the only type of seizures experienced by a child of otherwise normal development in the absence of any structural lesions. However, in many children, typical absence seizures coexist with other types of seizures and constitute a number of distinct epileptic syndromes such as juvenile myoclonic epilepsy or juvenile absence epilepsy. This differentiation into typical versus atypical seizures is important, as the natural history and response to treatment varies in the two groups. Interventions for atypical absence seizures are not included in this chapter.

INCIDENCE/ PREVALENCE About 10% of seizures in children with epilepsy are typical absence seizures.[1] Annual incidence has been estimated at 0.7–4.6/100 000 people in the general population and 6–8/100 000 in children aged 0–15 years. Prevalence is 5–50/100 000 people in the general population.[2] Age of onset ranges from 3–13 years, with a peak at 6–7 years.

AETIOLOGY/ RISK FACTORS The cause of childhood absence epilepsy is presumed to be genetic. Seizures can be triggered by hyperventilation in susceptible children.

PROGNOSIS In childhood absence epilepsy, in which typical absence seizures are the only type of seizures suffered by the child, seizures generally cease spontaneously by 12 years of age or sooner. Less than 10% of children develop infrequent generalised tonic clonic seizures and it is very rare for them to continue having absence seizures.[3] In other epileptic syndromes (in which absence seizures may coexist with other types of seizure) prognosis is varied, depending on the syndrome. Absence seizures have a significant impact on quality of life. The episode of unconsciousness may occur at any time, and usually without warning. Affected children need to take precautions to prevent injury during absences and refrain from activities that would put them at risk if seizures occurred (e.g. climbing heights, swimming unsupervised, or cycling on busy roads). Often, school staff members are the first to notice the recurrent episodes of absence seizures, and treatment is generally initiated because of the adverse impact on learning.

AIMS OF INTERVENTION Cessation or decrease in the frequency of seizures, with minimum adverse effects of treatment.

OUTCOMES Seizure frequency measured as normalisation of the electroencephalogram; adverse effects of treatment with anticonvulsants. We found no studies assessing quality of life.

METHODS *Clinical Evidence* search and appraisal September 2003.

QUESTION **What are the effects of treatments for typical absence seizures in children?**

OPTION VALPROATE

We found one systematic review. It found no RCTs comparing valproate versus placebo. There is, however, consensus that valproate (sodium valproate or valproic acid) is beneficial, although it is associated with rare but serious adverse effects, including behavioural and cognitive abnormalities, liver necrosis, and pancreatitis. The review found three small RCTs comparing valproate versus ethosuximide. It found no significant difference between valproate and ethosuximide in clinical response (as determined by either electroencephalogram or telemetry recordings, or observer reports of seizure frequency). The review found no RCTs comparing valproate versus other anticonvulsants.

Benefits: We found one systematic review (search date 2003).[4] **Versus placebo:** The review found no RCTs.[4] **Versus ethosuximide:** The review[4] found three small RCTs.[5–7] Results from the RCTs could not be pooled because each assessed different outcomes. The first RCT (28 treatment-naïve children and adolescents aged 4–15 years with typical absence seizures) compared sodium valproate versus ethosuximide for up to 4 years.[5] Response was measured by 6 hour telemetry at two intervals 6 months apart, and parent and teacher reports of seizure frequency. The RCT found no significant difference in overall improvement between sodium valproate and ethosuximide (AR for > 50% decrease in the seizure frequency over 6 months: 12/14 [85.7%] with sodium valproate *v* 11/13 [84.6%] with ethosuximide; RR 1.01, 95% CI 0.74 to 1.39). The second RCT (45 children and adolescents aged 3–18 years with absence seizures, including children with other seizure types, children refractory to anticonvulsant treatment, and children who had not previously received any anticonvulsant treatment [naïve children]) compared valproic acid versus ethosuximide followed by a crossover after 6 weeks.[6] Response to treatment was defined as no generalised spike wave discharges on 12 hour telemetered electroencephalogram. The RCT found no significant difference in response between valproic acid and ethosuximide at 6 weeks (naïve: 6/7 [86%] with valproic acid *v* 4/9 [44 %] with ethosuximide; RR 1.93, 95% CI 0.88 to 4.25; refractory: 3/15 [20%] with valproic acid *v* 4/14 [29%] with ethosuximide; RR 0.70, 95% CI 0.19 to 2.59). The third RCT (20 children aged 5–8 years) compared sodium valproate versus ethosuximide for up to 2 years in children with recent (< 6 months) onset of absence seizures.[7] Seizure frequency was assessed using electroencephalogram recordings and parent completed record cards. The RCT found no significant difference in complete remission of seizures between sodium valproate and ethosuximide (AR for remission of seizures [time to follow up not reported]: 7/10 [70%] with sodium valproate *v* 8/10 [80%] with ethosuximide; RR 0.88, 95% CI 0.53 to 1.46).[7] **Versus other anticonvulsants:** The review found no RCTs.[4]

Harms: Common adverse effects associated with valproic acid include dyspepsia, weight gain, tremor, transient hair loss, and haematological abnormalities. Rare adverse effects include behavioural and

cognitive abnormalities, potentially fatal liver necrosis, and pancreatitis.[1] One RCT included in the review reported adverse events in children who had not previously received any anticonvulsant treatment.[6] The adverse events with valproic acid and ethosuximide included nausea, vomiting, poor appetite, drowsiness, dizziness, headache, and leukopenia. Transient thrombocytopenia occurred in two children with valproic acid. No child withdrew from the trial because of these events. Another RCT included in the review reported acute pancreatitis (1 child) and weight gain not responding to dietary restriction (1 child) with sodium valproate, and drowsiness (1 child receiving a high dose of ethosuximide).[5] The third RCT reported infrequent adverse events with both sodium valproate (transient nausea and vomiting, decreased number of platelets without thrombocytopenia) and ethosuximide (tiredness).[7]

Comment: The RCTs comparing sodium valproate versus ethosuximide suggest a beneficial effect with sodium valproate and ethosuximide.[5–7] We found one study (crossover, 35 children with typical absence seizures) comparing sodium valproate versus ethosuximide or placebo for 4 weeks.[8] This is an old study, reported in Japanese. A summary of the results in English, reported together with another RCT,[5] suggests that it found no significant difference in clinical effectiveness between sodium valproate and ethosuximide.[8]

OPTION ETHOSUXIMIDE

We found one systematic review. It found no RCTs comparing ethosuximide versus placebo. There is, however, consensus that ethosuximide is beneficial, although it is associated with rare but serious adverse effects, including aplastic anaemia, skin reactions, and renal and hepatic impairment. The review found three small RCTs comparing ethosuximide versus valproate. It found no significant difference between ethosuximide and valproate in clinical response (as determined by either electroencephalogram or telemetry recordings, or observer reports of seizure frequency). The review found no RCTs comparing ethosuximide versus other anticonvulsants.

Benefits: We found one systematic review (search date 2003).[4] **Versus placebo:** The review found no RCTs.[4] **Versus valproate:** See benefits of valproate, p 309. **Versus other anticonvulsants:** The review found no RCTs.[4]

Harms: Common adverse effects associated with ethosuximide include gastrointestinal disturbances, anorexia, weight loss, drowsiness, photophobia, headache, and behaviour and psychotic disturbances. Rare adverse effects include aplastic anaemia, serious skin reactions, and renal and hepatic impairment.[1] **Versus valproate:** See harms of valproate, p 309.

Comment: None.

OPTION LAMOTRIGINE

One RCT in children and adolescents who had previously benefited from lamotrigine found that lamotrigine increased the proportion of children who remained seizure free compared with placebo. However, lamotrigine is associated with serious skin reactions. We found no RCTs comparing lamotrigine versus other anticonvulsants.

Benefits: We found one systematic review (search date 2003).[4] **Versus placebo:** The review[4] found no RCTs in unselected children or adolescents with typical absence seizures, but it found one RCT in children and adolescents, in whom lamotrigine had previously been shown to be clinically effective.[9] The RCT (29 children and adolescents aged 3–15 years) with newly diagnosed typical absence seizures, in whom lamotrigine was clinically effective) compared lamotrigine versus placebo for four weeks.[9] Response was measured with 24 hour ambulatory electroencephalogram and a hyperventilation test (see glossary, p 312) during the electroencephalogram. The RCT found that lamotrigine significantly increased the proportion of children who remained seizure free for 4 weeks compared with placebo (AR for remaining seizure free: 64% with lamotrigine *v* 21% with placebo; $P = 0.03$). **Versus other anticonvulsants:** The review found no RCTs.[4]

Harms: **Versus placebo:** The RCT reported abdominal pain, headache, nausea, anorexia, dizziness, and hyperkinesia with lamotrigine.[9] Skin rash was reported in 10/29 (35%) children, but only in one did the investigator consider it to be causally related to lamotrigine. The children from this RCT were recruited into an open label continuation study (252 children; 43 [17%] with absence seizures), which looked at long term tolerability of lamotrigine.[10] A high proportion of these children (125/252 [49.6%]) discontinued, mostly because of inadequate response or for administrative reasons. The average duration of lamotrigine exposure was 96.7 weeks. The study found that the most common adverse events were dizziness (23/252 [9.1%]), somnolence (20/252 [7.9%]), nausea (16/252 [6.3%]), vomiting (13/252 [5.2%]), and headache (13/252 [5.2%]). We also found two open label add-on studies (study participants are receiving treatment for absence seizures at the time of enrolment and continue the treatment during the study) that reported on adverse events with lamotrigine.[11,12] The first add-on study (117 children aged 0–17 years with various drug resistant epilepsies) reported adverse events in 25/117 (21%) children during treatment with lamotrigine, including skin rash (mainly in children also receiving sodium valproate), ataxia, drowsiness, headache, and vomiting. Skin rash was reported as the main adverse event, occurring in 12 children (10 children were receiving valproic acid) 1–18 days after initiation of lamotrigine. No correlation was found with lamotrigine blood levels.[12] The second add-on study (285 children aged < 13 years with refractory epilepsies and ≥ 2 seizure types) found that rash was the most common adverse event leading to discontinuation of lamotrigine (withdrawal of 21/285 [7.4%] from the study).[11] A higher rate of withdrawal was reported from the group receiving concomitant sodium valproate (occurrence of rash according to concomitant medication, sodium valproate 22.8%, carbamazepine

11.7%, and phenytoin 10.8%). Other adverse events leading to withdrawal of two or more children treated with lamotrigine were increased seizure frequency (1.8%), somnolence (1.1%), agitation (0.7%), ataxia (0.7%), fever (0.7%), and vomiting (0.75%).

Comment: The RCT randomised a group of children who responded to treatment with lamotrigine in an open label trial (potentially introducing selection bias).[9]

OPTION GABAPENTIN

One small RCT found no significant difference between gabapentin and placebo in frequency of typical absence seizures. However, the trial may have lacked power to detect clinically important effects.

Benefits: We found no systematic review. **Versus placebo:** We found one RCT (33 children aged 4–16 years with absence seizures) comparing gabapentin (15–20 mg/kg daily) versus placebo.[13] The study consisted of a 2 week double blind treatment phase followed by a 6 week open label phase. Response was assessed as the change from baseline in seizure frequency (measured with quantified electroencephalogram) after 2 weeks. The RCT found no significant difference between gabapentin compared with placebo in frequency of typical absence seizures after 2 weeks. However, the trial may have lacked power to detect clinically important effects (see comment).**Versus other anticonvulsants:** We found no RCTs.

Harms: The RCT found that somnolence and dizziness were the most frequent adverse events.[13] All reported adverse events were mild to moderate and no children withdrew from the study because of adverse events of treatment. This is consistent with the adverse effect profile of gabapentin reported by one other study.[14]

Comment: The RCT was of short duration and used relatively small doses of gabapentin.[13] The target dosage range was 15–20 mg/kg daily, although the current maintenance dose used in children with other types of epilepsy is 30 mg/kg daily.

GLOSSARY

Epileptic syndrome The term used in the classification of childhood seizure disorders. It relates to a recognisable clinical and electroencephalogram pattern.
Hyperventilation test The test is performed by asking a child to breathe slowly and deeply for 3 minutes. In 90% of children with childhood absence epilepsy this will precipitate an absence attack.

Substantive changes

Valproate versus ethosuximide One systematic review added;[4] conclusions unchanged.

Acute otitis media

Search date June 2003

Paddy O'Neill and Tony Roberts

QUESTIONS

INTERVENTIONS

Key Messages

Treatment

- **Ibuprofen** One RCT in children aged 1–6 years receiving antibiotic treatment found that ibuprofen reduced earache as assessed by parental observation after 2 days compared with placebo.
- **Paracetamol** One RCT in children aged 1–6 years receiving antibiotic treatment found that paracetamol reduced earache as assessed by parental observation after 2 days compared with placebo.
- **Antibiotics compared with placebo** We found four systematic reviews comparing antibiotics versus placebo in acute otitis media but using different inclusion criteria and outcome measures. One review in children aged 4 months to 18 years found a reduction in symptoms with a range of antibiotics (cephalosporins, erythromycin, penicillins, trimethoprim–sulfamethoxazole [co-trimoxazole]) after 7–14 days of treatment compared with placebo. Another review in children younger than 2 years found no significant difference in clinical improvement between antibiotics (penicillins, sulphonamides, amoxicillin/clavulanic acid [co-amoxiclav]) and placebo alone or placebo with myringotomy after 7 days. A third review in children aged 4 weeks to 18 years found that antibiotics (ampicillin, amoxicillin) reduced clinical failure rate within

2–7 days compared with placebo or observational treatment. The fourth review in children aged 6 months to 15 years found that, compared with placebo, the early use of antibiotics (erythromycin, penicillins) reduced the proportion of children still in pain 2–7 days after presentation, and reduced the risk of developing contralateral acute otitis media. This review also found that antibiotics increased the risk of vomiting, diarrhoea, or rashes.

- **Choice of antibiotic regimen** One systematic review in children aged 4 months to 18 years found no significant difference between a range of antibiotics in rate of treatment success at 7–14 days or of middle ear effusion at 30 days. Another systematic review in children aged 4 weeks to 18 years found no significant difference between antibiotics in clinical failure rates within 3–14 days. The second review also found that adverse effects, primarily gastrointestinal, were more common with cefixime compared with amoxicillin or ampicillin, and were more common with amoxicillin/clavulanate (original formulation) compared with azithromycin.
- **Immediate compared with delayed antibiotic treatment** One RCT in children aged 6 months to 10 years found that immediate compared with delayed antibiotic treatment reduced the number of days of earache, ear discharge, and amount of daily paracetamol used after the first 24 hours of illness, but found no significant difference between groups in daily pain scores. It also found that immediate antibiotic treatment increased diarrhoea compared with delayed antibiotic treatment.
- **Short compared with longer courses of antibiotics** One systematic review and two subsequent RCTs have found that 10 day compared with 5 day courses of antibiotics reduce treatment failure, relapse, and reinfection at 8–14 days, but found no significant difference between groups at 20–42 days.
- **Myringotomy** One RCT in infants aged 3 months to 1 year found no significant difference in resolution of clinical symptoms between groups receiving myringotomy only, antibiotic only, and myringotomy plus antibiotic, but found higher rates of persistent infection with myringotomy only. A second RCT in children aged 2–12 years found no significant difference between myringotomy and no treatment in reduction of pain at 24 hours or 7 days. A third RCT in children aged 7 months to 12 years found higher rates of initial treatment failure (resolution of symptoms within 12 hours) for severe episodes of acute otitis media treated by myringotomy and placebo compared with antibiotic.

Prevention of recurrence

- **Xylitol chewing gum or syrup** One RCT found that xylitol syrup or chewing gum reduced the proportion of children with at least one episode of acute otitis media compared with control. It found no significant difference between xylitol lozenges and control gum. It found that more children taking xylitol withdrew because of abdominal pain or other unspecified reasons compared with control.
- **Antibiotic prophylaxis (long term)** One systematic review in children and adults has found that long term antibiotic prophylaxis reduced recurrence of acute otitis media compared with placebo. However, one subsequent RCT in children aged 3 months to 6 years found no significant difference between antibiotic prophylaxis and placebo in preventing recurrence. The RCTs provided insufficient evidence on adverse effects of long term antibiotic prophylaxis. We found insufficient evidence on which antibiotic to use, for how long, and how many previous episodes of acute otitis media justify starting preventive treatment.

Acute otitis media

- **Tympanostomy (ventilation tubes)** One small RCT found that tympanostomy tube insertion reduced the mean number of acute otitis media episodes during the first 6 month period after treatment compared with myringotomy alone or no surgery, but not during the subsequent 18 months. It also found a non-significant trend for more recurrent infections and worse hearing, after tube extrusion, in those treated with tympanostomy. It found more tympanosclerosis in ears that received ventilating tubes compared with myringotomy alone or no surgery.

DEFINITION Otitis media is an inflammation in the middle ear. Subcategories include acute otitis media (AOM), recurrent AOM, and chronic suppurative otitis media. AOM is the presence of middle ear effusion in conjunction with rapid onset of one or more signs or symptoms of inflammation of the middle ear. Uncomplicated AOM is limited to the middle ear cleft.[1] AOM presents with systemic and local signs, and has a rapid onset. The persistence of an effusion beyond 3 months without signs of infection defines otitis media with effusion (also known as "glue ear"; see otitis media with effusion, p 684). Chronic suppurative otitis media is characterised by continuing inflammation in the middle ear causing discharge (otorrhoea) through a perforated tympanic membrane (chronic suppurative otitis media, p 645).

INCIDENCE/ PREVALENCE AOM is common and has a high morbidity and low mortality in otherwise healthy children. In the UK, about 30% of children under 3 years of age visit their general practitioner with AOM each year, and 97% receive antimicrobial treatment.[2] By 3 months of age, 10% of children have had an episode of AOM. It is the most common reason for outpatient antimicrobial treatment in the USA.[3]

AETIOLOGY/ RISK FACTORS The most common bacterial causes for AOM in the USA and UK are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.[2] Similar pathogens are found in Colombia.[4] The incidence of penicillin resistant *S pneumoniae* has risen, but rates differ between countries. The most important risk factors for AOM are young age and attendance at daycare centres, such as nursery schools. Other risk factors include being white; male sex; a history of enlarged adenoids, tonsillitis, or asthma; multiple previous episodes; bottle feeding; a history of ear infections in parents or siblings; and use of a soother or pacifier. The evidence for an effect of environmental tobacco smoke is controversial.[2]

PROGNOSIS In about 80% of children, the condition resolves in about 3 days without antibiotic treatment. Serious complications are rare in otherwise healthy children but include hearing loss, mastoiditis (see glossary, p 326), meningitis, and recurrent attacks.[2] The World Health Organization estimates that each year 51 000 children under the age of 5 years die from complications of otitis media in developing countries.[5]

AIMS OF INTERVENTION To reduce the severity and duration of pain and other symptoms, to prevent complications, and to minimise adverse effects of treatment.

OUTCOMES Pain control (in infants this can be assessed by surrogate measures such as parental observation of distress/crying and analgesic use); incidence of complications such as deafness (usually divided into

short and long term hearing loss), recurrent attacks of AOM, mastoiditis, and meningitis; resolution of otoscopic appearances; incidence of adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION What are the effects of treatments?

OPTION ANALGESICS

One RCT in children aged 1–6 years receiving antibiotic treatment found that ibuprofen or paracetamol reduced earache as assessed by parental observation after 2 days compared with placebo.

Benefits: We found no systematic review but found one RCT (219 children aged 1–6 years with otoscopically diagnosed acute otitis media and receiving antibiotic treatment with cefaclor for 7 days) comparing the effect of three times daily treatment with ibuprofen or paracetamol versus placebo for 48 hours on earache (otalgia) and related outcomes.[6] It found that ibuprofen significantly reduced the incidence of earache after 2 days as assessed by parental observation compared with placebo (AR 5/71 [7%] with ibuprofen *v* 19/75 [25%] with placebo; RR 0.28, 95% CI 0.11 to 0.71; NNT 5, 95% CI 3 to 15) and with paracetamol compared with placebo (AR 7/73 [10%] *v* 19/75 [25%] with placebo; RR 0.38, 95% CI 0.17 to 0.85; NNT 6, 95% CI 3 to 28). It found no difference between paracetamol and ibuprofen for reducing earache, and no difference between ibuprofen or paracetamol and placebo for other outcomes (appearance of the tympanic membrane; rectal temperature; and parental assessment of appetite, sleep, and playing activity).

Harms: The RCT found that 11 children experienced mild nausea, vomiting, and abdominal pain (5 [7%] taking ibuprofen, 3 [4%] taking paracetamol, and 3 [4%] taking placebo). None were withdrawn from treatment.[6]

Comment: The evidence from this RCT is limited because the assessment of the child's pain relief was based on parental observation using a scale of 0 or 1.[6] The paracetamol versus placebo result has been recalculated by *Clinical Evidence* from data in the original publication, and corrects the stated conclusions of the RCT.

OPTION ANTIBIOTICS

We found four systematic reviews comparing antibiotics versus placebo in acute otitis media, which used different inclusion criteria and outcome measures. One review in children aged 4 months to 18 years found a reduction in symptoms with a range of antibiotics (cephalosporins, erythromycin, penicillins, trimethoprim–sulfamethoxazole [co-trimoxazole]) after 7–14 days of treatment compared with placebo. Another review in children younger than 2 years found no significant difference in clinical improvement between antibiotics (penicillins, sulphonamides, amoxicillin/clavulanic acid [co-amoxiclav]) and placebo alone or placebo with myringotomy after 7 days. A third review in children aged 4 weeks to 18 years found that antibiotics (ampicillin, amoxicillin) reduced clinical failure rate within 2–7 days compared with placebo or

observational treatment. The fourth review in children aged 6 months to 15 years found that, compared with placebo, the early use of antibiotics (erythromycin, penicillins) reduced the proportion of children still in pain 2–7 days after presentation and reduced the risk of developing contralateral acute otitis media. This review also found that antibiotics increased the risk of vomiting, diarrhoea, or rashes.

Benefits: We found four systematic reviews.[1,7–9] **Versus placebo or no treatment:** One systematic review (search date 1992, 33 RCTs, 5400 children aged 4 months to 18 years) identified four RCTs (535 children receiving analgesics or other symptomatic relief).[7] Acute otitis media (AOM) was defined as bulging or opacification of the tympanic membrane with or without erythema, accompanied by at least one of the following signs: fever, otalgia, irritability, otorrhoea, lethargy, anorexia, vomiting, diarrhoea, and mobility of the tympanic membrane absent or markedly decreased. It found a significant reduction in symptoms with a range of antibiotics (cephalosporins, erythromycin, penicillins, trimethoprim–sulfamethoxazole [co-trimoxazole]) after 7–14 days of treatment compared with placebo (4 RCTs; ARR 13.7%, 95% CI 8.2% to 19.2%; NNT 7, 95% CI 5 to 12).[7] The second systematic review (search date 1997, 741 children aged < 2 years) identified four RCTs comparing antibiotics (penicillins, sulphonamide, amoxicillin/clavulanic acid [co-amoxiclav]) versus placebo alone or versus placebo with myringotomy (see glossary, p 326).[8] Three RCTs used diagnosis of AOM based on otoscopic appearance of the tympanic membrane and clinical signs of acute infection, and one RCT used otoscopy alone. The systematic review found no significant difference between antibiotics and placebo in symptomatic clinical improvement within 7 days (OR 1.31, 95% CI 0.83 to 2.08). Otoscopic appearance, middle ear effusion, and bacteriology were not considered as end points.[8] A third systematic review (search date 1999, 5 RCTs, 1518 children aged 4 weeks to 18 years) compared the effects of antibiotics (ampicillin, amoxicillin [amoxycillin]) versus placebo or observational treatment.[1] AOM was defined as the presence of middle ear effusion in conjunction with rapid onset of one or more signs or symptoms of inflammation of the middle ear, and was categorised as uncomplicated AOM when limited to the middle ear cleft. Clinical failure was defined as the presence of pain, fever, middle ear effusion, clinical signs of otitis media, or suppurative complications such as mastoiditis (see glossary, p 326). The review found that antibiotics (ampicillin, amoxicillin) significantly reduced clinical failure rate within 2–7 days compared with placebo or observational treatment (reduction of 12.3%, 95% CI 21.8% to 2.8%; NNT 8, 95% CI 5 to 36).[1] A fourth systematic review (search date 2000, 9 RCTs, 2288 children aged 6 months to 15 years) compared early use of antibiotics (erythromycin, penicillins, sulphonamides) versus placebo.[9] AOM was defined as acute earache with at least one abnormal eardrum, otoscopic middle ear effusion, and general signs and symptoms. Pain was assessed using parental report/score card/diary or clinician assessment at 4 days. The review found that antibiotics significantly reduced the proportion of children still in pain 2–7 days after presentation compared with placebo (175/1160 [15.1%] with antibiotics *v* 234/1128 [20.7%] with placebo; ARR 5.6%, 95% CI 2.5% to 8.7%; RR 0.72, 95% CI 0.62 to 0.85;

NNT 17, 95% CI 11 to 40). In addition, it found significantly fewer children experienced contralateral AOM with antibiotics (35/329 [10.6%] with antibiotics *v* 56/337 [16.6%] with placebo; ARR 5.9%, 95% CI 1.0% to 10.8%; RR 0.65, 95% CI 0.45 to 0.94). The review found no significant difference between groups in the rate of subsequent recurrence of AOM (187/864 [21.6%] with antibiotics *v* 175/804 [21.8%] with placebo; RR 0.99, 95% CI 0.83 to 1.19), abnormal tympanometry at 1 month (85/234 [36.3%] with antibiotics *v* 91/238 [38.2%] with placebo; RR 0.94, 95% CI 0.74 to 1.19), or abnormal tympanometry at 3 months (38/182 [20.9%] with antibiotics *v* 49/188 [26.1%] with placebo; RR 0.80, 95% CI 0.55 to 1.16). Four RCTs (717 children) reported pain outcomes (parental report of pain or symptom diary) 24 hours after presentation. All four RCTs found no significant difference in pain outcomes between antibiotics and placebo (RR 1.02, 95% CI 0.85 to 1.22). Most RCTs did not state the time interval between onset of symptoms and starting treatment; the two RCTs that did, stated 1–24 hours and about 30 hours. Only 1/2202 children developed mastoiditis (in a penicillin treated group).[9]

Harms: Two systematic reviews gave no information on adverse events.[7,8] The third systematic review found that adverse effects, primarily gastrointestinal, were more common in children taking cefixime than in children taking amoxicillin or ampicillin (5 RCTs, rate difference 8.4%, 95% CI 3.8% to 13.1%; NNH 12, 95% CI 8 to 27), and were more common in children taking amoxicillin/clavulanate (original formulation) than in those taking azithromycin (3 RCTs, rate difference –18.0, 95% CI –28.0 to –8.0; NNH 6, 95% CI 4 to 13).[1] The fourth systematic review found that antibiotics significantly increased the risk of vomiting, diarrhoea, or rashes (AR 57/345 [17%] with antibiotics *v* 38/353 [11%] with control; RR 1.55, 95% CI 1.11 to 2.16; NNH 17, 95% CI 9 to 152).[9]

Comment: One systematic review[7] excluded two placebo controlled trials that were included in another review[9] because they included myringotomy as part of the treatment. This may have biased the results in favour of antibiotic treatment and may explain the higher absolute risk reduction quoted in the first review.[7] Another systematic review commented on the difficulty of performing meta-analyses because of the varying criteria between studies for defining AOM and outcome measures.[1] The variation between the systematic reviews that provide numbers needed to treat for the effect of antibiotics versus placebo is because of differences in entry criteria and outcome measures. We found inadequate evidence for the effectiveness of antibiotics in countries where the incidence of complicating mastoiditis is high.

OPTION CHOICE OF ANTIBIOTIC REGIMEN

One systematic review in children aged 4 months to 18 years found no significant difference between a range of antibiotics in rate of treatment success at 7–14 days or of middle ear effusion at 30 days. Another systematic review in children aged 4 weeks to 18 years found no significant difference between antibiotics in clinical failure rates within 3–14 days. The second review also found that adverse effects, primarily

gastrointestinal, were more common with cefixime compared with amoxicillin or ampicillin, and were more common with amoxicillin/clavulanate (original formulation) compared with azithromycin.

Benefits: We found two systematic reviews.[1,7] One systematic review (search date 1992, 33 RCTs, 5400 children aged 4 months to 18 years) compared a range of antibiotics (cephalosporins, erythromycin, penicillins, co-trimoxazole).[7] Acute otitis media was defined as bulging or opacification of the tympanic membrane with or without erythema, accompanied by at least one sign (fever, otalgia, irritability, otorrhoea, lethargy, anorexia, vomiting, diarrhoea, mobility of the tympanic membrane absent or markedly decreased). Treatment success was defined as the absence of all presenting signs and symptoms of acute otitis media at the evaluation point closest to 7–17 days after start of treatment. The systematic review found no significant differences between different antibiotics in rate of treatment success at 7–14 days or of middle ear effusion at 30 days.[7] A second systematic review (search date 1999) found no significant difference between penicillin and ampicillin or amoxicillin (amoxycillin) in clinical failure rates within 7–14 days (3 RCTs, 491 children aged 4 weeks to 18 years; clinical failure rate difference +4.5%, 95% CI –1.8% to +10.7%).[1] The same review found no significant difference in clinical failure rates within 3–7 days between cefaclor and ampicillin or amoxicillin (4 RCTs, 56 children aged 4 weeks to 18 years; clinical failure rate difference –5.4%, 95% CI –15.2% to +4.4%). Clinical failure was defined as the presence of pain, fever, middle ear effusion, clinical signs of otitis media, or suppurative complications such as mastoiditis (see glossary, p 326).[1]

Harms: See harms of antibiotics, p 319.

Comment: None.

OPTION IMMEDIATE VERSUS DELAYED ANTIBIOTIC TREATMENT

One RCT in children aged 6 months to 10 years found that immediate compared with delayed antibiotic treatment reduced the number of days of earache, ear discharge, and amount of daily paracetamol used after the first 24 hours of illness, but found no significant difference between groups in daily pain scores. It also found that immediate antibiotic treatment increased diarrhoea compared with delayed antibiotic treatment.

Benefits: We found one RCT (315 children aged 6 months to 10 years) comparing immediate versus delayed antibiotic (amoxicillin [amoxycillin] or erythromycin) use.[10] Acute otitis media was defined as acute otalgia and otoscopic evidence of acute inflammation of the ear drum, such as dullness or cloudiness with erythema, bulging, or perforation. Immediate antibiotic treatment was defined as a prescription given to parents at the initial consultation. Delayed antibiotic treatment was defined as parents asked to wait 72 hours after seeing the doctor before using the prescription and only if the child still had substantial otalgia or fever, or was not starting to get better. Earache was assessed from daily diary of symptoms and perceived severity of pain scores (1 = no pain to 10 = extreme pain). The RCT found that, after the first 24 hours of illness,

immediate compared with delayed antibiotic use significantly reduced the duration of earache (mean difference –1.10 days, 95% CI –0.54 days to –1.48 days), duration of ear discharge (mean difference –0.66 days, 95% CI –0.19 days to –1.13 days), number of disturbed nights (mean difference –0.72 days, 95% CI –0.30 days to –1.13 days), number of days crying (mean difference –0.69 days, 95% CI –0.31 days to –1.08 days), and the number of teaspoons of paracetamol used (mean difference –0.52 teaspoons daily, 95% CI –0.26 to –0.79 teaspoons daily). The RCT found no significant difference between groups in mean daily pain score (mean difference –0.16, 95% CI –0.42 to +0.11), number of daily episodes of distress (mean difference –0.12, 95% CI –0.34 to +0.11), or days absence from school (mean difference –0.18 days, 95% CI –0.76 days to +0.41 days).

Harms: The RCT found that immediate treatment significantly increased diarrhoea compared with delayed treatment (AR 25/135 [19%] with immediate *v* 14/150 [9%] with delayed; RR 1.9, 95% CI 1.08 to 3.66; NNH 11, 95% CI 5 to 125), but had no significant effect on rash (AR 6/133 [5%] with immediate *v* 8/149 [5%] with delayed; RR 0.84, 95% CI 0.30 to 2.36).[10]

Comment: None.

OPTION SHORT VERSUS LONGER COURSES OF ANTIBIOTICS

One systematic review and two subsequent RCTs have found that 10 day compared with 5 day courses of antibiotics reduce treatment failure, relapse, and reinfection at 8–14 days, but found no significant difference between groups at 20–42 days.

Benefits: We found one systematic review[11] and two subsequent RCTs.[12,13] The systematic review (search date 1998, 30 RCTs in children aged 4 weeks to 18 years with acute otitis media) found that treatment failure, relapse, or reinfection at an early evaluation (8–19 days) was significantly more likely to occur with shorter courses of antibiotics (5 days) than with longer courses (8–10 days; summary OR *v* longer courses 1.52, 95% CI 1.17 to 1.98).[11] However, by 20–30 days there were no significant differences between treatment groups (summary OR 1.22, 95% CI 0.98 to 1.54).[11] The first subsequent RCT (385 younger children with newly diagnosed acute otitis media, mean age 13.3 months, range 4.0–30.0 months) compared amoxicillin (amoxycillin)/clavulanate in three divided doses for 10 days versus 5 days followed by 5 days of placebo.[12] Clinical success or failure was assessed at 12–14 days and again at 28–42 days after starting treatment. Intention to treat analysis found that the 10 day regimen significantly increased clinical success on days 12–14 compared with the 5 day regimen (AR 158/186 [85%] for 10 days *v* 141/192 [73%] for 5 days; RR 1.16, 95% CI 1.04 to 1.28; NNT 8, 95% CI 5 to 30). However, by days 28–42 there was no significant difference in clinical success between the two groups (AR 108/185 [58%] for 10 days *v* 102/190 [54%] for 5 days; RR 1.09, 95% CI 0.91 to 1.30). The second subsequent RCT compared cefpodoxime/proxetil twice daily at 8 mg/kg daily for 10 days versus cefpodoxime/proxetil for 5 days followed by 5 days of

placebo. It found that success rates were higher with the 10 day compared with the 5 day treatment group after 12–14 days (AR 199/222 [90%] for 10 day treatment *v* 180/226 [80%] for 5 day treatment; RR 1.13, 95% CI 1.04 to 1.22; NNT 10, 95% CI 6 to 30), but no significant difference was found after 28–42 days (AR 149/222 [67%] for 10 day treatment *v* 141/226 [62%] for 5 day treatment; RR 1.08, 95% CI 0.94 to 1.23).[13]

Harms: The systematic review[11] and the two subsequent RCTs[12,13] found no difference with short versus long courses of antibiotics in diarrhoea and/or vomiting and rash.

Comment: None.

OPTION MYRINGOTOMY

One RCT in infants aged 3 months to 1 year found no significant difference in resolution of clinical symptoms between groups receiving myringotomy only, antibiotic only, and myringotomy plus antibiotic, but found higher rates of persistent infection with myringotomy only. A second RCT in children aged 2–12 years found no significant difference between myringotomy and no treatment in reduction of pain at 24 hours or 7 days. A third RCT in children aged 7 months to 12 years found higher rates of initial treatment failure (resolution of symptoms within 12 hours) for severe episodes of acute otitis media treated by myringotomy and placebo compared with antibiotic.

Benefits: We found no systematic review but found three RCTs.[14–16] The first RCT (105 infants aged 3 months to 1 year with acute otitis media [AOM]) compared antibiotic only (co-amoxiclav); myringotomy (see glossary, p 326) plus placebo; and myringotomy plus antibiotic (co-amoxiclav). AOM was defined as the presence of middle ear effusion and bulging (with or without redness of the tympanic membrane) associated with recent irritability or fever. It found that after 3–6 days of treatment, irritability and fever had resolved in more than three quarters of the children, with no significant differences between groups receiving antibiotic (co-amoxiclav) only, or myringotomy plus placebo, or both antibiotic plus myringotomy.[15] The second RCT (171 children aged 2–12 years with AOM) compared no treatment (40 children); myringotomy only (36 children); amoxicillin (250 mg 3 times daily for 7 days) only (47 children); and amoxicillin plus myringotomy (48 children).[14] AOM was diagnosed by the general practitioner on the basis of history and clinical picture. Diffuse redness and/or bulging of the eardrum was taken as decisive. The RCT found no significant difference between myringotomy alone and no treatment in pain at 24 hours (26/36 [72%] *v* 29/40 [72%]) or pain at 7 days (31/35 [89%] *v* 34/38 [90%]).[14] The third RCT (536 infants and children stratified 7–23 months, 2–5 years, and 6–12 years with AOM or recurrent AOM) compared children receiving antibiotics (amoxycillin 40 mg/kg per day in 3 divided doses for 14 days) or myringotomy, or in children aged over 2 years, myringotomy and placebo.[16] AOM was diagnosed on the basis of fever, otalgia, or irritability with redness and/or bulging of the eardrum. An episode of AOM was classified as severe or non-severe according to the child's temperature and an otalgia

score. The RCT found significantly higher rates of initial treatment failure (no resolution of symptoms within 12 hours) for severe episodes of AOM treated by myringotomy and placebo compared with antibiotic (8/34 [23.5%] *v* 1/32 [3.1%]). It found no significant difference in the percentage of children who developed ultimate treatment failure defined as more than 180 days of ear effusion, more than four episodes of severe AOM, protocol defined need for fourth myringotomy, or a fifth myringotomy within 12 months, or a suppurative complication (16/88 [18.2%] *v* 13/80 [16.3%] for non-severe episodes, and 1/13 [7.7%] *v* 3/12 [25%] for severe episodes).

Harms: In the first RCT, children in the myringotomy alone or placebo group were more likely than those receiving myringotomy plus antibiotics to have persistent ear infection (28/35 [80%] *v* 11/35 [31%]; NNH 2, 95% CI 1 to 3). At 9–11 days those in the myringotomy/placebo group compared with those receiving antibiotics had higher rates of persistent ear infection (21/30 [70%] *v* 2/30 [7%]; NNH 3, 95% CI 2 to 12) and lower rates of otoscopic recovery (7/32 [23%] *v* 18/32 [60%]; NNH 3, 95% CI 2 to 5).[15] The second RCT reported no difference in harm between the two groups.[14] The third RCT did not comment on adverse effects beyond treatment failures in the three arms of the study.[16]

Comment: Two RCTs provided results in the form of children or ears as the unit measured. As randomisation was based on children, the figures reported here exclude those based on ears.[14,15]

QUESTION What are the effects of interventions to prevent recurrence?

OPTION ANTIBIOTIC PROPHYLAXIS (LONG TERM)

One systematic review in children and adults found that long term antibiotic prophylaxis reduced recurrence of acute otitis media compared with placebo. However, one subsequent RCT in children aged 3 months to 6 years found no significant difference between antibiotic prophylaxis and placebo in preventing recurrence. The RCTs provided insufficient evidence on adverse effects of long term antibiotic prophylaxis. We found insufficient evidence on which antibiotic to use, for how long, and how many episodes of acute otitis media justify starting preventive treatment.

Benefits: **Versus placebo:** We found one systematic review[17] and one subsequent RCT.[18] The systematic review (search date 1993) identified 33 RCTs comparing antibiotics versus placebo to prevent recurrent acute otitis media (AOM) and otitis media with effusion.[17] Nine of the RCTs (945 people) looked at recurrent AOM only. It was not clear from the review which of the studies referred only to children; four either included the word "children" in the title or appeared in paediatric journals. Most studies defined recurrent AOM as at least three episodes of AOM in 6 months. The most commonly used antibiotics were amoxicillin (amoxycillin), co-trimoxazole, and sulfamethoxazole (sulphamethoxazole) given for 3 months to 2 years. All nine studies showed a lower rate of recurrence with antibiotic treatment, although in seven of the

studies the difference was not significant. Overall, the review found that antibiotics significantly reduced recurrence of AOM (AR of recurrence per person per month 8% with antibiotics *v* 19% with placebo; ARR 11%, 95% CI 3% to 19%; NNT per month to prevent 1 acute episode 9, 95% CI 5 to 33). The subsequent RCT (194 children aged 3 months to 6 years with 3 documented episodes of AOM within the preceding 6 months) compared amoxicillin (20 mg/kg/day) versus placebo.[18] The children were followed up monthly if asymptomatic or within 3–5 days if they had symptoms of upper respiratory tract infection for up to 90 days. The RCT found no significant difference between antibiotics and placebo in preventing recurrent AOM (RR of remaining AOM free, diagnosed by otoscopy and tympanometry 1.00, 95% CI 0.66 to 1.52 using completer analysis, 36 children lost to follow up). Calculations including those children lost to follow up yielded similar results whether the outcomes were assumed in favour of placebo or in favour of antibiotics. **Choice of antibiotic:** The systematic review found no significant difference in rate of recurrence between antibiotics.[17]

Harms: The studies gave no information on harms.

Comment: We found insufficient evidence on which antibiotic to use, for how long, and how many episodes of acute otitis media justify starting preventive treatment.

OPTION XYLITOL CHEWING GUM OR SYRUP

One RCT found that xylitol syrup or chewing gum reduced the proportion of children with at least one episode of acute otitis media compared with control. It found no significant difference between xylitol lozenges and control gum. It found that more children taking xylitol withdrew because of abdominal pain or other unspecified reasons compared with control.

Benefits: We found no systematic review but found one RCT (857 children, 54% boys) comparing xylitol (either as chewing gum, syrup, or lozenges) versus control (syrup or chewing gum) for 3 months.[19] The RCT randomised children into two groups according to their ability to chew gum. Children who could chew gum received xylitol gum (8.4 g/day, 179 children), xylitol lozenges (10 g/day, 176 children), or control gum (xylitol 0.5 g/day, 178 children). Children who could not chew gum received xylitol syrup (10 g/day, 159 children) or control syrup (0.5 g day, 165 children). Each time the child showed any signs of acute respiratory infection, acute otitis media (AOM) was excluded using tympanometry and otoscopy. In the first group, xylitol gum significantly reduced the proportion of children with at least one episode of AOM compared with control gum (AR 29/179 [16%] *v* 49/178 [28%]; RR 0.59, 95% CI 0.39 to 0.89; NNT 8, 95% CI 5 to 36), but it found no significant difference between xylitol lozenges and control gum (AR 39/176 [22%] *v* 49/178 [28%]; RR 0.81, 95% CI 0.56 to 1.16). In the second group, xylitol syrup significantly reduced the proportion of children with at least one episode of AOM compared with control syrup (AR 46/159 [29%] *v* 68/165 [41%]; RR 0.70, 95% CI 0.52 to 0.95; NNT 8, 95% CI 4 to 53).

Harms: The RCT found that significantly more children taking xylitol lozenges or syrup withdrew from the trial compared with control treatment (xylitol lozenges *v* control gum, 26/176 [15%] *v* 8/178 [5%], $P < 0.001$; xylitol syrup *v* control syrup, 30/159 [19%] *v* 17/165 [10%]; $P < 0.03$).[19] Most withdrawals were because of either an unwillingness to take the intervention, having left the area, or because of abdominal discomfort. We found no evidence on the long term effects of xylitol.

Comment: The children in this study received xylitol or the control intervention five times daily — a regimen that might be difficult to maintain long term.[19] The incidence of AOM in those who withdrew from the trial was not described; therefore, the reported effect of xylitol may be underestimated or overestimated.

OPTION TYMPANOSTOMY (VENTILATION) TUBES

One small RCT found that tympanostomy tube insertion reduced the mean number of acute otitis media episodes during the first 6 month period after treatment compared with myringotomy alone or no surgery, but not during the subsequent 18 months. It also found a non-significant trend for more recurrent infections and worse hearing, after tube extrusion, in those treated with tympanostomy. It found more tympanosclerosis in ears that received ventilating tubes compared with myringotomy alone or no surgery.

Benefits: We found no systematic review but found one RCT.[20] The RCT (44 children aged 9 months to 7 years with bilateral recurrent acute otitis media of equal severity in each ear despite over 3 months of antibiotic prophylaxis) compared tympanostomy (see glossary, p 326) with ventilation tube insertion into a randomly selected ear, with the contralateral ear receiving either no surgery, or myringotomy (see glossary, p 326) alone. Recurrent acute otitis media was defined as the recurrent presence (more than 4 episodes) of otalgia with red and bulging tympanic membranes. The RCT found that tympanostomy tube insertion significantly reduced the mean number of AOM episodes during the first 6 month period after treatment compared with myringotomy alone or no surgery (–1.2, 95% CI –2.2 to –0.9), but not during the subsequent 18 months.

Harms: The RCT reported a non-significant trend ($P = 0.30$) for more recurrent infections and worse hearing in ears that had received tympanostomy tubes, which became apparent after tube extrusion.[20] Anatomical abnormalities (tympanosclerosis, atrophy, or retraction and chronic perforation, though not thought to be clinically significant) were more common in the ears receiving tympanostomy tubes. There was significantly more tympanosclerosis in ears that received ventilating tubes than in those that received myringotomy alone (35/61 [57.4%] *v* 5/26 [19.2%]; $P = 0.004$) or no surgery (35/61 [57.4%] *v* 2/27 [7.4%]; $P \leq 0.0001$). At the 2 year evaluation, the hearing was poorer in ears with anatomical abnormalities.

Comment: This RCT included some children with otitis media with effusion, although the results concerning benefits presented here refer only to those children in the study with recurrent acute otitis media. It

was not possible from the data available to differentiate the evidence on harms into children with recurrent acute otitis media compared with otitis media with effusion. Medical treatment and antibiotic prophylaxis were allowed "whenever indicated". It was not possible from the data presented to tell whether the different groups differed in the amount of medical treatment and prophylactic antibiotics.

GLOSSARY

Mastoiditis The presence of infection in mastoid cavity.
Myringotomy The surgical creation of a perforation in tympanic membrane.
Tympanostomy The surgical creation of a perforation in tympanic membrane for the purpose of inserting a ventilation tube.

QUESTIONS

INTERVENTIONS

Key Messages

Treating acute asthma in children

- **Oxygen** An RCT comparing oxygen treatment with no oxygen treatment in acute severe asthma would be considered unethical. One prospective cohort study and clinical experience support the need for oxygen in acute asthma.
- **High dose inhaled corticosteroids** We found one systematic review that identified four RCTs comparing high dose inhaled with oral corticosteroids in children. Three RCTs found no significant difference in hospital admission with nebulised budesonide or dexamethasone compared with oral prednisolone in children with mild to moderate asthma. One RCT in children with moderate to severe asthma found that, compared with inhaled fluticasone, oral prednisolone reduced hospital admission and improved lung function at 4 hours. A subsequent RCT in children aged 4–16 years found that, compared with oral prednisolone, nebulised fluticasone improved lung function over 7 days. Another RCT in children aged 5–16 years admitted to hospital with severe asthma found no significant difference with nebulised budesonide compared with oral prednisolone in lung function at 24 hours or 24 days after admission.
- **Inhaled ipratropium bromide added to β_2 agonists (in emergency room)** One systematic review has found that, compared with β_2 agonist alone, multiple doses of inhaled ipratropium bromide plus an inhaled β_2 agonist (fenoterol or salbutamol) reduced hospital admissions and improved lung function in children aged 18 months to 17 years with severe asthma exacerbations. In children with mild to moderate asthma exacerbations, a single dose of inhaled ipratropium bromide plus a β_2 agonist (fenoterol, salbutamol, or terbutaline) compared with a β_2 agonist alone improved lung function for up to 2 hours, but did not reduce hospital admissions.
- **Metered dose inhaler plus spacer devices for delivery of β_2 agonists (as effective as nebulisers)** One systematic review in children with acute but not life threatening asthma, who were old enough to use a spacer, has found no significant difference in hospital admission rates with a metered dose inhaler plus a spacer versus nebulisation for delivering β_2 agonists (fenoterol, salbutamol, or terbutaline) or β agonist (orciprenaline). Children using a metered dose inhaler with a spacer may have shorter stays in emergency departments, less hypoxia, and lower pulse rates compared with children receiving β_2 agonist by nebulisation.

- **Systemic corticosteroids** One systematic review has found that systemic corticosteroids increase the likelihood of early discharge and reduce the frequency of relapse within 1–3 months in children hospitalised with acute asthma.
- **Intravenous theophylline** One systematic review found that in children aged 1–19 years admitted to hospital with severe asthma, intravenous theophylline improved lung function and symptom scores 6–8 hours after treatment compared with placebo, but found no significant difference in number of bronchodilator treatments required or length of hospital stay. A subsequent RCT in children aged 1–17 years admitted to an intensive care unit with severe asthma found that, compared with controls, intravenous theophylline decreased the time to reach a clinical asthma score of 3 or less but found no significant difference in length of stay in the intensive care unit.
- **Inhaled ipratropium bromide added to salbutamol (after initial stabilisation)** One RCT in children admitted to hospital with initially stabilised severe asthma found no significant difference in clinical asthma scores during the first 36 hours with nebulised ipratropium bromide compared with placebo added to salbutamol (a β_2 agonist) and corticosteroid (hydrocortisone or prednisone).

Single agent prophylaxis in childhood asthma

- **Inhaled corticosteroids** One systematic review has found that, compared with placebo, prophylactic inhaled corticosteroids improve symptoms and lung function in children with asthma. Several RCTs have found that inhaled corticosteroids slightly reduce growth rate compared with placebo, although studies with long term follow up suggest attainment of normal adult height. Inhaled corticosteroids have been associated with rare reports of adrenal suppression. One RCT in children aged 6–16 years found no significant difference in improvement of asthma symptoms with inhaled beclometasone compared with theophylline, but found less use of bronchodilators and oral corticosteroids with inhaled beclometasone. Small RCTs have found inhaled corticosteroids to be more effective than sodium cromoglicate in improving symptoms and lung function. RCTs in children aged 5–16 years have found that, compared with inhaled long acting β_2 agonists (salmeterol) or inhaled nedocromil, inhaled corticosteroids (beclometasone, budesonide, or fluticasone) improve symptoms and lung function in children with asthma.
- **Inhaled nedocromil** Two RCTs in children aged 6–12 years found that, compared with placebo, inhaled nedocromil reduces asthma symptom scores, asthma severity, bronchodilator use, and improves lung function. One large RCT in children aged 5–12 years with mild to moderate asthma found no significant difference between nedocromil and budesonide or placebo in lung function, hospital admission rate, or the symptom score on diary cards, but found that budesonide was superior to nedocromil, and that nedocromil was superior to placebo in several measures of asthma symptoms and morbidity.
- **Oral montelukast** One RCT in children aged 6–14 years found that, compared with placebo, oral montelukast (a leukotriene receptor antagonist) increased from baseline the mean morning forced expiratory volume in 1 second and reduced the total daily β_2 agonist use, but found no significant difference in daytime asthma symptom score or in nocturnal awakenings with asthma. Another RCT in children aged 2–5 years found that, compared with placebo, oral montelukast improved average daytime symptom scores and reduced the need for rescue oral steroid courses, but found no significant difference in average overnight asthma symptom scores. We found no RCTs directly comparing oral montelukast with inhaled corticosteroids.

- **Inhaled salmeterol** Two RCTs in children aged 4–14 years found that, compared with placebo, inhaled salmeterol improved lung function but found conflicting evidence about reduced use of salbutamol. One RCT comparing inhaled salmeterol with beclometasone found that salmeterol was associated with a significant deterioration in bronchial reactivity.
- **Oral theophylline** One small RCT in children aged 6–15 years found that, compared with placebo, oral theophylline increased mean morning peak expiratory flow rate and reduced the mean number of acute night time attacks and doses of bronchodilator used. Another RCT in children aged 6–16 years found no significant difference in improvement of asthma symptoms with oral theophylline compared with inhaled beclometasone, but found greater use of bronchodilators and oral corticosteroids with theophylline over 1 year. Theophylline has serious adverse effects (cardiac arrhythmia, convulsions) if therapeutic blood concentrations are exceeded.
- **Inhaled sodium cromoglicate** One systematic review found insufficient evidence for prophylactic treatment with sodium cromoglicate in children aged less than 1 year to 18 years. Several small comparative RCTs found sodium cromoglicate to be less effective than inhaled corticosteroids in improving symptoms and lung function.

Additional prophylactic treatments in childhood asthma inadequately controlled by standard dose inhaled corticosteroids

- **Increased dose of inhaled beclometasone** One RCT in children aged 6–16 years taking inhaled beclometasone (a corticosteroid) comparing the addition of a second dose of beclometasone with placebo found no significant difference in lung function, symptom scores, exacerbation rates, or bronchial reactivity but found a reduction in growth velocity at 1 year.
- **Inhaled salmeterol** One RCT in children aged 6–16 years found that addition of salmeterol (a long acting β_2 agonist) increased peak expiratory flow rates in the first few months of treatment but found no increase after 1 year. A second short term RCT in children aged 4–16 years also found increased morning peak expiratory flow rates and more symptom free days at 3 months with addition of salmeterol.
- **Oral montelukast** One crossover RCT in children aged 6–14 years with persistent asthma who had been taking inhaled budesonide for at least 6 weeks found that, compared with addition of placebo, oral montelukast (a leukotriene receptor antagonist) reduced asthma exacerbations over 4 weeks. This difference was statistically significant but modest in clinical terms.
- **Oral theophylline** One small RCT found that addition of theophylline, compared with placebo, to previous treatment increased the proportion of symptom free days and reduced the use of additional orciprenaline (a β agonist) and additional corticosteroid (beclometasone or prednisolone) over 4 weeks. We found insufficient evidence to weigh these short term benefits and possible long term harms.

Treating acute wheeze in infants

- **Addition of ipratropium bromide to fenoterol** One RCT identified by a systematic review in infants aged 3–24 months found that addition of ipratropium bromide to fenoterol (a long acting β_2 agonist) compared with fenoterol alone reduced the proportion of infants receiving further treatment 45 minutes after initial treatment.

Asthma and other wheezing disorders in children

- **Inhaled salbutamol** One RCT in infants aged 3 months to 2 years found that, compared with placebo, nebulised salbutamol (a short acting β_2 agonist) improved respiratory rate but found no significant difference in hospital admission. Another RCT that included infants aged less than 18 months to 36 months found no significant difference in change from baseline in clinical symptom scores with nebulised salbutamol versus placebo.
- **Short acting β_2 agonists delivered by metered dose inhaler/spacer versus nebuliser** Two RCTs in children aged up to 5 years found no significant difference in hospital admissions with delivery of salbutamol through a metered dose inhaler plus spacer versus nebulised salbutamol. Another RCT in infants aged 1–24 months found no significant difference in improvement of symptoms with delivery of terbutaline through a metered dose inhaler plus spacer compared with nebulised terbutaline. Nebulised β_2 agonists may cause tachycardia, tremor, and hypokalaemia.
- **High dose inhaled corticosteroids** One systematic review found that high dose inhaled corticosteroids compared with placebo reduced the requirement for oral corticosteroids, but the difference was not statistically significant. The review also found a clear preference for the inhaled corticosteroids by the children's parents over placebo. The clinical importance of these results is unclear.
- **Inhaled ipratropium bromide** We found no RCTs comparing inhaled ipratropium bromide compared with placebo for treating acute wheeze.
- **Oral prednisolone** One small RCT found no significant difference in daily symptom scores with oral prednisolone (a corticosteroid) versus placebo.

Prophylaxis in wheezing infants

- **Oral salbutamol** One RCT identified by a systematic review in infants aged 3–14 months found that oral salbutamol (a short acting β_2 agonist) compared with placebo reduced treatment failures.
- **Higher dose inhaled budesonide** One RCT in infants aged 6–30 months found that higher prophylactic doses of inhaled budesonide (a corticosteroid) compared with placebo reduced symptoms and the proportion of children with acute wheezing episodes during a 12 week period but found no significant reduction in the proportion of wheezing episodes per infant. Another RCT in infants aged 11–36 months found that higher prophylactic doses of inhaled budesonide reduced the proportion of days requiring oral prednisolone, and symptoms of wheezing and sleep disturbance, but found no significant improvement for cough. Higher doses of inhaled corticosteroids have the potential for adverse effects.
- **Inhaled ipratropium bromide** One small RCT identified by a systematic review found no significant difference in relief of symptoms with nebulised ipratropium bromide compared with placebo. The study may have lacked power to exclude a clinically important difference between treatments.
- **Inhaled salbutamol** Two RCTs identified by a systematic review in infants aged up to 2 years found no significant improvement in symptoms with inhaled salbutamol (a short acting β_2 agonist) compared with placebo.
- **Lower dose inhaled budesonide** Three RCTs found no clear evidence of effectiveness with lower prophylactic doses of inhaled budesonide (a corticosteroid) in children aged 1 week to 6 years with recurrent wheeze.
- **Addition of inhaled beclometasone to salbutamol** One RCT found no significant improvement in symptoms with addition of inhaled beclometasone (a corticosteroid) compared with placebo to inhaled salbutamol (a short acting β_2 agonist).

DEFINITION

Differentiation between asthma and non-asthmatic viral associated wheeze may be difficult; persisting symptoms and signs between acute attacks are suggestive of asthma, as are a personal or family history of atopic conditions such as eczema and hay fever. **Childhood asthma** is characterised by chronic or recurrent cough and wheeze. The diagnosis is confirmed by demonstrating reversible airway obstruction, preferably on several occasions over time, in children old enough to perform peak flow measurements or spirometry. Diagnosing asthma in children requires exclusion of other causes of recurrent respiratory symptoms. Acute asthma is a term used to describe a severe exacerbation of asthma symptoms accompanied by tachycardia and tachypnoea. The aim of prophylactic treatments in asthma is to minimise persistent symptoms and prevent acute exacerbations. **Wheezing in infants** is characterised by a high pitched purring or whistling sound produced mainly on the out breath and is commonly associated with an acute viral infection such as bronchiolitis (see bronchiolitis, p 360) or asthma. These are not easy to distinguish clinically.

INCIDENCE/ PREVALENCE

Childhood asthma: Surveys have found an increase in the proportion of children diagnosed with asthma. The increase is higher than can be explained by an increased readiness to diagnose asthma. One questionnaire study from Aberdeen, Scotland, surveyed 2510 children aged 8–13 years in 1964 and 3403 children in 1989. Over the 25 years, the diagnosis of asthma rose from 4% to 10%.[1] The increase in the prevalence of childhood asthma from the 1960s to 1980s was accompanied by an increase in hospital admissions over the same period. In England and Wales this was a sixfold increase.[2] **Wheezing in infants** is common and seems to be increasing, although the magnitude of any increase is not clear. One Scottish cross-sectional study (2510 children aged 8–13 years in 1964 and 3403 children in 1989) found that the prevalence of wheeze rose from 10% in 1964 to 20% in 1989, and episodes of shortness of breath rose from 5% to 10% over the same period.[1] Difficulties in defining clear groups (phenotypes) and the transient nature of the symptoms, which often resolve spontaneously, have confounded many studies.

AETIOLOGY/ RISK FACTORS

Childhood asthma: Asthma is more common in children with a personal or family history of atopy, increased severity and frequency of wheezing episodes, and presence of variable airway obstruction or bronchial hyperresponsiveness. Precipitating factors for symptoms and acute episodes include infection, house dust mites, allergens from pet animals, exposure to tobacco smoke, and anxiety. **Wheezing in infants:** Most wheezing episodes in infancy are precipitated by viral respiratory infections.

PROGNOSIS

Childhood asthma: A British longitudinal study of children born in 1970 found that 29% of 5 year olds wheezing in the past year were still wheezing at the age of 10 years.[3] Another study followed a group of children in Melbourne, Australia from the age of 7 years (in 1964) into adulthood. The study found that a large proportion (73%) of 14 year olds with infrequent symptoms had few or no symptoms by the age of 28 years, whereas two thirds of those 14 year olds with frequent wheezing still had recurrent attacks at

the age of 28 years.[4] **Wheezing in infants:** One cohort study (826 infants followed from birth to 6 years) suggests that there may be at least three different prognostic categories for wheezing in infants: "persistent wheezers" (14% of total, with risk factors for atopic asthma such as elevated immunoglobulin E levels and a maternal history of asthma), who initially suffered wheeze during viral infections, and in whom the wheezing persisted into school age; "transient wheezers" (20% of total, with reduced lung function as infants but no early markers of atopy), who also suffered wheeze during viral infections but stopped wheezing after the first 3 years of life; and "late onset wheezers" (15% of total), who did not wheeze when aged under 3 years but had developed wheeze by school age.[5] Another retrospective cohort study found that 14% of children with one attack and 23% of children with four or more attacks in the first year of life had experienced at least one wheezing illness in the past year at the age of 10 years.[3] Administering inhaled treatments to young children can be difficult. Inconsistencies in results could reflect the effects of the differences in the drugs used, delivery devices used, dosages used, and the differences in the pattern of wheezing illnesses and treatment responses among young children.

AIMS OF INTERVENTION To reduce or abolish cough and wheeze; to attain best possible lung function; to reduce the risk of severe attacks; to minimise sleep disturbance and absence from school; to minimise adverse effects of treatment; and to allow normal growth.

OUTCOMES **Childhood asthma:** Wheeze, cough, nights disturbed by asthma, days lost from school or normal activities, diary card symptom scores, frequency of use of short acting β_2 agonists for symptom control, lung function tests (peak expiratory flow rates and forced expiratory volume in 1 second), airway hyperresponsiveness (measured using methacholine challenge tests), rates of health service use (emergency consultations, casualty attendances, hospital admissions). In acute episodes — blood oxygen saturation, admission rate from casualty, duration of admission, need for intensive care or intubation, mortality. **Wheezing in infants:** There are no suitable objective outcome parameters by which a response can be adequately measured, as clinical assessment of an infant's lung function is impractical. Symptoms and signs are usually subjective, vary between observers, and can be affected by short term changes. The main outcomes used in trials include: respiratory rate, work of breathing (suprasternal/sternal/intercostal/subcostal recession, grunting, nasal flare, and head bobbing), agitation, and oxygen saturations. Parental preference is considered to be a relevant outcome.

METHODS *Clinical Evidence* search and appraisal June 2003. We have excluded studies with heterogeneous groups of infants (those that included infants with bronchiolitis, episodic viral wheeze [see glossary, p 356] and chronic, persistent wheeze).

QUESTION **What are the effects of treatments for acute asthma in children?**

Duncan Keeley

OPTION OXYGEN

An RCT comparing oxygen treatment with no oxygen treatment in acute severe asthma would be considered unethical. One prospective cohort study and clinical experience support the need for oxygen in acute asthma.

Benefits: We found no systematic review or RCTs (see comment below). One double blind, prospective cohort study (280 children) found that decreased oxygen saturation upon entry to an emergency department was correlated with increased treatment with intravenous aminophylline (see glossary, p 356) and corticosteroids, and increased rates of hospital admission or subsequent readmission (arterial oxygen saturation ≤91% *v* arterial oxygen saturation ≥96%: OR 35, 95% CI 11 to 150; for arterial oxygen saturation 92–95% *v* ≥96%: OR 4.2, 95% CI 2.2 to 8.8).[6]

Harms: We found no evidence about harms.

Comment: An RCT of oxygen versus no oxygen treatment in acute severe asthma would be considered unethical. The cohort study does not address directly whether oxygen should be given therapeutically but it does suggest, along with clinical experience, that oxygen should continue to be given promptly to children with acute asthma.[6]

OPTION INHALED IPRATROPIUM BROMIDE ADDED TO β_2 AGONISTS

One systematic review has found that, compared with β_2 agonist alone, multiple doses of inhaled ipratropium bromide plus an inhaled β_2 agonist (fenoterol or salbutamol) reduced hospital admissions and improved lung function in children aged 18 months to 17 years with severe asthma exacerbations. In children with mild to moderate asthma exacerbations, a single dose of inhaled ipratropium bromide plus a β_2 agonist (fenoterol, salbutamol, or terbutaline) compared with a β_2 agonist alone improved lung function for up to 2 hours, but did not reduce hospital admissions. One subsequent RCT in children admitted to hospital with initially stabilised severe asthma found no significant difference in clinical asthma scores during the first 36 hours with nebulised ipratropium bromide compared with placebo added to salbutamol and corticosteroid (hydrocortisone or prednisone).

Benefits: We found one systematic review[7] and one subsequent RCT.[8] **Single dose:** The systematic review (search date 2000, 13 RCTs, children aged 18 months to 17 years with acute asthma)[7] found that in children with mild to moderate exacerbations, adding a single dose of inhaled ipratropium bromide to inhaled β_2 agonists (fenoterol, salbutamol [see glossary, p 356], or terbutaline) versus the β_2 agonist alone significantly improved forced expiratory volume in 1 second (FEV_1) at 1 hour (3 RCTs: standardised mean difference 0.57, 95% CI 0.21 to 0.93) and at 2 hours (3 RCTs: standardised

mean difference 0.53, 95% CI 0.17 to 0.90), but found no significant reduction in hospital admission (3 RCTs: RR 0.93, 95% CI 0.65 to 1.32).[7] **Multiple doses:** The systematic review found that in children with mild, moderate, or severe exacerbations, adding multiple doses of inhaled ipratropium bromide to an inhaled β_2 agonist (fenoterol or salbutamol) improved FEV_1 (4 RCTs: WMD 9.7% of predicted FEV_1, 95% CI 5.7% to 13.7%, 1 hour after last ipratropium bromide inhalation) and reduced hospital admissions (6 RCTs: RR 0.75, 95% CI 0.62 to 0.89; NNT 13, 95% CI 8 to 32). Subgroup analysis found a significant reduction in children with only severe exacerbations (baseline $FEV_1 < 50\%$ of predicted or change of 7–9 in baseline clinical score after last combined inhalation; RR 0.71, 95% CI 0.58 to 0.89; NNT 7, 95% CI 5 to 20).[7] The subsequent RCT (80 children and adolescents aged 1–18 years admitted to hospital with moderate to severe asthma, FEV_1 25–85% predicted or clinical asthma score [see glossary, p 356] of 3–9, initially stabilised in emergency department) compared addition of nebulised ipratropium bromide versus placebo (sodium chloride) to nebulised salbutamol and intravenous hydrocortisone or oral prednisone.[8] The RCT found no significant difference between groups during the first 36 hours in clinical asthma scores, oxygen saturation, or number of nebulisations needed.

Harms: The systematic review found no significant increase in risk of nausea (3 RCTs: RR 0.59, 95% CI 0.30 to 1.14), vomiting (3 RCTs: RR 1.03, 95% CI 0.37 to 2.87), or tremor (4 RCTs: RR 1.01, 95% CI 0.63 to 1.63) in children treated with multiple doses of ipratropium bromide.[7] The subsequent RCT found a significant increase in heart rate with ipratropium bromide compared with placebo ($P = 0.01$).[8]

Comment: None.

OPTION METERED DOSE INHALER PLUS SPACER DEVICES VERSUS NEBULISERS FOR DELIVERING β_2 AGONISTS

One systematic review, in children with acute but not life threatening asthma who were old enough to use a spacer, has found no significant difference in hospital admission rates with a metered dose inhaler plus a spacer compared with nebulisation for delivery of β_2 agonists (fenoterol, salbutamol, or terbutaline) or β agonist (orciprenaline). Children using a metered dose inhaler with a spacer may have shorter stays in emergency departments, less hypoxia, and lower pulse rates compared with children receiving β_2 agonist by nebulisation.

Benefits: We found one systematic review (search date 2001, 13 RCTs, 880 children with acute asthma but excluding life threatening asthma) comparing a spacer/holding chamber attached to a metered dose inhaler versus single or a multiple treatment with nebuliser for delivery of β_2 agonists (fenoterol, salbutamol [see glossary, p 356], or terbutaline) or β agonist (orciprenaline [see glossary, p 356]).[9] The review found no significant difference between spacer and multiple treatments with nebulisers in hospital admission rates (OR 0.65, 95% CI 0.40 to 1.06). It found a significant increase in pulse rate with nebulisers (WMD 7.8% from baseline, 95% CI 5.3% to 10.2%). One RCT (152 children ≥ 2 years) included in the review

found that the time spent in the emergency department was shorter in children using metered dose inhaler plus spacer (WMD –37 minutes, 95% CI –50 minutes to –24 minutes).[10] Two small RCTs included in the review comparing delivery of β_2 agonists (salbutamol or terbutaline) through a spacer versus single treatment with nebuliser found less deterioration in blood gases with the spacer.[9]

Harms: The systematic review found no significant deterioration in any of the outcome measures with delivery of β_2 agonists using metered dose inhaler plus a spacer versus nebulisation.[9]

Comment: These findings suggest that, in children old enough to use a spacer, metered dose inhaler with spacer could be substituted for nebulisation in the treatment of acute asthma in emergency departments and hospital wards.

OPTION SYSTEMIC CORTICOSTEROIDS

One systematic review has found that, compared with placebo, systemic corticosteroids increase the likelihood of discharge after 4 hours and reduce the frequency of relapse within 1–3 months in children hospitalised with acute asthma.

Benefits: **Versus placebo:** We found one systematic review (search date 2002) evaluating effects of systemic corticosteroids in children and adolescents with acute asthma.[11] The review found that oral corticosteroids significantly increased discharge from hospital at first review after 4 hours and reduced relapse within 3 months compared with placebo (2 RCTS, 210 children, mean age 5 years; discharge at first review after 4 hours: OR 7.00, 95% CI 2.98 to 16.45; NNT 3, 95% CI 2 to 8; relapse within 1–3 months: OR 0.19, 95% CI 0.07 to 0.55; NNT 3, 95% CI 2 to 7).[11] The review found no significant difference between oral or intravenous corticosteroids and placebo in mean length of hospital stay (3 RCTs, 132 children, mean age range 4–10 years; mean length of hospital stay: WMD –8.75 hours, 95% CI –19.23 hours to +1.74 hours), pulmonary function (2 RCTs, 64 children, mean age range 9–12 years; pulmonary function, % predicted peak expiratory flow rate: WMD +7.21, 95% CI –7.01 to +21.25). The corticosteroids used in the studies were oral or intravenous prednisolone, intravenous hydrocortisone, or intravenous methylprednisolone. **Oral corticosteroids versus high dose inhaled corticosteroids:** See benefits of high dose inhaled corticosteroids, p 338.

Harms: The studies included in the systematic review did not formally address the issue of harms.[11] We found few reports of adverse effects with short courses of systemic corticosteroids. **Varicella infection:** Several case reports have associated systemic corticosteroid treatment with severe varicella infection. One case control study (167 cases, 134 controls) in otherwise immunocompetent children with complicated and uncomplicated varicella infection did not find significant risk attributable to corticosteroid exposure (OR 1.6, 95% CI 0.2 to 17.0), but it was too small to exclude a clinically important risk.[12]

Comment: The studies included in the systematic review[11] probably excluded the most severely ill children; this was explicitly stated in one study. The authors of the review comment on the surprising paucity of evidence from RCTs for this accepted standard intervention. RCTs of systemic steroids versus placebo in severe acute asthma would now be considered unethical.

OPTION HIGH DOSE INHALED CORTICOSTEROIDS

We found one systematic review that identified four RCTs comparing high dose inhaled with oral corticosteroids in children. Three RCTs found no significant difference in hospital admissions with nebulised budesonide or dexamethasone compared with oral prednisolone in children with mild to moderate asthma. One RCT in children with moderate to severe asthma found that, compared with inhaled fluticasone, oral prednisolone reduced hospital admissions and improved lung function at 4 hours. A subsequent RCT in children aged 4–16 years found that, compared with oral prednisolone, nebulised fluticasone improved lung function over 7 days. Another RCT in children aged 5–16 years admitted to hospital with severe asthma found no significant difference with nebulised budesonide compared with oral prednisolone in lung function at 24 hours or 24 days after admission.

Benefits: **Versus oral corticosteroids:** We found one systematic review (search date 2000, 4 RCTs),[13] one subsequent RCT,[14] and one additional RCT.[15] The systematic review compared effects of initial treatment with high dose inhaled corticosteroids versus oral corticosteroids in hospital emergency departments on admission rates.[13] The results from the four RCTs were not pooled because of marked heterogeneity between studies. One RCT (100 children with moderate to severe asthma, aged 5–16 years, mean initial forced expiratory volume in 1 second, 45%) compared fluticasone (2 mg through metered dose inhaler with spacer) versus prednisone (2 mg/kg orally).[16] It found that prednisone reduced hospital admission (31% with fluticasone *v* 10% with prednisone; $P = 0.01$) and increased mean forced expiratory volume in 1 second at 4 hours (9% with fluticasone *v* 19% with prednisone; $P \leq 0.001$).[16] The second RCT (111 children with mild to moderate asthma, aged 1–17 years) compared dexamethasone (1.5 mg/kg through nebuliser) versus prednisone (2 mg orally).[17] It found no significant difference between nebulised dexamethasone and oral prednisone in rates of hospital admission (12/56 [21%] with dexamethasone *v* 17/55 [31%] with prednisone; ARR +9.5%, 95% CI –8.0% to +21.0%; RR 0.69, 95% CI 0.36 to 1.27), but found fewer relapses with nebulised dexamethasone within 48 hours after discharge (0/44 [0%] *v* 6/38 [16%]; ARR –16.0%, 95% CI –27.0% to –4.5%); however, all children in the RCT received a 5 day course of prednisone (2 mg/kg/day) on discharge.[17] Two other RCTs (104 children with mild to moderate asthma) compared budesonide (800 µg through nebuliser at 1, 30, and 60 minutes; 1600 µg through turbohaler) versus prednisolone (2 mg/kg orally).[18,19] Overall, no significant differences were found between the groups in admission rates (OR for inhaled corticosteroids *v* oral corticosteroids 0.49, 95% CI 0.22 to 1.07).[18,19] The subsequent RCT (321 children aged 4–16 years, peak expiratory flow rate 40–75% predicted) compared

nebulised fluticasone (1 mg twice daily for 7 days) versus oral prednisolone (2 mg/kg for 4 days then 1 mg/kg for 3 days). It found that nebulised fluticasone versus oral prednisolone significantly improved mean morning peak expiratory flow rate over 7 days (difference 9.5 L/minute, 95% CI 2.0 L/minute to 17.0 L/minute). No significant differences were found in symptom scores, withdrawals, or adverse events.[14] The additional RCT (46 children, aged 5–16 years, admitted to hospital with severe exacerbations of asthma) compared nebulised budesonide (2 mg/hour) with oral prednisolone (2 mg/kg) at admission and after 24 hours.[15] It found no significant difference between groups in flow expiratory volume in 1 second at 24 hours, or at 3 and 24 days after admission. All children in this trial were treated with budesonide (800 μg/day) after discharge from hospital.

Harms: The systematic review found no significant adverse effects with inhaled corticosteroids.[13] The subsequent RCT found no significant difference in the profile of adverse events between inhaled fluticasone and oral prednisolone, except a slightly higher frequency of oral candidiasis with fluticasone (8% with fluticasone *v* 3% with prednisolone).[14]

Comment: These RCTs suggest that high dose inhaled corticosteroids may be substituted for oral corticosteroids in the initial phase of treatment of moderately severe acute asthma. This may be useful for children who vomit oral corticosteroids or for children with frequent exacerbations where there is concern about the cumulative dose of oral steroids. One RCT was funded by the manufacturers of fluticasone.[14]

OPTION INTRAVENOUS THEOPHYLLINE

One systematic review found that in children aged 1–19 years admitted to hospital with severe asthma, intravenous theophylline improved lung function and symptom scores 6–8 hours after treatment compared with placebo, but found no significant difference in the number of bronchodilator treatments required or length of hospital stay. A subsequent RCT in children aged 1–17 years admitted to the intensive care unit with severe asthma found that, compared with controls, intravenous theophylline decreased the time to reach a clinical asthma score of 3 or less but found no significant difference in length of stay in the intensive care unit.

Benefits: We found one systematic review[20] and one subsequent RCT.[21] The systematic review (search date 2001, 7 RCTs, 380 children and adolescents aged 1–19 years admitted to hospital with severe asthma, flow expiratory volume in 1 second 35–45% predicted) compared the effects of intravenous theophylline versus placebo on lung function (measured as change from baseline in flow expiratory volume in 1 second).[20] The review found that at 6–8 hours, intravenous theophylline versus placebo significantly improved lung function (2 RCTs; WMD 8.4%, 95% CI 0.8% to 15.9%) and clinical symptom scores (WMD –0.71, 95% CI –0.82 to –0.60) but found no significant difference in the number of nebulised bronchodilator treatments required (2 RCTs; WMD +0.15; 95% CI –0.52 to

+0.83) or length of hospital stay (3 RCTs; WMD +4.29; 95% CI −4.16 to +12.74). The subsequent RCT (47 children aged 1–17 years admitted to intensive care unit with severe asthma receiving salbutamol [see glossary, p 356]), ipratropium, and methylprednisolone) compared intravenous theophylline versus controls on time to reach a clinical asthma score of 3 or less.[21] The RCT found that intravenous theophylline significantly decreased the time to reach a clinical asthma score of 3 or less compared with control (18.6 hours with theophylline *v* 31 hours with control; $P < 0.05$) but found no significant difference in length of stay in the intensive care unit.

Harms: The systematic review found that theophylline significantly increased the risk of vomiting (5 RCTs; RR 3.69, 95% CI 2.15 to 6.33) compared with placebo, but found no significant differences for headache, tremor, seizures, and arrhythmia. There were no deaths reported in the included studies.[20] The subsequent RCT found significantly higher incidence of emesis with theophylline and tremor with controls (both $P < 0.05$).[21] Theophylline can cause serious adverse effects (cardiac arrhythmia or convulsions) if therapeutic blood concentrations are exceeded.

Comment: None.

QUESTION What are the effects of single agent prophylaxis in childhood asthma?

Duncan Keeley

OPTION INHALED CORTICOSTEROIDS

One systematic review has found that, compared with placebo, prophylactic inhaled corticosteroids improve symptoms and lung function in children with asthma. Several RCTs have found that inhaled corticosteroids slightly reduce growth rate compared with placebo, although studies with long term follow up suggest attainment of normal adult height. Inhaled corticosteroids have been associated with rare reports of adrenal suppression. One RCT in children aged 6–16 years found no significant difference in improvement of asthma symptoms between inhaled beclometasone and theophylline, but found less use of bronchodilators and oral corticosteroids with inhaled beclometasone. Small RCTs have found inhaled corticosteroids to be more effective than sodium cromoglicate in improving symptoms and lung function. RCTs in children aged 5–16 years have found that inhaled corticosteroids (beclometasone, budesonide, or fluticasone) versus inhaled long acting β_2 agonist (salmeterol) or inhaled nedocromil improve symptoms and lung function in children with asthma.

Benefits: **Versus placebo:** We found one systematic review (search date 1996, 24 RCTs, 1087 children, 10/24 RCTs in preschool children, duration 4–88 weeks) comparing effects of regular inhaled corticosteroids (betamethasone, beclometasone, budesonide, flunisolide, or fluticasone) versus placebo on asthma symptoms (see comment below), concomitant drug use, and peak expiratory flow rate (PEFR).[22] It found that corticosteroids significantly improved

symptom score (overall weighted relative improvement in symptom score 50%, 95% CI 49% to 51%), reduced β_2 agonist use (RR 0.37, 95% CI 0.36 to 0.38), reduced oral corticosteroid use (RR 0.68, 95% CI 0.66 to 0.70), and improved peak flow rate (weighted mean improvement in PEFR 11% predicted, 95% CI 9.5% to 12.5%). **Versus theophylline:** We found no systematic review. We found one RCT (195 children aged 6–16 years, followed for 12 months) comparing inhaled beclometasone (360 μg/day) versus oral theophylline.[23] It found no significant difference with inhaled beclometasone versus oral theophylline in the mean asthma symptom score (0 = no symptoms, 6 = incapacitating symptoms: mean score 0.5–0.8 for beclometasone *v* 0.6–0.9 for theophylline) with less use of bronchodilators and oral corticosteroids with inhaled beclometasone.[23] **Versus sodium cromoglicate:** We found no systematic review. We found four RCTs comparing inhaled corticosteroids (betamethasone, budesonide, fluticasone) versus inhaled sodium cromoglicate.[24–27] One RCT (20 children aged 6–14 years) found that betamethasone versus sodium cromoglicate significantly improved symptoms and lung function (mean PEFRs; $P < 0.001$).[24] The second RCT (crossover, 75 children aged 5–15 years) found that budesonide or fluticasone versus sodium cromoglicate significantly reduced bronchodilator use ($P < 0.05$) and lung function (forced expiratory volume in 1 second [FEV_1]; $P < 0.01$).[25] The third RCT (unblinded, 335 children aged 2–6 years) found that budesonide versus sodium cromoglicate significantly reduced the rate of asthma exacerbations over 52 weeks ($P \leq 0.001$). Asthma exacerbations were defined as use of systemic corticosteroids or additional maintenance treatment, emergency department or urgent care visit, or admission to hospital.[26] The fourth RCT (unblinded, multicentre, 225 children aged 4–12 years) found that fluticasone versus sodium cromoglicate significantly improved mean percentage PEFR (at 6–8 weeks; $P = 0.0001$) and symptoms (at 6–8 weeks; $P < 0.05$) but found no significant difference for relief medication use or FEV_1.[27] **Versus nedocromil:** We found no systematic review. We found one RCT (1041 children aged 5–12 years, with mild to moderate asthma, mean prestudy FEV_1 94% predicted, all using salbutamol [see glossary, p 356]) for asthma symptoms) that compared inhaled budesonide (200 μg twice daily) and inhaled nedocromil (8 mg twice daily) versus placebo for 4–6 years.[28] It found no significant difference with budesonide compared with nedocromil or placebo in lung function, hospital admission rate, or the symptom score on diary cards but found that budesonide was superior to nedocromil, and that nedocromil was superior to placebo in several measures of asthma symptoms and morbidity (see table 1, p 359). The mean change in post-bronchodilator FEV_1 over the study period was not significantly different among the three groups. **Versus inhaled long acting β_2 agonists:** We found no systematic review but found two RCTs of beclometasone (200 μg twice daily) versus salmeterol (50 μg twice daily) for 1 year.[29,30] The first RCT (67 children aged 6–16 years) found that beclometasone was more effective than salmeterol in improving FEV_1 (mean change of FEV_1 −4.5% of predicted with salmeterol, 95% CI −9.0% to +0.1% *v* +10% with beclometasone, CI not reported; mean difference beclometasone *v* salmeterol

14.2%, 95% CI 8.3% to 20.0%), reducing the use of rescue salbutamol (0.44 uses/day with salmeterol *v* 0.07 uses/day with beclometasone; $P \leq 0.001$).[29] Both treatments improved symptom scores (before trial 3% of children asymptomatic with salmeterol *v* 6% with beclometasone; at 1 year 36% with salmeterol *v* 55% with beclometasone) and PEFR (improvement in morning PEFR 49 L/minute with salmeterol *v* 61 L/minute with beclometasone), but there was no significant difference between treatments at 1 year. There were two exacerbations in the beclometasone group compared with 17 in the salmeterol group.[29] The second RCT (241 children aged 6–14 years) compared beclometasone (81 children) versus salmeterol (80 children) versus placebo (80 children).[30] It found that beclometasone reduced airway hyperresponsiveness more than salmeterol (methacholine PC20 36 hours after study medication 12 months into the study: 2.1 mg/mL with beclometasone *v* 0.9 mg/mL with salmeterol; $P = 0.009$). Beclometasone versus placebo reduced rescue bronchodilator use (92% with beclometasone *v* 83% with placebo days and nights without need for salbutamol; $P \leq 0.001$) and treatment withdrawals because of exacerbations (5 with beclometasone *v* 15 with placebo; $P = 0.03$). Salmeterol versus placebo did not significantly reduce the use of a rescue bronchodilator (88% with salmeterol *v* 83% with placebo days and nights without need for salbutamol; $P = 0.09$) or treatment withdrawals because of exacerbations (15 with salmeterol *v* 15 with placebo; $P = 0.55$). Both salmeterol and beclometasone improved FEV_1 compared with placebo, but the difference between beclometasone and salmeterol was not significant (10% with beclometasone *v* 10% with salmeterol *v* 5% with placebo). **Versus oral montelukast:** We found no RCTs comparing inhaled corticosteroids versus oral montelukast in children. A systematic review of mainly adult studies comparing inhaled corticosteroids with leukotriene receptor antagonists found similar exacerbation rates, but greater improvement in lung function and symptoms with inhaled steroids.[31] See benefits section of leukotriene antagonists in adults with mild to moderate, persistent asthma option in asthma in adults topic, p 1966.

Harms:

Versus placebo: One systematic review (search date 1996) found no significant difference with inhaled corticosteroids (betamethasone, budesonide, flunisolide, or fluticasone) versus placebo in adrenal function (12 RCTs) and found clinical cases of oral candidiasis (4 RCTs).[22] Case reports[32] and a national survey of paediatricians and endocrinologists[33] have indicated the possibility of adrenal suppression leading to adrenal crisis associated with hypoglycaemia in children on high dose inhaled corticosteroids. Most cases involved fluticasone, in daily doses of 500–2000 μg. Observational studies have found little or no biochemical evidence of change in bone metabolism with inhaled corticosteroids.[34,35] Two cross-sectional studies using a slit lamp to screen for lenticular changes in children taking long term inhaled corticosteroids (beclometasone, budesonide) found no posterior subcapsular cataracts.[36,37] The systematic review identified eight RCTs reporting growth velocity and found no significant difference with inhaled corticosteroids versus placebo.[22] One systematic review (search date 1993, 21 studies) reported height for age in 810 children with

asthma treated with oral or inhaled corticosteroids. It found no evidence of growth impairment with inhaled beclometasone (12 studies, 331 children).[38] A second systematic review (search date 1999, 3 RCTs) identified one RCT (94 children, aged 7–9 years) comparing effect of inhaled beclometasone (400 μg/day) versus placebo on growth as a primary outcome measure in children with recurrent viral induced wheeze.[39] It found a significant decrease in growth with beclometasone versus placebo (mean growth at end of 7 month treatment period, 2.7 cm with beclometasone *v* 3.7 cm with placebo; 95% CI –1.4 cm to –0.6 cm; $P < 0.0001$) and found no significant catch up growth during a follow up 4 month washout period.[40] We found one large subsequent RCT that evaluated the effects of inhaled budesonide on growth in children with mild asthma.[41] The RCT found that children receiving budesonide grew less than children receiving placebo over 3 years (1 RCT, 3195 children aged 5–17 years; mean difference in growth per year: –0.43 cm, 95% CI –0.54 cm to –0.32 cm; $P < 0.0001$). The differences in growth rate were similar between children under 11 years treated with budesonide 200 μg per day (–0.45 cm per year, 95% CI –0.56 cm to –0.34 cm; $P < 0.0001$) and children over 11years being treated with budesonide 400 μg per day (–0.40 cm per year, 95% CI –0.66 cm to –0.14 cm; $P = 0.003$). In children less than 11 years being treated with 200 μg per day, the effect was more pronounced during the first year (–0.58 cm per year, 95% CI –0.76 cm to –0.40 cm; $P < 0.0001$) than during the third year (–0.33 cm per year, 95% CI –0.52 cm to –0.14 cm; $P = 0.0005$).[41]

Versus theophylline or sodium cromoglicate: One RCT compared inhaled beclometasone (360 μg/day) versus oral theophylline for 1 year.[23] It found a significantly higher rate of growth (more notable in boys) in the theophylline group (mean rate of growth in prepubescent boys 4.3 cm/year with beclometasone *v* 6.2 cm/year with theophylline). This effect was not sufficient to be noticed by the children or by their parents, and no child was withdrawn from the study on this account.[23] One controlled, prospective study compared 216 children treated with budesonide (400–600 μg/day) with 62 children treated with theophylline or sodium cromoglicate over 3–5 years' follow up.[42] No significant changes in growth velocity were found at doses up to 400 μg/day (5.5 cm/year with budesonide *v* 5.6 cm/year with controls). The adult height of 142 of these budesonide treated children (mean treatment period 9.2 years, mean dosage 412 μg/day) was compared with 18 controls never treated with inhaled corticosteroids and 51 healthy siblings. There were no significant differences. Children in all groups attained their target adult height (mean difference between measured and target adult height: +0.3 cm, 95% CI –0.6 cm to +1.2 cm for budesonide treated children; –0.2 cm, 95% CI –2.4 cm to +2.1 cm for control children with asthma; +0.9 cm, 95% CI –0.4 cm to +2.2 cm for healthy siblings).[43] Two RCTs found no clinically relevant differences between inhaled corticosteroids (betamethasone, budesonide) and sodium cromoglicate.[24,26] One RCT found that budesonide versus fluticasone or sodium cromoglicate significantly reduced growth (decrease in height standard deviation score > 2 standard deviation compared with mean height standard deviation score change during preceding year; $P < 0.05$).[25] Another RCT found that a

higher proportion of children taking sodium cromoglicate withdrew because of adverse events (breathlessness and wheeze, burning sensation in chest, sore throat, sickness) compared with fluticasone.[27] **Versus nedocromil:** A large RCT (1041 children with mild to moderate asthma) compared budesonide (400 µg/day) versus nedocromil versus placebo with 4–6 years' follow up.[28] The mean increase in height in the budesonide group was 1.1 cm less than in the placebo group (22.7 cm with budesonide *v* 23.8 cm with placebo; P = 0.005); the difference occurred mainly within the first year of treatment.[28] **Versus inhaled long acting β_2 agonists:** Two RCTs comparing beclometasone with salmeterol found slowing in linear growth with beclometasone (growth over year of treatment 5.4 cm[29] and 6.1 cm[30] in the salmeterol groups; 4.0 cm[29] and 4.7 cm[30] in the beclometasone groups; P = 0.004;[29] P = 0.007[30]). One RCT comparing inhaled beclometasone versus salmeterol found that symptom improvement in the salmeterol group was accompanied by significant deterioration in bronchial reactivity, indicating a failure to control underlying bronchial inflammation.[29]

Comment: Treatment with inhaled corticosteroids should be reviewed regularly and the dose gradually reduced to the lowest that is compatible with good symptom control.

OPTION INHALED SODIUM CROMOGLICATE

One systematic review found insufficient evidence for prophylactic treatment with inhaled sodium cromoglicate in children aged 1–18 years. Several small comparative RCTs found sodium cromoglicate to be less effective than inhaled corticosteroids in improving symptoms and lung function.

Benefits: **Versus placebo:** We found one systematic review (search date 1999, 24 RCTs, about 1000 children aged 0–18 years with moderate to severe asthma) comparing inhaled sodium cromoglicate versus placebo.[44] The RCTs differed in design, severity of asthma, number of children included, age of children, duration of intervention, and follow up period. The review found heterogeneity between RCTs but did not separately analyse RCTs in terms of asthma severity, age of children, or the outcome measured. The review found that sodium cromoglicate versus placebo significantly improved symptom scores for cough (point estimate not reported; 95% CI 0.11 to 0.26) and wheeze (point estimate not reported; 95% CI 0.13 to 0.27) but also found significant publication bias by the absence of small, negative trials (P = 0.01 for cough and wheeze). The review concluded that there is insufficient evidence for prophylactic treatment with sodium cromoglicate in children with asthma. **Versus inhaled corticosteroids:** See benefits of inhaled corticosteroids, p 340.

Harms: **Versus placebo:** Fifteen RCTs included in the systematic review reported adverse effects described as minor and of low incidence, including cough, bitter taste, wheezing, sneezing, throat irritation, and perioral eczema.[44] **Versus inhaled corticosteroids:** See harms of inhaled corticosteroids, p 342.

Comment: The conclusions of the systematic review[44] have been criticised in correspondence and the assertion made that analysis of trials using sodium cromoglicate by spinhaler in children over 5 years of age was consistent with a beneficial effect of sodium cromoglicate compared with placebo.[45]

OPTION INHALED NEDOCROMIL

Two RCTs in children aged 6–12 years found that, compared with placebo, inhaled nedocromil reduces asthma symptom scores, asthma severity, bronchodilator use, and improves lung function. One large RCT in children aged 5–12 years with mild to moderate asthma found no significant difference between nedocromil and budesonide or placebo in lung function, hospital admission rate, or the symptom score on diary cards, but found that budesonide was superior to nedocromil, and that nedocromil was superior to placebo in several measures of asthma symptoms and morbidity.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[46,47] The first RCT (209 children and adolescents aged 6–7 years allowed to continue using usual medication) compared inhaled nedocromil (4 mg 4 times daily) versus placebo for 12 weeks. Symptoms were recorded by the children in daily diary cards, including scoring day and night time asthma and cough severity, use of all medication, and morning and evening peak expiratory flow rates. The RCT found that inhaled nedocromil versus placebo significantly reduced total symptom scores, clinician assessed asthma severity, β_2 agonist use, and improved lung function (forced expiratory volume in 1 second).[46] The second RCT (parallel group study, 79 children aged 6–12 years recovering from acute asthma and allowed to use inhaled bronchodilators) compared inhaled nedocromil (2 mg 3 times daily) versus placebo for 12 weeks.[47] Symptoms were recorded by the children in daily diary cards, including day and night time asthma severity, morning and evening peak expiratory flow rates, and usage of bronchodilators. The RCT found that after 6 weeks, inhaled nedocromil versus placebo significantly improved (from baseline) the morning peak expiratory flow rate (difference, 20 L/minute; $P = 0.036$), evening peak expiratory flow rate (difference, 22 L/minute; $P = 0.033$), night time asthma score (difference on a 5 point scale, 0.48; $P = 0.001$), and daytime asthma score (difference on a 5 point scale, 0.38; $P = 0.03$). The RCT found no significant difference before 6 weeks of treatment. **Versus inhaled corticosteroids:** See benefits of inhaled corticosteroids, p 340.

Harms: **Versus placebo:** Sore throat and headache were reported marginally more often with nedocromil than placebo in the first RCT.[46] The second RCT found no significant difference between nedocromil and placebo in adverse event rates except for more frequent respiratory adverse events with placebo.[47] **Versus inhaled corticosteroids:** See harms of inhaled corticosteroids, p 342.

Comment: None.

OPTION INHALED LONG ACTING β_2 AGONISTS

Two RCTs in children aged 4–14 years found that, compared with placebo, inhaled salmeterol improved lung function but found conflicting evidence about reduced use of salbutamol. One RCT comparing inhaled salmeterol with beclometasone found that salmeterol was associated with a significant deterioration in bronchial reactivity.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[30,48] The first RCT (241 children aged 6–14 years with clinically stable asthma and < 1 month of prior glucocorticoid use) compared inhaled salmeterol (80 children) versus beclometasone (81 children) versus placebo (80 children) for 1 year.[30] The RCT found that salmeterol versus placebo significantly improved lung function (mean change in forced expiratory volume in 1 second as a percentage of predicted, 10% with salmeterol *v* 5% with placebo; $P < 0.001$) but found no significant difference in the use of rescue salbutamol (see glossary, p 356) ($P = 0.09$) or withdrawals because of exacerbations ($P = 0.55$).[30] The second RCT (parallel group study, 207 children aged 4–11 years with asthma diagnosed according to American Thoracic Society guidelines, forced expiratory volume in 1 second [without medication] 50–80% predicted) compared inhaled salmeterol (50 μg twice daily) versus placebo for 12 weeks.[48] The RCT found that salmeterol significantly improved lung function compared with placebo (change in mean morning peak expiratory flow 25 L/minute with salmeterol *v* 13.2 L/minute with placebo; $P < 0.001$; change in mean evening peak expiratory flow 20 L/minute with salmeterol *v* 10.1 L/minute with placebo; $P = 0.01$) and reduced salbutamol use (–0.8 with salmeterol *v* –0.3 with placebo; $P = 0.004$). It found no significant difference in the number of nights without awakenings between salmeterol and placebo.[48] **Versus inhaled corticosteroids:** See benefits of inhaled corticosteroids, p 340.

Harms: **Versus placebo:** One RCT found no evidence of adverse effects from salmeterol over 1 year.[30] The second RCT found no significant difference between salmeterol and placebo for adverse effects.[48] **Versus inhaled corticosteroids:** See harms of inhaled corticosteroids, p 342. Long acting β_2 agonists occasionally cause tremor or tachycardia.

Comment: Monotherapy with long acting β_2 agonists is not advised because of the possibility of significant deterioration in bronchial reactivity indicating a failure to control underlying bronchial inflammation (see harms of inhaled corticosteroids, p 342).

OPTION ORAL THEOPHYLLINE

One small RCT in children aged 6–15 years found that, compared with placebo, oral theophylline increased mean morning peak expiratory flow rate and reduced the mean number of acute night time attacks and doses of bronchodilator used. Another RCT in children aged 6–16 years found no significant difference in improvement of asthma symptoms with oral theophylline compared with inhaled beclometasone, but found

greater use of bronchodilators and oral corticosteroids with theophylline over 1 year. Theophylline has serious adverse effects (cardiac arrhythmia, convulsions) if therapeutic blood concentrations are exceeded.

Benefits: We found no systematic review. **Versus placebo:** We found one RCT (crossover study, 24 children aged 6–15 years experiencing at least 2 night awakenings/week) comparing once daily oral sustained release theophylline (mean theophylline level of 11.2 mg/L) versus placebo for 6 weeks.[49] The RCT found that theophylline versus placebo significantly increased mean morning peak expiratory flow (244 L/minute with theophylline *v* 207 L/minute with placebo; $P < 0.001$) and significantly reduced the mean number of acute night time attacks (3.2 with theophylline *v* 10.7 with placebo; $P < 0.001$) and the mean number of doses of bronchodilator used (6.5 with theophylline *v* 23.7 with placebo; $P < 0.001$). **Versus inhaled corticosteroids:** See benefits of inhaled corticosteroids, p 340.

Harms: **Versus placebo:** One RCT found significantly higher rates of gastric symptoms including dyspepsia, nausea, and vomiting with oral sustained release theophylline versus placebo (30% with theophylline *v* 6% with placebo; $P < 0.001$).[49] One systematic review (search date not stated, 12 studies, 340 children) of the behavioural and cognitive effects of theophylline found no evidence of significant adverse effects.[50] Theophylline has serious adverse effects (cardiac arrhythmia, convulsions) if therapeutic blood concentrations are exceeded.[51] **Versus inhaled corticosteroids:** See harms of inhaled corticosteroids, p 342.

Comment: None.

OPTION ORAL LEUKOTRIENE RECEPTOR ANTAGONISTS

One RCT in children aged 6–14 years found that, compared with placebo, oral montelukast increased from baseline the mean morning forced expiratory volume in 1 second and reduced the total daily β_2 agonist use, but found no significant difference in daytime asthma symptom score or in nocturnal awakenings with asthma. Another RCT in children aged 2–5 years found that, compared with placebo, oral montelukast improved average daytime symptom scores and reduced the need for rescue oral steroid courses, but found no significant difference in average overnight asthma symptom scores. We found no RCTs directly comparing oral montelukast with inhaled corticosteroids.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[52,53] The first RCT (parallel group study, 336 children aged 6–16 years with mean forced expiratory volume in 1 second 72% predicted, concomitant inhaled steroid treatment in 33% of placebo group and 39% of montelukast group) compared oral montelukast (5 mg/day) versus placebo for 8 weeks.[52] The RCT found that montelukast versus placebo significantly increased (from baseline) the mean morning flow expiratory volume in 1 second (8.2% with montelukast *v* 3.6% with placebo; $P < 0.001$) and significantly reduced the total daily β_2 agonist use (reduced by 13% with montelukast and increased by 9.5% with placebo; $P = 0.01$).[52] The RCT found no significant difference between montelukast versus

placebo in daytime asthma symptom score or in nocturnal awakenings with asthma.[52] The second RCT (parallel group study, 689 children aged 2–5 years, concomitant inhaled steroid treatment in 29% of the placebo group, 27% of the montelukast group, 2 : 1 ratio montelukast : placebo group) compared oral montelukast (4 mg/day) versus placebo for 12 weeks.[53] The RCT found that montelukast versus placebo significantly improved average daytime symptom scores (improved by 0.37 with montelukast *v* 0.26 with placebo on a 6 point scale; P = 0.003) and reduced the need for rescue oral steroid courses (needed in 19% with montelukast *v* 28% with placebo; P = 0.008). The RCT found no significant difference between montelukast versus placebo in average overnight asthma symptom scores.[53] **Versus inhaled corticosteroids:** We found no RCTs comparing oral montelukast versus inhaled corticosteroids directly.

Harms: **Versus placebo:** Two RCTs found no significant difference in the incidence of adverse effects with montelukast versus placebo.[52,53]

Comment: None.

QUESTION **What are the effects of additional prophylactic treatments in childhood asthma inadequately controlled by standard dose inhaled corticosteroids?**

Duncan Keeley

OPTION **INCREASED DOSE OF INHALED CORTICOSTEROID**

One RCT in children aged 6–16 years taking inhaled beclometasone comparing the addition of a second dose of inhaled corticosteroid (beclometasone) with placebo found no significant difference in lung function, symptom scores, exacerbation rates, or bronchial reactivity but found a reduction in growth velocity at 1 year.

Benefits: We found no systematic review but found one RCT (177 children, age 6–16 years, 1 year of follow up, mean pre-bronchodilator flow expiratory volume in 1 second 86% predicted) comparing beclometasone (200 µg twice daily), salmeterol (50 µg twice daily), and placebo in children already taking beclometasone (200 µg twice daily).[54] No significant differences were found at 1 year in lung function (mean change in flow expiratory volume in 1 second 5.8% of predicted, 95% CI 2.9% to 8.7% with double dose beclometasone *v* 4.3%, 95% CI 2.1% to 6.5% with placebo), symptom scores, exacerbation rates, bronchial reactivity, or changes in airway responsiveness (1.30 units of methacholine, 95% CI 0.73 to 1.87 with salmeterol *v* 0.80, 95% CI 0.33 to 1.27 with placebo). No benefit of either adding salmeterol or a second dose of beclometasone was found in this group of children, whose compliance with pre-existing medication was good.

Harms: Growth was significantly slower in children receiving higher dose inhaled corticosteroids (3.6 cm, 95% CI 3.0 cm to 4.2 cm with double dose beclometasone *v* 5.1 cm, 95% CI 4.5 cm to 5.7 cm with salmeterol *v* 4.5 cm, 95% CI 3.8 cm to 5.2 cm with placebo).

Comment: Higher dose inhaled corticosteroids are frequently used, despite lack of evidence of benefit. In some children, higher prescribed doses may compensate for poor compliance or incorrect inhaler technique.

OPTION ADDITION OF REGULAR LONG ACTING β_2 AGONIST

One RCT in children aged 6–16 years found that addition of inhaled salmeterol (a long acting β_2 agonist) increased peak expiratory flow rates in the first few months of treatment but found no increase after 1 year. A second short term RCT in children aged 4–16 years also found increased morning peak expiratory flow rates and more symptom free days at 3 months with addition of salmeterol.

Benefits: We found no systematic review but found two RCTs.[54,55] One RCT (177 children) found that at 1 year the addition of inhaled salmeterol did not improve lung function, airway responsiveness, symptom scores, exacerbation rates, or bronchial reactivity.[54] Salmeterol versus placebo increased mean morning peak expiratory flow rates slightly after 3 months (difference: +12 L/minute). There were no significant differences in symptom scores at any time. The second RCT (210 children aged 4–16 years, 12 weeks' follow up, mean morning peak flow expiratory rate 79% predicted) compared salmeterol (50 μg twice daily) versus placebo in children inadequately controlled on inhaled corticosteroids (average dose 750 μg/day).[55] At 12 weeks, mean morning peak expiratory flow rate (relative to the predicted peak flow expiratory rate) was 4% higher in the salmeterol group. Mean evening peak expiratory flow rate was not significantly different. The median proportion of symptom free days improved more with salmeterol than with placebo (60% with salmeterol *v* 30% with placebo for the third month of treatment).

Harms: The RCTs found no significant adverse effects associated with salmeterol.[54,55]

Comment: The second RCT was organised and funded by the manufacturer of salmeterol. Studies of adults with poor control on low dose inhaled corticosteroids have found greater benefit with additional long acting β_2 agonists than with higher doses of inhaled steroid (see salmeterol *v* high dose inhaled corticosteroids in the chapter on asthma in adults, p 1966).

OPTION ADDITION OF ORAL THEOPHYLLINE

One small RCT found that addition of theophylline, compared with placebo, to previous treatment increased the proportion of symptom free days and reduced the use of additional β agonist (orciprenaline) and additional corticosteroid (beclometasone or prednisolone) over 4 weeks. We found insufficient evidence to weigh these short term benefits and possible long term harms.

Benefits: We found no systematic review but found one RCT (double blind crossover trial, 33 children, age 6–19 years, recruited from a hospital asthma clinic, 22 children using inhaled beclometasone [mean 533 μg/day], 11 using oral prednisolone [mean 30 mg alternate days]).[43] It found that the addition for 4 weeks of oral

theophylline (serum concentration 10–20 μg/mL) versus placebo increased the mean number of symptom free days (63% with theophylline *v* 42% with placebo; P ≤ 0.01). Inhaled β agonist (orciprenaline — see glossary, p 356) was needed twice as often with placebo (0.5 doses/day with theophylline *v* 1.0 with placebo; P ≤ 0.01). Additional daily prednisolone was needed by fewer children while on theophylline than while on placebo (3/32 [9%] with theophylline *v* 10/32 [31%] with placebo; P = 0.02).

Harms: In the RCT, short term adverse effects included mild transient headache and nausea in six children after the crossover from placebo to the theophylline dose that they had previously tolerated.[56]

Comment: One child was excluded from the analysis because of poor compliance. The RCT was too brief to assess long term harms.

OPTION ADDITION OF ORAL LEUKOTRIENE RECEPTOR ANTAGONISTS

One crossover RCT in children aged 6–14 years with persistent asthma who had been taking inhaled budesonide for at least 6 weeks found that, compared with addition of placebo, oral montelukast (a leukotriene receptor antagonist) reduced asthma exacerbations over 4 weeks. This difference was statistically significant but modest in clinical terms.

Benefits: We found no systematic review but found one crossover RCT (279 children aged 6–14 years previously treated with inhaled corticosteroid for at least 6 weeks, with mean forced expiratory volume in 1 second 78% predicted after 1 month run-in with budesonide 200 μg) comparing adding oral montelukast versus placebo to inhaled budesonide over 4 weeks.[57] It found fewer asthma exacerbation days (decrease from baseline peak flow of > 20%, or increase from baseline of β_2 agonist use of > 70%) with montelukast versus placebo (12.2% with montelukast *v* 15.9% with placebo; P = < 0.001). No significant differences were found in quality of life measurements, global evaluations, or asthma attacks requiring unscheduled medical intervention or treatment with oral corticosteroid.

Harms: The RCT found no significant difference with montelukast versus placebo in asthma exacerbation, upper respiratory tract infection, headache, cough, pharyngitis, and fever.[57]

Comment: The RCT in children was brief (4 weeks treatment).[57] We found one large RCT of montelukast added to beclometasone in adults with inadequately controlled asthma that found benefit over a 16 week period.[58] Both RCTs were funded by the manufacturers of montelukast.

QUESTION What are the effects of treatments for acute wheezing in infants?

Michael McKean

OPTION SHORT ACTING β_2 AGONISTS

One RCT in infants aged 3 months to 2 years found that nebulised salbutamol improved respiratory rate and clinical symptom score compared with placebo but found no significant difference in hospital admission. Another RCT that included infants aged less than 18 months to 36 months found no significant difference in change from baseline in clinical symptom scores with nebulised salbutamol compared with placebo. Two RCTs in children aged up to 5 years found no significant difference in hospital admission with delivery of salbutamol through a metered dose inhaler plus spacer compared with nebulised salbutamol. Another RCT in infants aged 1–24 months found no significant difference in improvement of symptoms with delivery of terbutaline through a metered dose inhaler plus spacer compared with nebulised terbutaline. Nebulised β_2 agonists may cause tachycardia, tremor, and hypokalaemia.

Benefits:

Nebulised salbutamol versus placebo: We found one systematic review (search date not stated)[59] that identified two RCTs in children with an acute exacerbation of wheeze in hospital emergency room settings.[60,61] One RCT (28 infants aged 3 months to 2 years) compared nebulised salbutamol (see glossary, p 356) (0.3 mg/kg in 2 doses over 1 hour) versus placebo on respiratory rate and symptom score (assessment of heart rate, respiratory rate, wheeze, and accessory muscle score).[60] The RCT found that nebulised salbutamol versus placebo significantly improved respiratory rate (WMD –5.10 breaths/minute, 95% CI –9.45 breaths/minute to –0.75 breaths/minute) and total clinical symptom score for heart rate, respiratory rate, wheezing, and accessory muscle use (clinical symptom score on scale 0 [none] to 3 [severe], WMD –2.50, 95% CI –3.88 to –1.12) but found no significant difference in hospital admission (OR 1.95, 95% CI 0.27 to 13.98).[60] The second RCT (28 infants aged < 18 months and 13 infants aged 18–36 months with acute wheeze) found no significant difference in change from baseline in clinical symptom scores with nebulised salbutamol (2 doses of 0.15 mg/kg) versus placebo groups. Some improvement was observed in children aged more than 18 months, but this was not statistically significant.[61] **Delivery through metered dose inhaler versus nebuliser:** We found no systematic review. We found three RCTs comparing delivery of short acting β_2 agonists through metered dose inhaler versus nebuliser.[62–64] The first RCT (64 children aged 1–5 years with acute recurrent wheezing) found no significant difference in hospital admissions with delivery of salbutamol (50 μg/kg) through a metered dose inhaler plus spacer versus nebulised salbutamol (150 μg/kg).[62] The second RCT (42 infants, mean age < 2 years with acute wheezing) found no significant difference in hospital admissions with delivery of salbutamol (400 μg) through a metered dose inhaler plus spacer versus nebulised salbutamol (2.5 mg).[63] The third RCT (34 infants aged 1–24 months) found no significant difference in the rate

of improvement from baseline of a clinical score (assessing respiratory rate, wheezing, retractions, degree of cyanosis, colour, and pulse oximetry data) with delivery of terbutaline (500 μg) through a metered dose inhaler plus spacer versus nebulised terbutaline (4 mg).[64]

Harms: **Nebulised salbutamol versus placebo:** The systematic review did not comment on any adverse effects of nebulised salbutamol in infants with acute wheezing.[59] Nebulised β_2 agonists may cause tachycardia, tremor, and hypokalaemia.[63] **Delivery through metered dose inhaler versus nebuliser:** Three RCTs found no clinically significant adverse events.[62–64]

Comment: None.

OPTION INHALED IPRATROPIUM BROMIDE

We found no RCTs comparing inhaled ipratropium bromide with placebo. One RCT identified by a systematic review in infants aged 3–24 months found that addition of ipratropium bromide to fenoterol compared with fenoterol alone reduced the proportion of infants receiving further treatment 45 minutes after initial treatment.

Benefits: **Versus placebo:** We found no systematic review and no RCTs. **Addition to long acting β_2 agonist:** We found one systematic review (search date not stated), which identified one RCT in infants aged under 2 years with wheeze.[65] The RCT (61 infants aged 3–24 months with acute wheeze) found that addition of ipratropium bromide (50 μg) to fenoterol (0.1 mg/kg) versus fenoterol (0.1 mg/kg) alone significantly reduced the proportion of infants receiving further treatment 45 minutes after initial treatment (OR 0.22, 95% CI 0.08 to 0.61).

Harms: The systematic review found no evidence of harm specific to the use of ipratropium bromide.[65]

Comment: The results of the review do not support the widespread, indiscriminate use of anticholinergic agents in the treatment of children under the age of 2 years with airways obstruction and wheeze. It is possible that infants did obtain symptomatic relief but that this was not always identified by the outcomes chosen.

OPTION ORAL CORTICOSTEROIDS

One small RCT found no significant difference in daily symptom scores with oral prednisolone compared with placebo.

Benefits: We found no systematic review. We found one RCT (38 acutely wheezing infants aged 3–17 months with wheezing episode lasting ≥ 48 hours, including 30 infants who had previously been admitted to hospital with wheeze)[66] comparing oral prednisolone (2 mg/kg/day) versus placebo given for 5 days during an acute wheezing episode. It found no significant difference in daily symptom scores (cough, wheeze, breathlessness) for the 56 acute wheezing episodes studied.[66]

Harms: The RCT found no adverse effects.[66]

Comment: None.

OPTION HIGH DOSE INHALED CORTICOSTEROIDS

One systematic review found that high dose inhaled corticosteroids compared with placebo reduced the requirement for oral corticosteroids but the difference was not statistically significant. The review also found a clear preference for the inhaled corticosteroids by the children's parents over placebo. The clinical importance of these results is unclear.

Benefits: We found one systematic review (search date not stated, 2 RCTs in infants with acute viral wheeze [see glossary, p 356]).[67] The primary outcome for the review was wheeze episodes requiring oral corticosteroids. The review found that episodic high dose inhaled corticosteroids (budesonide, beclometasone) reduced the need for oral corticosteroids compared with placebo, but the difference was not statistically significant (2 crossover RCTs, 67 infants; RR 0.53, 95% CI 0.27 to 1.04). The review also found a clear preference for the inhaled corticosteroids by the children's parents over placebo (2 crossover RCTs, 67 infants; RR 0.64, 95% CI, 0.48 to 0.87).[67]

Harms: The systematic review did not report any adverse events. See harms of inhaled corticosteroids, p 342.[67]

Comment: Most of the RCTs included in the systematic review were carried out before the 1990s, when it was commonly thought that wheeze was synonymous with asthma and different patterns of wheeze in young children were seldom recognised. Although there is some evidence to support the use of high dose inhaled corticosteroids in acute episodes of viral wheeze, the practicalities of delivering treatment may limit applicability.

QUESTION What are the effects of prophylactic treatments for wheezing in infants?

Michael McKean

OPTION INHALED IPRATROPIUM BROMIDE

One small RCT identified by a systematic review found no significant difference in relief of symptoms with nebulised ipratropium bromide compared with placebo. The study may have lacked power to exclude a clinically important difference between treatments.

Benefits: We found one systematic review (search date not stated),[65] which found one RCT of high quality, although the power of the RCT was low.[68] The RCT (crossover, 23 infants aged 4–23 months) compared nebulised ipratropium bromide versus placebo or sodium cromoglicate. The RCT found no significant difference in relief of symptoms, as defined by diary cards, for ipratropium bromide versus placebo (OR 0.60, 95% CI 0.19 to 1.88).[68]

Harms: The RCT reported no significant adverse effects with ipratropium bromide.[68]

Comment: The study may have lacked power to exclude a clinically important difference between treatments. We found insufficient data to support the use of ipratropium bromide as a prophylactic agent for wheezing in infants.

OPTION SHORT ACTING β_2 AGONISTS

Two RCTs identified by a systematic review in infants aged up to 2 years found no significant improvement in symptoms with inhaled salbutamol compared with placebo. Another RCT identified by the same systematic review in infants aged 3–14 months found that oral salbutamol compared with placebo reduced treatment failures.

Benefits: We found one systematic review (search date not stated), which identified three RCTs in infants aged under 2 years with recurrent wheeze but no apparent history of acute viral bronchiolitis.[59] **Inhaled short acting β_2 agonists:** One RCT (crossover, 80 infants aged < 1 year with persistent or recurrent wheeze and a personal or family history of atopy) compared inhaled salbutamol (see glossary, p 356) (200 μg/day) versus placebo for 4 weeks. It found no significant difference between salbutamol versus placebo in symptoms (recorded in a diary) or lung function.[69] Another RCT (29 infants aged 2–18 months with a history of recurrent wheeze) compared inhaled salbutamol (600 μg) plus inhaled beclometasone (300 μg) versus inhaled salbutamol (600 μg) alone or placebo for 6 weeks.[70] It found no significant improvement in symptoms (cough, wheezing, sleep problems, expectorations) with salbutamol versus placebo.[70] **Oral short acting β_2 agonists:** One RCT (59 infants aged 3–14 months with at least 1 previous wheezy episode) compared oral salbutamol plus placebo, placebo plus prednisolone, and placebo plus placebo for 14 days.[71] It found that oral salbutamol versus placebo significantly reduced treatment failures (RR 2.51, 95% CI 1.09 to 5.79) and found no significant difference between salbutamol alone and the combination of salbutamol plus prednisolone.[71]

Harms: **Inhaled short acting β_2 agonists:** The RCTs did not report any adverse events.[69,70] **Oral short acting β_2 agonists:** The RCTs did not report any adverse events.[71]

Comment: None.

OPTION INHALED CORTICOSTEROIDS

Three RCTs found no clear evidence of effectiveness with lower prophylactic doses of inhaled corticosteroids (budesonide) in children aged 1 week to 6 years with recurrent wheeze. One RCT in infants aged 6–30 months found that higher prophylactic doses of inhaled corticosteroids (budesonide) compared with placebo reduced symptoms and the proportion of children with acute wheezing episodes during a 12 week period but found no significant reduction in the proportion of wheezing episodes per infant. Another RCT in infants aged 11–36 months found that higher prophylactic doses of inhaled corticosteroid (budesonide) reduced the proportion of days requiring oral prednisolone and symptoms of wheezing and sleep disturbance, but found no significant improvement for cough. Higher doses of inhaled

corticosteroids have the potential for adverse effects. One RCT found no significant improvement in symptoms with the addition of inhaled beclometasone compared with placebo to inhaled salbutamol.

Benefits: We found one systematic review (search date not stated)[67] and four additional RCTs.[72–75] **Lower dose versus placebo:** The systematic review identified one RCT.[76] The RCT (57 children aged 8 months to 6 years) found no significant difference after 4 months in acute episodes of wheeze with inhaled budesonide (400 μg/day by metered dose inhaler) versus placebo.[76] The RCT did not analyse infants separately. The first additional RCT (29 infants aged 4–17 months with recurrent wheeze) found that inhaled budesonide (150 μg through a metered dose inhaler) versus placebo significantly improved some symptoms (breathlessness, daytime wheeze, daytime cough) but not others (night time wheeze and cough), and found no significant difference in the need for bronchodilators.[74] The second additional RCT (60 infants aged 1–42 weeks ready for discharge after an episode of acute viral bronchiolitis requiring hospital admission) compared inhaled budesonide (200 μg/day through a metered dose inhaler) versus placebo for 12 months.[75] Symptoms of coughing and wheezing were recorded in a diary kept by parents. The RCT found no significant difference after 6 months in symptoms of coughing and wheezing with inhaled budesonide versus placebo.[75] **Higher dose versus placebo:** One additional RCT (40 infants aged 6–30 months with severe asthma) compared nebulised budesonide (1 mg twice daily) versus placebo for 12 weeks.[72] The RCT found that nebulised budesonide versus placebo significantly reduced the proportion of children with acute wheezing episodes (40% with budesonide *v* 83% with placebo; $P < 0.01$), incidence of daytime wheezing (2.2% with budesonide *v* 11.6% with placebo; $P < 0.05$), and incidence of night time wheezing (0.6% with budesonide *v* 6.5% with placebo; $P < 0.01$) but did not significantly reduce the number of acute wheezing episodes per child (0% with budesonide *v* 1% with placebo; $P = 0.13$). The second additional RCT (77 infants aged 11–36 months with moderate to severe recurrent wheezing) compared inhaled budesonide (400 μg twice daily) versus placebo for 12 weeks.[73] The RCT found that budesonide versus placebo significantly improved symptom scores from baseline for wheezing and sleep disturbance ($P < 0.05$ for both symptoms) but found no significant difference for cough or for restriction in physical activity because of coughing or wheezing. It also found that inhaled budesonide versus placebo significantly reduced the proportion of days requiring oral prednisolone.[73] **Addition of inhaled corticosteroid to short acting β_2 agonist:** We found one RCT (31 infants aged 13–18 months with recurrent wheeze) comparing the addition of inhaled beclometasone (200 μg twice daily) to inhaled salbutamol (see glossary, p 356) (taken when needed) versus addition of inhaled placebo to inhaled salbutamol (as needed).[76] It found no significant difference between adding beclometasone versus placebo in clinical score, number of salbutamol doses, sleep disturbance, or number of symptom free days.[77]

Harms: The RCTs did not report any adverse events.[72–77] Higher doses of inhaled corticosteroids have the potential for adverse effects (see harms of inhaled corticosteroids, p 342).

Comment: None.

Asthma and other wheezing disorders in children

GLOSSARY

Aminophylline A stable combination of theophylline and ethylenediamine; the ethylenediamine is added to increase the solubility of theophylline in water.
Clinical asthma score is used to assess asthma severity. It involves five clinical variables (respiratory rate, wheezing, inspiratory–expiratory ratio, indrawing, dyspnoea), which are scored 0, 1, or 2. The scores for each variable are added together with a possible total score of 10.[78]
Orciprenaline is known as metaproterenol in USA; it is a non-selective β agonist.
Salbutamol is known as albuterol in USA; it is a short acting selective β_2 agonist.
Viral wheeze is defined as wheeze in association with nasal congestion and discharge but minimal or no intercurrent lower respiratory tract symptoms.

Substantive changes

Treating acute asthma in children: systemic corticosteroids One systematic review added;[11] option title change, conclusions unchanged
Single agent prophylaxis in childhood asthma: inhaled corticosteroids One RCT added;[41] information on effect of budesonide on growth in children, conclusions unchanged
Single agent prophylaxis in childhood asthma: inhaled sodium cromoglicate Evidence re-evaluated, categorisation changed to Unknown effectiveness
Treating acute wheeze in infants: inhaled ipratropium bromide Evidence re-evaluated, categorisation changed to Likely to be beneficial
Treating acute wheeze in infants Short acting β_2 agonists Evidence re-evaluated, categorisation changed to Likely to be beneficial

QUESTIONS

INTERVENTIONS

See glossary, p 370

Key Messages

Prevention

- **Respiratory syncytial virus immunoglobulins or palivizumab (monoclonal antibody) in children at high risk** One systematic review has found that, in children born prematurely, in children with bronchopulmonary dysplasia, and in children with a combination of risk factors, prophylactic respiratory syncytial virus immunoglobulin or palivizumab (monoclonal antibody) reduces admission rates to hospital and intensive care units compared with placebo or no prophylaxis.
- **Nursing interventions (cohort segregation, handwashing, gowns, masks, gloves, and goggles) in children admitted to hospital** We found no RCTs about the effects of these interventions to prevent spread of bronchiolitis to other children.

Treatment

- **Bronchodilators (inhaled salbutamol, inhaled adrenaline [epinephrine])** Systematic reviews have found that, inhaled bronchodilators achieve short term improvement in overall clinical scores compared with placebo in children treated in hospital, emergency departments, and outpatient clinics. They have found no evidence that bronchodilators reduce admission rates or produce a

clinically important improvement in oxygen saturation. Subsequent RCTs found no evidence that nebulised adrenaline, changed short term outcomes during the first 4 days of illness in infants or the duration of hospital stay compared with 0.9% sodiumk chloride. One small RCT found that nebulised adrenaline reduced the rate of hospital admission compared with salbutamol. However, we were unable to draw reliable conclusions from this small study.

- **Corticosteroids** One systematic review and 10 additional RCTs found limited and conflicting evidence on the effects of corticosteroids compared with placebo.
- **Routine broad spectrum antibiotics** We found no evidence in children with bronchiolitis alone. One unblinded RCT in children with bronchiolitis and uncomplicated pneumonia (crackles on auscultation or consolidation on a chest radiograph) found no significant difference in clinical scores with routine use of antibiotics (ampicillin, penicillin, or erythromycin) compared with placebo. However, the RCT may have lacked power to exclude a clinically important effect.
- **Ribavirin** One systematic review found insufficient evidence that ribavirin reduced mortality, risk of respiratory deterioration, or duration of hospital stay in children admitted to hospital with respiratory syncytial virus bronchiolitis. It found some evidence that ribavirin reduced the duration of mechanical ventilation. Two subsequent RCTs found no evidence that ribavirin reduced duration of hospital stay, admission rate because of lower respiratory tract symptoms during the first year after the acute episode, or the frequency of recurrent wheezing illness over 1 year of follow up.
- **Respiratory syncytial virus immunoglobulins, pooled immunoglobulins, or palivizumab (monoclonal antibody)** RCTs found insufficient evidence on the effects of immunoglobulin treatment.

DEFINITION Bronchiolitis is a virally induced acute bronchiolar inflammation that is associated with signs and symptoms of airway obstruction. Diagnosis is based on clinical findings. Clinical manifestations include fever, rhinitis (inflammation of the nasal mucosa), tachypnoea, expiratory wheezing, cough, rales, use of accessory muscles, apnoea (absence of breathing), dyspnoea (difficulty in breathing), alar flaring (flaring of the nostrils), and retractions (indrawing of the intercostal soft tissues on inspiration). Disease severity (see glossary, p 370) of bronchiolitis may be classified clinically as mild, moderate, or severe.

INCIDENCE/ PREVALENCE Bronchiolitis is the most common lower respiratory tract infection in infants, occurring in a seasonal pattern with highest incidence in the winter in temperate climates,[1] and in the rainy season in warmer countries. Each year in the USA, about 21% of infants have lower respiratory tract disease and 6–10/1000 infants are admitted to hospital for bronchiolitis (1–2% of children < 12 months of age).[2] The peak rate of admission occurs in infants aged 2–6 months.[3]

AETIOLOGY/ RISK FACTORS Respiratory syncytial virus is responsible for bronchiolitis in 70% of cases. This figure reaches 80–100% in the winter months. However, in early spring, parainfluenza virus type 3 is often responsible.[1]

PROGNOSIS **Morbidity and mortality:** Disease severity is related to the size of the infant, and to the proximity and frequency of contact with infective infants. Children at increased risk of morbidity and mortality are those with congenital heart disease, chronic lung disease,

history of premature birth, hypoxia, and age less than 6 weeks.[4] Other factors associated with a prolonged or complicated hospital stay include a history of apnoea or respiratory arrest, pulmonary consolidation seen on a chest radiograph, and (in North America) people of Native American or Inuit race.[5] The risk of death within 2 weeks is high for children with congenital heart disease (3.4%) or chronic lung disease (3.5%) as compared with other groups combined (0.1%).[4] Rates of admission to intensive care units (range 31–36%) and need for mechanical ventilation (range 11–19%) are similar among all high risk groups.[4] The percentage of these children needing oxygen supplementation is also high (range 63–80%).[4] In contrast, rates of intensive care unit admission (15%) and ventilation (8%) in such children are markedly lower.[6] **Long term prognosis:** Information on long term prognosis varies among studies. One small prospective study of two matched cohorts (25 children with bronchiolitis; 25 children without) found no evidence that bronchiolitis requiring outpatient treatment is associated with an increased risk of asthma in the long term.[7] Possible confounding factors include variation in illness severity, smoke exposure, and being in overcrowded environments.[8] We found one prospective study in 50 randomly selected infants admitted with bronchiolitis, followed up by questionnaires for 5 years and a visit in the fifth year. It found a doubling of asthma incidence compared with the general population, although there was large (30%) loss to follow up and no matched control group.[9]

AIMS OF INTERVENTION To decrease morbidity and mortality, shorten hospital stay, and prevent transmission of infection, with minimum adverse effects.

OUTCOMES Death rate; rates of hospital admission; rate of intubation or admission to intensive care units; clinical score (clinical score is a subjective, unvalidated measure that is based on judgements made by the clinician); rates of clinical and serological infection. Oxygen saturation is a proxy outcome, but the clinical significance and sensitivity of this outcome are unclear.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION What are the effects of prophylactic measures in high risk children?

OPTION IMMUNOGLOBULINS

One systematic review has found that, in children born prematurely or children with bronchopulmonary dysplasia, prophylactic respiratory syncytial virus immunoglobulin or palivizumab (monoclonal antibody) given monthly reduces hospital admission and admission to intensive care compared with placebo or no prophylaxis. Treatment duration varied between 4 and 6 months across studies.

Benefits: We found one systematic review (search date 1999, 4 RCTs, 2598 children) comparing monthly respiratory syncytial virus immunoglobulin (RSV Ig) or palivizumab (monoclonal antibody) with placebo or no prophylaxis.[10] Three of the RCTs used intravenous RSV Ig and one used intramuscular palivizumab. Two of the RCTs using RSV Ig were unblinded and both of them used no prophylaxis as the control

intervention. The review found that RSV Ig or palivizumab compared with placebo reduced admission to hospital. (95/1535 [6%] for RSV Ig or palivizumab *v* 138/1063 [13%] with placebo; OR 0.48, 95% CI 0.37 to 0.64) and intensive care unit (27/1535 [2%] for RSV Ig or palivizumab *v* 43/1063 [4%] with placebo; OR 0.47, 95% CI 0.29 to 0.77), but did not reduce the incidence of mechanical ventilation (16/1535 [1%] for RSV Ig or palivizumab *v* 14/1063 [1%] with placebo; OR 0.99, 95% CI 0.48 to 2.07). Follow up duration varied across studies in the systematic review from 150 days up to 17 months.[10]

Harms: See harms of immunoglobulins, p 370.

Comment: Premature infants included in the RCTs were children under 6 months old, with gestational age at birth of less than either 32 or 35 weeks. Children with bronchopulmonary dysplasia were under 2 years old and still undergoing treatment for this anomaly. Planned subgroup analysis in the review found that prophylaxis reduced hospital admission in children whose only risk factor was prematurity (OR 0.27, 95% CI 0.15 to 0.49) and in children with bronchopulmonary dysplasia alone (OR 0.54, 95% CI 0.37 to 0.80), but not in children with cardiac comorbidity alone (OR 0.64, 95% CI 0.37 to 1.10).[10] A cost-effectiveness analysis suggests that the clinical effect of palivizumab when used in all children who meet the licensed indication for it is small, and its benefits are likely to be clinically and economically relevant in children at the highest risk.[11]

QUESTION What are the effects of measures to prevent transmission in hospital?

OPTION NURSING INTERVENTIONS (COHORT SEGREGATION, HANDWASHING, GOWNS, MASKS, GLOVES, AND GOGGLES)

We found no direct evidence from RCTs that cohort segregation, handwashing, use of gowns, masks, gloves, or goggles reduced nosocomial transmission of respiratory syncytial virus to other children.

Benefits: We found no systematic review and no good quality RCTs examining effects of cohort segregation (see glossary, p 370), handwashing, gowns, masks, gloves, or goggles, used either singly or in combination, on nosocomial transmission of bronchiolitis in children.

Harms: **Cohort segregation:** Potential risks associated with cohort segregation include misdiagnosing respiratory syncytial virus infection and putting non-infected people at risk by subsequent placement into the wrong cohort. **Handwashing:** Dermatitis is a potential adverse effect of repeated handwashing with some products, affecting care providers. **Other interventions:** No harms reported.

Comment: Handwashing is a well established technique for reducing cross-infection in other contexts, and so RCTs may not be ethically feasible. **Single nursing interventions:** We found four observational studies comparing nosocomial infection rates in separate series of children before and after introduction of cohort segregation, handwashing, gowns and masks, and goggles.[12–15] No study

adjusted results for variations in baseline incidence. Three studies found a lower incidence of transmission after introduction of cohort segregation alone, handwashing alone, and eye–nose goggles alone.[12–14] The fourth study found no significant difference in transmission after introducing gowns and masks.[15] **Combinations of nursing interventions:** We found one RCT (58 medical personnel caring for children admitted with bronchiolitis), which found no significant difference in nosocomial infection rate in staff when they used gowns and masks in addition to handwashing (5/28 [18%] of those using gowns, masks, and handwashing *v* 4/30 [13%] in the control group; RR 1.3, 95% CI 0.4 to 3.6).[16] The RCT did not report transmission rates in the children. One non-randomised prospective trial (233 children at risk of severe nosocomial infection) compared transmission rates in wards using different nursing policies.[17] It found that a combination of cohort segregation, gowns, and gloves reduced nosocomial transmission rates compared with all other policies (cohort segregation alone, gown and gloves alone, no special precautions) taken together. However, the control interventions did not remain constant throughout the trial, the results were based on an interim analysis, and the definition of "at risk" children was not stated clearly.

QUESTION What are the effects of treatment for children with bronchiolitis?

OPTION BRONCHODILATORS (INHALED SALBUTAMOL, INHALED ADRENALINE [EPINEPHRINE])

Good quality systematic reviews have found that, inhaled bronchodilators overall clinical scores in the short term compared with placebo in children treated in hospital, emergency departments, and outpatient clinics. They have found no evidence that bronchodilators reduce admission rates or produce a clinically important improvement in oxygen saturation. Subsequent RCTs found no evidence that nebulised adrenaline, changed short term outcomes during the first 4 days of illness in infants or the duration of hospital stay compared with 0.9% sodium chloride. One small RCT found that nebulised adrenaline reduced the rate of hospital admission when compared with salbutamol.

Benefits:

Compared with placebo: We found two systematic reviews[18,19] and two subsequent RCTs.[20,21] The first review (search date 1998, 8 RCTs, 485 children) evaluated children in outpatient clinics or the emergency department and after admission to hospital.[18] The second review (search date 1995, 5 RCTs, 251 children) considered children treated in outpatient clinics.[19] Four RCTs were common to both reviews. The first review found that, in the short term, bronchodilators improved clinical scores in children with mild and moderately severe bronchiolitis (lack of improvement in clinical score, bronchodilator *v* placebo; RR 0.76, 95% CI 0.60 to 0.95).[18] Both reviews found evidence that bronchodilators improved oxygen saturation by a clinically unimportant amount (mean difference in oxygen saturation +1.2%, 95% CI +0.8% to +1.6%[19]). Both reviews found no evidence that bronchodilators compared with placebo reduced admission rates in children treated in outpatient

clinics or emergency departments (RR 0.85, 95% CI 0.47 to 1.53;[18] 23/97 [24%] children treated with bronchodilator admitted *v* 21/90 [23%] with placebo; RR 1.0, 95% CI 0.6 to 1.7[19]). The first subsequent RCT (38 infants without previous wheezing episodes) compared a single dose (3 mg in 3 mL) of nebulised levo-adrenaline (epinephrine) compared with 0.9% sodium chloride placebo during the first 4 days of their respiratory illness.[20] There were no significant differences in respiratory and heart rates, oxygen saturation, and the RDAI (see glossary, p 370) measured during the following 60 minutes. Results were reported graphically. The second RCT (149 hospitalised infants without previous history of wheezing and with a clinical diagnosis of acute viral bronchiolitis) compared nebulisations of racemic adrenaline (0.03 mL/kg/dose of a 2.25% solution), salbutamol (0.03 mL/kg/dose of a 5 mg/mL solution), and placebo (0.03 mL/kg/dose of 0.9% sodium chloride) given every 1–6 hours, at the discretion of the attending medical team. There were no significant differences in the length of hospital stay (placebo *v* adrenaline: mean difference +3.5 hours, 95% CI −18.6 hours to +25.6 hours; placebo *v* salbutamol: mean difference +1.9 hours, 95% CI −18.3 hours to +22.1 hours) or in the mean time to normal oxygenation, adequate fluid intake, RDAI of 4 or less, or infrequent nebulisations.[21] **Compared with other treatments:** We found four RCTs comparing nebulised adrenaline with salbutamol (see table 1, p 373).[21–24] The first RCT (24 sedated, hospitalised infants without previous wheeze) found a significant improvement in clinical scores after administration of racemic adrenaline, as compared with baseline score (mean difference 1.80, 95% CI 0.79 to 2.80), which was not present after salbutamol inhalation (mean difference +0.40, 95% CI −0.61 to +1.40).[22] However, the clinical importance of this finding is not clear, and a comparison between groups was not provided. The second RCT (42 infants aged 6 weeks to 1 year seen in the emergency department) compared inhaled adrenaline with salbutamol.[23] It found a significant improvement in oxygen saturation after 60 minutes of treatment in favour of adrenaline (mean difference 2%, CI not provided; P = 0.02). The clinical importance of this finding is unclear, given that this was one of many statistical comparisons and because the change is below the 3% difference in oxygen saturation that the authors had previously established as clinically important. It also found a significant reduction in admissions (7/20 [35%] with adrenaline *v* 17/21 [81%] with salbutamol; RR 0.43, 95% CI 0.23 to 0.81; NNT 3, 95% CI 2 to 7). The third RCT (100 infants aged 1–24 months, randomised in the emergency department to 4 treatments: nebulised racemic adrenaline followed by 0.9% sodium chloride placebo; nebulised salbutamol followed by 0.9% sodium chloride placebo; 0.9% sodium chloride placebo followed by racemic adrenaline; 0.9% sodium chloride placebo followed by salbutamol) found no significant differences in RDAI scores between the four groups during the study.[24] The fourth RCT that compared racemic adrenaline, salbutamol, and placebo did not find differences between adrenaline and salbutamol in any of the study outcomes (see above).[21]

Harms: One systematic review reported tachycardia, increased blood pressure, decreased oxygen saturation, flushing, hyperactivity, prolonged cough, and tremor after use of bronchodilators.[18] The review did not report the frequency of adverse events. The second review did not report harms.[19] One RCT reported a higher incidence of pallor in children treated with adrenaline than in those receiving salbutamol (at 30 minutes: 10/20 [50%] with adrenaline *v* 3/21 [14%] with salbutamol; RR 3.50, 95% CI 1.12 to 10.90; NNH 3, 95% CI 2 to 8).[23] Three RCTs made no mention of harms.[20,22,24] One RCT reported asymptomatic transient (< 1 hour) tachycardia, mild hypertension, and slight tremor which were equally frequent in all treatment groups (figures not provided).[21]

Comment: None of the RCTs considered respiratory failure as an outcome. One systematic review found significant heterogeneity among RCTs in the effects of bronchodilators on oxygen saturation.[18] Discrepancies in primary studies included differences in study populations such as inclusion of sedated children, short duration of follow up, and validity of clinical scores. Bronchodilators may improve the clinical appearance of a child through a general stimulatory effect rather than by improving respiratory function.[25]

OPTION CORTICOSTEROIDS

One systematic review and 10 additional RCTs found limited and conflicting evidence on the effects of corticosteroids compared with placebo.

Benefits: We found one systematic review (search date 1999, 6 RCTs, 347 children in hospital)[26] and 10 additional RCTs (969 children) of corticosteroids compared with placebo in children with bronchiolitis.[27–36] Three of the additional RCTs had been mentioned in the systematic review but excluded because of data inconsistency,[31] treatment outside hospital,[32] or failure to report the outcome markers sought by the systematic review.[33] The systematic review found no significant difference in the mean duration of stay (5 RCTs, 229 children: WMD –0.43 days, 95% CI –1.05 days to +0.18 days), in the RCTs with clearly identified randomisation methods (4 RCTs, 253 children: WMD –0.35 days, 95% CI –0.84 days to +0.14 days), and after exclusion of RCTs that included children with previous wheezing (4 RCTs, 264 children: WMD –0.29 days, 95% CI –0.71 days to +0.13 days).[26] Interpretation of the effect of corticosteroids compared with placebo on clinical symptoms found by the systematic review is difficult (see comment below). The RCTs in the systematic review reported different clinical scales at varying times after starting treatment. The scales usually included measurements of oxygen saturation, wheezing, accessory muscle use, and respiratory rate. Results reported 72 hours after starting treatment were too heterogeneous for analysis. Only three RCTs (197 children) provided results for 24 hours after starting treatment. The systematic review pooled the standardised effect size for clinical scores from these three RCTs and found that corticosteroids produced a significant improvement, compared with placebo.[26] Although statistically significant, the clinical importance of such an improvement is not clear because different scales are

combined across studies. Seven of the nine additional RCTs that compared the clinical score found no significant benefit from corticosteroids (see table 2, p 374).[27–30,32–34] One RCT found a significant transient improvement in a "bronchiolitis score" with oral prednisolone for 2 days.[34] This change, limited to the clinical score, is of doubtful clinical importance. One subsequent RCT (70 children aged between 8 weeks and 23 months old without previous wheezing episodes) compared oral dexamethasone 1 mg/kg with placebo in the emergency department, along with nebulised salbutamol. After a 4 hour observation period, children were discharged to their homes and continued to receive either daily oral dexamethasone 0.6 mg/kg/dose or placebo for 5 days, as well as inhaled salbutamol. Compared with placebo, a significant reduction in the RACS (see glossary, p 370) measured after 4 hours was found in the dexamethasone group (means difference –1.8, 95% CI –0.175 to –3.425), but no significant difference was found at day 7 (difference in means +0.4, 95% CI –2.1 to +2.8). Admission rates measured at the emergency ward were significantly reduced with dexamethasone (7/36 [19%] with dexamethasone *v* 15/34 [44%] with placebo; RR 0.44, 95% CI 0.21 to 0.95).[35] Another subsequent RCT (41 children aged < 24 months with respiratory syncytial virus-positive infection who required mechanical ventilation) compared intravenous dexamethasone 0.5 mg/kg/dose or an equal volume of placebo every 12 hours for 4 days. No significant difference was found in median number of ventilator days (median 5.50 days [interquartile range 4.0 days] with dexamethasone *v* 6.0 days [interquartile range 4.5 days] with placebo; P = 0.86), duration of intensive care unit stay (median 7.0 days [interquartile range 7.0 days] with dexamethasone *v* 8.0 days [interquartile range 4.0 days] with placebo; P = 0.76), or duration of hospital stay (median 11.0 days [interquartile range 6.0 days] with dexamethasone *v* 10.0 days [interquartile range 5.5 days] with placebo; P = 0.40). However, this study, aimed at detecting differences in virus quantities in tracheal aspirates, had a power of 80% to exclude differences of 50% or more in ventilator days, or 40% or more in hospital days with a power of 80%. Therefore it is not possible to rule out smaller but still clinically important differences in these outcomes.[36] Three small long term follow up RCTs (3 years,[37] 3–5 years,[38] and 2 years[39]) used telephone questionnaires to examine the effect of corticosteroids during the acute episode on subsequent wheezing. Two of the three RCTs did not observe any benefit from corticosteroids. The third was an unblinded RCT in which 117 hospitalised infants (mean age 2.6 months, requiring hospital treatment because of respiratory syncytial virus bronchiolitis) were allocated to be in a control group (41 infants), and received inhaled budesonide for 7 days (40 infants) or inhaled budesonide for 2 months (36 infants).[39] However, this RCT had several problems that compromised its validity (see comment below).

Harms: The acute adverse effects of oral corticosteroids are well documented, and include hyperglycaemia and immunosuppression.[40] The RCTs did not give information on these.[27–36] See harms of corticosteroids in asthma and other wheezing disorders in children, p 328.

Bronchiolitis

Comment: The evidence presented in the systematic review[26] is difficult to interpret because some of the RCTs did not exclude children with a history of wheezing who may have asthma, a condition likely to respond to corticosteroids. The clinical scales used in the RCTs included oxygen saturation, but the clinical relevance of changes in this parameter are unclear. Even if the results are accepted at face value, the clinical significance of an effect size is unclear. Furthermore, eight RCTs with more than double the number of people were not included in the meta-analysis. All of these RCTs, except one, did not find a benefit of corticosteroids, and the single RCT that did, only observed a transient improvement in clinical score at one time point. Another systematic review is underway (Lozano JM, personal communication, 2003). We found inadequate evidence to evaluate the effects of systemic compared with inhaled corticosteroids. The unblinded RCT comparing two different regimens of inhaled budesonide in hospitalised children had several problems that further compromised its validity.[39] Diagnosis of asthma was based only on a telephone survey; the children were not assessed to establish whether they had received additional interventions or exposures that could explain the results.

OPTION ROUTINE BROAD SPECTRUM ANTIBIOTICS

We found no evidence in children with bronchiolitis alone. One unblinded RCT in children with bronchiolitis and uncomplicated pneumonia (crackles on auscultation or consolidation on a chest radiograph) found no significant difference in clinical scores with routine use of antibiotics (ampicillin, penicillin, or erythromycin) compared with placebo. However, the RCT may have lacked power to exclude a clinically important effect.

Benefits: We found no systematic review. We found one unblinded RCT (138 children admitted to hospital with clinically apparent pneumonia, 45% of whom were diagnosed with respiratory syncytial virus infection) comparing the routine use of antibiotics (ampicillin, penicillin, or erythromycin) to no antibiotics (no placebo, see comment below).[41] It found no significant difference between treatment groups in the proportion of children infected with respiratory syncytial virus. It found no evidence that antibiotics reduced duration of hospital stay or respiratory rate, or improved clinical symptoms, clinical signs, or radiographic assessment scores for pulmonary disease.

Harms: The RCT did not report harms,[41] although potential risks include superinfection with resistant bacteria and drug reactions.[42]

Comment: The RCT was unblinded and used block randomisation (children were randomised in groups of 20).[41] This reduces confidence in the results. The RCT may have been too small to exclude a clinically important effect. Two children initially treated without antibiotics were switched to antibiotics because of complicating purulent infections. Analysis was by intention to treat.

OPTION RIBAVIRIN

One systematic review found no good evidence that ribavirin reduced mortality, risk of respiratory deterioration, or duration of hospital stay in children admitted to hospital with respiratory syncytial virus bronchiolitis.

It found some evidence that ribavirin reduced the duration of mechanical ventilation. Two subsequent RCTs found no evidence that ribavirin reduced duration of hospital stay or admission rate because of lower respiratory tract symptoms during the first year after the acute episode or the frequency of recurrent wheezing illness over 1 year of follow up.

Benefits: We found one systematic review (search date 1999, 10 small RCTs)[43] and two subsequent RCTs.[44,45] The review found that, in children and infants hospitalised with respiratory syncytial virus bronchiolitis, ribavirin (tribavirin) compared with placebo did not significantly reduce mortality (5/86 [6%] with ribavirin *v* 7/72 [10%] with placebo; RR 0.61, 95% CI 0.21 to 1.75), respiratory deterioration (4/56 [7%] with ribavirin *v* 11/60 [18%] with placebo; RR 0.42, 95% CI 0.15 to 1.17), or duration of hospital stay (–1.9 days with ribavirin *v* placebo, 95% CI –0.9 to +4.6 days), but duration of ventilation was reduced significantly (–1.2 days, 95% CI –0.2 days to –3.4 days).[43] The high mortality in both groups may have been because of severe disease at baseline. The first subsequent RCT (40 hospitalised infants who received ribavirin or placebo within 12 hours of admission) found no significant differences in outcomes measured during the acute episode, such as the duration of oxygen supplementation need (ribavirin 2.72 days *v* placebo 1.92 days; mean difference +0.80 days, 95% CI –0.73 days to +2.32 days) or hospital stay (ribavirin 4.94 days *v* placebo 3.36 days; mean difference +1.58 days, 95% CI –0.18 days to +3.35 days).[44] That RCT also followed the infants for 1 year after the initial episode. It found no significant differences in admission rates associated with recurrent lower respiratory illness (2/16 [13%] with ribavirin *v* 3/19 [16%] with placebo; RR 0.79, 95% CI 0.15 to 4.17) or use of bronchodilators (5/16 [31%] with ribavirin *v* 8/19 [42%] with placebo; RR 0.74, 95% CI 0.30 to 1.82). However, the sample size may have been too small to rule out a clinically important difference.[44] A second RCT (45 previously healthy infants < 180 days old and hospitalised because of severe respiratory syncytial virus confirmed bronchiolitis) compared nebulised ribavirin (60 mg/mL over 3 2-hour periods for a total of 6 g/100 mL every 24 hours for 3 days) with no ribavirin in an open manner. There were no significant differences in the frequency of recurrent wheezing illness over 1 year of follow up (15/24 [63%] with ribavirin *v* 17/21 [81%] with placebo; RR 0.78, 95% CI 0.53 to 1.12).[45]

Harms: We found no results from prospective studies. The review and the two RCTs did not report harms.[43–45] We found case reports of headaches and contact lens dysfunction in carers.[46] Ribavirin has been reported to be associated with acute bronchospasm in treated children. The standard aerosol is sticky, and clogging of ventilatory equipment has been reported.[47]

Comment: We found one small prospective study comparing pulmonary function tests in 54 children previously randomised to inpatient treatment with ribavirin or placebo.[48] It found no evidence of long term differences in outcome, although the study was not sufficiently powerful to rule out a clinically important difference.

Bronchiolitis

OPTION IMMUNOGLOBULINS

Small, low powered RCTs found insufficient evidence about the effects of immunoglobulins compared with albumin solution or with 0.9% sodium chloride in children admitted to hospital with bronchiolitis.

Benefits: We found no systematic review but found five RCTs (4 using albumin solution as control, 1 using 0.9% sodium chloride, 335 children in total).[49–53] Two RCTs used pooled immunoglobulins, two RCTs used respiratory syncytial virus immunoglobulin (RSV Ig), and one RCT used palivizumab (synthetic monoclonal antibody). Neither RCT using RSV Ig found evidence that RSV Ig shortened duration of hospital stay compared with albumin (in high risk children [see glossary, p 370]: mean duration of hospital stay 8.41 days with RSV Ig *v* 8.89 days with albumin, P = NS; in non-high risk children: mean stay 4.58 days with RSV Ig *v* 5.52 days with albumin, P = NS; CIs not reported).[49,50] The third RCT (35 children) found no evidence that palivizumab reduced duration of hospital stay (mean 14.5 days, 95% CI 12.4 days to 16.6 days with RSV Ig *v* 11.5 days, 95% CI 10.0 days to 13.0 days with placebo; P = 0.25), duration of ventilation (mean 8.8 days, 95% CI 6.5 days to 11.1 days with palivizumab *v* 6.2 days, 95% CI 4.7 days to 7.7 days with placebo; P = 0.45), or duration of treatment with supplemental oxygen (mean 12.3 days, 95% CI 10.0 days to 14.6 days with palivizumab *v* 9.5 days, 95% CI 7.9 days to 11.1 days with placebo; P = 0.47).[51] Neither of the remaining RCTs found any evidence that pooled immunoglobulins improved outcome in children with bronchiolitis.[52,53]

Harms: The RCTs found that RSV Ig was associated with elevation in liver enzymes and anoxic spells (no frequencies provided).[49] One unblinded RCT (249 children) of prophylactic RSV Ig found that adverse effects occurred in about 3% of treated children.[10] That RCT and a subsequent analysis of the data found that effects included increased respiratory rate, mild fluid overload during the first infusion, urticarial reaction at the infusion site, mild decreases in oxygen saturation, and fever (no frequencies provided).[10,54]

Comment: Four RCTs used albumin as control. The effects of albumin in bronchiolitis are not known.

GLOSSARY

Cohort segregation Children infected with different viral strains are segregated from each other and treated separately, with the aim of preventing cross infection.

Disease severity Mild: not requiring admission to hospital. Moderate: requiring admission to hospital but not intubation. Severe: requiring intubation or artificial ventilation.

High risk children Premature infants with or without bronchopulmonary dysplasia, or infants and children with congenital heart disease.

RACS Respiratory Assessment Change Score.

RDAI Respiratory Distress Assessment Instrument.

Cardiorespiratory arrest in children

Search date June 2003

Kate Ackerman and David Creery

QUESTIONS

INTERVENTIONS

*Although we found no direct evidence to support their use, widespread consensus holds that, on the basis of indirect evidence and extrapolation from adult data, these interventions should be universally applied to children who have arrested. Placebo controlled trials would be considered unethical.

See glossary, p 381

Key Messages

- **Bag–mask ventilation** We found no RCTs. One controlled clinical trial in children requiring airway management in the community found no significant difference in survival or neurological outcome between endotracheal intubation and bag–mask ventilation in children with non-submersion cardiorespiratory arrest.
- **Bystander cardiopulmonary resuscitation** It is widely accepted that cardiopulmonary resuscitation and ventilation should be undertaken in children who have arrested. Placebo controlled trials would be considered unethical. One systematic review of observational studies has found that children whose arrest was witnessed and who received bystander cardiopulmonary resuscitation were more likely to survive to hospital discharge compared with no bystander cardiopulmonary resuscitation. We found no RCTs on the effects of training parents to perform cardiopulmonary resuscitation.
- **Intubation** We found no RCTs. One controlled trial found no significant difference in survival or neurological outcome between endotracheal intubation and bag–mask ventilation in children with non-submersion cardiorespiratory arrest.

Cardiorespiratory arrest in children

- **Airway management and ventilation; direct current cardiac shock (for ventricular fibrillation or pulseless ventricular tachycardia); standard dose intravenous adrenaline (epinephrine)** Although we found no direct evidence to support their use, widespread consensus based on indirect evidence and extrapolation from adult data holds that these interventions should be universally applied to children who have arrested. Placebo controlled trials would be considered unethical.
- **High dose intravenous adrenaline (epinephrine); intravenous sodium bicarbonate; intravenous calcium; training parents to perform cardiopulmonary resuscitation** We found no RCTs or prospective observational studies on the effects of these interventions in children who have arrested in the community.

DEFINITION

This chapter deals with non-submersion out of hospital cardiorespiratory arrest in children, which is defined as a state of pulselessness and apnoea occurring outside of a medical facility and not caused by submersion in water.[1]

INCIDENCE/PREVALENCE

We found 12 observational studies (3 prospective, 9 retrospective) reporting the incidence of non-submersion out of hospital cardiorespiratory arrest in children (see table 1, p 383).[2–13] Eleven studies reported the incidence in both adults and children, and eight reported the incidence in children.[2–9,11–13] Incidence of arrests in the general population ranged from 2.2–5.7/100 000 people a year (mean 3.1, 95% CI 2.1 to 4.1). Incidence of arrests in children ranged from 6.9–18.0/100 000 children a year (mean 10.6, 95% CI 7.1 to 14.1).[8] One prospective study (300 children) found that about 50% of out of hospital cardiorespiratory arrests occurred in children under 12 months, and about two thirds occurred in children under 18 months.[11]

AETIOLOGY/RISK FACTORS

We found 26 observational studies reporting the causes of non-submersion pulseless arrests in a total of 1574 children. The commenest causes were undetermined (as in sudden infant death syndrome [see glossary, p 381]) (39%), trauma (18%), chronic disease (7%), and pneumonia (4%) (see table 2, p 384).[1,3–12,14–28]

PROGNOSIS

We found no observational studies that investigated non-submersion arrests alone. We found 27 studies (5 prospective, 22 retrospective; total of 1754 children) that reported out of hospital arrest.[1–12,14–28] The overall survival rate following out of hospital arrest was 5% (87 children). Nineteen of these studies (1140 children) found that of the 48 surviving children, 12 (25%) had no or mild neurological disability and 36 (75%) had moderate or severe neurological disability. We found one systematic review (search date 1997), which reported outcomes after cardiopulmonary resuscitation for both in hospital and out of hospital arrests in children of any cause, including submersion.[29] Studies were excluded if they did not report survival. The review found evidence from prospective and retrospective observational studies that out of hospital arrest of any cause in children has a poorer prognosis than arrest within hospital (132/1568 children [8%] survived to hospital discharge after out of hospital arrest *v* 129/544 children [24%] after in hospital arrests). About half of the survivors were involved in studies that reported neurological outcome. Of these, survival with "good neurological

outcome" (i.e. normal or mild neurological deficit) was higher in children who arrested in hospital compared with those who arrested elsewhere (60/77 surviving children [78%] in hospital *v* 28/68 [41%] elsewhere).[29]

AIMS OF INTERVENTION To improve survival and minimise neurological sequelae.

OUTCOMES Out of hospital death rate; rate of death in hospital without return of spontaneous circulation; return of spontaneous circulation with subsequent death in hospital; and return of spontaneous circulation with successful hospital discharge with mild, moderate, severe, or no neurological sequelae; adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal June 2003, including a search for observational studies. In addition, the authors searched citation lists of retrieved articles and relevant review articles. Studies reporting out of hospital arrest in adults that listed "adolescent" as a MeSH heading were also reviewed. Both authors reviewed the retrieved studies independently and differences were resolved by discussion. Studies were excluded if data relating to submersion could not be differentiated from non-submersion data (except where we found no data relating exclusively to non-submersion arrest; in such cases we have included studies that did not differentiate these types of arrest and indicated their limitation in this regard). Some features of cardiorespiratory arrest in adults appear to be different from arrest in children, so studies were excluded if data for adults could not be differentiated from data for children.

QUESTION What are the effects of treatments for non-submersion out of hospital cardiorespiratory arrest?

OPTION AIRWAY MANAGEMENT AND VENTILATION

It is widely accepted, based on indirect evidence and extrapolation from adult data, that good airway management and rapid ventilation should be undertaken in a child who has arrested, and it would be considered unethical to test its role in a placebo controlled trial. We found no RCTs or prospective observational studies of airway management and ventilation.

Benefits: We found no systematic review, RCTs, or observational studies of sufficient quality.

Harms: We found no prospective evidence.

Comment: None.

OPTION INTUBATION VERSUS BAG–MASK VENTILATION

We found no RCTs. One non-randomised controlled trial found no significant difference in survival or neurological outcome with endotracheal intubation versus bag–mask ventilation in children with non-submersion cardiorespiratory arrest requiring airway management in the community.

Cardiorespiratory arrest in children

Benefits: We found no systematic review or RCTs. We found one non-randomised controlled trial (830 children requiring airway management in the community, including 98 children who had arrested after submersion) comparing (using alternate day allocation) bag–mask ventilation versus endotracheal intubation (given by paramedic staff trained in these techniques).[30] Treatments were allocated on alternate days. Analysis was by intention to treat (see comment below). The trial found no significant difference in rates of survival or good neurological outcome (normal, mild deficit, or no change from baseline function) between the two treatment groups in children with non-submersion cardiorespiratory arrest (105/349 [30%] survived with bag–mask ventilation *v* 90/373 [24%] with intubation; good neurological outcome achieved in 80/349 [23%] of children with bag–mask ventilation *v* 70/373 [19%] with intubation).

Harms: The trial found that time spent at the scene of the arrest was longer when intubation was intended, and this was the only significant determinant of a longer total time from dispatch of paramedic team to arrival at hospital (mean time at scene: 9 minutes with bag–mask *v* 11 minutes with intubation; $P < 0.001$; mean total time: 20 minutes with bag–mask *v* 23 minutes with intubation; $P < 0.001$).[30] However, it found no significant difference between bag–mask ventilation and intubation in complications (complications in 727 children for whom data were available: gastric distension 31% with bag–mask *v* 7% with intubation; $P = 0.20$; vomiting 14% *v* 14%; $P = 0.82$; aspiration 14% *v* 15%; $P = 0.84$; oral or airway trauma 1% with bag–mask *v* 2% with intubation; $P = 0.24$). A total of 186 children across both treatment groups were thought by paramedical staff to be successfully intubated. Of these, oesophageal intubation occurred in three children (2%); the tube became dislodged in 27 children (14%; unrecognised in 12 children, recognised in 15); right main bronchus intubation occurred in 33 children (18%); and an incorrect size of tube was used in 44 children (24%). Death occurred in all but one of the children with oesophageal intubation or unrecognised dislodging of the tube.[30]

Comment: **Population characteristics:** The baseline characteristics of children did not differ significantly between groups in age, sex, ethnicity, or cause of arrest. The trial did not report the frequency of pulseless arrest compared with that of respiratory arrest (see glossary, p 381). **Intention to treat:** Intubation and bag–mask ventilation were not mutually exclusive in the trial.[30] The trial protocol allowed bag–mask ventilation before intubation and after unsuccessful intubation. Of 420 children allocated to intubation, 115 received bag–mask ventilation before intubation, 128 received bag–mask ventilation after attempted intubation, four were lost to follow up, and the remainder received intubation that was believed to be successful. Of 410 children allocated to bag–mask ventilation, 10 children were intubated successfully (although in violation of study protocol), nine received bag–mask ventilation after attempted intubation, six were lost to follow up, and the remainder received bag–mask ventilation in accordance with study protocol.[30]

OPTION INTRAVENOUS ADRENALINE (EPINEPHRINE)

Intravenous adrenaline (epinephrine) at "standard dose" (0.01 mg/kg) is a widely accepted treatment for establishing return of spontaneous circulation and it would be considered unethical to test its role in a placebo controlled trial. We found no RCTs or prospective observational studies in children who have arrested in the community comparing adrenaline versus placebo or comparing standard or single doses versus high or multiple doses of adrenaline.

Benefits: We found no systematic review, RCTs, or prospective observational studies on the effects of intravenous adrenaline.

Harms: We found no prospective evidence.

Comment: **High versus low dose:** Two small retrospective observational studies (128 people) found no evidence of a difference in survival to hospital discharge between low or single dose and high or multiple dose adrenaline, although the studies were too small to rule out an effect.[8,12]

OPTION INTRAVENOUS SODIUM BICARBONATE

We found no RCTs or observational studies of sufficient quality on the effects of intravenous bicarbonate in out of hospital cardiorespiratory arrest in children.

Benefits: We found no systematic review, RCTs, or observational studies of sufficient quality.

Harms: We found no prospective evidence.

Comment: Sodium bicarbonate is widely believed to be effective in arrest associated with hyperkalaemic ventricular tachycardia or fibrillation, but we found no prospective evidence supporting this.

OPTION INTRAVENOUS CALCIUM

We found no RCTs or observational studies of sufficient quality on the effects of intravenous calcium in out of hospital cardiorespiratory arrest in children.

Benefits: We found no systematic review, RCTs, or observational studies of sufficient quality.

Harms: We found no prospective evidence.

Comment: Calcium is widely believed to be effective in arrest associated with hyperkalaemic ventricular tachycardia or fibrillation, but we found no prospective evidence supporting this.

OPTION BYSTANDER CARDIOPULMONARY RESUSCITATION

It is widely accepted that cardiopulmonary resuscitation and ventilation should be undertaken in children who have arrested. Placebo controlled trials would be considered unethical. One systematic review of observational studies has found that children whose arrest was witnessed and who received bystander cardiopulmonary resuscitation

were more likely to survive to hospital discharge compared with no bystander cardiopulmonary resuscitation. We found no RCTs on the effects of training parents to perform cardiopulmonary resuscitation.

Benefits: We found no RCTs. We found one systematic review (search date 1997, 1420 children who had arrested outside hospital) of prospective and retrospective observational studies.[29] This concluded that survival was improved in children who were witnessed to arrest and received cardiopulmonary resuscitation from a bystander. Of 150 witnessed arrests outside hospital, 28/150 (19%) survived to hospital discharge. Of those children who received bystander cardiopulmonary resuscitation, 20/76 (26%) survived to discharge.[29] The review did not report survival rates in children whose arrests were not witnessed, but the overall survival rate for out of hospital cardiac arrest was 8%. **Training parents to perform cardiopulmonary resuscitation:** We found no systematic review, RCTs, or prospective observational studies examining the effects of training parents to perform cardiopulmonary resuscitation in children who have arrested outside hospital.

Harms: Potential harms include injury resulting from unnecessary chest compression after respiratory arrest with intact circulation.

Comment: The review of observational studies found that children who received bystander cardiopulmonary resuscitation had a hospital discharge rate of 20/76 (26%) versus 8/74 (11%) in children whose arrest was witnessed but had not received cardiopulmonary resuscitation.[29] Cardiopulmonary resuscitation was not randomly allocated and children resuscitated may be systematically different from those who did not receive resuscitation. The apparent survival rates for witnessed arrests and arrests with bystander initiated cardiopulmonary resuscitation may be artificially high because of inappropriate evaluation of true arrest. However, assuming confounding variables were evenly distributed between groups, then the best estimate of the benefit of cardiopulmonary resuscitation is a 15% absolute increase in the probability that children will be discharged alive from hospital.

OPTION DIRECT CURRENT CARDIAC SHOCK

It is widely accepted that children who arrest outside hospital and are found to have ventricular fibrillation or pulseless ventricular tachycardia should receive direct current cardiac shock treatment. Placebo controlled trials would be considered unethical. We found no RCTs or prospective observational studies on the effects of direct current cardiac shock in children who have arrested in the community, regardless of the heart rhythm.

Benefits: We found no systematic review, RCTs, or observational studies of sufficient quality.

Harms: We found no prospective evidence.

Comment: **In children with ventricular fibrillation:** One retrospective study (29 children with ventricular fibrillation who had arrested out of hospital from a variety of causes, including submersion) found that of 27 children who were defibrillated, 11 survived (5 with no

sequelae, 6 with severe disability). The five children with good outcome all received defibrillation within 10 minutes of arrest (time to defibrillation not given for those who died). Data on the two children who were not defibrillated were not presented.[31] **In children with asystole:** One retrospective study in 90 children with asystole (see glossary, p 381) (including those who had arrested after submersion) found that 49 (54%) had received direct current cardiac shock treatment. None of the children survived to hospital discharge, regardless of whether or not direct current cardiac shock was given.[32] We found one systematic review of observational studies that recorded electrocardiogram rhythm (search date 1997, 1420 children who had arrested outside hospital).[29] Bradyasystole or pulseless electrical activity were found in 73%, whereas ventricular fibrillation or pulseless ventricular tachycardia (see glossary, p 381) were found in 10%.[29] The review found that survival after ventricular fibrillation or ventricular tachycardia arrest was higher than after asystolic arrest in children. Survival to discharge reported in the systematic review was 39/802 (5%) for children with initial rhythm asystole and 30% (29/97) with initial rhythm ventricular fibrillation (see glossary, p 381) or ventricular tachycardia.[29]

GLOSSARY

Asystole The absence of cardiac electrical activity.
Bradyasystole Bradycardia clinically indistinguishable from asystole.
Initial rhythm asystole The absence of cardiac electrical activity at initial determination.
Initial rhythm ventricular fibrillation Electrical rhythm is ventricular fibrillation at initial determination.
Pulseless arrest Absence of palpable pulse.
Pulseless electrical activity The presence of cardiac electrical activity in absence of a palpable pulse.
Pulseless ventricular tachycardia Electrical rhythm of ventricular tachycardia in absence of a palpable pulse.
Respiratory arrest Absence of respiratory activity.
Sudden infant death syndrome The sudden unexpected death of a child, usually between the ages of 1 month and 1 year, for which a thorough postmortem examination does not define an adequate cause of death. Near miss sudden infant death syndrome refers to survival of a child after an unexpected arrest of unknown cause.

INTERVENTIONS

CONSTIPATION

Trade off between benefits and harms

Unknown effectiveness

*Not widely licensed for use in children. Clinical use in adults was recently restricted because of heart rhythm abnormalities. See comments on cisapride under gastro-oesophageal reflux in children, p 414.

Covered elsewhere in *Clinical Evidence*

Constipation in adults, p 571

Key Messages

Constipation

- **Cisapride with or without magnesium oxide** Two RCTs in people aged 2–18 years found that cisapride improved stool frequency and symptoms of constipation after 8–12 weeks of treatment in an outpatient setting compared with placebo. One RCT in children aged 1–7 years with chronic constipation found that combined treatment with cisapride and magnesium oxide significantly improved stool frequency after 3–4 weeks of treatment in an outpatient setting compared with magnesium oxide alone. We found no evidence from primary care settings. Use of cisapride has been restricted in some countries because of adverse cardiac effects.
- **Biofeedback training** One systematic review found no significant difference between biofeedback plus conventional treatment and conventional treatment alone in children with persisting defecation disorders at 12 months.
- **Increased dietary fibre** We found no systematic review or RCTs on the effects of increasing dietary fibre.
- **Osmotic laxatives** We found no RCTs that compared osmotic laxatives versus placebo in children. Two small RCTs found no significant difference in stool frequency or consistency between lactulose and lactitol after 2–4 weeks in children aged 8 months to 16 years. One of the RCTs found that lactulose increased abdominal pain and flatulence compared with lactitol. A third RCT in non-breastfed constipated infants found no difference between different strengths of lactulose.
- **Stimulant laxatives** One systematic review found no reliable RCTs comparing stimulant laxatives versus placebo or other treatments.

Constipation in children

DEFINITION

Constipation is characterised by infrequent bowel evacuations; hard, small faeces; or difficult or painful defecation. The frequency of bowel evacuation varies from person to person.[1] According to the Rome II diagnostic criteria for childhood defecation disorders, functional constipation can be defined as "either having hard or pellet-like stools for the majority of stools or firm stools two or less times per week in the absence of structural, endocrine or metabolic diseases".[2] Some studies reported in this chapter used other diagnostic criteria.[3] **Encopresis** is defined as involuntary bowel movements in inappropriate places at least once a month for 3 months or more, in children aged 4 years and older.[4]

INCIDENCE/ PREVALENCE

Constipation with or without encopresis is common in children. It accounts for 3% of consultations to paediatric outpatient clinics and 25% of paediatric gastroenterology consultations in the USA.[5] Encopresis has been reported in 2% of children at school entry. The peak incidence is at 2–4 years of age.

AETIOLOGY/ RISK FACTORS

No cause is discovered in 90–95% of children with constipation. Low fibre intake and a family history of constipation may be associated factors.[6] Psychosocial factors are often suspected, although most children with constipation are developmentally normal.[5] Chronic constipation can lead to progressive faecal retention, distension of the rectum, and loss of sensory and motor function. Organic causes for constipation are uncommon, but include Hirschsprung's disease (1/5000 births; male to female ratio of 4 : 1; constipation invariably present from birth), cystic fibrosis, anorectal physiological abnormalities, anal fissures, constipating drugs, dehydrating metabolic conditions, and other forms of malabsorption.[5] This chapter aims to cover children in whom no underlying cause is identified.

PROGNOSIS

Childhood constipation can be difficult to treat and often requires prolonged support, explanation, and medical treatment. In one long term follow up study of children presenting under the age of 5 years, 50% recovered within 1 year and 65–70% recovered within 2 years; the remainder required laxatives for daily bowel movements or continued to soil for several years.[5] It is not known what proportion continue to have problems into adult life, although adults presenting with megarectum or megacolon often have a history of bowel problems from childhood.

AIMS OF INTERVENTION

To remove faecal impaction and to restore a bowel habit in which stools are soft and passed without discomfort; to ensure self toileting and passing stools in appropriate places.

OUTCOMES

Number of defecations per week; gut transit time as measured by timing the passage of radio-opaque pellets, which may be ingested within a gelatin capsule; use of laxatives; stool consistency; pain; difficulty in defecation; blood in stool; number of soilings per month.

METHODS

Clinical Evidence search and appraisal August 2003 using the following keywords: constipation, encopresis, diet therapy, diagnosis, therapy, psychology, stimulant laxatives, dietary fibre, and lactulose. The search was limited to infants and children. Trials were

selected for inclusion if they focused on the management of constipation or encopresis, or both; if they were relevant to primary health care; and if they included children without an organic cause for constipation.

QUESTION What are the effects of treatments for constipation?

OPTION CISAPRIDE

Two RCTs in people aged 2–18 years found that cisapride improved stool frequency and symptoms of constipation after 8–12 weeks of treatment in an outpatient setting compared with placebo. One RCT in children aged 1–7 years with chronic constipation found that combined treatment with cisapride and magnesium oxide significantly improved stool frequency after 3–4 weeks of treatment in an outpatient setting compared with magnesium oxide alone. We found no evidence from primary care settings. Use of cisapride has been restricted in some countries because of adverse cardiac effects.

Benefits: We found no systematic review but found three RCTs.[7–9] **Versus placebo:** One RCT (69 children and young adults aged 4–18 years, attending hospital with constipation, defined as pain, difficulty in defecation, or ≤ 3–4 bowel movements/week for at least 3 months in the absence of a history of bowel disease) found that cisapride 0.3 mg/kg daily (as a syrup) significantly increased stool frequency and decreased gut transit time after 8 weeks compared with placebo (mean stool frequency/week 6.75 with cisapride *v* 1.31 with placebo).[7] The second RCT (40 children aged 2–16 years with a history of chronic constipation referred to a paediatric hospital gastroenterology clinic) found significant benefit for cisapride compared with placebo at 12 weeks, measured by a composite of improved stool frequency, absence of faecal soiling, and no use of other laxatives (improvement in composite index 14/20 [70%] with cisapride *v* 7/20 [35%] with placebo; RR 2.00, 95% CI 1.03 to 3.88; NNT 3, 95% CI 1 to 24).[8] **Cisapride plus magnesium oxide versus magnesium oxide alone:** The third RCT (84 children aged 1–7 years, attending hospital with chronic constipation, defined as fewer than 2 spontaneous bowel movements/week for at least 1 month in the absence of any underlying medical condition or concomitant drug use) compared cisapride 0.2 mg/kg three times daily (as a syrup) plus magnesium oxide (125 mg 3 times daily for children weighing less than 20 kg and 250 mg 3 times daily for children weighing more than 20 kg) versus magnesium oxide alone.[9] Both groups showed a similar increase in stool frequency after 1 week of treatment (30/44 [68%] with cisapride plus magnesium oxide v 23/40 [58%] with magnesium oxide alone; P = 0.369). Although the number of children responding to magnesium oxide alone remained constant after 1–2 weeks of therapy, the number of those responding to the combined treatment was significantly greater after 4 weeks (40/44 [91%] with cisapride plus magnesium oxide *v* 27/40 [68%] with magnesium oxide alone; P = 0.013). No significant difference between the two treatment groups was found regarding stool consistency (softened in 29/44

[66%] children treated with cisapride plus magnesium oxide *v* 27/40 [68%] children treated with magnesium oxide; no change in 11 children of each treatment group; P = 0.876) or the incidence of blood in the stools (3 children in each treatment group; P = 1.0) after 4 weeks.

Harms: **Versus placebo:** The RCTs comparing the use of cisapride versus placebo did not report harms (see comment below).[7,8] **Cisapride plus magnesium oxide versus magnesium oxide alone:** Adverse events reported in the RCT comparing cisapride plus magnesium oxide versus magnesium oxide alone were minimal, limited to gastrointestinal upset, and showed no significant difference between the two treatment groups (adverse effects occurred in 2–4 children [5–9%] receiving combined treatment *v* 1–2 children [3–5%] in the group receiving monotherapy). None of the children in the study reported any arrhythmia-related symptoms.[9]

Comment: Use of cisapride has been restricted in some countries because of its association with heart rhythm abnormalities in adults. See comments on cisapride under gastro-oesophageal reflux in children, p 414.

OPTION INCREASED DIETARY FIBRE

We found no systematic review or RCTs on the effects of increasing dietary fibre.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION OSMOTIC LAXATIVES

We found no RCTs that compared osmotic laxatives versus placebo in children. Two small RCTs found no significant difference in stool frequency or consistency between lactulose and lactitol after 2–4 weeks in children aged 8 months to 16 years. One of the RCTs found that lactulose increased abdominal pain and flatulence compared with lactitol. A third RCT in non-breastfed constipated infants found no difference between different strengths of lactulose.

Benefits: **Versus placebo:** We found no systematic review and no placebo controlled RCTs of osmotic laxatives in children. **Versus each other:** We found two small RCTs[10,11] comparing the effects of lactitol versus lactulose on stool frequency and consistency and a third RCT[12] comparing the effects of two different dosages of lactulose in infants. The first RCT (51 children, aged 8 months to 16 years visiting a physician for chronic idiopathic constipation) found no significant difference in stool frequency or consistency between lactitol and lactulose at 4 weeks (stool frequency per week increased from 2.5 to 5.6 with lactitol *v* 2.0 to 4.8 for lactulose; significance not reported; stool consistency normal or soft in 15/23 [65%] children with lactitol *v* 16/19 [84%] with lactulose; reported as non-significant, no other data).[10] The second RCT (39 children,

aged 11 months to 13 years) compared lactitol 150–350 mg/kg daily versus lactulose 150 mg/kg daily over 2 weeks.[11] It found no significant difference in stool frequency between lactulose and lactitol (stool frequency in both groups was 1–1.5/day). A third RCT (220 non-breastfed, constipated infants aged 0–6 months) compared 2% and 4% lactulose mixed with an artificial milk preparation.[12] At 14 days, over 90% of parents in both groups reported easy passage of normal or thin consistency stools. However, the RCT did not compare outcomes between treatment groups.

Harms: **Versus each other:** The first RCT found that significantly fewer children taking lactitol had abdominal pain or flatulence compared with lactulose (abdominal pain: 22% with lactitol *v* 58% with lactulose; $P < 0.005$; flatulence: 30% with lactitol *v* 63% with lactulose; $P < 0.01$).[10]

Comment: **Versus each other:** The benefits shown in the third RCT are comparisons of outcomes before and after treatment, and were not necessarily a result of the treatments.[12]

OPTION STIMULANT LAXATIVES

One systematic review found no reliable RCTs comparing stimulant laxatives versus placebo or other treatments.

Benefits: **Versus placebo or alternative treatment:** We found one systematic review (search date 2001), which found no RCTs of adequate methodological rigour comparing stimulant laxatives versus either placebo or alternative treatment in children (see comment below).[13] We found no subsequent placebo controlled RCTs of the effects of stimulant laxatives in children.

Harms: None identified.

Comment: **Versus placebo or alternative treatment:** The studies identified by the review were all comparative, used multiple interventions, and had small sample sizes.[13] One quasi-randomised study (using last hospital number digit to allocate patients) in 37 children (aged 3–12 years) with chronic constipation found that senna was significantly less effective in achieving daily bowel movements after 6 months than mineral oil concentrate (9/18 [50%] with senna *v* 16/19 [89%] with mineral oil; $P < 0.05$) and less effective in reducing involuntary faecal soiling after 6 months (8/18 [44%] children continuing to soil with senna *v* 1/19 [5%] with mineral oil; RR 8.44, 95% CI 1.52 to 16.70).[14] No significant differences were found in the number of children with at least one recurrence of constipation symptoms during the treatment period (16/18 [89%] with senna *v* 12/19 [66%] with mineral oil; RR 0.71, 95% CI 0.48 to 1.04).

OPTION BIOFEEDBACK TRAINING

One systematic review found no significant difference between biofeedback plus conventional treatment and conventional treatment alone at 12 months.

Constipation in children

Benefits: We found one systematic review (search date 2001, 8 RCTs).[3] The review found no significant difference in rates of persisting problems between conventional treatment plus biofeedback and conventional treatment alone at 12 months (OR 1.34, 95% CI 0.92 to 1.94). There was heterogeneity of borderline significance (P = 0.087). One included RCT (41 children) found a different trend from the other seven RCTs for reasons that were not apparent.[15] After exclusion of this RCT, results were no longer heterogeneous. Meta-analysis excluding this RCT found that biofeedback plus conventional treatment increased rates of persisting problems compared with conventional treatment alone (OR 1.59, 95% CI 1.07 to 2.35; heterogeneity P = 0.53).

Harms: None reported.

Comment: In the systematic review, sample sizes were generally small, and interventions and outcomes varied among trials.[3]

Depression in children and adolescents

Search date May 2003

Philip Hazell

QUESTIONS

INTERVENTIONS

See glossary, p 400

Key Messages

- **Cognitive behavioural therapy** One systematic review in children and adolescents with mild to moderate depression has found that cognitive behavioural therapy improves symptoms compared with non-specific support. One RCT in depressed adolescents with depressed parents found no significant difference in recovery from depression between cognitive behavioural therapy plus usual care and usual care alone over 2 years.
- **Interpersonal therapy** Two RCTs found that interpersonal therapy versus clinical monitoring or waiting list control increased recovery rate over 12 weeks in adolescents with mild to moderate depression.
- **Selective serotonin reuptake inhibitors** We found limited evidence that selective serotonin reuptake inhibitors improved symptoms of depression compared with placebo; one RCT found no significant difference, one RCT found significant results on some depression measures but not others, while one RCT found improvement in depressive symptoms with fluoxetine compared with placebo after 8–9 weeks. One RCT found that, in adolescents with major depression, paroxetine improved remission after 8 weeks compared with placebo. Another RCT found no significant difference in effects on outcomes

Depression in children and adolescents

between paroxetine and clomipramine, although it may have lacked power to detect clinically important effects. We found no RCTs on other selective serotonin reuptake inhibitors. Selective serotonin reuptake inhibitors are frequently associated with dizziness, light-headedness, drowsiness, poor concentration, nausea, headache, and fatigue if treatment is reduced or stopped.

- **Electroconvulsive therapy** We found no RCTs on electroconvulsive therapy in children and adolescents with depression.
- **Intravenous clomipramine** One small RCT found that, in non-suicidal adolescents, intravenous clomipramine improved depression scores at 6 days compared with placebo. However, the trial was too small and brief for us to draw reliable conclusions.
- **Lithium** One small RCT in children with depression and a family history of bipolar affective disorder found no significant difference between lithium and placebo in global assessment or depression scores after 6 weeks. However, the study may have lacked power to detect clinically important effects.
- **Monoamine oxidase inhibitors** One RCT found insufficient evidence to compare the reversible monoamine oxidase inhibitor moclobemide versus placebo in children aged 9–15 years with major depression, some of whom had a comorbid disorder. We found no RCTs on non-reversible monoamine oxidase inhibitors in children or adolescents.
- **St John's Wort** We found no RCTs on St John's Wort (*Hypericum perforatum*) in children or adolescents with depression.
- **Venlafaxine** One small RCT in children and adolescents with major depression receiving psychotheray found no significant difference between venlafaxine and placebo in improvement of depressive symptoms after 6 weeks. However, the study may have lacked power to detect clinically important effects.
- **Tricyclic antidepressants (in adolescents)** One systematic review in adolescents and children found no significant difference in depression scores between oral tricyclic antidepressants (amitriptyline, desipramine, imipramine, nortriptyline) and placebo after 4–10 weeks. However, subgroup analyses found that oral tricyclic antidepressants improved symptoms compared with placebo in adolescents but not children. There was no significant difference in rates of remission. The review also found that oral tricyclic antidepressants were associated with adverse effects. One RCT found no significant difference in improvement rates between oral clomipramine and paroxetine after 8 weeks.
- **Tricyclic antidepressants (in children)** Subgroup analyses in one systematic review found no significant difference between oral tricyclic antidepressants (amitriptyline, desipramine, imipramine, nortriptyline) and placebo in children with depression. The review also found that oral tricyclic antidepressants were associated with adverse effects.
- **Family therapy; specific psychological treatments other than cognitive behavioural therapy** We found insufficient evidence in children and adolescents about the effects of these interventions.

DEFINITION Compared with adult depression (see depressive disorders, p 1278), depression in children (6–12 years) and adolescents (13–18 years) may have a more insidious onset, may be characterised more by irritability than sadness, and occurs more often in association with other conditions such as anxiety, conduct disorder, hyperkinesis, and learning problems.[1] The term "major depression" is used to distinguish discrete episodes of depression from mild, chronic (1 year or longer) low mood or irritability, which is known as "dysthymia".[1] The severity of depression may be defined by the level

of impairment and the presence or absence of psychomotor changes and somatic symptoms (see depressive disorders, p 1278). In some studies, severity of depression is defined according to cut off scores on depression rating scales. A manic episode is defined by abnormally and persistently elevated, expansive, or irritable mood. Additional symptoms may include grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, psychomotor agitation, and impaired judgement.[2]

INCIDENCE/ PREVALENCE Estimates of prevalence of depression among children and adolescents in the community range from 2–6%.[3,4] Prevalence tends to increase with age, with a sharp rise at around the onset of puberty. Pre-adolescent boys and girls are affected equally by the condition, but depression is seen more frequently among adolescent girls than boys.[5]

AETIOLOGY/ RISK FACTORS The aetiology is uncertain, but may include genetic vulnerability,[6] childhood events, and current psychosocial adversity.[1]

PROGNOSIS In children and adolescents, the recurrence rate after a first depressive episode is 70% by 5 years, which is similar to the recurrence rate in adults. It is not clear whether this is related to the severity of depression.[1] Young people experiencing a moderate to severe depressive episode may be more likely than adults to have a manic episode within the following few years.[1,7] Trials of treatments for child and adolescent depression have found high rates of response to placebo (as much as two thirds of people in some inpatient studies).[8] A third of young people who experience a depressive episode will make a suicide attempt at some stage, and 3–4% will die from suicide.[1]

AIMS OF INTERVENTION To improve mood, social and occupational functioning, and quality of life; to reduce morbidity and mortality; to prevent recurrence of depressive disorder; and to minimise adverse effects of treatment.

OUTCOMES In children and adolescents, there are developmentally specific pseudo-continuous measures such as the Children's Depression Rating Scale and the Children's Depression Inventory, although some studies of adolescents use scales developed for use in adults such as the Hamilton Rating Scale for Depression. Pseudo-continuous measures reported by parents, such as the Children's Depression Inventory for Parents, are also used. Categorical outcomes are sometimes expressed as people no longer meeting specified criteria for depression on a structured psychiatric interview such as the Kiddie-SADS, which combines data from children and their parents. Global improvement in symptoms as judged by an investigator is sometimes reported using the Clinical Global Impressions Scale or the Clinical Global Assessment Scale.

METHODS *Clinical Evidence* search and appraisal May 2003, plus additional references identified by contributor.

Depression in children and adolescents

QUESTION What are the effects of treatments?

OPTION TRICYCLIC ANTIDEPRESSANTS

One systematic review in adolescents and children found no significant difference in depression scores between oral tricyclic antidepressants (amitriptyline, desipramine, imipramine, nortriptyline) and placebo after 4–10 weeks. However, subgroup analyses found that oral tricyclic antidepressants improved symptoms compared with placebo in adolescents, but not in children. There was no significant difference in rates of remission. The review also found that oral tricyclic antidepressants were associated with adverse effects. One RCT found no significant difference in improvement rates between oral clomipramine and paroxetine after 8 weeks. One small RCT found that, in non-suicidal adolescents, intravenous clomipramine improved depression scores at 6 days compared with placebo.

Benefits:

Oral tricyclic antidepressants versus placebo: We found one systematic review (search date 2000, 13 RCTs, 506 children and adolescents aged 6–18 years, severity of depression not stated) comparing oral tricyclic antidepressants (amitriptyline, desipramine, imipramine, and nortriptyline) versus placebo.[8] It found no significant difference in overall improvement between tricyclic antidepressants and placebo after 4–10 weeks (OR 0.84, 95% CI 0.56 to 1.25). Subgroup analyses found a significant reduction in symptoms with tricyclic antidepressants versus placebo in adolescents (7 RCTs; 351 people; effect size SMD –0.47, 95% CI –0.92 to –0.02). However, there was no significant difference in children (3 RCTs; 65 people; effect size SMD +0.15, 95% CI –0.64 to +0.34). **Oral tricyclic antidepressants versus selective serotonin reuptake inhibitors:** See benefits of selective serotonin reuptake inhibitors (paroxetine with the predominantly serotonergic tricyclic antidepressant clomipramine), p 396. **Pulsed intravenous clomipramine:** We found one RCT (16 non-suicidal adolescent outpatients, aged 14–18 years, with major depression [21-item Hamilton Rating Scale for Depression score ≥ 18]), which compared pulse intravenous clomipramine (see glossary, p 401) 200 mg versus placebo.[9] It found that intravenous clomipramine significantly reduced Hamilton Rating Scale for Depression scores compared with placebo at 6 days (mean reduction in score: 15.0 with clomipramine *v* 9.0 with placebo, $P < 0.05$). However, it found no significant difference in remission rate (remission defined as ≥ 50% decrease in Hamilton Rating Scale for Depression scores; AR 7/8 [88%] with intravenous clomipramine *v* 3/8 [38%] with placebo; $P = 0.06$).[9] The study may have lacked power to detect a clinically important effect.

Harms:

Oral tricyclic antidepressants: The systematic review found that tricyclic antidepressants were more commonly associated with vertigo (OR 8.47, 95% CI 1.40 to 51.00), orthostatic hypotension (OR 4.77, 95% CI 1.11 to 20.50), tremor (OR 6.29, 95% CI 1.78 to 22.17), and dry mouth (OR 5.19, 95% CI 1.15 to 23.5) than placebo.[8] The review found no significant differences between tricyclic antidepressants and placebo in tiredness (OR 1.52, 95%

CI 0.63 to 3.67), sleep problems (OR 1.87, 95% CI 0.84 to 4.14), headache (OR 1.15, 95% CI 0.68 to 1.95), palpitations (OR 1.20, 95% CI 0.17 to 8.68), perspiration (OR 2.01, 95% CI 0.39 to 10.44), constipation (OR 1.94, 95% CI 0.72 to 5.24), or problems with micturition (OR 0.30, 95% CI 0.01 to 7.89). **Pulsed intravenous clomipramine:** The RCT did not report any adverse effects.[9]

Comment: We found single case reports and case series of toxicity and mortality from tricyclic antidepressants in overdose and therapeutic doses. Further research is needed to determine long term effects of intravenous clomipramine.

OPTION MONOAMINE OXIDASE INHIBITORS

One RCT found insufficient evidence to compare moclobemide versus placebo in children aged 9–15 years with major depression, some of whom had a comorbid disorder. We found no RCTs on non-reversible monoamine oxidase inhibitors in children or adolescents.

Benefits: We found no systematic review. **Reversible monoamine oxidase inhibitors:** We found one small RCT (20 Turkish children aged 9–15 years with major depression, including 13 children with a comorbid disorder) comparing moclobemide versus placebo for 5 weeks.[10] The RCT found that moclobemide significantly improved clinician rated scale scores (Clinical Global Impressions Scale — investigator assessment of severity of depression, adverse effects, and global recovery) compared with placebo after 5 weeks but not on parent rated (Children's Depression Inventory for Parents) and self reported measures (Children's Depression Inventory).[10] The small sample size limits the conclusions that may be drawn from this RCT.[10] **Non-reversible monoamine oxidase inhibitors:** We found no RCTs.

Harms: The RCT found no significant difference in adverse events assessed using Clinical Global Impression of adverse effects scale and self assessed adverse effects forms between moclobemide and placebo.[10] We found no information on the safety of moclobemide usage in children younger than 9 years.

Comment: None.

OPTION SELECTIVE SEROTONIN REUPTAKE INHIBITORS

We found limited evidence that selective serotonin reuptake inhibitors improved symptoms of depression compared with placebo; one RCT found no significant difference, one RCT found significant results on some depression measures but not others, and one RCT found improvement in depressive symptoms with fluoxetine compared with placebo after 8–9 weeks. One RCT found that, in adolescents with major depression, paroxetine improved remission after 8 weeks compared with placebo. Another RCT in people with major depression (aged 12–20 years) found no significant difference in effects on improvement rates between paroxetine and clomipramine, although it may have lacked power to detect clinically important effects. We found no RCTs on other selective

serotonin reuptake inhibitors. Selective serotonin reuptake inhibitors are frequently associated with dizziness, light-headedness, drowsiness, poor concentration, nausea, headache, and fatigue if treatment is reduced or stopped.

Benefits:

Fluoxetine: We found one systematic review (search date 1998,[11] 2 RCTs[12,13]) and one subsequent RCT.[14] The systematic review did not pool results.[11] The first RCT identified by the review (40 adolescents, aged 13–18 years, of whom 30 completed the trial, severity of depression not stated) found no significant difference in the mean number of depression symptoms or psychosocial functioning (Clinical Global Impressions Scale) between fluoxetine 20–60 mg and placebo after 8 weeks (RR of failure to improve 1.00, 95% CI 0.36 to 2.75).[12] The second RCT identified by the review (96 children and adolescents aged 7–17 years with major depression) found that fluoxetine 20 mg significantly improved depression symptoms according to the self reported Children's Depression Scale compared with placebo after 8 weeks (proportion with improved Clinical Global Impressions Scale: 27/48 [56%] with fluoxetine *v* 16/48 [33%] with placebo; RR of failure to improve 0.66, 95% CI 0.45 to 0.96; proportion with improved self reported Children's Depression Rating Scale: 34% with fluoxetine *v* 18% with placebo; $P < 0.01$). The subsequent RCT (219 children and adolescents aged 8–17 years with major depression) found no significant difference between fluoxetine and placebo in response defined a priori on the Children's Depression Rating Scale at 8 weeks (response defined as ≥ 30% improvement in score: 71/109 [65%] with fluoxetine *v* 54/101 [54%] with placebo; $P = 0.093$).[14] The RCT found that fluoxetine significantly improved Children's Depression Rating Scale or Clinical Global Impressions Severity scale compared with placebo at 8 weeks (difference in mean improvement with fluoxetine *v* placebo; Children's Depression Rating Scale: 7.1, 95% CI 3.3 to 10.9; Clinical Global Impressions Severity Scale: 0.6, 95% CI 0.3 to 1.0). **Paroxetine:** We found two RCTs. The first RCT (180 adolescents, aged 12–18 years, of whom 133 completed the trial, severity of depression score of at least 12 on the Hamilton Rating Scale for Depression and < 60 on the Children's Global Assessment Scale) that compared effects of paroxetine 20–40 mg, imipramine (gradual upward titration to 200–300 mg), and placebo for 8 weeks with respect to end point response (Hamilton Rating Scale for Depression score ≤ 8 or a 50% reduction from baseline score) and change from baseline score (Hamilton Rating Scale for Depression).[15] The RCT did not include a direct statistical comparison of paroxetine with imipramine. The RCT found that paroxetine significantly improved response rate compared with placebo (AR for failure to respond 37% with paroxetine *v* 54% with placebo; ARI 17%, CI not reported; RR 0.68, 95% CI 0.49 to 0.95; $P = 0.02$). The second RCT (121 people aged 12–20 years with major depression) compared paroxetine versus clomipramine.[16] The RCT found no significant difference in rates of improvement after 8 weeks of treatment (achieving a score of 2 ["much" improved] or 1 ["very

much" improved] on the Clinical Global Impressions Scale: 35/59 [59%] with paroxetine *v* 32/55 [58%] with clomipramine; P = 0.71). However, the trial may have lacked power to detect clinically important differences. **Other selective serotonin reuptake inhibitors:** We found no RCTs.

Harms: **Fluoxetine:** One of the RCTs included in the systematic review found significantly more weight loss with fluoxetine compared with placebo (data not reported).[12] The other included RCT did not report on adverse effects.[13] The subsequent RCT found that headache was reported significantly more often with fluoxetine versus placebo (P = 0.017).[14] **Paroxetine:** The first RCT reported more serious adverse events with paroxetine compared with placebo (12% with paroxetine *v* 2% with placebo).[15] The most common adverse events were somnolence (17% with paroxetine *v* 3% with placebo) and tremor (11% with paroxetine *v* 2% with placebo) but no statistical analyses were reported. A discontinuation syndrome after abrupt stopping or reduction in the dose of selective serotonin reuptake inhibitors has been described in a series of six cases.[17] The most frequent symptoms included dizziness, lightheadedness, drowsiness, poor concentration, nausea, headache, and fatigue.[17] The second RCT found significantly fewer adverse effects with paroxetine than with clomipramine (31/63 [49%] with paroxetine *v* 40/58 [69%] with clomipramine; P = 0.027).[16] The most common adverse events were dizziness (6.3% with paroxetine *v* 34.5% with clomipramine; P value not reported), headache (17.5% with paroxetine *v* 24.1% with clomipramine; P value not reported), and nausea (11.1% with paroxetine *v* 24.1% with clomipramine; P value not reported). There have been concerns about the safety of paroxetine in people under 18 years.

Comment: None.

OPTION VENLAFAXINE

One small RCT in children and adolescents with major depression receiving psychotherapy found no significant difference between venlafaxine and placebo in improvement of depressive symptoms after 6 weeks. However, the study may have lacked power to detect clinically important effects.

Benefits: We found one systematic review (search date 1998,[11] 1 RCT[18]). The RCT (33 children and adolescents aged 8–17 years with major depression receiving psychotherapy) compared venlafaxine (37.5–75.0 mg/day in divided doses) and placebo for 6 weeks.[18] It found no significant difference in improvement of depressive symptoms with venlafaxine compared with placebo (Children's Depression Inventory: P = 0.37; Hamilton Rating Scale for Depression: P = 0.50; Children's Depression Rating Scale: P = 0.48).

Harms: The RCT reported nausea in a subgroup of participants aged ≥ 13 years.[18]

Comment: The RCT lacked power to rule out a clinically important difference.

Depression in children and adolescents

OPTION LITHIUM

One small RCT in children with depression and a family history of bipolar affective disorder found no significant difference between lithium and placebo in global assessment or depression scores after 6 weeks. However, the study may have lacked power to detect clinically important effects.

Benefits: We found no systematic review. We found one RCT (30 children, aged 6–12 years, with non-bipolar depression and family history of bipolar affective disorder) comparing lithium with placebo for 6 weeks.[19] The RCT found no significant difference between lithium and placebo (global assessment: P = 0.07; 9 depression items of the Kiddie-SADS interview: P = 0.91).

Harms: Of the 17 children randomised to lithium treatment, four were withdrawn because of adverse effects (3 had confusion, 1 had nausea and vomiting).[19]

Comment: The RCT lacked power to rule out a clinically important difference. It is not routine practice to give lithium alone to depressed children. Lithium is sometimes used to augment antidepressants and to prevent mania from developing with antidepressant use, but we found no RCTs of lithium for this indication.

OPTION ST JOHN'S WORT (*HYPERICUM PERFORATUM*)

We found no RCTs on St John's Wort (*H perforatum*) in children or adolescents with depression.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ELECTROCONVULSIVE THERAPY

We found no RCTs on electroconvulsive therapy in children and adolescents with depression.

Benefits: We found no systematic review and no RCTs.

Harms: We found no specific evidence on harms in children and adolescents. Known adverse effects in adults include memory impairment. See electroconvulsive therapy under depressive disorders, p 1278.

Comment: None.

OPTION SPECIFIC PSYCHOLOGICAL TREATMENTS

One systematic review has found that cognitive behavioural therapy increases resolution of symptoms compared with non-specific supportive therapies for children and adolescents with mild to moderate depression. One subsequent RCT in depressed adolescents with depressed parents found no significant difference in recovery from depression. We found limited evidence from two small RCTs that interpersonal therapy increases recovery in adolescents with mild to moderate depression

compared with clinical monitoring alone or placement on a waiting list. We found insufficient evidence that family therapy or group treatments other than cognitive behavioural therapy are effective for depression in children and adolescents.

Benefits:

Cognitive behavioural therapy: We found one systematic review (search date 1997, 6 RCTs, 376 children and adolescents with mild to moderate depression) of cognitive behavioural therapy (see glossary, p 400) versus other treatments ranging from waiting list control to supportive psychotherapy,[20] and one subsequent RCT.[21] The systematic review found that cognitive behavioural therapy significantly increased the rate of resolution of symptoms of depression compared with other treatments (OR 3.2, 95% CI 1.9 to 5.2; NNT 4, 95% CI 3 to 5).[20] The subsequent RCT (88 adolescents aged 13–18 years with major depression or dysthymia who had depressed parents) compared cognitive behavioural therapy (16 sessions) plus usual care with usual care alone.[21] The RCT found no significant difference in recovery rate between cognitive behavioural therapy plus usual care and usual care alone at 2 years (≥ 8 weeks with few or no depressive symptoms: 13/41 [31.7%] with cognitive behavioural therapy plus usual care *v* 14/47 [29.8%] with usual care alone; RR and P value not reported). A factor that could have contributed to the absence of a treatment effect was the higher level of impairment in the participants compared with other RCTs. **Interpersonal therapy:** We found two small RCTs comparing 12 weekly sessions of interpersonal therapy (see glossary, p 401) with clinical monitoring or waiting list control in adolescents with depression.[22,23] The first RCT (48 adolescents aged 12–18 years with major depressive disorder) found that interpersonal therapy significantly increased recovery rate compared with clinical monitoring (Hamilton Rating Scale for Depression < 6 or Beck Depressive Inventory score < 9: 18/24 [75%] with interpersonal therapy *v* 11/24 [46%] with clinical monitoring alone; RR 1.64, 95% CI 1.00 to 2.68; ARR 29%, 95% CI 3% to 56%).[22] The second RCT (46 adolescents with major depression) found no significant difference in the proportion of adolescents not manifesting severe depression between interpersonal therapy and being on a waiting list (defined by a cut off score on the Children's Depression Inventory: 17/19 [89%] with interpersonal therapy *v* 12/18 [67%] with waiting list; RR 1.33, 95% CI 0.94 to 1.93; ARR +22%, 95% CI –3% to +49%).[23] However, if the Children's Depression Inventory score was considered as a continuous measure, then the mean Children's Depression Inventory score was significantly lower after interpersonal therapy versus waiting list ($P < 0.01$). **Attachment based family therapy** We found one RCT (32 adolescents aged 13–17 years with major depression) comparing 6 weeks of attachment based family therapy (see glossary, p 401) versus 6 weeks of waiting list control.[24] It found no significant difference in remission rates between attachment based family therapy and waiting list control at 6 weeks (people no longer meeting criteria for major depression on the Kiddie-SADS interview: 13/16 [81%] with attachment based family therapy *v* 7/15 [47%] on the waiting list; RR 1.74, 95% CI 0.97 to 3.14). However, the study may have lacked the power to detect a clinically important difference between groups. **Systemic behavioural family therapy:** We found one RCT

(78 adolescents with major depressive disorder) comparing systemic behavioural family therapy (see glossary, p 401) versus non-specific supportive therapy.[25] The RCT found no significant difference in remission rates (combination of no longer meeting DSM-III-R criteria for major depression as determined by the Kiddie-SADS interview and Beck Depression Inventory score < 9: 29% with family therapy *v* 34% with non-specific supportive therapy). **Group administered cognitive behavioural therapy:** We found one RCT (123 adolescents aged 14–18 years with major depression or dysthymia) comparing group administered cognitive behavioural therapy versus waiting list control.[26] It found that cognitive behavioural therapy significantly increased the remission rate (as determined by Longitudinal Interval Follow-up Evaluation interview for DSM-III-R diagnoses: 46/69 [67%] with group cognitive behavioural therapy *v* 13/27 [48%] with waiting list control; $P < 0.05$). **Group therapeutic support versus group social skills training:** We found one RCT (66 adolescents aged 13–17 years, of whom 47 completed the protocol; 58 with major depression in the past year, 8 with dysthymia in the past year) comparing group therapeutic support versus group social skills training.[27] In 26 adolescents whose Kiddie-SADS scores were in the clinical range in the week before treatment, the RCT found no significant difference in remission rates (score of < 4 on Kiddie-SADS dysphoria and anhedonia symptoms: 8/16 [50%] with group therapeutic support *v* 4/10 [40%] with group social skills training; RR and P value not provided).

Harms: The RCTs did not report any adverse events.[21–30] We found no report of harms specifically for children and adolescents.

Comment: In the first RCT of interpersonal therapy, sessions were augmented by telephone contact.[22] No long term trials of pure treatment have been reported. However, we found one prospective study, in which 107 adolescents with depression had been randomised to cognitive behavioural therapy, systemic behavioural family therapy, or non-directive supportive therapy (see glossary, p 401).[31] After the initial trial phase of 16 weeks, they were allowed booster treatments and also had access to open treatment in any modality for the 2 years of follow up. They were assessed at 3 monthly intervals for the first 12 months and then again at 24 months. The study found no significant difference between groups in depressive symptoms (of 104 adolescents for whom there were sufficient follow up data, 38% experienced sustained recovery, 21% experienced persistent depression, and 41% had a relapsing course).[31]

GLOSSARY

Cognitive behavioural therapy A brief structured treatment (20 sessions over 12–16 weeks) aimed at changing the dysfunctional beliefs and negative automatic thoughts that characterise depressive disorders.[32] Cognitive behavioural therapy requires a high level of training for the therapist, and has been adapted for children and adolescents suffering from depression. A course of treatment is characterised by 8–12 weekly sessions, in which the therapist and the child collaborate to solve current difficulties. The treatment is structured and often directed by a manual. Treatment generally includes cognitive elements, such as the challenging of negative thoughts, and behavioural elements, such as structuring time to engage in pleasurable activity.

Interpersonal therapy A standardised form of brief psychotherapy (usually 12–16 weekly sessions) intended primarily for outpatients with unipolar non-psychotic depressive disorders. It focuses on improving the individual's interpersonal functioning and identifying the problems associated with the onset of the depressive episode.[33] In children and adolescents, interpersonal therapy has been adapted for adolescents to address common adolescent developmental issues, for example separation from parents, exploration of authority in relationship to parents, development of dyadic interpersonal relationships, initial experience with the death of a relative or friend, and peer pressure.

Non-directive supportive therapy Helping people to express feelings, and clarify thoughts and difficulties; therapists suggest alternative understandings and do not give direct advice but try to encourage people to solve their own problems.

Pulsed intravenous clomipramine An intravenous loading procedure for clomipramine.

Systemic behavioural family therapy A combination of two treatment approaches that have been used effectively for dysfunctional families. In the first phase of treatment, the therapist clarifies the concerns that brought the family into treatment, and provides a series of reframing statements designed to optimise engagement in therapy and identification of dysfunctional behaviour patterns (systemic therapy). In the second phase, the family members focus on communication and problem solving skills and the alteration of family interactional patterns (family behaviour therapy).

Attachment based family therapy A brief structured psychotherapy directed to adolescents and their parents or caregivers. It aims to repair attachment while promoting the autonomy of the adolescent. The treatment has five specific tasks; the focus of the family is shifted from "fixing" the individual to improving family relationships; an alliance is established with the individual; parental empathy for the individual is enhanced by exploring the parents' own stressors and history of attachment failure; the individual is encouraged to express previously unexpressed anger about core conflicts, and the individual is encouraged to make successful connections outside the home (e.g. at school, with peers, and at work).

Substantive changes

Paroxetine One RCT added;[16] conclusion unchanged.

Attachment based family therapy versus no treatment One RCT added;[24] conclusion unchanged.

QUESTIONS

INTERVENTIONS

Key Messages

- **Oral rehydration solutions (as effective as iv fluids)** One systematic review and two additional RCTs in children with mild to moderate dehydration in developed countries found no significant difference between oral rehydration solutions versus intravenous fluids in duration of diarrhoea, time spent in hospital, or weight gain at discharge. One small RCT in children with mild to moderate dehydration managed in the emergency department found that oral rehydration reduced length of stay in the department but did not significantly reduce admission to hospital compared with intravenous fluids. One RCT in children with severe dehydration in a developing country found that oral rehydration solutions reduced the duration of diarrhoea and increased weight gain at discharge, and was associated with fewer adverse effects compared with intravenous fluids.
- **Lactose-free feeds (for duration of diarrhoea)** We found evidence from one systematic review and subsequent RCTs that lactose-free feeds versus feeds containing lactose reduce the duration of diarrhoea in children with mild to severe dehydration.
- **Loperamide (reduces duration of diarrhoea, but adverse effects unclear)** Two RCTs found that, in children with mild to moderate dehydration, loperamide versus placebo significantly reduces the duration of diarrhoea. Another RCT found no significant difference with loperamide versus placebo in the duration of diarrhoea. We found insufficient evidence about adverse effects.
- **Clear fluids (other than oral rehydration solutions)** We found no systematic review or RCTs on "clear fluids" (water, carbonated drinks, and translucent fruit juices) versus oral rehydration solutions for treatment of mild to moderate dehydration caused by acute gastroenteritis.

Diarrhoea in children

DEFINITION Acute gastroenteritis is characterised by rapid onset of diarrhoea with or without vomiting, nausea, fever, and abdominal pain.[1] In children, the symptoms and signs can be non-specific.[2] Diarrhoea is defined as the frequent passage of unformed liquid stools.[3]

INCIDENCE/ PREVALENCE Worldwide, about 3 billion–5 billion cases of acute gastroenteritis occur in children under 5 years of age each year.[4] In the UK, acute gastroenteritis accounts for 204/1000 general practitioner consultations each year in children under 5 years of age.[5] Gastroenteritis leads to hospital admission in 7/1000 children under 5 years of age a year in the UK[5] and 13/1000 in the USA.[6] In Australia, gastroenteritis accounts for 6% of all hospital admissions in children under 15 years of age.[7]

AETIOLOGY/ RISK FACTORS In developed countries, acute gastroenteritis is predominantly caused by viruses (87%), of which rotavirus is most common;[8–11] bacteria cause most of the remaining cases, predominantly Campylobacter, Salmonella, Shigella, and *Escherichia coli*. In developing countries, bacterial pathogens are more frequent, although rotavirus is also a major cause of gastroenteritis.

PROGNOSIS Acute gastroenteritis is usually self limiting but if untreated can result in morbidity and mortality secondary to water and electrolyte losses. Acute diarrhoea causes 4 million deaths a year in children under 5 years of age in Asia (excluding China), Africa, and Latin America, and over 80% of deaths occur in children under 2 years of age.[12] Although death is uncommon in developed countries, dehydration secondary to gastroenteritis is a significant cause of morbidity and need for hospital admission.[6,7,13]

AIMS OF INTERVENTION To reduce the duration of diarrhoea and quantity of stool output, and duration of hospital stay; to prevent and treat dehydration; to promote weight gain after rehydration; to prevent persistent diarrhoea associated with lactose intolerance (see glossary, p 408).

OUTCOMES Total stool volume; duration of diarrhoea (time until permanent cessation); failure rate of oral rehydration treatment (as defined by individual RCTs); weight gain after rehydration; length of hospital stay; mortality.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION **What are the effects of treatments for acute gastroenteritis?**

OPTION CLEAR FLUIDS

We found no systematic review or RCTs on "clear fluids" (water, carbonated drinks, and translucent fruit juices) versus oral rehydration solutions for treatment of mild to moderate dehydration caused by acute gastroenteritis.

Benefits: We found no systematic review or RCTs of "clear fluids" versus oral rehydration solutions (see comment below).

Harms: We found no RCTs.

Comment: In this review, oral rehydration solutions are defined as glucose plus electrolyte or food (e.g. rice) based electrolyte solutions. Fruit juices and carbonated drinks are low in sodium and potassium, and usually have a high sugar content, which can exacerbate diarrhoea.

OPTION ORAL VERSUS INTRAVENOUS FLUIDS

One systematic review and two additional RCTs in children with mild to moderate dehydration in developed countries found no significant difference between oral rehydration solutions versus intravenous fluids in duration of diarrhoea, time spent in hospital, or weight gain at discharge. One RCT in children with mild to moderate dehydration managed in the emergency department found that oral rehydration reduced length of stay in the department but did not significantly reduce length of hospital stay compared with intravenous fluids. One RCT in children with severe dehydration in a developing country found that oral rehydration solutions reduced the duration of diarrhoea and increased weight gain at discharge, and was associated with fewer adverse effects compared with intravenous fluids.

Benefits:

Mild to moderate dehydration: We found one systematic review[14] (search date 1993, 6 RCTs,[15–20] 371 children in developed countries with acute gastroenteritis, most with mild to moderate dehydration and in hospital), two additional RCTs[21,22] and one subsequent RCT[23] comparing oral rehydration solutions versus intravenous fluids (see table 1, p 410). The review and the additional RCTs found no significant difference with oral versus intravenous fluids in the duration of diarrhoea, time spent in hospital, or weight gain at discharge. If children responded poorly to oral fluids, they were given intravenous fluids, which was used as a measure of failure of oral fluids. However, the failure rate of intravenous treatment was not recorded. The subsequent RCT (34 children managed in the emergency department) did not report on duration of diarrhoea, length of hospital stay, or weight gain.[23] However, it found that oral rehydration significantly reduced length of stay in the emergency department compared with intravenous fluids, but found no significant difference for hospitalisation rate (mean length of stay in emergency department: 225 minutes with oral rehydration *v* 358 minutes with iv rehydration, $P < 0.01$; hospitalisation rate: 11% with oral rehydration *v* 25% with iv rehydration, $P = 0.2$).

Severe dehydration: We found one RCT (470 children in Iran with acute gastroenteritis with severe dehydration) comparing oral rehydration solutions versus intravenous fluids (see table 1, p 410).[24] It found that oral versus intravenous treatment significantly reduced the duration of diarrhoea (4.8 days with oral rehydration *v* 5.5 days with iv rehydration; difference 0.7 days; $P < 0.01$), and increased weight gain at discharge (percentage increase in admission weight 9% with oral rehydration *v* 7% with iv rehydration; $P < 0.001$). Failure of oral treatment (defined as the need to move to intravenous treatment) occurred in 1/236 children (0.4%; CI not reported). It found no significant difference in mortality between oral and intravenous fluids (2/236 [1%] with oral rehydration *v* 5/234 [2%] with iv rehydration; RR 0.40, 95% CI 0.08 to 2.02). Causes of death were not reported.

Diarrhoea in children

Harms: **Mild to moderate dehydration:** The systematic review reported no adverse effects.[14] One additional RCT (100 children in Afghanistan) reported fever and rigors in 9/50 children (18%) receiving intravenous fluids versus none receiving oral fluids.[21] **Severe dehydration:** The RCT in children in Iran found that significantly more children receiving intravenous treatment vomited during the first 6 hours of rehydration (47/236 [20%] with oral rehydration *v* 70/234 [30%] with iv rehydration; RR 0.64, 95% CI 0.46 to 0.89).[24] There was no significant difference in the risk of peri-orbital oedema (RR 0.99, 95% CI 0.25 to 3.92) or abdominal distension (RR 8.90, 95% CI 0.48 to 164.00). Phlebitis at the injection site requiring antibiotics occurred in 5/234 (2%) children. In the same RCT, subgroup analysis of 58 children with hypernatraemia found that fewer children taking oral versus intravenous fluids developed seizures during rehydration, although the difference did not quite reach significance (2/34 [6%] with oral rehydration *v* 6/24 [25%] with iv rehydration; RR 0.23, 95% CI 0.05 to 1.07).

Comment: The quality of the RCTs was difficult to assess because of poor reporting. Two RCTs reported the method of allocation concealment[17,23] and two reported the method of randomisation.[21,23] Blinding of outcomes was impossible owing to the nature of the intervention. Intention to treat analysis was used in all but one RCT.[17] The RCT in children managed in the emergency department was small and may have lacked power to detect clinically important effects.

OPTION LOPERAMIDE

Two RCTs found that, in children with mild to moderate dehydration, loperamide reduced the duration of diarrhoea compared with placebo. Another RCT found no significant difference between loperamide and placebo in the duration of diarrhoea. We found insufficient evidence to assess the risk of adverse effects.

Benefits: We found no systematic review. We found five RCTs in children with acute diarrhoea (701 children, most with mild to moderate dehydration) (see table 2, p 412).[25–29] Of the three RCTs that assessed the duration of diarrhoea, two[25,27] found that loperamide significantly reduced duration of diarrhoea compared with placebo (largest RCT, 315 children; risk of having diarrhoea at 24 hours, 36/100 [36%] with loperamide *v* 112/203 [55%] with placebo; RR 0.83, 95% CI 0.73 to 0.94).[25] Another RCT found no significant difference.[26] The results of other outcomes are included in table 2, p 412.

Harms: Four RCTs reported no adverse effects from loperamide.[25–27,29] One RCT found significantly more mild abdominal distension, excessive sleep, and lethargy in children taking loperamide versus placebo (3/16 [19%] with loperamide 0.8 mg/kg *v* 1/18 [6%] with 0.4 mg/kg *v* 0/18 [0%] with placebo; RR loperamide *v* placebo 4.90, 95% CI 0.28 to 86.00). Adverse effects caused one child to withdraw from the trial.[28] We found one evidence based guideline that identified case studies reporting lethargy, intestinal ileus, respiratory depression, and coma, especially in infants.[2]

Comment: We found insufficient evidence to estimate accurately the risk of adverse effects of loperamide in children.

OPTION LACTOSE-FREE FEEDS

We found evidence from one systematic review and subsequent RCTs that lactose-free feeds reduce the duration of diarrhoea compared with lactose-containing feeds in children with mild to severe dehydration.

Benefits: We found one systematic review (search date not stated, 13 RCTs, 873 children with mild to severe dehydration)[30] and four subsequent RCTs[31–34] comparing feeds containing lactose versus lactose-free feed. The review was limited by flaws in its methods (see comment below). It found that feeds containing lactose versus lactose-free feeds significantly increased "treatment failure" (89/399 [22%] with lactose *v* 56/474 [12%] with lactose-free; RR 2.1, 95% CI 1.6 to 2.7). The definition of treatment failure varied among trials and included increasing severity or persistence of diarrhoea or recurrence of dehydration. It found that lactose-free feeds versus feeds containing lactose significantly reduced the duration of diarrhoea (9 RCTs; 826 children with mild or no dehydration receiving oral rehydration treatment; 92 hours with lactose *v* 88 hours with lactose-free; SMD 0.2 hours after initiation of the study; $P = 0.001$). When the three RCTs that included children given additional solid food were excluded, it found that lactose-free versus feeds containing lactose significantly reduced the duration of diarrhoea (6 RCTs; 604 children; 95 hours with lactose *v* 82 hours with lactose-free; SMD 0.3 hours; $P < 0.001$). Children receiving lactose-free versus feeds containing lactose had significantly reduced stool frequency (4 RCTs; 387 children; 4.0 stool movements/day with lactose *v* 3.5 stool movements/day with lactose-free; SMD 0.3 stool movements/day; $P < 0.004$). Total stool volume was greater in children who received feeds containing lactose (4 RCTs; 209 children; SMD 0.4 g; $P = 0.002$). Differences in weight gain during treatment could not be assessed because of the use of solid food in two studies and considerable heterogeneity among studies. We found four subsequent RCTs (see table 3, p 413).[31–34] Two found that lactose-free versus feeds containing lactose significantly reduced the duration of diarrhoea,[31,34] and the other two found no significant difference.[32,33] The results of other outcomes are summarised in table 3, p 413.

Harms: The one RCT assessing adverse effects reported none in the treatment or control groups.[33]

Comment: Although the systematic review stated criteria for inclusion and exclusion of RCTs, only published studies were included and the method of determining RCT quality was not stated.[30] There was considerable heterogeneity among studies. Lactose-free feeds were superior to feeds containing lactose for the duration of diarrhoea. Differences for other outcomes, although statistically significant, were not clinically important.

Diarrhoea in children

GLOSSARY

Lactose intolerance Malabsorption of lactose can occur for a short period after acute gastroenteritis because of mucosal damage and temporary lactase deficiency.

QUESTIONS

INTERVENTIONS

*Not widely licensed for use in children. Clinical use in adults has been restricted because of heart rhythm abnormalities.

See glossary, p 421

Key Messages

- **Feed thickeners in infants** One systematic review of feed thickeners found no RCTs in newborn infants. One RCT in infants aged 14–120 days found that a pre-thickened infant formula reduces regurgitation, choking and gagging, and coughing within a week without causing constipation. One small RCT in infants aged 1–16 weeks found no significant difference between carob flour and placebo thickening after 1 week, although the study may have lacked power to detect a clinically important difference.
- **Sodium alginate** Two RCTs in infants and in children under 2 years found that sodium alginate reduced the frequency of regurgitation at 8–14 days compared with placebo. A third small RCT of children under 17 years of age comparing sodium alginate with metoclopramide and with placebo found no significant difference between treatments.
- **Domperidone** One small RCT provided insufficient evidence about the effects of domperidone in children with gastro-oesophageal reflux.
- **H_2 antagonists** Two small RCTs provided insufficient evidence about the effects of H_2 antagonists in children with gastro-oesophagael reflux. Neither RCT reported clinically meaningful results.
- **Metoclopramide** We found insufficient evidence from three small RCTs about the clinical effects of metoclopramide compared with placebo or other treatments.
- **Proton pump inhibitors** We found no RCTs of proton pump inhibitors for gastro-oesophageal reflux in children.
- **Surgery** We found no RCTs of surgery for gastro-oesophageal reflux in children.

- **Positioning (left lateral or prone)** Three crossover RCTs in children aged under 6 months found limited evidence that prone or left lateral positioning improved oesophageal pH variables compared with supine positioning. Both prone and left lateral positions may be associated with a higher risk of sudden infant death syndrome compared with supine positioning.
- **Cisapride** One systematic review found no significant difference between cisapride and placebo in the proportion of children with improved symptoms at the end of treatment. Cisapride has been withdrawn or restricted in several countries because of an association with heart rhythm abnormalities.

DEFINITION

Gastro-oesophageal reflux disease is the passive transfer of gastric contents into the oesophagus due to transient or chronic relaxation of the lower oesophageal sphincter.[1] A survey of 69 children (median age 16 months) with gastro-oesophageal reflux disease attending a tertiary referral centre found that presenting symptoms were recurrent vomiting (72%), epigastric and abdominal pain (36%), feeding difficulties (29%), failure to thrive (28%), and irritability (19%).[2] However, results may not be generalisable to younger children or children presenting in primary care, who make up the majority of cases. Over 90% of children with gastro-oesophageal reflux disease have vomiting before 6 weeks of age.[1]

INCIDENCE/ PREVALENCE

Gastro-oesophageal regurgitation is considered a problem if it is frequent, persistent, and is associated with other symptoms such as increased crying, discomfort with regurgitation, and frequent back arching.[1,3] A cross-sectional survey of parents of 948 infants attending 19 primary care paediatric practices found that regurgitation of at least one episode a day was reported in 51% of infants aged 0–3 months. "Problematic" regurgitation occurred in significantly fewer infants (14% *v* 51%; $P < 0.001$).[3] Peak regurgitation reported as "problematic" was reported in 23% of infants aged 6 months.[3]

AETIOLOGY/ RISK FACTORS

Risk factors for gastro-oesophageal reflux disease include immaturity of the lower oesophageal sphincter, chronic relaxation of the sphincter, increased abdominal pressure, gastric distension, hiatus hernia, and oesophageal dysmotility.[1] Premature infants and children with severe neurodevelopmental problems or congenital oesophageal anomalies are particularly at risk.[1]

PROGNOSIS

Regurgitation is considered benign, and most cases resolve spontaneously by 12–18 months of age.[4] In a cross-sectional survey of 948 parents, the peak age for reporting four or more episodes of regurgitation was at 5 months of age (23%), which decreased to 7% at 7 months ($P < 0.001$). One cohort study found that infants with frequent spilling (see glossary, p 421) in the first 2 years of life (90 days or more in the first 2 years) were more likely to have symptoms of gastro-oesophageal reflux at 9 years of age than those with no spilling (RR 2.3, 95% CI 1.3 to 4.0).[5] The prevalence of "problematic" regurgitation also reduced from 23% in infants aged 6 months to 3.25% in infants aged 10–12 months.[3] Rare complications of gastro-oesophageal reflux disease include oesophagitis with haematemesis and anaemia, respiratory problems (such as cough, apnoea, and recurrent wheeze), and failure to thrive.[1] A small comparative study (40 children) suggested that, when compared

Gastro-oesophageal reflux in children

with healthy children, infants with gastro-oesophageal reflux disease had slower development of feeding skills and had problems affecting behaviour, swallowing, food intake, and mother–child interaction.[6]

AIMS OF INTERVENTION To relieve symptoms, maintain normal growth, prevent complications such as oesophagitis, and minimise adverse effects of treatment.

OUTCOMES Clinical condition (in terms of improvement in symptoms of vomiting and regurgitation); growth; parental distress; and incidence of complications (e.g. oesophagitis). Reflux Index, a measure of the percentage of time with a low oesophageal pH (frequently < pH 4), is a surrogate outcome that is often used in RCTs. Clinical interpretation of the resulting data is problematic. We have only reported Reflux Index findings where clinical outcomes are unavailable.

METHODS *Clinical Evidence* search and appraisal September 2003. The authors also searched Cinahl for studies on incidence and prevalence. Studies did not often discuss whether breastfeeding was also undertaken or withdrawn in treatment groups. Presence or absence of concomitant breastfeeding may have confounded study results.

QUESTION What are the effects of treatment for symptomatic gastro-oesophageal reflux?

OPTION DIFFERENT SLEEP POSITIONS IN INFANTS

Three crossover RCTs in children aged under 6 months found limited evidence that prone or left lateral positioning improved oesophageal pH variables compared with supine positioning. Both prone and left lateral positions may be associated with a higher risk of sudden infant death syndrome compared with supine positioning.

Benefits: We found no systematic review or RCTs on the effect of posture on clinical symptoms, but found three small crossover RCTs on the effect of posture on oesophageal pH variables such as Reflux Index.[7–9] The first RCT (crossover, 24 infants, age < 5 months) assessed four sleep positions (supine, prone, left lateral, right lateral) over 48 hours; for the first 24 hours, the infant was held horizontally, and for the remaining 24 hours the infant's head was elevated.[7] It found that the prone and left lateral positions significantly reduced the Reflux Index over 48 hours compared with the supine and right lateral positions ($P < 0.001$); it found no significant difference in the Reflux Index with horizontal positioning compared with head elevation. The second RCT (crossover, 15 infants, age < 6 months) alternated placing infants for 2 hours in a prone position (head elevated in a harness) and placing infants for 2 hours in a supine position (in an infant seat where the head and trunk were elevated to 60°) after a feed of apple juice.[8] It found that prone positioning significantly reduced the Reflux Index over 72 normal hours compared with supine positioning ($P < 0.001$). The third RCT (crossover, 18 infants, < 37 weeks gestation but > 7

days old) compared prone versus left lateral versus right lateral positions over 24 hours. It found that prone and left lateral positions significantly reduced Reflux Index compared with right lateral position ($P < 0.001$), the number of reflux episodes ($P < 0.001$), and duration of longest reflux episode ($P < 0.001$).[9]

Harms: The RCTs gave no information on adverse effects (see comment below).[7–9]

Comment: All three RCTs measured the surrogate outcome of Reflux Index, and it is difficult to interpret the clinical importance of the observed changes.[7–9] The results of these RCTs should be interpreted with caution because oesophageal pH variable may change over time, and the results were not assessed before crossover. Both prone and left lateral positioning have been associated with an increased risk of sudden infant death syndrome (see sudden infant death syndrome for prone positioning, p 498). One large, prospective cohort study found that the left lateral sleeping position compared with the supine position increased the risk of sudden infant death syndrome (at 2 months, adjusted OR 6.6, 95% CI 1.7 to 25.2).[10]

OPTION FEED THICKENERS IN INFANTS

One systematic review of feed thickeners found no RCTs in newborn infants. One RCT in infants aged 14–120 days found that a pre-thickened infant formula reduces regurgitation, choking and gagging, and coughing within a week without causing constipation. One small RCT in infants aged 1–16 weeks found no significant difference between carob flour and placebo thickening after 1 week, although the study may have lacked power to detect a clinically important difference.

Benefits: We found one systematic review (search date 2001), full-term infants < 28 days of age and preterm infants up to 44 weeks postmenstrual corrected age)[11] and two RCTs in older infants.[12,13] The review identified no RCTs that reported results separately for neonates. **Versus placebo:** The first RCT (20 infants aged 1–16 weeks with regurgitation > 5 times daily, receiving formula feeds, parental reassurance and prone positioning) compared carob flour thickened feeds with placebo thickening (Saint John's bread, which is free of fibre and polysaccharides).[12] It found no significant difference in regurgitation rates between carob flour and placebo thickening after 1 week of treatment (mean regurgitation score 2.2 with carob flour *v* 3.3 with placebo; $P = 0.14$). The second RCT (104 infants aged 14–120 days, with regurgitation ≥ 5 times a day) compared pre-thickened milk formula (Enfamil AR®) versus standard milk formula.[13] It found that thickened feed significantly reduced regurgitation after feeding and the volume regurgitated compared with placebo at 1 and 5 weeks (% decrease in feeds that were followed by regurgitation, 1 week: –34% with thickened feed *v* –22% with standard feed, $P = 0.045$; week 5: –38% with thickened feed *v* –24% with standard feed, $P = 0.036$; decrease in regurgitation volume, 1 week: –4.5% with thickened feed *v* –3.4% with standard feed, $P = 0.035$; week 5: –4.6% with thickened feed *v* –3.4% with standard feed, $P = 0.050$). It found that thickened feed significantly reduced the percentage of feeds

with choke-gag reflux (see glossary, p 421) at 1 and 5 weeks (1 week decrease from baseline: 27% with thickened feed *v* 15% with control, P = 0.004; 5 week decrease from baseline significant in favour of thickened feed: P = 0.049, no other data provided).

Harms: The second RCT (104 infants) found no significant difference in discontinuation rates between thickened feed and control (discontinuation: 13% with thickened feed *v* 20% with standard formula, P not reported).[13] It is not clear in the paper what the babies who discontinued from standard formula moved on to. One RCT (24 children, age 0–6 months with gastro-oesophageal reflux disease), assessing the effects of feed thickeners on cough, found that feeds thickened with dry rice cereal significantly increased coughing after feeding compared with isocaloric unthickened feeds (mean cough salvos/hour 3.1 with thickened feeds *v* 2.0 with unthickened feeds; P = 0.034).[14]

Comment: The clinical significance of changes in regurgitation scores in the first RCT is unclear.[12] One small crossover RCT (24 infants, age 5–11 months) found that carob flour significantly reduced a symptom score and the frequency of vomiting recorded by parents compared with traditional formula thickened with rice after 2 weeks (symptom score: mean relative reduction 70% with carob flour *v* 49% with traditional formula plus rice, P < 0.01; frequency of vomiting as recorded by parents, P < 0.05).[15] The results of this crossover RCT should be treated with caution because symptoms may change over time and the results were not assessed before crossover.[15]

OPTION SODIUM ALGINATE

Two RCTs in infants and in children under 2 years found that sodium alginate reduced the frequency of regurgitation at 8–14 days compared with placebo. A third small RCT of children under 17 years of age comparing sodium alginate with metoclopramide and with placebo found no significant difference between treatments.

Benefits: We found no systematic review but we found three RCTs.[16–18] The first RCT (90 infants aged 0–12 months attending 25 general practices) found that aluminium-free alginate reduced the number of episodes of vomiting after 14 days and increased the number of symptom free days compared with placebo (median number of episodes in previous 24 hours: 3.0 with alginate *v* 5.0 with placebo, P = 0.009; at least 10% symptom free days: 31% with alginate *v* 11% with placebo, P = 0.027).[16] The second RCT (20 children, mean age 28 months) found that sodium alginate reduced the total number of reflux episodes per 24 hours, as detected with pH monitoring, compared with baseline (episodes: alginate 131.6 at baseline to 65.0 after treatment; placebo 87 at baseline to 91 post-treatment; between treatment comparisons were not reported).[17] The third RCT (30 children aged 4 months to 17 years) found no significant difference in the frequency of regurgitation episodes over 24 hours with sodium alginate, metoclopramide, or placebo given before a meal (episode defined as pH < 4) or in Reflux Index over 24 hours (reported as non-significant; no further data reported).[18]

Harms: One RCT found no significant difference in adverse effects between aluminium-free alginate and placebo.[16] One other RCT found no adverse effects.[17]

Comment: The high sodium content of sodium alginate may be inappropriate in preterm babies.[19]

OPTION CISAPRIDE

One systematic review found no significant difference between cisapride and placebo in the proportion of children with improved symptoms or in prevalence of oesophagitis at the end of treatment. Cisapride has been withdrawn or restricted in several countries because of an association with life-threatening heart rhythm abnormalities.

Benefits: We found one systematic review (search date 2002, 10 RCTs, 415 children aged up to 5 years).[20] It found no significant difference between cisparide and placebo at 2–8 weeks in vomiting score or endoscopically confirmed oesophagitis (5 RCTs, 156 children: standardised WMD in vomiting score −0.18; 95% CI −0.51 to +0.15; oesophagitis, 2 RCTs, 37 children: RR 0.80, 95% CI 0.40 to 1.61).[20]

Harms: The systematic review found no significant difference between cisapride and placebo in adverse events (6 RCTs: RR 1.16; 95% CI 0.95 to 1.41).[20] Adverse effects included fever, insomnia, nervousness, irritability, diarrhoea, vomiting, eructations, cough, upper respiratory tract infection, and asthma. One of the included RCTs (68 children aged 6 months to 4 years) assessed mean corrected QTc on electrocardiograph and found no significant difference between cisapride and placebo.[21] See comment below.

Comment: The authors of the systematic review stated that, in view of the small number of children analysed, there was still uncertainty about the beneficial effect of cisapride. They estimated that a minimum sample size of 120 children per treatment arm would be required to detect a 30% reduction in vomiting with cisapride. Limitations in the identified RCTs included incomplete reporting of study design, lack of clear description of methods used to randomise children, and adverse effects not reported as clearly or completely as the benefits. Cisapride has been withdrawn or its use restricted in several countries because of an increased frequency of heart rhythm abnormalities that are associated with sudden death.[22] One case control study (201 children, age 1–12 months) found that cisapride significantly prolonged the QTc interval on electrocardiogram in a subgroup of infants younger than 3 months, but in older infants the difference was not significant.[23] A second case control study (252 infants) found similar results.[24] A third case control study (120 children) found prolonged QT interval in some normal children with or without cisapride.[25] Gastrointestinal adverse effects (borborygmi, cramps, and diarrhoea) occurred in 2% of infants.[23] Rash, pruritus, urticaria, bronchospasm, extrapyramidal effects, headache, dose-related increases in urinary frequency, hyperprolactinaemia, and reversible liver function abnormalities were extremely rare. Most macrolide antibiotics and cimetidine elevate plasma cisapride levels and may increase the clinical risk.[23]

Gastro-oesophageal reflux in children

OPTION DOMPERIDONE

One small RCT provided insufficient evidence about the effects of domperidone in children with gastro-oesophageal reflux.

Benefits: We found no systematic review. One small RCT (17 children, age 5 months to 11 years) found no significant difference in symptoms (vomiting, spitting, irritability, heartburn, coughing, choking), as assessed by daily parent record or Reflux Index, after 4 weeks of treatment between domperidone and placebo.[26] The RCT might have been too small to exclude a clinically important difference.

Harms: The RCT found that four children taking domperidone had mild self limiting diarrhoea compared with two children taking placebo.[26]

Comment: None.

OPTION H_2 ANTAGONISTS

Two small RCTs provided insufficient evidence about the effects of H_2 antagonists on children with gastro-oesophageal reflux.

Benefits: We found no systematic review but found two small RCTs.[27,28] The first RCT (double blind, 37 children aged 1 month to 14 years with gastro-oesophageal reflux disease complicated by oesophagitis, 32 analysed) found that cimetidine 30–40 mg/kg daily significantly increased the proportion of children who improved compared with placebo at 12 weeks (67.4% improved in clinical score from baseline with cimetidine *v* 29.6% with placebo; $P < 0.01$).[27] The clinical score was developed for the study and the clinical importance of this result is unclear. The second small RCT (27 children, aged 3–14 years with gastro-oesophageal reflux disease) compared different doses of cimetidine but reported only physiological outcomes (gastric pH, gastric acid suppression).[28] We found no RCTs of ranitidine in children.

Harms: The RCTs found no adverse effects.[27,28]

Comment: Both RCTs were small and provide insufficient evidence about clinical effects. Cimetidine has been reported to cause bradycardia in a small subgroup of people and may increase cisapride plasma levels.[23] Uncontrolled studies of ranitidine have reported bronchospasm, acute dystonic reactions, sinus node dysfunction, bradycardia, and vasovagal reactions.[23]

OPTION METOCLOPRAMIDE

We found insufficient evidence from three small RCTs about the clinical effects of metoclopramide compared with placebo or other treatments.

Benefits: We found no systematic review but found three RCTs.[18,29,30] The first RCT (crossover; 30 infants aged 1–9 months receiving formula feed) found that metoclopramide 1 mg/kg four times daily significantly reduced the Reflux Index over 2 weeks compared with placebo ($P < 0.001$), but it found no significant difference in average daily symptoms (see comment below).[29] A second RCT (44 infants aged under 1 year) found no significant difference in the Reflux

Index at 14 days between metoclopramide 0.2 mg three times daily and placebo before a meal.[30] A third RCT (30 infants aged 4 months to 17 years) compared three treatments: metoclopramide sodium alginate, and placebo (see benefits of sodium alginate, p 418).[18]

Harms: The RCTs gave no information on adverse effects.[18,29,30]

Comment: The results of the crossover RCT should be treated with caution as it did not assess the effects of metoclopramide versus placebo before crossover.[29] In the second RCT 5/44 (11%) of infants withdrew from the study, three because of lack of efficacy and two for unknown reasons; the results given are not intention to treat.[30] One observational study (42 infants), which assessed the effect of metoclopramide 0.2 mg or 0.3 mg on pH parameters, found that metoclopramide was associated with dystonia in one infant and increased irritability in three infants.[31]

OPTION PROTON PUMP INHIBITORS

We found no RCTs of proton pump inhibitors for gastro-oesophageal reflux in children.

Benefits: We found no systematic review or RCTs on proton pump inhibitors. One small case series did not report clinical outcomes.[32]

Harms: We found no systematic review or RCTs.

Comment: Proton pump inhibitors have been reported to cause hepatitis, and omeprazole chronically elevates serum gastrin.[32]

OPTION SURGERY

We found no RCTs of surgery for gastro-oesophageal reflux in children.

Benefits: We found no systematic review or RCT.

Harms: A retrospective review (106 children) of modified Nissen's fundoplication found a failure rate of 8% and, when neurologically impaired children were included, a long term mortality of 8%.[33] If only neurologically normal children were considered, then the mortality was 2% in the immediate postoperative period and 3% on long term follow up (3 deaths in 62 children; all deaths were in children with congenital abnormalities).

Comment: We found a case series of 22 children who had undergone anterior gastric fundoplication.[34] Twenty children (91%) remained asymptomatic at 2 years. Complications of surgical treatment include dumping, retching, intestinal obstruction, "gas bloat", and recurrence of gastro-oesophageal reflux disease.[19]

GLOSSARY

Spilling When liquid or substance in small particles falls or spills out of the mouth.

Choke-gag reflux Regurgitation of food into the pharynx and upper oesophagus that causes choking and gagging as the person tries to protect the airway in an automatic reflex action.

Gastro-oesophageal reflux in children

Substantive changes

Feed thickeners One additional RCT found that feed thickeners decreased regurgitation compared with control.[13] Feed thickeners recategorised as Likely to be beneficial.

Cisapride One systematic review added;[20] categorisation unchanged.

Infantile colic

Search date September 2003

Teresa Kilgour and Sally Wade

QUESTIONS

INTERVENTIONS

See glossary, p 433

Key Messages

- **Whey hydrolysate milk** One small RCT found limited evidence that replacing cows' milk formula with whey hydrolysate formula reduced crying recorded in a parental diary.
- **Dicycloverine (dicyclomine)** Two systematic reviews of RCTs of variable quality found limited evidence that dicycloverine reduced crying in infants with colic compared with placebo. RCTs found that dicycloverine increased drowsiness, constipation, and loose stools compared with placebo, but the difference did not reach significance. Case reports of harms in infants have included breathing difficulties, seizures, syncope, asphyxia, muscular hypotonia, and coma.
- **Advice to reduce stimulation** One RCT found limited evidence that advice to reduce stimulation (by not patting, lifting, or jiggling the baby, or by reducing auditory stimulation) reduced crying after 7 days in infants under 12 weeks of age compared with an empathetic interview giving no advice. However, we were unable to draw reliable conclusions from this small study.
- **Car ride simulation** One RCT found no significant difference between car ride simulation plus reassurance; counselling mothers about specific management techniques plus reassurance; and reassurance alone, in terms of maternal anxiety or hours of infant crying over 2 weeks.
- **Casein hydrolysate milk** Two RCTs found insufficient evidence about the effects of replacing cows' milk formula with casein hydrolysate hypoallergenic formula.
- **Cranial osteopathy** We found no RCTs about the effects of cranial osteopathy in infants with colic.

Clin Evid 2004;11:424–435.

- **Counselling** One RCT found no significant difference between counselling mothers about specific management techniques (responding to crying with gentle soothing motion, avoiding over stimulation, using a pacifier, and prophylactic carrying) plus reassurance; a car ride simulation plus reassurance; and reassurance alone, in terms of maternal anxiety or hours of infant crying over 2 weeks. Another small RCT found that counselling decreased duration and extent of crying compared with substitution of soya or cows' milk with casein hydrolysate formula.
- **Herbal tea** One small RCT found that herbal tea (containing extracts of camomile, vervain, liquorice, fennel, and balm mint in a sucrose solution) improved symptoms of colic rated by parents at 7 days compared with sucrose solution alone. However, we were unable to draw reliable conclusions from this small study.
- **Infant massage** One RCT found no significant difference between massage and a crib vibrator in colic related crying or parental rating of symptoms of infantile colic, but it may have lacked power to detect a clinically important difference.
- **Low lactose (lactase treated) milk** Four small crossover RCTs found insufficient evidence on the effects of low lactose milk in infants with colic.
- **Soya based infant feeds** One small RCT found that soya based infant feeds reduced the duration of crying in infants with colic compared with standard cows' milk formula. However, we were unable to draw reliable conclusions from this small study.
- **Spinal manipulation** Two RCTs found insufficient evidence about the effects of spinal manipulation.
- **Sucrose solution** One small crossover RCT found limited evidence that sucrose solution improved symptoms of colic as rated by parents after 12 days compared with placebo. However, we were unable to draw reliable conclusions from this small study.
- **Advice to increase carrying** One RCT found no significant difference in daily crying time between advice to carry the infant, even when not crying, for at least an additional 3 hours a day, and general advice (to carry, check baby's nappy, feed, offer pacifier, place baby near mother, or use background stimulation such as music). The "advice to carry" group carried their babies for 4.5 hours daily compared with 2.6 hours daily in the general advice group.
- **Simethicone (activated dimeticone)** One RCT found no significant difference between simethicone and placebo in colic rated by carers. Another RCT found no significant difference between simethicone and placebo in improvement as rated by parental interview, 24 hour diary, or behavioural observation. Another poor quality RCT found that simethicone reduced the number of crying attacks on days 4–7 of treatment compared with placebo.

DEFINITION Infantile colic is defined as excessive crying in an otherwise healthy baby. The crying typically starts in the first few weeks of life and ends by 4–5 months. Excessive crying is defined as crying that lasts at least 3 hours a day, for 3 days a week, for at least 3 weeks.[1] Due to the natural course of infantile colic, it can be difficult to interpret trials which do not include a placebo or no treatment group for comparison.

INCIDENCE/ PREVALENCE Infantile colic causes one out of six families (17%) to consult a health professional. One systematic review of 15 community based studies found a wide variation in prevalence, which depended on

Infantile colic

study design and method of recording.[2] Two prospective studies identified by the review yielded prevalence rates of 5% and 19%.[2] One RCT (89 breast and formula fed infants) found that, at 2 weeks of age, the prevalence of crying more than 3 hours a day was 43% among formula fed infants and 16% among breast fed infants. The prevalence at 6 weeks was 12% (formula fed) and 31% (breast fed).[3]

AETIOLOGY/ RISK FACTORS The cause is unclear and, despite its name, infantile colic may not have an abdominal cause. It may reflect part of the normal distribution of infantile crying. Other possible explanations are painful intestinal contractions, lactose intolerance, gas, or parental misinterpretation of normal crying.[1]

PROGNOSIS Infantile colic improves with time. One study found that 29% of infants aged 1–3 months cried for more than 3 hours a day, but by 4–6 months of age the prevalence had fallen to 7–11%.[4]

AIMS OF INTERVENTION To reduce infant crying and distress, and the anxiety of the family, with minimal adverse effects of treatment.

OUTCOMES Duration of crying or colic, as measured on dichotomous, ordinal, or continuous scales; parents' perceptions of severity, recorded in a diary.

METHODS *Clinical Evidence* search and appraisal September 2003. The contributors also searched Cinahl up to 1999 for publications using reduction in crying or colic as the main outcome. Trials were excluded for the following reasons: infants studied had normal crying patterns, infants were older than 6 months, interventions lasted less than 3 days, trials had no control groups, or had low scores on the Jadad Scale (see glossary, p 433).[5]

QUESTION What are the effects of treatments for infantile colic?

OPTION DICYCLOVERINE (DICYCLOMINE)

Two systematic reviews of RCTs of variable quality found limited evidence that dicycloverine reduced crying in infants with colic compared with placebo. RCTs found that dicycloverine increased drowsiness, constipation, and loose stools compared with placebo, but the difference did not reach significance. Case reports of harms in infants have included breathing difficulties, seizures, syncope, asphyxia, muscular hypotonia, and coma.

Benefits: We found two systematic reviews.[1,6] The first systematic review (search date 1996)[1] identified five RCTs (134 infants) comparing the effect of dicycloverine (see glossary, p 433) versus placebo on crying or the presence of colic. It found that dicycloverine (most frequently 5 mg 4 times daily) significantly reduced crying over about 1 week's treatment compared with placebo (5 RCTs; effect size 0.46, 95% CI 0.33 to 0.60).[1] The clinical importance of this result is unclear (see comment below).[6] The second systematic review (search date 1999)[6] identified three RCTs included in the first systematic review,[1] but did not pool results. One RCT[7] identified by the review found that dicycloverine significantly reduced colic compared with placebo (cherry syrup) (elimination of colic: 63%

with dicycloverine *v* 25% with placebo; RR 0.50, 95% CI 0.28 to 0.88).[6] The other two RCTs identified by the review used definitions of colic that included symptoms but not duration and frequency, and reported results in terms of clinical scores.[6] The review reported that both RCTs found significantly better mean clinical scores with dicycloverine compared with placebo (P values not reported).

Harms: Two of five RCTs[8,9] in the systematic reviews[1,6] assessed harms of dicycloverine compared with placebo. The first RCT (crossover design, 30 infants) found more drowsiness with dicycloverine compared with placebo (4/30 [13%] with dicycloverine *v* 1/30 [3%] with placebo; ARI +10%, 95% CI −4% to +24%).[8] The second RCT (crossover design, 25 infants) found more loose stools or constipation in infants taking dicycloverine compared with placebo (3/25 [12%] with dicycloverine *v* 1/25 [4%] with placebo; ARI +8%, 95% CI −7% to +23%).[9] Case reports of harms in infants have included breathing difficulties, seizures, syncope, asphyxia, muscular hypotonia, and coma.[10]

Comment: The first review is limited because it pooled different outcome measures from RCTs and included crossover studies that only report outcomes after crossover.[1] The crossover design is unlikely to provide valid evidence because infantile colic has a naturally variable course, and the effects of dicycloverine may continue even after a washout period.[11] Only one RCT identified by the reviews stated measures to make the control syrup taste the same as the drug syrup.[8]

OPTION SIMETHICONE (ACTIVATED DIMETICONE [DIMETHICONE])

One RCT found no significant difference between simethicone and placebo in colic rated by carers. Another RCT found no significant difference between simethicone and placebo in improvement as rated by parental interview, 24 hour diary, or behavioural observation. Another poor quality RCT found that simethicone reduced the number of crying attacks on days 4–7 of treatment compared with placebo.

Benefits: We found two systematic reviews (search dates 1996,[1] 1999,[6] same 3 RCTs in each review, 136 infants) comparing the effect of simethicone (see glossary, p 434) versus placebo on the duration of crying or the presence of colic. The first RCT identified by the reviews (double blind, crossover, 83 infants aged 2–8 weeks) compared 0.3 mL of simethicone versus placebo before feeds.[12] It found no significant difference in colic when rated by carers (28% improved with simethicone *v* 37% with placebo *v* 20% with both; effect size for simethicone versus placebo −0.10, 95% CI −0.27 to +0.08).[1,12] The second RCT identified by the reviews (double blind, crossover trial, 27 infants aged 2–8 weeks) found no significant difference between simethicone and placebo in improvement as rated by parental interview, 24 hour diary, or behavioural observation (effect size +0.06, 95% CI −0.17 to +0.28).[1,13] The third, poor quality RCT identified by the reviews (26 infants aged 1–12 weeks) reported no details on how cases of colic were defined.[14] It found that simethicone significantly reduced the number of crying attacks on days 4–7 of treatment compared with placebo (effect size 0.54, 95% CI 0.21 to 0.87).[1,14]

Harms: None of the RCTs reported adverse effects with either simethicone or placebo.[12–14]

Comment: The crossover design of two of the RCTs limits their validity as they did not report results before crossover and infantile colic has a naturally variable course; therefore the effects of simethicone may continue even after a washout period.[12,13]

OPTION SOYA BASED INFANT FEEDS (COMPARED WITH COWS' MILK)

One small RCT found that soya based infant feeds reduced the duration of crying in infants with colic compared with standard cows' milk formula. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found two systematic reviews (search dates 1996[1] and 1999,[6] 2 RCTs). One RCT (19 infants) found that soya based infant feeds (see glossary, p 434) significantly reduced the duration of crying compared with standard cows' milk formula (4.3–12.7 hours with soya based infant feeds *v* 17.3–20.1 hours with cows' milk; mean difference –10.3 hours, 95% CI –16.2 hours to –4.3 hours).[15] The other RCT provided insufficient evidence as it considered infants admitted to hospital for colic and used weak methods (Jadad score 1 [see glossary, p 433]).[16]

Harms: None reported in the RCTs.[15,16]

Comment: In the first RCT, mothers were not told which milk the babies received, but differences between the milks may have been detected from smell and texture.[15] We were unable to draw reliable conclusions from the second small RCT.

OPTION CASEIN HYDROLYSATE MILK (COMPARED WITH COWS' MILK)

Two RCTs found insufficient evidence about the effects of replacing cows' milk formula with casein hydrolysate hypoallergenic formula.

Benefits: We found two systematic reviews (search dates 1996[1] and 1999[6]), which identified the same two RCTs.[17,18] The first RCT (double blind, crossover, 17 infants) included in the reviews studied the effect of each of three changes of infant diet over 4 days.[17] Bottle fed infants received casein hydrolysate milk (see glossary, p 433) and cows' milk alternately. By the third change, it found no notable difference in the incidence of colic between groups. A total of 8/17 (47%) infants left the study before completion. The second RCT (122 infants) included in the reviews compared bottle fed infants (38 infants) given casein hydrolysate milk (active diet) versus cows' milk formula and breast fed infants (77 infants) with mothers on a hypoallergenic diet (see glossary, p 433) (active diet) versus controls on an unmodified diet.[18] A total of 54 infants received the active diet, but the RCT did not specify which of these were bottle fed and which were breast fed. The RCT pooled the results of breast

and bottle fed babies and found that the active diet versus control diet reduced infant distress as measured by parents on a validated chart. The number of bottle fed infants was too small to establish or exclude important effects in infants bottle fed casein hydrolysate milk versus cows' milk.

Harms: None reported in the RCTs.[17,18]

Comment: None.

OPTION WHEY HYDROLYSATE FORMULA (COMPARED WITH COWS' MILK FORMULA)

One small RCT found limited evidence that replacing cows' milk formula with whey hydrolysate formula reduced crying recorded in a parental diary.

Benefits: We found two systematic reviews (search dates 1996[1] and 1999[6]) and one subsequent RCT.[19] The systematic reviews found no RCTs of adequate quality. The subsequent, double blind RCT (43 infants) found that whey hydrolysate formula (see glossary, p 434) reduced the time that babies cried each day compared with standard cows' milk formula, measured by a validated parental diary (crying reduced by 63 minutes/day, 95% CI 1 minute/day to 127 minutes/day).[19] Parents may not have been blind to the intervention. When asked, six indicated that they were aware of allocation, but two of these falsely identified the formula. When these infants' results were removed from the analysis, the crying time with whey hydrolysate formula was still significantly reduced compared with standard cows' milk formula (crying reduced by 58 minutes/day; $P = 0.03$).[19]

Harms: None identified in the subsequent RCT.[19]

Comment: None.

OPTION LOW LACTOSE (LACTASE TREATED) MILK

Four small crossover RCTs provided insufficient evidence on the effects of low lactose milk in infants with colic.

Benefits: We found two systematic reviews (search dates 1996[1] and 1999,[6] 2 RCTs) and two additional RCTs.[20,21] The first RCT included in the reviews (double blind, crossover, 10 weaned infants) compared four interventions: bottle feeding using pooled breast milk; low lactose (lactase treated) breast milk; cows' milk; and low lactose (lactase treated) cows' milk.[22] It found no evidence that low lactose milk reduced the timing, severity, or duration of colic recorded by parents (days with colic: lactose containing milks *v* lactase treated milks, $P > 0.05$; duration and severity of colic: lactose containing milks *v* lactase treated milk, $P > 0.05$).[22] The second RCT (12 breast fed infants) included in the reviews compared low lactose versus placebo drops given within 5 minutes of feeding.[6] It found no significant difference in time spent feeding, sleeping, or crying. The first additional RCT (crossover, 13 infants) compared low lactose milk versus placebo treated milk.[20] It found a significant reduction in crying time with low lactose milk (1.1 hours/day, 95% CI 0.2 hours/day to 2.1 hours/day); however, caution should be applied in

interpreting the results because of the small number of infants in the trial and the crossover design (see comments below). The second additional RCT (crossover, 53 infants) found that low lactose formula/breast milk reduced crying time after crossover at 25 days compared with untreated formula/breast milk, but the difference was not significant (median 11.0 hours with lactase *v* 14.1 hours with no lactase; median difference in crying time 23%; P = 0.09).[21]

Harms: None reported in the RCTs.[1,6,20,21]

Comment: It is difficult to draw firm conclusions from these RCTs.[1,6,20,21] The babies were not selected on the basis of confirmed lactose intolerance. The crossover design of three of the RCTs limits their validity and clinical utility because infantile colic has a naturally variable course.[20–22]

OPTION SUCROSE SOLUTION

One small crossover RCT found limited evidence that sucrose solution improved symptoms of colic as rated by parents after 12 days compared with placebo. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found one systematic review (search date 1999,[6] 1 RCT[23]). The small crossover RCT (19 infants) included in the review compared 2 mL of 12% sucrose solution versus placebo given to babies when they continued to cry despite comforting.[23] Parents, blind to the intervention, scored the effect of the treatment on a scale of 1–5. Treatments were crossed over after 3–4 days and again after 6–8 days. The RCT found that sucrose significantly increased parent rated improvement after 12 days compared with placebo (12/19 [63%] with sucrose *v* 1/19 [5%] with placebo; ARI 58%, 95% CI 10% to 89%; NNT 2, 95% CI 1 to 10; RR 12, 95% CI 3 to 19).[23]

Harms: None reported in the RCT.[23]

Comment: We were unable to draw reliable conclusions from this small study.

OPTION HERBAL TEA

One small RCT found that herbal tea (containing extracts of camomile, vervain, licorice, fennel, and balm mint in a sucrose solution) improved symptoms of colic rated by parents at 7 days compared with sucrose solution alone. However, we were unable to draw reliable conclusions from this small study.

Benefits: We found two systematic reviews (search dates 1996[1] and 1999,[6] 1 RCT[24]). The RCT (68 infants) included in the reviews compared herbal tea (containing extracts of camomile, vervain, licorice, fennel, and balm mint in a sucrose solution) versus sucrose solution alone given by parents up to three times daily in response to episodes of colic.[24] Allocation was known only to the pharmacist, and the taste and smell of the tea and placebo were similar. Parents rated the response using a symptom diary. The RCT found that, at 7 days, herbal tea eliminated colic significantly more frequently than sucrose solution (number of infants colic free: 19/33 [58%] with herbal tea *v* 9/35 [26%] with sucrose; ARI 32%, 95% CI 7% to 53%; RR 2.2, 95% CI 1.3 to 3.1; NNT 3, 95% CI 2 to 14).

Harms: None reported in the RCT.[24]

Comment: The RCT did not state the exact proportion of the herbs used in the preparation.[24] We were unable to draw reliable conclusions from this small study.

OPTION BEHAVIOURAL MODIFICATION

One RCT found no significant difference between counselling mothers about specific management techniques (responding to crying with gentle soothing motion, avoiding over stimulation, using a pacifier, and prophylactic carrying) plus reassurance; car ride simulation plus reassurance; and reassurance alone, in terms of maternal anxiety or hours of infant crying over 2 weeks. Another small RCT found that counselling decreased duration and extent of crying compared with substitution of soya or cows' milk with casein hydrolysate formula. One RCT found limited evidence that advice to reduce stimulation (by not patting, lifting, or jiggling the baby, or by reducing auditory stimulation) reduced crying after 7 days in infants under 12 weeks compared with an empathetic interview giving no advice. One RCT found no significant difference in daily crying time between advice to carry the infant, even when not crying, for at least an additional 3 hours a day and general advice (to carry, check baby's nappy, feed, offer pacifier, place baby near mother, or use background stimulation such as music).

Benefits: We found two systematic reviews (search dates 1996[1] and 1999,[6] 4 RCTs). **Counselling plus reassurance versus car ride simulation plus reassurance versus reassurance alone:** One RCT (38 infants) assessed maternal anxiety and the hours of crying each day by questionnaire.[25] The RCT compared three interventions: counselling mothers about specific management techniques (responding to crying with gentle soothing motion, avoiding over stimulation, using a pacifier, and prophylactic carrying) plus reassurance (see glossary, p 434) and support; car ride simulation device plus reassurance and support; and reassurance and support alone. It found no significant difference among groups in maternal anxiety or hours of infant crying over 2 weeks (mean hours of crying: results presented graphically, P value not provided; mean maternal anxiety score: results presented graphically, P value not provided).[25] **Counselling versus elimination of cows' milk protein:** One RCT (20 infants) found that counselling parents to respond to their baby's cries by feeding, holding, offering a pacifier, stimulating, or putting the baby down to sleep, decreased the duration and extent of crying significantly more than substitution of soya or cows' milk with casein hydrolysate formula (mean decrease in crying, recorded by parent diary, 2.1 hours/day with counselling *v* 1.2 hours/day with dietary change; $P = 0.05$).[26] **Advice to increase carrying versus general advice:** One RCT (66 infants) compared advising mothers of babies with colic to carry their infant, even when not crying, for at least an additional 3 hours a day versus general advice (to carry, check baby's nappy, feed, offer pacifier, place baby near mother, or use background stimulation such as music).[27] Women in the "advice to carry" group carried their babies for 4.5 hours daily compared with 2.6 hours daily in the general advice group. The RCT found no significant difference in daily crying time (mean difference

3 minutes less, 95% CI 37 minutes less to 32 minutes more).[27] **Advice to reduce stimulation versus no advice:** One RCT (42 infants, median age 10 weeks) compared advising mothers to reduce stimulation (by not patting, lifting, or jiggling the baby, or reducing auditory stimulation) versus empathetic interview giving no advice.[28] For infants under 12 weeks, advice to reduce stimulation significantly improved a change rating scale for more infants compared with no advice (after 7 days: 14/15 [93%] improved with advice *v* 6/12 [50%] with control; ARI 43%, 95% CI 8% to 49%; RR 1.9, 95% CI 1.2 to 2.0; NNT 2, 95% CI 2 to 13).[28] Improvement in the change rating scale was defined as a score of +2 or better on a scale from –5 to +5 that indicated a perceived change in crying since the start of the trial. It is unclear whether this scale has been validated (see comment below).

Harms: None reported in the RCTs identified by the reviews.[1,6]

Comment: Behavioural modification involves interventions to change the way in which parents respond to their babies crying from colic. Mothers given advice to reduce stimulation were also given permission to leave their infants if they felt they could no longer tolerate the crying. It is unclear whether the improved change score represents a true change in the hours that the baby cried, or altered maternal perception.

OPTION CRANIAL OSTEOPATHY

We found no RCTs on the effects of cranial osteopathy in infants with colic.

Benefits: We found no systematic review and no RCTs on the effects of cranial osteopathy (see glossary, p 433) in infants with colic.

Harms: We found no RCTs.

Comment: None.

OPTION INFANT MASSAGE

One RCT found no significant difference between massage and a crib vibrator for colic related crying or parental rating of symptoms of infantile colic, but it may have lacked power to detect a clinically important difference.

Benefits: We found no systematic review. **Versus usual care:** We found no RCTs. **Versus other care:** We found one RCT (58 infants, 47% with colic; see comment below) comparing massage versus a crib vibrator over a 4 week period.[29] Infant massage (performed 3 times daily) included gentle stroking of the skin over different parts of the head, body, and limbs, using olive oil and while maintaining eye contact. The crib vibrator was used for 25 minute periods at least three times daily (see comment below). Colic symptom ratings were obtained from parental diaries of crying. The RCT found no significant difference between massage and a crib vibrator for colic related crying or parental rating of symptoms (AR for less colicky crying: 64% with massage *v* 52% with crib vibrator; P = 0.24).[29]

Harms: None reported in the RCT.[29]

Comment: Only 47% of infants in the RCT had colic, so the results may not apply specifically to infants with colic.[29] The RCT stated that "use of a crib vibrator was chosen for control intervention or placebo treatment because it had been ineffective in a previous study".[29] It is unclear whether reduced crying in this RCT reflects the natural course of infantile colic or the specific effect of interventions.[29] The RCT may have lacked power to detect clinically important effects.

OPTION SPINAL MANIPULATION

Two RCTs found insufficient evidence about the effects of spinal manipulation.

Benefits: We found no systematic review. We found two RCTs that considered the effects of spinal manipulation (see glossary, p 434).[30,31] **Versus simethicone (activated dimeticone [dimethicone]):** One RCT (41 infants) compared 2 weeks of spinal manipulation versus 2 weeks of daily treatment with simethicone (see glossary, p 434); parents recorded length of crying in a colic diary. It found that spinal manipulation significantly reduced crying compared with simethicone (mean reduction in crying for days 4–7: 2.4 hours with spinal manipulation *v* 1.0 hours with simethicone; $P = 0.04$).[30] Parents were not blinded to treatment allocation. **Versus holding:** One RCT (86 infants) compared spinal palpation by a chiropractor versus holding of the infant by a nurse (in each case 3 times over 8 days).[31] The parents, who were blind to the intervention, rated symptom severity on a five point scale and recorded crying in a diary. The RCT found no significant difference between spinal palpation and holding for crying reduction (by day 8, mean reduction 3.1 hours for both groups; $P = 0.98$).

Harms: None reported in the RCTs.[30,31]

Comment: It is unclear whether reduced crying reflected the effects of interventions or spontaneous improvement.

GLOSSARY

Casein hydrolysate milk Contains casein protein; it is used in the same way as soya based infant feeds.

Cranial osteopathy Involves gentle manipulation of the tissues of the head by an osteopath.

Dicycloverine (dicyclomine) This has direct antispasmodic action on the gastrointestinal tract and anticholinergic effects, which are similar to atropine.

Hypoallergenic diet In bottle fed infants, a hypoallergenic diet uses a casein hydrolysate formula. In breast fed infants, a hypoallergenic diet involves a maternal diet free of artificial colourings, preservatives, and additives, and low in common allergens (e.g. milk, egg, wheat, and nuts).

Jadad Scale This measures factors that have an impact on trial quality. Poor description of the factors, rated by low figures, are associated with greater estimates of effect. The scale includes three items: was the study described as randomised? (0–2); was the study described as double blind? (0–2); was there a description of withdrawals and drop outs? (0–1).[5]

Infantile colic

Reassurance Informing the parent that infantile colic is a self limiting condition resolving by 3–4 months of age, and is not caused by disease or any fault in parental care.

Simethicone (activated dimeticone [dimethicone]) It has defoaming properties, which can aid dispersion of gas in the gastrointestinal tract.

Soya based infant feeds Contain proteins from soya beans; the feeds are used as lactose free vegetable milks for those with lactose or cows' milk protein intolerance.

Spinal manipulation Chiropractic manual treatment of the infant's vertebral column.

Whey hydrolysate milk Contains whey protein; it is used in the same way as soya based infant feeds.

See glossary, p 448

Key Messages

- **Monovalent measles vaccine or combined MMR vaccine (versus placebo or no vaccine)** We found no RCTs comparing the clinical effects of combined measles, mumps, and rubella (MMR) versus no vaccine or placebo. One large RCT, one quasi randomised trial, a large retrospective cohort study, and several observational studies have found that monovalent vaccine reduces the incidence of measles. Mass population cohort studies and other observational studies have also consistently found important reductions in child mortality after measles vaccination. Observational studies have found that measles vaccination programmes have been followed by a reduction in the incidence of subacute sclerosing panencephalitis. Several features of measles infection occur or are suspected to occur after the vaccine, but we found no studies comparing rates of occurrence between people with naturally acquired measles and those who have been vaccinated. Severe complications are rare with measles immunisation. One non-systematic review found that, compared with placebo, measles vaccination increased the incidence of fever and febrile seizures, although febrile seizures are rare and do not progress into afebrile seizures. Observational studies found that aseptic meningitis, a rare complication, increased after mass vaccination with the L-Z and Urabe strains of MMR, but no increased incidence has been reported with Jeryl Lynn, Hoshino, or Rubini strains. Observational studies have found that both measles vaccination and naturally acquired measles increase the incidence of idiopathic thrombocytopenic purpura. Observational studies found no significant change in the incidence of asthma in healthy children or in the frequency of acute exacerbations in children with asthma. They also found no significant change in the incidence of Guillain–Barré syndrome, autism, or inflammatory bowel disease as a result of measles vaccination. Anaphylaxis has been reported after vaccination with MMR, but this is extremely rare.
- **Comparative effects of combined MMR and monovalent measles vaccine** We found no RCTs comparing the clinical effects of MMR versus monovalent vaccines in children. Seroconversion rates are similar with both vaccines.

DEFINITION Measles is an infectious disease caused by a ribonucleic acid paramyxovirus. The illness is characterised by an incubation period of 6–19 days (median 13);[1] a prodromal period of 2–4 days with upper respiratory tract symptoms; conjunctivitis, Koplik's spots on mucosal membranes, and high fever; followed by a widespread maculopapular rash that persists, with fever, for 5–6 days.

INCIDENCE/ PREVALENCE Incidence varies according to vaccination coverage. Worldwide, there are an estimated 30 million cases of measles each year,[2] but the incidence is only 0–10/100 000 people in countries with widespread vaccination programmes such as the USA, UK, Mexico, India, China, Brazil, and Australia.[3] In the USA, before licensing of effective vaccines, over 90% of people were infected by the age of 15 years. After licensing in 1963, incidence fell by about 98%.[4] Mean annual incidence in Finland was 366/100 000 in 1970,[5] but declined to about zero by the late 1990s.[6] Similarly, annual incidence declined to about zero in Chile, the English speaking Caribbean, and Cuba during the 1990s when vaccination programmes were introduced.[7,8]

AETIOLOGY/ RISK FACTORS Measles is highly contagious and spreads through airborne droplets. As with most other infectious diseases, risk factors include overcrowding and low herd immunity (see glossary, p 448). Newborn babies have a lower risk of measles than older infants, owing to protective maternal antibodies although, in recent US outbreaks, maternal antibody protection was lower than expected.[4] Antibody levels are lower in babies born to immunised mothers compared with offspring of naturally infected mothers.[9,10]

PROGNOSIS The World Health Organization estimated that measles caused 777 000 deaths and 27.5 million disability adjusted life years in 2000.[11] **Disease in healthy people:** In developed countries, most prognostic data come from the pre-vaccination era and from subsequent outbreaks in non-vaccinated populations. The overall rate of complications in the UK was 6.7% before the introduction of measles vaccination. Encephalitis affected 1.2/1000 diseased people, and respiratory complications in 38/1000 diseased people.[12] Other complications before the introduction of the vaccine included seizures, with or without fever, affecting five out of every 1000 people with measles.[13] Idiopathic thrombocytopenic purpura has been reported, but the frequency is not known. Subacute sclerosing panencephalitis (SSPE) is an inevitably fatal, progressive degenerative disorder of the central nervous system with a mean onset 7–10 years after measles infection. It is more common when measles occurs under the age of 1 year (18/100 000 in children < 1 year of age *v* 4/100 000 overall), as identified by a passive reporting system set up in England and Wales to monitor the incidence of SSPE.[14] Between 1989–1991 in the USA, measles resurgence among young children (< 5 years) who had not been immunised led to 55 622 cases, with more than 11 000 hospital admissions and 166 deaths.[15–17] Measles complications include diarrhoea (9%), pneumonia (6%), and acute encephalitis (about 0.14%).[17] Measles during pregnancy results in higher risk of premature labour,[18] but no proven increase in congenital anomalies.[19] **Disease in malnourished or immunocompromised people:** In

malnourished people, particularly those with vitamin A deficiency, measles case fatality can be as high as 25%. Immunocompromised people have a higher morbidity and mortality. Children younger than 5 years, and adults older than 20 years, have a higher risk of severe complications and death.[15,20] In the period 1974–1984, four UK centres reported that 15/51 (29%) deaths in children in their first remission from leukaemia resulted from measles.[21] Another report reviewing cases from the same four UK centres between 1973 and 1986 found that five out of 17 cases of measles in children with malignancies proved fatal.[22] At least 5 out of 36 (14%) measles associated deaths in 1991 in the USA were in HIV infected persons.[15] Worldwide, measles is a major cause of blindness, and causes 5% of deaths in young children (< 5 years).[23]

AIMS OF INTERVENTION Preventing measles, with minimum adverse effects.

OUTCOMES Rates of clinically apparent measles and measles related complications, including death. If no clinical outcomes were available we reported rates of seroconversion (see glossary, p 448) because it is highly correlated with vaccine efficacy (see glossary, p 448). Rates of adverse effects of vaccination: acute fever, febrile seizures, inflammatory bowel disease, developmental regression (see glossary, p 448), autism, aseptic meningitis, idiopathic thrombocytopenic purpura, arthritis and arthralgia, anaphylaxis, asthma, subacute sclerosing panencephalitis, and Guillain–Barré syndrome.

METHODS *Clinical Evidence* search and appraisal March 2003; including a search for observational studies. The authors also searched World Health Organization, US Communicable Disease Control, Eurosurveillance website, UK Public Health Laboratory Service websites, and hand searched national and international policy documents. For additional information on vaccine strains and branding, see table A on web extra. Where possible, original articles were sought and critiqued in preference to non-systematic reviews. Comprehensive or systematic reviews were included. We included studies involving vaccine strains that are currently widely used. In the benefits section comparing different vaccines and schemes, we included RCTs and stronger observational studies, because after the high clinical efficacy against measles shown in early RCTs, further RCTs have been considered unethical (see benefits, p 439). In the harms sections, we included RCTs and robust observational studies (see harms, p 441). In the comment section, we have included weaker studies (see comment, p 447).

QUESTION What are the effects of measles vaccination?

OPTION MONOVALENT MEASLES VACCINE OR COMBINED MMR VACCINE VERSUS PLACEBO OR NO VACCINE

We found no RCTs comparing the clinical effects of combined measles, mumps, and rubella (MMR) versus no vaccine or placebo. One large RCT, one quasi randomised trial, a large retrospective cohort study, and several observational studies have found that monovalent vaccine reduces the incidence of measles. Mass population cohort studies and

other observational studies have also consistently found important reductions in child mortality after measles vaccination. Observational studies have found that measles vaccination programmes have been followed by a reduction in the incidence of subacute sclerosing panencephalitis. Several features of measles infection occur or are suspected to occur after the vaccine, but we found no studies comparing rates of occurrence between people with naturally acquired measles and those who have been vaccinated. Severe complications are rare with measles immunisation. One non-systematic review found that, compared with placebo, measles vaccination increased the incidence of fever and febrile seizures, although afebrile seizures are rare and do not progress into afebrile seizures. Observational studies found that aseptic meningitis, a rare complication, increased after mass vaccination with the L-Z and Urabe strains of MMR, but no increased incidence has been reported with Jeryl Lynn, Hoshino, or Rubini strains. Observational studies have found that both measles vaccination and naturally acquired measles increase the incidence of idiopathic thrombocytopenic purpura. Observational studies found no significant change in the incidence of asthma in healthy children or in the frequency of acute exacerbations in children with asthma. They also found no significant change in the incidence of Guillain–Barré syndrome, autism, or inflammatory bowel disease as a result of measles vaccination. Anaphylaxis has been reported after vaccination with MMR, but this is extremely rare.

Benefits:

Measles: We found no systematic reviews. We found no RCTs comparing the clinical effects of MMR (see glossary, p 448) versus no vaccine or placebo. We found one RCT from the USA,[24] one quasi randomised controlled trial from the UK of monovalent measles vaccine versus placebo or no vaccines,[25] one large retrospective cohort study,[26] and several other large observational studies.[5,27,28] The quasi randomised trial conducted in the UK followed 36 211 children aged 10 months to 2 years for 9 months.[25] Children were allocated according to birth date to live vaccine alone (9538 children); killed vaccine (E-E-B strain) followed by live vaccine (SWZ strain; 10 434 children); or no vaccination (16 239 children). The trial found an 85% efficacy over 6 months' follow up in children who had been vaccinated with either live vaccine alone or killed vaccine followed by live vaccine compared with an unvaccinated control group. Follow up of a subset of these children (live vaccine group [7889]; killed/live vaccine [8171], and unvaccinated [5593]) found an increase in protective effect 2 years 9 months after vaccination (94% live vaccine *v* 88% killed/live vaccine) after exposure to two major epidemics.[25] After 15 years' follow up (at 12–27 years after recruitment) of 9106 children there was a higher incidence of measles in the unvaccinated group.[29] The difference between vaccinated and unvaccinated children remained after controlling for subsequent vaccination in initial placebo groups, but not after controlling for growing herd immunity (see glossary, p 448) after mass vaccination (AR 0.3/1000 person years with vaccine *v* 1/1000 person years with no vaccine; $P < 0.001$). The overall protective efficacy was high (92%, 95% CI 86 to 95%) between 1976 and 1990.[29] The RCT carried out in the USA compared measles infection rates in children receiving two doses of killed vaccine followed by one dose of either live (combined schedule) or killed vaccine given at monthly intervals (strain not specified).[24]

Infection rates were then compared with the two groups receiving three doses of placebo at the same intervals. It was found that, over 14 months, protection was offered best by the "combined" schedule, with 96% efficacy (95% CI 94.7% to 97.2%). The large retrospective cohort study of the entire US population from 1985–1992 compared measles infection rates in children who were vaccinated versus children whose parents had declined vaccination (17 390 cases from a vaccinated population of 51 264 140 to 52 377 192 from 1985–1992 *v* 2827 measles cases from an unvaccinated population of 234 040 to 245 887 from 1985–1992).[26] The cohort study did not state what proportion of vaccinated children received monovalent or MMR vaccine, although MMR was already widely used in the USA by 1985. The study found that, although overall measles incidence was low because of herd immunity, vaccination significantly reduced measles infection compared with no vaccination (RR of measles in unvaccinated *v* vaccinated 4–170, depending on age group and year of survey). We also found many population based studies from different countries with different healthcare systems and different socioeconomic and demographic distributions. These studies have consistently found measles vaccination coverage to be associated with a steep decline in measles.[5,28] In most resource rich countries, 95% of the population must be vaccinated to eliminate measles. In countries with greater population density, coverage may need to reach 99% to eliminate measles.[30] One time series from the World Health Organization found a global decline in reported measles incidence (which underestimates true incidence) from about 4 500 000 a year in 1980 to about 1 000 000 a year in 2000.[27] The decline was associated with the rise in reported measles vaccination coverage from about 10% in 1980 to about 80% in 2000. One population based time series of measles incidence from Finland found that, in a population of about 5 million people, after the introduction of a live monovalent vaccination programme (1975–1981), the number of new measles cases each year fell from an average of 2074 cases in 1977–1981 to 44 cases in 1985. New cases declined to about zero by the mid 1990s. Shortly after introducing the MMR programme in Finland in 1982, rubella and mumps incidence also fell to about zero.[5] One cross sectional study in a Brazilian city, which was repeated before and after a measles vaccination campaign in 1987 (8163 people, strain not stated), found that reported measles incidence fell from 222/100 000 in 1987 to 2.7/100 000 in 1988.[28] However, measles outbreaks in countries with high vaccine coverage (see glossary, p 448) can still occur. During 1999–2000 in the Netherlands, a measles outbreak took place in a school in which only 7% of the schoolchildren were vaccinated.[31] Eventually, 94% of unvaccinated people from closed communities were affected, amounting to 3292 cases. Although the Netherlands had one of the lowest rates of measles disease with high vaccine coverage (96%), the epidemic was attributed to the presence of small unvaccinated pockets.

Mortality: We found one systematic review (search date not reported, 10 cohort studies, 2 case control studies)[32] and one subsequent cohort study[33] evaluating monovalent measles vaccination. The systematic review found that live monovalent measles

vaccination in seven developing countries reduced all cause mortality in vaccinated children by 30–80% compared with unvaccinated children, depending on follow up period and country.[32] The subsequent cohort study compared a group of children in Bangladesh vaccinated with live Schwarz strain monovalent measles vaccine versus age matched unvaccinated children (8135 matched pairs).[33] It found a significant reduction in mortality with vaccination (16 270 children aged 9–60 months at vaccination; RR for death at 43 months 0.54, 95% CI 0.45 to 0.65) A recent Italian outbreak resulted in three deaths among 981 people.[34] All fatalities were unvaccinated (ML Ciofi degli Atti personal communication, 2003). In contrast, an outbreak of 910 cases in Coburg, Germany, in 2002 had no casualties.[35] **Subacute sclerosing panencephalitis:** Wherever it has been monitored, subacute sclerosing panencephalitis (SSPE) has shown a major fall in prevalence after the introduction of measles containing vaccines.[36–38] A case control study found that a history of measles vaccination was less likely among people with SSPE than among healthy controls (OR 0.25, 95% CI 0.05 to 0.54).[39] We found no other studies for MMR vaccine, but SSPE is uncommon where any measles containing vaccine is in widespread use. No measles virus recovered from brain biopsies of 19 people who suffered SSPE were linked to a vaccine like strain.[40]

Harms:

Acute fever and febrile convulsions: We found one non-systematic review,[41] one RCT,[42] one cohort study,[43] and one observational study of a population based surveillance programme reporting fever due to vaccination in otherwise healthy children.[44] The review (search date 1998) reported that up to 5% of non-immune people develop moderate to high fever (≥ 38.6 °C) within 7–21 days of vaccination.[41] The RCT (crossover design) compared the acute harms of MMR versus placebo in 1162 twins (460 children aged 1 year, of whom 1.3% had previously been vaccinated; 702 aged ≥ 2 years, 95% of whom had been previously vaccinated or experienced measles).[42] One member of each twin pair was randomly selected and allocated to MMR vaccination followed 3 weeks later by placebo. The other twin was allocated to the opposite combination. The RCT found that, among children aged 14–18 months, MMR increased the incidence of moderate fever (range 38.6°C to 39.5°C) within 21 days (25% with MMR *v* 6% with placebo; OR 3.28, 95% CI 2.23 to 4.82) and high fever (> 39.5°C; 7% with MMR *v* 3% with placebo; OR 2.83, 95% CI 1.47 to 5.45). Among children older than 6 years of age there was no significant difference in incidence rates of fever (5 per 1000 in children receiving vaccine or placebo; P > 0.10). One retrospective cohort study in 679 942 children from four health maintenance organisations (see glossary, p 448) in the USA found that children who had received MMR (strains not listed) were more likely to experience febrile convulsions 8–14 days after receiving MMR compared with children of the same age who had not been vaccinated (ARI 25–34 additional seizures per 100 000 immunised children; RR 2.83, 95% CI 1.44 to 5.55; ARI estimated by comparison with background seizure risk in all children aged 12–24 months: 0.025%; NNH 4000; CI not reported).[43] No significant increase in febrile seizures was found during the first week (RR for first week 1.73, 95% CI 0.72 to 4.15) or 15–30 days after vaccination

(RR 0.97, 95% CI 0.49 to 1.95). The study followed up 562 children with febrile convulsions (22 within 7–21 days of MMR, 18 within 0–7 days of diphtheria-tetanus-pertussis [DTP — see glossary, p 448], one after both vaccines and 521 whose seizures occurred outside these periods following vaccination). It found that, in comparing MMR or DTP versus no vaccine, there was no significant difference in the risk of developing subsequent seizures (RR 0.65, 95% CI 0.32 to 1.35). No child with a febrile seizure after vaccination went on to develop afebrile seizures. Similarly, among 273 children with febrile convulsions in one of the four participating organisations, the study found no evidence that MMR vaccination before seizure significantly increased the risk of learning disability or developmental delay compared with no vaccination before seizure (RR after adjusting for age at first febrile seizure 0.56, 95% CI 0.07 to 4.20). It found no significant increase in afebrile seizures after MMR vaccination. We found a population based passive surveillance of harms of MMR in all 1.8 million people vaccinated over a 14 year period in Finland.[44] Surveillance relied on healthcare personnel's awareness of the programme and their reporting of adverse events felt to be associated with MMR. Advertisements of the programme appeared in seminars, the media, and the medical press. Acute reactions were more likely to have been reported than long term effects. Fever was associated with MMR in 277 children (AR 15 per 100 000 vaccinees or 9.2 per 100 000 doses). Febrile seizures were reported in 52 children (AR 17 per million doses), of which 28 could have been caused by MMR (9 per million doses) according to predefined clinical and serological criteria. These are gross underestimates compared with the US retrospective study,[43] and suggest an inadequacy of the Finnish study for detecting relatively minor events.[44] We found one self controlled case series (see glossary, p 448), which examined the incidence of febrile convulsions after MMR vaccination.[45] There was an increased risk of hospital admission 6–11 days after receiving MMR vaccine at between 12 and 24 months of age (AR 50 per 100 000; ARI 33 additional seizures per 100 000 doses), but not in the period 15–35 days after the Jeryl Lynn containing vaccine. In the same period after vaccination with the Urabe containing vaccine, there was an absolute risk of febrile convulsions or aseptic meningitis of 91 per 100 000 vaccinees with an attributable risk of 38 per 100 000 vaccinees compared with no vaccination. **Aseptic meningitis:** Observational studies using differing methods have reported a wide range of risk estimations for aseptic meningitis after MMR vaccination (AR 7 to 250 per million vaccines), even in the same country.[46] Using self controlled case series in the UK, the risk of aseptic meningitis was assessed for MMR vaccines containing either Urabe or Jeryl Lynn mumps vaccine virus strains.[45] The case series found that the vaccine increased the risk of aseptic meningitis 15–35 days after receiving Urabe containing vaccines (AR 67 per million, ARI 63 per million vaccinated children). No cases of aseptic meningitis were reported with the Jeryl Lynn containing MMR vaccine. This latter finding was confirmed using similar methodology in a US study.[47] An observational study based on hospital admissions before and after a mass immunisation campaign using Urabe containing MMR, in part of Brazil, found that MMR increased

the risk of aseptic meningitis 3–5 weeks after vaccination (RR 30.4, 95% CI 11.5 to 80.8; attributable risk 71 per million doses; 32 cases in 452 344 doses).[48] A case cross over study (see glossary, p 448) of hospitalised children found no significant risk of developing aseptic meningitis with the Jeryl Lynn or the Rubini strains of the vaccine (RR 0.6, 95% CI 0.18 to 1.97), but found an increased risk after vaccination with the Urabe or Hoshino strains, particularly in the third week after vaccination (RR 15.6, 95% CI 5.9 to 41.2).[49] However, the assignment of vaccine strains was based on assuming a pattern of provider usage rather than individual records, and there was no evidence that this assumption was tested. Reported cases of aseptic meningitis increased during a mass MMR immunisation campaign using the Leningrad-Zagreb (L-Z) mumps strain in Brazil in 1997, compared with the previous 2 years (28.7 cases per 10 000 person weeks *v* 4.5 cases per 10 000 person weeks).[50] The absolute risk of aseptic meningitis 15–35 days after vaccination was 29 per 100 000 doses. Other causes of aseptic meningitis were not ruled out and therefore the attributable risk could not be calculated, but the temporal pattern of increase in cases suggests that most were due to the vaccine. The risk of aseptic meningitis following L-Z containing MMR seems to be higher than that following both Urabe and Jeryl Lynn containing vaccines. Similar findings were reported after a mass immunisation campaign with L-Z vaccine in two states in Brazil in 1998.[51] The incidence of aseptic meningitis increased compared with the previous 2 years. The estimated attributable risk of aseptic meningitis after vaccination ranged from 52 per million to 160 per million vaccinations depending on the criteria used. **Idiopathic thrombocytopenic purpura:** Naturally acquired measles and measles vaccination have been associated with idiopathic thrombocytopenic purpura (ITP). We found two self controlled case series, the second including the cases from the first.[45,52] In these studies, vaccination records were linked with computerised hospital admission records, and the incidence of ITP during a risk period (0–42 days after MMR vaccine) was compared with the incidence outside this risk period. ITP increased after MMR vaccination (AR 45 per million people, ARI 31 per million people; RR 3.27, 95% CI 1.49 to 7.16). The study included 14 children who had had a first episode of ITP before MMR immunisation. Although three of these children had further episodes of ITP, none were within 6 weeks of immunisation.[45,52] A case control study carried out in the UK found that MMR was associated with an increased incidence of ITP within 6 weeks of administration (ARI 40 per million vaccines, 95% CI 11 per million to 47 per million).[53] **Arthritis and arthralgia:** One crossover RCT in twin children found that vaccination with MMR, given either at 14–18 months of age or 6 years of age increased the risk of developing arthralgia compared with placebo (14–18 months: OR 3.66, CI 1.74 to 7.70; $P < 0.001$).[42] The duration of arthralgia was not described, but it is implied that it was mild. **Anaphylaxis:** Anaphylaxis after MMR has been reported, albeit infrequently.[54] We found no accurate figures. During the 1994 measles rubella vaccine campaign in the UK, 5.8 million children (5–16 years of age) were vaccinated. A passive surveillance using "yellow cards" (see glossary, p 448) identified 123 reports of children with signs or symptoms of allergic reactions in

varying degrees of severity, but with no deaths or anaphylaxis within 24 hours of vaccination.[55] The absolute risk is therefore 15 per million doses. If confined to anaphylactic reactions, the rate was 1 per 100 000 doses.[56] **Asthma:** A case control study carried out in New Zealand in children aged 7–9 years, and diagnosed with asthma, found no significant association between MMR vaccine and diagnosed asthma (OR 1.43, 95% CI 0.85 to 2.41).[57] The authors of this report concluded that there may be some under ascertainment of children with asthma. A cohort study in four health maintenance organisations in the USA compared the immunisation status of children with diagnosed and treated asthma.[58] Inclusion criteria were children with asthma after the age of 1 year. Children also had to be enrolled with the health maintainance organisation at birth, and remain so until at least the age of 18 months. The median age of last follow up for the whole group of children was 28 months. The median age of first episode of asthma was 11 months. It found no significant difference in the risk of developing asthma after MMR vaccination (RR 0.97, 95% CI 0.91 to 1.04). It found no significant change in these figures when only those children with asthma requiring emergency room attendance or hospital admission were included. Although the duration of follow up was relatively short the authors argue that this was probably long enough to pick up most cases.[58] **Guillain-Barré syndrome:** Guillain-Barré syndrome has been reported after measles containing vaccines.[41] In the 1994–5 Measles-Rubella campaign in UK, three cases of Guillain-Barré syndrome were reported, but this is well within the expected background rate.[55] A retrospective study of Finnish hospital discharges in people who developed Guillain-Barré syndrome looked at vaccination records over a 4 year period and found no cases of Guillain-Barré syndrome within 6 weeks of immunisation.[44] The shortest interval was 10 weeks and was in a person who also suffered an infectious illness during this interval. **Developmental regression (see glossary, p 448) or autistic spectrum disorders:** We found one non-systematic review of observational studies,[59] one large retrospective cohort study (738 cases of autistic spectrum disorders [see glossary, p 448]),[60] and two additional population surveillance studies (498 cases of autistic spectrum disorders analysed in two studies[62,63] and an estimated total population of 1.8 million vaccinated people in the other study[44]). The non-systematic review (search date not reported) found no causal relationship between MMR and autism.[59] The review included two large cross sectional time series,[64,65] which reported that the incidence of autism increased independently of MMR coverage. They found no association between MMR vaccination and autism. The first cross sectional time series was carried out among kindergarten children in California in 1999.[64] It looked at children born between 1980–1994 and immunised with MMR by 17 months or 24 months and compared these figures with autism cases referred to the state developmental services department over the same time (absolute figures not reported).[64] It found that MMR coverage at 24 months rose slightly (from 72% in 1980 to 82% in 1994; 14% proportional rise). Referral rates for new autism cases increased disproportionately in the same period (from 44/100 000 births in 1980 to 208/100 000 live births in 1994; a 373%

proportional rise). The authors of the report found it difficult to attribute the large increase in referral rates to the small rise in immunisation rates. However, referral rates to the department may not reflect accurately the incidence of autistic syndromes. The second cross sectional time series was carried out in the UK.[65] It found that, during the period 1988–1993, the risk of autism among boys increased, whereas MMR coverage remained almost constant at about 97% (AR of first diagnosis of autism aged 2–5 years 8 per 100 000, 95% CI 4 to 14 per 100 000 for children born in 1988 *v* 29 per 100 000, 95% CI 20 to 43 per 100 00 for children born in 1993; 305 cases of autism over just greater than 3 million person years at risk).[65] The large retrospective cohort study (537 303 children born in Denmark between January 1991 and December 1998; 2 129 864 person years exposure) found no association between MMR vaccination and autistic spectrum disorders (82% of population vaccinated; RR of autistic disorder in vaccinated *v* non-vaccinated children 0.92, 95% CI 0.68 to 1.24; RR of other autistic spectrum disorder in vaccinated *v* non-vaccinated children 0.83; 95% CI 0.65 to 1.07).[60] It also found no association between autistic spectrum disorder and age at time of vaccination ($P = 0.23$), time since vaccination ($P = 0.42$), or calendar date of vaccination ($P = 0.06$). Results remained unchanged when children with autistic disorders due to fragile X syndrome, tuberous sclerosis, congenital rubella, or Angelman's syndrome were included. The first population surveillance study used records at child development centres and special schools to identify 498 children diagnosed with autism before the age of 5 years born in eight health districts in the UK between 1979 and 1998.[62] It was found that the incidence of autism increased over this period.[62] However, there was no change in the rate after the start of the MMR vaccination programme. Using the same methods and birth cohort, but including fewer districts (473 children diagnosed with autism before the age of 5 years), the proportion of children with autism who had developmental regression or bowel symptoms was assessed.[63] The study found no significant change in these proportions during this time period (P value for trend = 0.50 and 0.47, respectively). The second long term population surveillance study from Finland was based on passive reporting and found no cases of vaccination related developmental regression among 1.8 million people vaccinated with MMR.[44] However, events that did not result in hospital admission or were not temporally closely associated with the vaccination may not have been reported in this study. This would particularly apply to conditions such as autism, so it is not possible to draw any conclusions from this study about a possible link between MMR and autism spectrum disorders in either the long or the short term. **Inflammatory bowel disease:** We found one non-systematic review,[41] one cohort study,[66] one population surveillance study,[44] one case control study,[61] and one case series.[67] The non-systematic review (search date 1998, 6 large observational studies from different developed countries) found no evidence of an association between inflammatory bowel disease and measles vaccine (meta-analysis not performed).[41] The first additional study was a retrospective cohort study comparing rates of ulcerative colitis, Crohn's disease, and inflammatory bowel disease

(assessed by postal questionnaire) in 7616 people who had received live monovalent measles vaccination compared with those who had not received measles vaccination by the age of 5 years (mean age at vaccination 17.6 months, standard deviation 7.4 months).[66] Participants were those available from an original population based cohort of all 16 000 children born in the first week of 1970 in the UK. It found no significant difference in the risk of developing ulcerative colitis, Crohn's disease, or inflammatory bowel disease among people (aged 26 years at the time of the study) who had received monovalent measles vaccine and those who had not, whether or not the result was adjusted for sex, socioeconomic status, or crowding (AR for Crohn's disease 0.25% with vaccine *v* 0.31% without; adjusted OR 0.7, 95% CI 0.3 to 1.6; AR for ulcerative colitis 0.16% with vaccine *v* 0.27% without; adjusted OR 0.6, 95% CI 0.2 to 1.6; AR for inflammatory bowel disease 0.41% with vaccine *v* 0.58% without; adjusted OR 0.6, 95% CI 0.3 to 1.2). The second additional study, a long term, population based passive surveillance study from Finland, found no cases of inflammatory bowel disease associated with vaccination in 1.8 million people vaccinated with MMR followed up for 14 years but, as discussed earlier, there are major limitations to the methodology of this study.[44] The third additional study, a case control study, included 142 people in the USA with definite or probable inflammatory bowel disease from members of four health maintenance organisations (67 people with ulcerative colitis and 75 people with Crohn's disease).[61] Cases (people with inflammatory bowel disease) were identified by computerised search of electronic records and manual abstraction of medical records from 1958–1989 for three organisations and from 1979–1989 for the remaining one. The date of data collection is not clear and so the potential age range was not reported; people who were not members of the health maintenance organisation between 6 months of age and disease onset were excluded. The study found that people with inflammatory bowel disease were not more likely to have received MMR than people without inflammatory bowel disease taken from the same health maintenance organisation and matched for sex and year of birth (OR for Crohn's disease 0.40, 95% CI 0.08 to 2.00; OR for ulcerative colitis 0.80, 95% CI 0.18 to 3.56; OR for all inflammatory bowel disease 0.59, 95% CI 0.21 to 1.69). The study similarly found no association between other measles containing vaccines, Crohn's disease, ulcerative colitis, or all inflammatory bowel disease. The analysis in the paper was by MMR or other measles containing vaccines compared with no measles containing vaccine. The other measles containing vaccines are almost certain to be single measles vaccine, but this was not made explicit in the paper so it is deemed inappropriate to comment further. The fourth additional study was a case series.[67] It raised the question of a possible relation between MMR and developmental regression in 12 children with bowel symptoms. The series was retrospective (parents surveyed up to 8 years after vaccination), small, lacked a control group, and was selective in its sample. The authors stated that it does not prove a link or causal association between MMR vaccination and their postulated syndrome of autism and enterocolitis.

Comment: **Benefits:** RCTs comparing the clinical effects of MMR versus no vaccine or placebo are deemed unethical because of the existing evidence of efficacy of measles vaccine and the harms associated with naturally acquired measles. Results of studies assessing fever in children vaccinated against measles should be interpreted in light of the very high prevalence of acute fever in children with measles infection.[42,68,69] **Harms:** A large proportion of the literature on adverse events after immunisation is based on passive reporting, albeit enhanced.[44] This has major limitations. Events may be under reported and yet events that are reported may not be linked to the intervention. Similarly, a case series postulated a possible causal association between MMR and a syndrome of autism and enterocolitis, despite no evidence being found to prove this association.[67] Such studies can flag up issues for further investigation but cannot be used as definitive evidence either of size of risk or even causal association, as they are only hypothesis generating.

OPTION MMR VERSUS MONOVALENT MEASLES VACCINE

We found no RCTs comparing the clinical effects of MMR versus monovalent vaccines in children. Seroconversion rates are similar with both vaccines.

Benefits: We found no RCTs comparing clinical effects of MMR (see glossary, p 448) versus monovalent vaccine. We found two RCTs comparing rates of measles seroconversion (see glossary, p 448) after live MMR (Schwarz measles plus Urabe Am 9 mumps plus RA 27/3 rubella) versus Schwarz strain monovalent measles vaccine. The first RCT (420 children with no clinical history of measles or mumps, mean age about 15 months) found similar seroconversion rates in both groups after 6 weeks (92.6% with MMR *v* 96.8% with monovalent measles).[69] The second RCT (319 children, mean age 13 months) also found similar seroconversion rates in both groups at 6 weeks (93% with MMR *v* 92% with Schwarz strain monovalent measles vaccine).[70]

Harms: We found one RCT comparing MMR containing Schwarz strain measles vaccine versus Schwarz strain monovalent measles vaccine in infants with no history of measles.[69] It found no significant difference in fever incidence rates (fever after MMR 38.3%; after measles vaccine 37.8%; $P > 0.05$). The RCT is likely to have been underpowered to detect other clinically important adverse effects.

Comment: MMR vaccine also protects against mumps and rubella, which cause serious complications in non-immune people. Mumps causes orchitis, pancreatitis, meningoencephalitis, sensorineural deafness, infertility, and rarely death. Rubella acquired during the first trimester can cause fetal death or severe fetal damage with deafness, blindness, heart defects, liver, spleen, and brain damage. The use of MMR rather than monovalent measles, mumps, and rubella vaccines provides earlier protection against all three diseases. Use of single vaccines also requires more injections over a longer period of time, which may lower uptake rates thereby increasing prevalence of these diseases. **Measles risk after seroconversion:** One systematic review of cohort studies (search

date 1995) examined risk of measles infection at least 21 days after vaccine induced seroconversion (monovalent or polyvalent vaccine).[71] It identified 10 studies that met inclusion criteria. In the subset of six cohort studies examining live vaccine, in which vaccination status was cross checked against medical records, risk of clinical measles infection in children who had seroconverted after vaccination was about zero (0 infections from 2061 people exposed; CI not reported).

GLOSSARY

Autistic spectrum disorders are defined by early onset (diagnosed at < 36 months) difficulties in social reciprocity and communication as well as restrictive, repetitive behaviour. The disorders include autistic disorder, childhood disintegrative disorder, Rett's syndrome, and Asperger's disorder.

Case cross over study is in effect the same as a self controlled case series, in which each person serves as his or her own control.

Combined measles, mumps, and rubella (MMR) vaccine Vaccine with components that aim to raise immunity to measles, mumps, and rubella infections. Contains live attenuated measles virus (Schwarz strain).

Developmental regression is defined as loss of acquired developmental skills.

DTP Diphtheria, tetanus and pertussis combined vaccine.

Health Maintenance Organisation (HMO) These are medical centres in the USA that have primary, secondary and tertiary medical care facilities and are generally funded by private healthcare insurance. The relevance of HMOs is their participation in the Vaccine Safety Datalink (VSD) project set up by the Centre for Disease Control (CDC) in 1991. This project links medical event information, vaccine history and selected demographic information from the computerised databases of four staff HMOs: Group Health Co-operative of Puget Sound in Seattle, Kaiser Permanate Northwest in Portland, Kaiser Permanante Medical Care Program of North California in Oakland, and Southern California Kaiser Permanante in Los Angeles.

Herd immunity Background level of immunity in the community. A high level of herd immunity reduces risk of infection even in non-immune individuals, because there is no pool of at risk individuals who may transmit the infectious agent.

Self controlled case series A case series in which people act as their own controls by comparing event rates within a defined time period of exposure with earlier and/or later periods.[45]

Seroconversion Development in the blood of specific antimeasles antibody. Seroconversion is a proxy for clinical efficacy.

Vaccine coverage Prevalence of vaccination in the community.

Vaccine efficacy An estimate of the proportional reduction in cases associated with the use of a vaccine. Efficacy % = (1 – [attack rate in vaccinated/ attack rate in unvaccinated] x 100).

Yellow cards A passive reporting system, in which a health professional becomes aware of a significant adverse event after a medication has been administered and reports this to the UK Committee on Safety of Medicines using a yellow card.

Substantive changes

Measles aetiology/risk factors Two studies assessing risk factors added.[9,10]

Measles prognosis 11 studies assessing prognosis, both in healthy and in malnourished or immunocompromised people, added.[12–22]

Measles vaccination: benefits One quasi randomised trial[25], three retrospective observational studies,[31,34,35] and one case control study[39] added; categorisation unchanged.

Measles vaccination: harms Observational data from 13 reports of case control, case series and national databases of adverse effects added.[45–51,53–58] Harms data enhanced; categorisation unchanged.

Migraine headache in children

Search date September 2003

Nick Barnes, Guy Millman, and Elizabeth James

QUESTIONS

INTERVENTIONS

See glossary, p 458

Key Messages

Treatment

- **Antiemetics; codeine phosphate; non-steroidal anti-inflammatory drugs; paracetamol; $5HT_1$ antagonists** We found insufficient evidence to compare these interventions versus placebo or each other in children with migraine headache.

Prevention

- **Stress management** We found limited evidence from one small RCT that self administered stress management improved headache severity and frequency compared with no stress management.
- **β Blockers** We found insufficient evidence from small RCTs about effects of β blockers compared with placebo in children with migraine headache.
- **Dietary manipulation; pizotifen; progressive muscle relaxation; thermal biofeedback** We found insufficient evidence about effects of these interventions to prevent migraine in children.

DEFINITION Migraine is defined by the International Headache Society (IHS) as a recurrent headache that occurs with or without aura (see glossary, p 458) and lasts 2–48 hours.[1] It is usually unilateral in nature, pulsating in quality, of moderate or severe intensity, and is aggravated by routine physical activity. Nausea, vomiting, photophobia, and phonophobia are common accompanying symptoms. This topic focuses on children younger than 18 years. Diagnostic criteria for children are broader than criteria for adults, allowing for a broader range of duration and a broader localisation of the pain (see table 1, p 459).[2] Diagnosis is difficult in young children, because the condition is defined by subjective symptoms. Studies that do not explicitly use criteria that are congruent with IHS diagnostic criteria (or revised IHS criteria in children under 15 years of age) have been excluded from this topic.

INCIDENCE/ PREVALENCE Migraine occurs in 3–10% of children,[3–7] and currently affects 50/1000 school age children in the UK and an estimated 7.8 million children in the European Union.[8] Studies in developed countries suggest that migraine is the most common diagnosis among children presenting with headache to a medical practitioner. It is rarely diagnosed in children under 2 years of age because of the symptom based definition, but increases steadily with age thereafter.[1,9,10] It affects boys and girls similarly before puberty, but after puberty girls are more likely to suffer from migraine.[4,6,10] See incidence/prevalence of migraine headache, p 1696.

AETIOLOGY/ RISK FACTORS The cause of migraine headaches is unknown. We found few reliable data identifying risk factors or quantifying their effects in children. Suggested risk factors include stress, foods, menses, and exercise in genetically predisposed children and adolescents.[10,11]

PROGNOSIS We found no reliable data about prognosis of childhood migraine headache diagnosed by IHS criteria. It has been suggested that more than half the children will have spontaneous remission after puberty.[10] It is believed that migraine that develops during adolescence tends to continue in adult life, although attacks tend to be less frequent and severe in later life.[12] We found one longitudinal study from Sweden (73 children with "pronounced" migraine and mean age onset 6 years) with over 40 years follow up, which predated the IHS criteria for migraine headache.[13] It found that migraine headaches had ceased before the age of 25 years in 23% of people. However, by the age of 50 years, more than 50% of people continued to have migraine headaches. We found no prospective data examining long term risks in children with migraine.

AIMS OF INTERVENTION To provide relief from symptoms; to prevent recurrent attacks in the long term, and to minimise the disruption of childhood activities, with minimal adverse effects.

OUTCOMES Pain scores (usually on visual analogue scales); migraine recurrence; functional indicators (such as time off school, behavioural scores, sleep scores, and sleep satisfaction); any adverse effects of treatment. Migraine index is a validated scale for measuring severity in adult migraine. Its validity in children is unclear.

METHODS *Clinical Evidence* search and appraisal September 2003.

Migraine headache in children

QUESTION **What are the effects of treatments for acute attacks of migraine headache in children?**

OPTION PARACETAMOL

We found no RCTs of sufficient quality addressing the effects of paracetamol (acetaminophen) in children or adolescents with migraine headache.

Benefits: We found no systematic review or RCTs of sufficient quality (see comment below) evaluating the effects of paracetamol (acetaminophen) compared with placebo or no treatment in children with migraine headache.

Harms: We found no RCTs assessing adverse effects of licensed doses of paracetamol in children with migraine. See paracetamol poisoning for symptoms and treatment of paracetamol overdose, p 1826.

Comment: We found one three way crossover RCT (106 children) comparing paracetamol, ibuprofen, and placebo. The RCT had high withdrawal rates (17%) and did not report results before crossover.[14] This may have introduced bias due to continued treatment effects after crossover, and due to unequal withdrawals among groups.

OPTION NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

We found no reliable RCTs assessing the effects of non-steroidal anti-inflammatory drugs in children and adolescents with migraine headache.

Benefits: We found no systematic review or reliable RCTs evaluating the effects of non-steroidal anti-inflammatory drugs in children or adolescents with migraine headache.

Harms: We found no RCTs addressing harms of non-steroidal anti-inflammatory drugs in children or adolescents with migraine headache.

Comment: We found one three-way crossover RCT (106 children) comparing paracetamol, ibuprofen, and placebo. It was excluded because it had methodological flaws that compromised the validity of its results, including failure to report results before crossover.[14]

OPTION CODEINE PHOSPHATE

We found no RCTs addressing the effects of codeine phosphate in children or adolescents with migraine headache.

Benefits: We found no systematic review or RCTs addressing the effects of codeine phosphate in children or adolescents with migraine headache.

Harms: We found no RCTs assessing the effects of codeine phosphate in children with migraine. Known adverse effects of codeine include nausea, vomiting, constipation, drowsiness, potential for respiratory depression in overdose, difficulty for micturition, and dry mouth.

Comment: None.

OPTION 5HT$_1$ ANTAGONISTS (E.G. TRIPTANS)

We found insufficient evidence about effects of oral or nasal 5HT$_1$ antagonists in children and adolescents with migraine headache.

Benefits: **Sumatriptan versus placebo:** We found no systematic review. We found two RCTs.[15,16] The first RCT (653 children aged 12–17 years) compared three different doses of nasal sumatriptan (5, 10, or 20 mg) with placebo.[15] It found that nasal sumatriptan increased complete resolution compared with placebo at 2 hours, although the result was significant only for the lowest dose (74/118 [63%] with 20 mg; 85/133 [64%] with 10 mg; 84/128 [66%] with 5 mg; 69/131 [53%] with placebo; $P < 0.05$ for 5 mg *v* placebo, but not for other doses *v* placebo).[15] Rizatriptan versus placebo: The second RCT (360 children aged 12–17 years) compared rizatriptan versus placebo.[16] It found no significant difference between rizatriptan and placebo for partial or complete pain relief at 2 hours (pain free: 48/149 [32%] with rizatriptan *v* 40/142 [28%] with placebo, $P = 0.47$; partial pain relief: 98/149 [66%] with rizatriptan *v* 80/142 [56%] with placebo, $P = 0.08$).[16]

Harms: **Sumatriptan versus placebo:** The first RCT found that taste disturbance was more common with sumatriptan compared with placebo (2% with placebo *v* 19% with 5 mg *v* 30% with 10 mg *v* 26% with 20 mg).[15] However, it found no significant differences among treatments or placebo for other adverse effects. Rizatriptan versus placebo: The second RCT found that nausea and somnolence were significantly more common with placebo than with rizatriptan.[16] It reported that one child taking rizatriptan developed transient jaundice and hyperglycaemia, which resolved within 1 week.

Comment: **Sumatriptan versus placebo:** We found one RCT (only the abstract published).[17] It could not, therefore, be assessed adequately. A second double blind, placebo controlled, crossover RCT did not report results before crossover and had a high withdrawal rate (26%), and it has, therefore, been excluded.[18] We found one small crossover RCT (14 children aged 6.4–9.8 years).[19] However, it did not present results before crossover, and so has been excluded. **Rizatriptan versus placebo:** In the RCT comparing rizatriptan with placebo 360 children were originally enrolled. Of these, 64 children did not receive placebo or rizatriptan, the reasons for which were not stated. Seven children subsequently dropped out, although reasons for stopping treatment were not stated.

OPTION ANTIEMETICS

We found no RCTs of antiemetics in children with migraine headache.

Benefits: We found no systematic review or RCTs comparing antiemetics with placebo, no treatment, or other treatments in children with migraine headache.

Harms: We found no RCTs.

Comment: None.

Migraine headache in children

QUESTION **What are the effects of prophylaxis for migraine in children?**

OPTION β BLOCKERS

Three RCTs found insufficient evidence about the effects of β blockers compared with placebo in children with migraine headache.

Benefits: We found no systematic review. **Versus placebo:** We found three RCTs that compared propranolol versus placebo.[20–22] The first RCT (double blind, crossover, 32 children aged 7–16 years) found that propranolol (60–120 mg/day divided in three doses) significantly increased perception of benefit compared with placebo during a 3 month period (report of "some benefit" before crossover: 13/13 [100%] with propranolol *v* 4/15 [27%] with placebo; $P < 0.001$).[20] However, reliability may be limited because 13% of people were lost to follow up. The second RCT (double blind, crossover, 53 children aged 9–15 years) compared propranolol 40–120 mg daily with placebo.[21] It found that propranolol significantly increased headache duration compared with placebo (results before crossover: mean duration of headache 436 minutes with propranolol *v* 287 minutes with placebo, $P < 0.01$). The third RCT (double blind, crossover, 33 children aged 6–12 years) found no significant difference in the number of episodes of migraine between propranolol 3 mg/kg daily and placebo at 3 months (results before crossover: mean number of headaches 14.9 with propranolol *v* 13.3 with placebo, $P = 0.47$).[22] In five people in whom migraine was thought to be provoked by food, diet was restricted to avoid those foods (no details about type of foods reported). This may have confounded apparent treatment effects.

Harms: The first RCT reported insomnia in 2/13 (18%) children taking propranolol, but did not report on adverse effects in the placebo group.[20] The second RCT found no significant difference in adverse effects between placebo and propranolol (12 children affected in each group).[21] Adverse effects in both groups included abdominal pain, increased appetite, worsening of headaches, and fatigue. However, the trial was too small to yield reliable information about harms. The third trial did not report on adverse effects.[22] All RCTs probably lacked power to exclude clinically important differences.

Comment: None.

OPTION PIZOTIFEN

We found no RCTs of sufficient quality addressing the effects of pizotifen in children with migraine headache.

Benefits: We found no systematic review or RCTs of sufficient quality evaluating the effects of pizotifen in children with migraine headache.

Harms: We found no systematic review or RCTs that met International Headache Society (IHS) criteria for migraine (see comment below).

Comment: We found one RCT (47 children aged 7–14 years) comparing pizotifen with placebo.[23] It pre-dated the IHS diagnostic criteria for migraine and people in this study would not all fulfil the current IHS definition. The study has, therefore, been excluded. We found one further RCT comparing pizotifen with placebo.[24] It has only been published in abstract form and so we could not reliably review its methods.

OPTION DIETARY MANIPULATION

We found no RCTs of sufficient quality in children and adolescents with migraine headache.

Benefits: We found no systematic review and no RCTs of sufficient quality of dietary manipulation (see glossary, p 458) in children and adolescents with migraine headache (see comment below).

Harms: We found no RCTs.

Comment: We found one small RCT (39 children allocated to treatment), which attempted to investigate effects of excluding dietary vasoactive amines on morbidity related to migraine.[25] However, the study pre-dated the International Headache Society criteria for migraine and a large proportion (33%) of eligible children were excluded before randomisation. The study has, therefore, been excluded.

OPTION THERMAL BIOFEEDBACK

We found no RCTs of sufficient quality examining effects of thermal biofeedback (see glossary, p 458) in children with migraine headache.

Benefits: We found no systematic review and no RCTs of sufficient quality.

Harms: We found no RCTs.

Comment: We found two RCTs with more than 10 people in each treatment arm.[26,27] However, the first had high loss to follow up (46%),[26] and the second was published only as a conference abstract.[27]

OPTION PROGRESSIVE MUSCLE RELAXATION

We found no RCTs of sufficient quality examining effects of progressive muscle relaxation in children with migraine headache.

Benefits: We found no RCTs of sufficient quality (see comment below).

Harms: We found no RCTs.

Comment: We found one RCT (99 people aged 9–17 years), which compared progressive muscle relaxation (see glossary, p 458) with psychological counselling.[28] However, high loss to follow up (30%) precluded reliable conclusions.

OPTION STRESS MANAGEMENT

We found limited evidence from one RCT that a self administered stress management programme improved headache severity and frequency compared with no stress management at 1 month.

Migraine headache in children

Benefits: We found no systematic review. We found one RCT (87 people, aged 11–18 years).[29] It found that a self administered stress management (see glossary, p 458) programme reduced headache severity and frequency compared with both a stress management programme delivered by the clinic, and with no stress management, at 1 month (16/24 [67%] improved with self administered treatment *v* 10/23 [44%] with treatment delivered by the clinic *v* 6/25 [24%] with no stress management; $P < 0.01$ for self administered treatment *v* no treatment).[29]

Harms: The RCT did not report on harms.[29]

Comment: None.

GLOSSARY

Aura A premonitory sensation or warning experienced before the start of a migraine headache.

Dietary manipulation A change in diet aimed specifically at reducing or removing from the diet a foodstuff that is thought to provoke migraine headache.

Dietary vasoactive amines Dietary amines (protein subunits) that may have an effect on cerebral vascular tone.

Progressive muscle relaxation Volitional muscle relaxation aimed at altering the perception of symptoms such as headache.

Stress management Coping or relaxation strategies that aim to alter the perception of symptoms.

Thermal biofeedback A treatment in which an individual attempts to alter their skin temperature by responding to feedback about their skin temperature.

TABLE 1 **International Headache Society criteria for migraine.[1,2]**

At least 5 episodes **without aura** fulfilling **all** of criteria **1–3:**	**OR**	At least 2 episodes **with aura** fulfilling at least **three** of criteria **1–4:**
1. Headache lasting 1–48 hours		1. One or more fully reversible aura symptoms including focal cortical, brain stem dysfunction, or both
2. Headache meeting at least two of the following criteria: a) Unilaterial or bilateral (either frontal or temporal) distribution of pain b) Throbbing c) Moderate to severe intensity d) Aggravated by routine physical activity		2. At least one aura symptom that develops gradually over more than 4 minutes, or 2 or more symptoms that occur in succession
3. At least one of the following symptoms while headache is present: a) Nausea, vomiting, or both b) Photophobia, phonophobia, or both		3. No aura symptoms lasting more than 60 minutes
		4. Headache follows aura within 60 minutes

Neonatal jaundice

QUESTIONS

INTERVENTIONS

Beneficial

Unknown effectiveness

To be covered in future updates

Antenatal anti-D immunoglobulin
Continuous versus intermittent phototherapy
Immunoglobulin infusion for isoimmune haemolytic jaundice
Intrauterine blood transfusion
Lamp colour in phototherapy
Phenobarbitone
Position change versus static position in phototherapy
Routine intravenous fluids during phototherapy

*Although we found no RCTs, there is a general consensus that exchange transfusion is effective in reducing serum bilirubin levels

Key Messages

- **Exchange transfusion** We found no RCTs on the effects of exchange transfusion versus no treatment or versus phototherapy. There is general consensus that exchange transfusion is effective in reducing serum bilirubin levels and in preventing neuro-developmental sequelae. In most of the RCTs comparing other interventions, exchange transfusion was used successfully to reduce serum bilirubin levels when those interventions failed to control the rise of serum bilirubin.
- **Phototherapy** Two RCTs found that both conventional phototherapy and fibreoptic phototherapy reduced neonatal jaundice more effectively than no treatment. One systematic review (which included quasi-randomised as well as randomised controlled trials) and one subsequent RCT found that conventional phototherapy was more effective than fibreoptic phototherapy, although subgroup analysis in the systematic review found no significant difference between groups in preterm infants. No trials included in the review evaluated the impact of either phototherapy method on parent–infant bonding. One RCT found a greater effect with double conventional compared with single conventional phototherapy, whilst another RCT found no significant difference between double fibreoptic and single conventional phototherapy. One systematic review (which included quasi-randomised as well as randomised controlled trials) found no significant difference between fibreoptic plus conventional and conventional phototherapy alone in additional phototherapy, exchange transfusion, or percentage change in bilirubin after 24 hours, although it noted a trend favouring the fibreoptic plus conventional group. Most trials did not report Kernicterus as an outcome. We found insufficient evidence on the adverse effects of phototherapy.

- **Albumin infusion** We found no RCTs on the effects of albumin infusion versus no treatment or versus other treatment.
- **Home versus hospital phototherapy** We found no RCTs on the effects of home phototherapy versus no treatment or versus hospital phototherapy.

DEFINITION Neonatal jaundice refers to the yellow colouration of the skin and sclera of newborn babies that results from hyperbilirubinaemia.

INCIDENCE/ PREVALENCE Jaundice is the most common condition requiring medical attention in newborn babies. About 50% of term and 80% of preterm babies develop jaundice in the first week of life.[1] Jaundice is also a common cause of readmission to hospital after early discharge of newborn babies.[2] Jaundice usually appears 2–4 days after birth and disappears 1–2 weeks later, usually without the need for treatment.

AETIOLOGY/ RISK FACTORS In most infants with jaundice, there is no underlying disease and the jaundice is termed physiological. Physiological jaundice occurs when there is accumulation of unconjugated bilirubin in the skin and mucous membranes. It typically presents on the second or third day of life and results from the increased production of bilirubin (due to increased circulating red cell mass and a shortened red cell lifespan), and the decreased excretion of bilirubin (due to low concentrations of the hepatocyte binding protein, low activity of glucuronyl transferase, and increased enterohepatic circulation), which normally occur in newborn babies. In some infants, unconjugated hyperbilirubinaemia may be associated with breast feeding (breast milk jaundice), and this typically occurs after the third day of life. Although the exact cause of breast milk jaundice is not clear, it is generally believed to be due to an unidentified factor in breast milk. Other causes are non-physiological such as blood group incompatibility (Rhesus or ABO problems) causing haemolysis, other causes of haemolysis, sepsis, bruising, and metabolic disorders. Gilbert's and Crigler-Najjar syndromes are rare causes of neonatal jaundice.

PROGNOSIS In the newborn baby, unconjugated bilirubin can penetrate the blood–brain barrier and is potentially neurotoxic. Unconjugated hyperbilirubinaemia can, therefore, result in neuro-developmental sequelae including the development of kernicterus. Kernicterus is brain damage arising from the deposition of bilirubin in brain tissue. However, the exact level of bilirubin that is neurotoxic is unclear, and kernicterus at autopsy has been reported in infants in the absence of markedly elevated levels of bilirubin.[3] Recent reports suggest a resurgence of kernicterus in countries in which this complication had virtually disappeared.[4] This has been attributed mainly to early discharge of newborns from hospital.

AIMS OF INTERVENTION To prevent the development of bilirubin-associated neurodevelopmental sequelae; to reduce serum bilirubin levels; with minimal adverse effects.

OUTCOMES Mortality; hearing loss; incidence of kernicterus and other neurodevelopmental sequelae; adverse events due to treatment (including effects on parent–infant bonding); duration of treatment; failure of treatment (defined as the need to use other forms of treatment); length of hospital stay; need for transfusion; changes in serum bilirubin levels.

METHODS *Clinical Evidence* search and appraisal March 2003. This chapter focuses on interventions for treating unconjugated hyperbilirubinaemia. The prevention of this condition, and the specific treatment of its underlying causes, is not covered. Conjugated hyperbilirubinaemia, a condition that may indicate an underlying liver or biliary tract disorder, is beyond the scope of this chapter.

QUESTION **What are the effects of treatments for unconjugated hyperbilirubinaemia in term and preterm infants?** New

OPTION PHOTOTHERAPY

Two RCTs found that both conventional phototherapy and fibreoptic phototherapy reduced neonatal jaundice more effectively than no treatment. One systematic review (which included quasi-randomised as well as randomised controlled trials) and one subsequent RCT found that conventional phototherapy was more effective than fibreoptic phototherapy, although subgroup analysis in the systematic review found no significant difference between groups in preterm infants. No trials included in the review evaluated the impact of either phototherapy method on parent–infant bonding. One RCT found a greater effect with double conventional compared with single conventional phototherapy, whilst another RCT found no significant difference between double fibreoptic and single conventional phototherapy. One systematic review (which included quasi-randomised as well as randomised controlled trials) found no significant difference between fibreoptic plus conventional and conventional phototherapy alone in additional phototherapy, exchange transfusion, or percentage change in bilirubin after 24 hours, although it noted a trend favouring the fibreoptic plus conventional group. Most trials did not report Kernicterus as an outcome. We found insufficient evidence on the adverse effects of phototherapy.

Benefits: **Conventional phototherapy versus no treatment:** We found no systematic review but found one RCT.[5] The RCT compared conventional phototherapy using daylight fluorescent lamps versus no treatment in three birth weight groups: less than 2000 g; 2000–2499 g; and 2500 g and over.[5] Exchange transfusion was given at predetermined serum bilirubin levels in each group. It examined prevention of hyperbilirubinaemia in the lowest birth weight group, and treatment of established hyperbilirubinaemia in the remaining two groups. Only the results of treatment of established hyperbilirubinaemia are reported here. The RCT found that in the 2000–2499 g birth weight group (141 infants, serum bilirubin ≥ 10 mg/dL, average 12.4 mg/dL) phototherapy significantly reduced the proportion of infants with higher maximal serum bilirubin levels compared with no treatment (serum bilirubin ≥ 15 mg/dL: 18.6% with phototherapy *v* 42.3% with no treatment; P = 0.002). Overall, it found that phototherapy significantly decreased the proportion of infants with exchange transfusion compared with no treatment (4.3% with phototherapy *v* 25.4% with no treatment; P < 0.001). On subgroup analysis, it found that in non-haemolytic jaundice phototherapy significantly decreased exchange transfusion compared with no treatment, but it found no

significant difference between groups in haemolytic jaundice (non-haemolytic: 1.9% with phototherapy *v* 27.5% with no treatment, P = 0.0002; haemolytic: 16.7% with phototherapy *v* 22.2% with no treatment, reported as not significant). The RCT found that in the 2500 g or over birth weight group (276 infants, serum bilirubin ≥ 13 mg/dL, average 15.6–15.7 mg/dL) phototherapy significantly reduced mean serum bilirubin levels until 24 hours after the cessation of therapy compared with no treatment (results presented graphically; P value not reported). Overall, it found no significant difference between phototherapy and no treatment in the proportion of infants with exchange transfusion (10% with phototherapy *v* 16.9% with no treatment; reported as not significant). On subgroup analysis, it found that in non-haemolytic jaundice, phototherapy significantly decreased exchange transfusion compared with no treatment, but it found no significant difference between groups in haemolytic jaundice (non-haemolytic: 2.9% with phototherapy *v* 17.3% with no treatment, P = 0.05; haemolytic: 17.1% with phototherapy *v* 16.7% with no treatment, reported as not significant).[5] A subsequent report of the RCT noted that there were two deaths before hospital discharge (2000–2499 g group: 1 with phototherapy *v* 1 with no treatment; ≥ 2500 g group: none).[6] A further follow up report of the RCT found no significant difference in the two birth weight groups between treatment groups in cerebral palsy or other motor abnormalities (clumsiness, hypotonia, abnormal movement) after 1 and 6 years.[7] **Fibreoptic phototherapy versus no treatment:** We found one systematic review (search date 2000; term and preterm infants; randomised and quasi-randomised trials; see comment below).[8] The review found one RCT (46 term infants, haemolysis excluded) that compared fibreoptic phototherapy (Wallaby system) versus no treatment.[8] Conventional phototherapy was commenced if the serum bilirubin reached predetermined levels. The review found that, compared with no treatment, fibreoptic phototherapy significantly increased the percentage change in serum bilirubin per hour (WMD –0.44%, 95% CI –0.21% to –0.67%) and the percentage change after 24 hours of treatment (WMD –10.7%, 95% CI –3.26% to –18.14%).[8] It found that infants in the fibreoptic phototherapy group were less likely to require conventional phototherapy, but this did not reach significance (0/23 [0%] with fibreoptic phototherapy *v* 3/23 [13%] with no treatment: RR 0.14, 95% CI 0.01 to 2.62). **Conventional versus fibreoptic phototherapy:** We found one systematic review (search date 2000; term and preterm infants; randomised and quasi-randomised trials; see comment below)[8] and one subsequent RCT.[9] The review found that conventional phototherapy significantly increased the percentage change of serum bilirubin after 24 and 48 hours of treatment compared with fibreoptic phototherapy (24 hours: 5 trials, 203 infants, WMD 3.59%, 95% CI 1.27% to 5.92%; 48 hours: 4 trials, 183 infants, WMD 10.79%, 95% CI 8.33% to 13.26%).[8] It also found that fibreoptic phototherapy significantly increased the use of additional phototherapy compared with conventional phototherapy (8 trials; 52/366 [14%] with fibreoptic *v* 35/390 [9%] with conventional; RR 1.68, 95% CI 1.18 to 2.38). It found no significant difference between fibreoptic and conventional phototherapy in the use of exchange transfusion (3 trials; 4/97 [4%]

with fibreoptic *v* 3/117 [3%] with conventional; RR 1.62, 95% CI 0.38 to 6.93). In a subgroup analysis of preterm babies only, it found no significant difference between fibreoptic phototherapy and conventional phototherapy in the duration of phototherapy (3 trials, 232 infants; WMD +2 hours, 95% CI –3.5 hours to +7.52 hours), use of additional phototherapy (5 trials; 3/148 [2%] with fibreoptic *v* 3/156 [2%] with conventional; RR 1.07, 95% CI 0.27 to 4.27), percentage change in serum bilirubin after 24 hours of treatment (1 trial, 20 infants; WMD +1.7%, 95% CI –2.65% to +6.05%), and repeat phototherapy for rebound jaundice (3 trials; 10/122 [8%] with fibreoptic *v* 5/121 [4%] with conventional; RR 2.00, 95% CI 0.71 to 5.63).[8] The subsequent RCT (109 term infants, birth weight ≥ 2500 g, haemolysis excluded) found that conventional daylight phototherapy significantly increased the rate of decline of serum bilirubin and significantly decreased treatment duration compared with fibreoptic phototherapy (bilirubin decline rate: 0.15 ±0.06 mg/dL/hour with conventional *v* 0.1 ±0.05 mg/dL/hour with fibreoptic, $P < 0.05$; duration of phototherapy: 49.4 ± 14.4 hours with conventional *v* 61 ± 13.1 hours with fibreoptic; $P < 0.05$).[9] **Double versus single phototherapy:** We found one systematic review (search date 2000; term and preterm infants; randomised and quasi-randomised trials; see comment below)[8] and one additional RCT.[10] The systematic review found one RCT (86 term infants, haemolysis excluded) comparing double fibreoptic phototherapy (infants wrapped in 2 BiliBlankets) versus single conventional phototherapy.[8] It found no significant difference between groups in duration of treatment (WMD +2.24 hours, 95% CI –10.68 hours to +15.16 hours), percentage change in serum bilirubin per hour (WMD –0.04%, 95% CI –0.17% to +0.09%), percentage change in serum bilirubin per day (WMD +2.82%, 95% CI –1.84% to +7.48%), and the use of repeat phototherapy for rebound jaundice (RR 1.05, 95% CI 0.07 to 16.22).[8] The review also compared double phototherapy using a combination of fibreoptic plus conventional phototherapy versus conventional phototherapy alone. It found no significant difference between fibreoptic plus conventional phototherapy and single conventional phototherapy in exchange transfusion (1 trial; 0/19 [0%] with fibreoptic plus conventional *v* 2/23 [8%] with conventional; RR 0.24, 95% CI 0.01 to 4.72), additional phototherapy (1 trial; 0/90 [0%] with fibreoptic plus conventional *v* 4/90 [4%] with conventional; RR 0.11, 95% CI 0.01 to 2.02), and percentage change in serum bilirubin after 24 or 48 hours (1 trial, 26 infants; 24 hours: WMD –3.2%, 95% CI –17.2% to +10.8%; 48 hours: WMD –9.2%, 95% CI –25.02% to +6.62%), although it noted a trend favouring the fibreoptic plus conventional group. It found no significant difference between fibreoptic plus conventional phototherapy and single conventional phototherapy in repeat phototherapy for rebound jaundice (6 trials; 36/232 [16%] with fibreoptic plus conventional *v* 30/240 [13%] with conventional; RR 1.29, 95% CI 0.85 to 1.95).[8] The additional RCT (51 term infants, birth weight ≥ 2500 g, haemolysis included) compared double conventional phototherapy using daylight fluorescent lamps versus single conventional phototherapy.[10] It found that double conventional phototherapy reduced serum bilirubin significantly faster during the first 24 hours compared with

single conventional phototherapy (0.22 ± 0.12 mg/dL/hour with double *v* 0.14 ± 0.10 mg/dL/hour with single; P = 0.02). It found a trend for double conventional phototherapy to reduce bilirubin faster on the second day but this did not reach significance (P = 0.06). It found that double conventional phototherapy significantly reduced duration of treatment compared with single conventional phototherapy (34.9 ± 12.6 hours *v* 43.7 ± 17.5 hours; P = 0.039). It did not report on kernicterus or other long term outcomes.

Harms: Most RCTs did not report on adverse events. **Conventional versus fibreoptic phototherapy:** In the systematic review, one small trial found that transepidermal water loss (sweating) was significantly higher in infants treated with fibreoptic devices compared with conventional phototherapy, and one small trial found no significant difference between fibreoptic and conventional phototherapy in mothers developing migraine during their infant's treatment with phototherapy.[8] However, the clinical significance of this is uncertain. One RCT reported transient erythema (1/50 [2%] with conventional *v* 1/50 [2%] with fibreoptic) and mild watery stools not leading to dehydration (3/50 [6%] with conventional *v* 3/50 [6%] with fibreoptic).[9] **Double versus single phototherapy:** One RCT found no significant difference between double conventional and single conventional phototherapy in weight reduction, frequency of stooling, or fever.[10]

Comment: As well as including RCTs, the systematic review also included quasi-randomised controlled trials, all of which used alternate or sequential allocation.[8] This may limit the validity of its conclusions. Two different fibreoptic devices were used by trials included in the review: BiliBlanket and Wallaby. The irradiance of the Wallaby phototherapy system and BiliBlanket are different, and the irradiance setting of the BiliBlanket was not the same in different trials.[8] Conventional phototherapy varied between trials, with trials using either halogen or fluorescent lamps, emitting white light, blue light, or a mixture of the two.[8] Inclusion criteria in the trials varied, with some excluding infants with haemolysis and others including them. No trials including infants with haemolysis reported separate data for this group, and the review was unable to do a planned subgroup analysis on this group.[8] Phototherapy was instituted at different serum bilirubin levels in different trials. Outcomes of trials included in the review were reported mainly in terms of changes in serum bilirubin levels; the incidence of kernicterus was not reported in any of the trials.[8] No trials were identified to support or refute the view that fibreoptic devices interfere less with infant care or impact less on parent–child bonding.[8]

OPTION HOME PHOTOTHERAPY

We found no RCTs on the effects of home phototherapy versus no treatment or versus hospital phototherapy.

Benefits: **Versus no treatment:** We found no systematic review or RCTs. **Versus hospital phototherapy:** We found no systematic review or RCTs.

Neonatal jaundice

Harms: We found no RCTs.

Comment: None.

OPTION ALBUMIN INFUSION

We found no RCTs on the effects of albumin infusion versus no treatment or versus other treatment.

Benefits: **Versus no treatment:** We found no systematic review or RCTs. **Versus other treatment:** We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION EXCHANGE TRANSFUSION

We found no RCTs on the effects of exchange transfusion versus no treatment or versus phototherapy. There is general consensus that exchange transfusion is effective in reducing serum bilirubin levels and in preventing neuro-developmental sequelae. In most of the RCTs comparing other interventions, exchange transfusion was used successfully to reduce serum bilirubin levels when those interventions failed to control the rise of serum bilirubin.

Benefits: **Versus no treatment:** We found no systematic review or RCTs (see comment below). **Versus phototherapy:** We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: There is general consensus that exchange transfusion is effective in reducing serum bilirubin levels and preventing neuro-developmental sequelae. In most of the RCTs comparing other interventions, exchange transfusion was used successfully to reduce serum bilirubin levels when those interventions failed to control the rise of serum bilirubin.

QUESTIONS

INTERVENTIONS

Key Messages

- **Enuresis alarm plus dry-bed training (as effective as enuresis alarm alone)** One systematic review has found limited evidence that a higher proportion of children achieve 14 consecutive dry nights with alarm plus dry bed training than with no treatment. A second systematic review found no significant difference between alarm plus dry bed training and alarm alone for achieving 14 consecutive dry nights.
- **Desmopressin (in short term)** One systematic review has found that desmopressin reduces bedwetting by at least one night per week and increases the chance of attaining initial success (14 consecutive dry nights) compared with placebo. The review found insufficient evidence comparing either intranasal versus oral administration of desmopressin or desmopressin versus tricyclic drugs. There was some evidence that higher doses of desmopressin were more likely to reduce the number of wet nights during treatment compared with lower doses. The review found no difference between desmopressin and enuresis alarms in the number of children achieving initial success, although one RCT found that, after 3 months of treatment, enuresis alarms were better than desmopressin at reducing the number of wet nights per week. We found insufficient evidence about effects of desmopressin in the long term.
- **Dry bed training (in short term)** One systematic review has found that a greater proportion of children achieved 14 consecutive dry nights with dry bed training than with no treatment.

- **Enuresis alarm (in short and long term)**One systematic review has found that enuresis alarms increase initial success rates compared with no treatment and that 31–61% of children using alarms were still dry at 3 months. The review found that children using an alarm were nine times less likely to relapse than were children taking desmopressin. We found limited evidence from one small RCT that dry bed training reduced bedwetting compared with an enuresis alarm after initial treatment and after 6 months. One systematic review found no significant difference between alarm plus dry bed training and alarm alone for achieving 14 consecutive dry nights. Two RCTs found that adding intranasal desmopressin to treatment with an alarm reduced bedwetting in the short term (3–4 weeks) compared with treatment with alarm alone. However, one RCT found no significant difference between treatment with intranasal desmopressin plus alarm and treatment with placebo plus alarm on long term follow up at 6 months.
- **Laser acupuncture (as effective as desmopressin in one RCT)** One RCT found no difference between laser acupuncture and intranasal desmopressin in the number of wet nights in children aged over 5 years.
- **Standard home alarm clock (in short term)** One RCT found that a higher proportion of children achieved 14 consecutive dry nights with standard home alarm clock than with waking after 3 hours' sleep.
- **Adding desmopressin to an alarm (in long term)** One systematic review found that desmopressin plus alarm was better at reducing the number of wet nights per week during treatment compared with alarm alone or alarm plus placebo, although there was no significant difference between alarm plus desmopressin and alarm alone in the rate of initial success.
- **Dry bed training (in long term)** One systematic review has found no significant long term difference in the proportion of dry nights between dry bed training and no treatment. However, one small RCT showed some long-term advantages of dry bed training.
- **Standard home alarm clock (in long term)** One RCT found no significant difference in the proportion of dry nights achieved at 3 months between standard home alarm clock and waking after 3 hours' sleep.
- **Ultrasound** We found no RCTs. One small controlled trial in children aged 6–14 years found that ultrasound increased the proportion of dry nights for up to 12 months compared with control.
- **Tricyclic drugs (imipramine, desipramine)** One systematic review has found that tricyclic drugs (imipramine, desipramine) increase the chance of attaining 14 consecutive dry nights compared with placebo, although tricyclic drugs increased adverse effects such as anorexia, anxiety reaction, constipation, depression, diarrhoea, dizziness, drowsiness, dry mouth, headache, irritability, lethargy, sleep disturbance, upset stomach, and vomiting compared with placebo. We found no good studies comparing tricyctic drugs versus desmopressin. The review found no significant difference between imipramine and an enuresis alarm during the treatment period, but it found limited evidence that an alarm reduced bedwetting after the treatment had stopped compared with imipramine.

DEFINITION Nocturnal enuresis is the involuntary discharge of urine at night in the absence of congenital or acquired defects of the central nervous system or urinary tract in a child aged 5 years or older.[1] Disorders that have bedwetting as a symptom (termed "nocturnal incontinence") can be excluded by a thorough history, examination, and urinalysis. "Monosymptomatic" nocturnal enuresis is characterised

Nocturnal enuresis

by night time symptoms only and accounts for 85% of cases. Nocturnal enuresis is defined as primary if the child has not been dry for a period of more than 6 months, and secondary if such a period of dryness preceded the onset of wetting.

INCIDENCE/ PREVALENCE Between 15% and 20% of 5 year olds, 7% of 7 year olds, 5% of 10 year olds, 2–3% of 12–14 year olds, and 1–2% of people aged 15 years and over wet the bed twice per week on average.[2]

AETIOLOGY/ RISK FACTORS Nocturnal enuresis is associated with several factors, including small functional bladder capacity, nocturnal polyuria, and arousal dysfunction. Linkage studies have identified associated genetic loci on chromosomes 8q, 12q, 13q, and 22q11.[3–6]

PROGNOSIS Nocturnal enuresis has widely differing outcomes, from spontaneous resolution to complete resistance to all current treatments. About 1% of adults remain enuretic. Without treatment, about 15% of children with enuresis become dry each year.[7] We found no RCTs on the best age at which to start treatment in children with nocturnal enuresis. Anecdotal experience suggests that reassurance is sufficient below the age of 7 years. Behavioural treatments, such as alarms, require motivation and commitment from the child and a parent. Anecdotal experience suggests that children under the age of 7 years may not exhibit the commitment needed.

AIMS OF INTERVENTION To stay dry on particular occasions (e.g. when visiting friends); to reduce the number of wet nights; to reduce the impact of the enuresis on the child's lifestyle; to initiate successful continence; to avoid relapse, with minimal adverse effects.

OUTCOMES Rate of initial success (defined as 14 consecutive dry nights); average number of wet nights per week; number of relapses after initial success; average number of wet nights after treatment has ceased.

METHODS *Clinical Evidence* search and appraisal February 2003.

QUESTION What are the effects of interventions for relief of symptoms?

OPTION DESMOPRESSIN

One systematic review has found that desmopressin reduces bedwetting by at least one night per week and increases the chance of attaining initial success (14 consecutive dry nights) compared with placebo. The review found insufficient evidence comparing either intranasal versus oral administration of desmopressin or desmopressin versus tricyclic drugs. There was some evidence that higher doses of desmopressin were more likely to reduce the number of wet nights during treatment compared with lower doses. The review found no difference between desmopressin and enuresis alarms in the number of children achieving initial success, although one RCT found that, after 3 months of treatment, enuresis alarms were better than desmopressin at reducing the number of wet nights per week. One systematic review found that desmopressin plus alarm was better at reducing the number of wet nights per week during treatment compared with alarm alone or alarm plus placebo, although there was no significant difference in the rate of initial success.

Benefits: We found one systematic review (search date 2002, 41 RCTs, 2760 children).[8] **Versus placebo:** The systematic review identified 28 RCTs that compared desmopressin versus placebo.[8] It found that desmopressin (10–60 μg) significantly reduced the number of wet nights per week during treatment compared with placebo (desmopressin 20 μg; pooled WMD −1.34, 95% CI −1.57 to −1.11). Ten of the RCTs assessed the rate of initial success (14 consecutive dry nights) and found that desmopressin significantly increased the chance of initial success compared with placebo (RR for success with desmopressin [20 μg] *v* placebo 1.2, 95% CI 1.1 to 1.3) (see table 1, p 477). **Intranasal versus oral desmopressin:** The review found one RCT that compared intranasal desmopressin versus oral desmopressin.[8] The review found insufficient evidence comparing intranasal versus oral administration of desmopressin. **Versus tricyclic drugs:** The review found two RCTs that compared desmopressin versus tricyclic drugs.[8] It found insufficient evidence comparing desmopressin versus either amitriptyline or imipramine. **Versus enuresis alarm:** The review found three RCTs that compared desmopressin versus enuresis alarms.[8] It found no significant difference between desmopressin and alarm in the number of children achieving initial success (RR 1.34, 95% CI 0.94 to 1.91). However, one RCT (50 children) found that desmopressin significantly reduced the number of wet nights per week during the first week of treatment (RR −1.70, 95% CI −2.96 to −0.44) compared with alarm, although after 3 months of treatment enuresis alarms were significantly better than desmopressin at reducing the number of wet nights per week (RR 1.40, 95% CI 0.14 to 2.66). **Plus enuresis alarm:** The review found two RCTs that compared alarm plus desmopressin versus alarm alone.[8] It found that alarm plus desmopressin was significantly better at reducing the number of wet nights per week during treatment compared with alarm alone (RR −1.35, 95% CI −2.32 to −0.38). However, the review also found no significant difference between alarm plus desmopressin and alarm alone in the rate of initial success (RR 0.88, 95% CI 0.52 to 1.50). The review found two RCTs (149 children) that compared alarm plus desmopressin versus alarm plus placebo.[8] It found that alarm plus desmopressin was significantly better at reducing the number of wet nights per week during treatment compared with alarm plus placebo (RR −1.00, 95% CI −1.56 to −0.44). However, the review also found no significant difference between alarm plus desmopressin and alarm plus placebo in the rate of initial success (RR 1.12, 95% CI 0.83 to 1.51). **Versus laser acupuncture:** See benefits of laser acupuncture, p 475. **Lower versus higher doses of desmopressin:** The review found eight RCTs that compared different doses of desmopressin.[8] It found some evidence that higher doses were more likely to reduce the number of wet nights during treatment compared with lower doses (wet nights with desmopressin 20 μg *v* desmopressin 60 μg; WMD −0.72, 95% CI −0.3 to −0.14). However, there was no difference between doses in the rate of initial success.

Harms: The systematic review reported nasal discomfort, headache, nosebleeds, bad taste, rash, sight disturbance, and anorexia.[8] Rarely, water intoxication has been reported.[14]

Nocturnal enuresis

Comment: The systematic review included only studies of interventions used to remedy either primary or secondary nocturnal enuresis (incontinence was excluded by medical examination or explicitly mentioned in the inclusion/exclusion criteria of included RCTs), and included a systematic measurement of baseline wetting (with one exception) and outcomes. Many of the included RCTs were of poor quality.[8]

OPTION TRICYCLIC DRUGS (IMIPRAMINE, DESIPRAMINE)

One systematic review has found that tricyclic drugs (imipramine, desipramine) increase the chance of attaining 14 consecutive dry nights compared with placebo, although tricyclic drugs increased adverse effects such as anorexia, anxiety reaction, constipation, depression, diarrhoea, dizziness, drowsiness, dry mouth, headache, irritability, lethargy, sleep disturbance, upset stomach, and vomiting compared with placebo. We found no good studies comparing tricyclic drugs versus desmopressin. The review found no significant difference between imipramine and an enuresis alarm during the treatment period, but found limited evidence that an alarm reduced bedwetting compared with imipramine after the treatment had stopped.

Benefits: We found one systematic review (search date 1997, 22 RCTs, 1100 children).[9] Many of the trials were of poor quality. **Versus placebo:** The review identified 10 RCTs comparing the effect of imipramine versus placebo on mean number of wet nights per week.[9] It found that imipramine significantly reduced bedwetting by one night per week compared with placebo (WMD –0.84 nights, 95% CI –1.21 nights to –0.47 nights) The review also found that imipramine (4 RCTs) and desipramine (1 RCT) significantly increased the chance of attaining 14 consecutive dry nights compared with placebo (imipramine: RR 5.0, 95% CI 2.4 to 10.4; desipramine: RR 3.60, 95% CI 1.07 to 11.81) (see table 1, p 477). **Versus enuresis alarm:** The review (3 small RCTs, 103 children) found no significant difference in mean number of wet nights per week between imipramine and an enuresis alarm during the treatment period.[9] However, after treatment was stopped, two of the three RCTs found that the enuresis alarm reduced bedwetting compared with imipramine (WMD in number of dry nights per week: 1.03 nights, 95% CI 0.19 nights to 1.87 nights).[9] **Versus desmopressin:** We found no good studies comparing tricyclic drugs versus desmopressin.

Harms: The systematic review reported that tricyclic drugs increased adverse effects compared with placebo.[9] Effects included anorexia, anxiety reaction, burning sensation, constipation, depression, diarrhoea, dizziness, drowsiness, dry mouth, headache, irritability, lethargy, sleep disturbance, upset stomach, and vomiting. The review also found that tricyclic drugs increased adverse effects compared with desmopressin (AR for adverse effects: 83/480 [17.3%] with tricyclic drugs *v* 41/579 [7.1%] with desmopressin). Tricyclic drugs have been reported as fatal in overdose.

Comment: None.

OPTION ENURESIS ALARM

One systematic review has found that enuresis alarms increase initial success rates compared with no treatment, and that 31–61% of children using alarms were still dry at 3 months. We found limited evidence from one small RCT that dry bed training reduced bedwetting compared with an enuresis alarm after initial treatment and after 6 months. One systematic review found no significant difference between alarm plus dry bed training and alarm alone for achieving 14 consecutive dry nights. One systematic review found that desmopressin plus alarm was better at reducing the number of wet nights per week during treatment compared with alarm alone or alarm plus placebo, although there was no significant difference in the rate of initial success.

Benefits: **Versus no treatment:** We found one systematic review (search date 1997, 4 RCTs).[10] It found that significantly more children achieved 14 consecutive dry nights with enuresis alarm than with no treatment and that 31–61% were still dry at 3 months (see table 1, p 477). **Versus dry bed training:** See benefits of dry bed training, p 474. **Plus dry bed training:** See benefits of alarm plus dry bed training, p 474. **Versus desmopressin:** See benefits of desmopressin, p 471. **Plus desmopressin versus alarm plus placebo:** See benefits of desmopressin, p 471.

Harms: One systematic review found that adverse effects of alarms were limited to minor inconvenience because of alarm malfunction or disturbance.[12] One systematic review reported that adverse affects included fright, false alarms, and waking of other people in the house.[10] However, it was unable to estimate the frequency of these events.

Comment: None.

OPTION STANDARD HOME ALARM CLOCK

One RCT found that a standard home alarm clock, set to wake the child immediately before their usual time of enuresis, reduced bedwetting compared with a strategy of routinely waking the child after 3 hours' sleep, but it found no significant difference in the proportion of dry nights at 3 months.

Benefits: We found no systematic review but found one RCT.[11] It found that significantly more children achieved 14 consecutive dry nights with a standard home alarm clock to wake the child immediately before their usual time of enuresis compared with a strategy of routinely waking the child after 3 hours' sleep, but it found no significant difference in the proportion of dry nights at 3 months (see table 1, p 477).

Harms: No adverse effects were reported in the RCT.[11]

Comment: None.

Nocturnal enuresis

OPTION DRY BED TRAINING

Two RCTs found that dry bed training reduced bedwetting in the short term compared with no treatment, although we found insufficient reliable evidence about long term effects. We found limited evidence from one small RCT that dry bed training reduced bedwetting compared with an enuresis alarm after initial treatment and after 6 months.

Benefits: We found one systematic review (search date 1996, 1 RCT, 45 children)[12] and one subsequent small RCT (36 people).[13] **Versus no treatment:** The review found that significantly more children achieved 14 consecutive dry nights with dry bed training than with no treatment, although it found no long term advantage (see table 1, p 477). The subsequent small RCT compared three groups: dry bed training, alarm, and no treatment.[13] It found that, within the 16 week treatment period, dry bed training decreased bedwetting compared with no treatment (see table 1, p 477). However, it was not clear whether this difference was significant. **Versus enuresis alarm:** The subsequent small RCT described above found that dry bed training decreased bedwetting compared with alarm both during treatment and 6 months after treatment (see table 1, p 477).[13] However, it was not clear whether this difference was significant. **Plus enuresis alarm:** See benefits of enuresis alarm plus dry bed training, p 474.

Harms: Neither the review[12] nor the subsequent RCT[13] reported on harms.

Comment: The small RCT was conducted in children from families with low socioeconomic status, and reported lower success rates compared with other trials.[13] This may reduce the generalisability of results.

OPTION ENURESIS ALARM PLUS DRY BED TRAINING

One systematic review has found limited evidence that a higher proportion of children achieve 14 consecutive dry nights with alarm plus dry bed training than with no treatment. A second systematic review found no significant difference between alarm plus dry bed training and alarm alone for achieving 14 consecutive dry nights.

Benefits: **Versus no treatment:** We found one systematic review (search date 1996, 1 RCT, 45 children).[12] It found that significantly more children achieved 14 consecutive dry nights with dry bed training plus an alarm than with no treatment (1 RCT; RR 10, 95% CI 2.69 to 37.24) (see table 1, p 477). **Versus alarm alone:** We found one systematic review (search date 1997, 5 RCTs, 220 children).[10] It found no significant difference between alarm plus dry bed training and alarm alone for achieving 14 consecutive dry nights (RR for not achieving 14 consecutive dry nights 1.03, 95% CI 0.65 to 1.65).

Harms: See harms of dry bed training, p 474. See harms of enuresis alarm, p 473.

Comment: None.

OPTION ULTRASOUND

We found no RCTs of ultrasound in children with primary nocturnal enuresis. We found one small controlled trial in children aged 6–14 years, which found that ultrasound reduced the number of wet nights compared with control in both the short and long term.

Benefits: We found no systematic review of RCTs of ultrasound in children with primary nocturnal enuresis.

Harms: We found no RCTs.

Comment: We found one controlled trial (35 children with primary nocturnal enuresis, aged 6–14 years) comparing ultrasound (27 children) versus control (8 children treated without the apparatus being switched on).[15] Ultrasound treatment was applied daily to lumbosacral skin for 10 sessions. The trial found that ultrasound versus control reduced the number of wet nights per week at 1 week, 3 months, 6 months, and 12 months after treatment ($P < 0.05$ at all times). The study did not find any adverse effects.[15]

OPTION LASER ACUPUNCTURE

One RCT found no significant difference between laser acupuncture and intranasal desmopressin in reduction of wet nights in children aged over 5 years.

Benefits: We found no systematic review. **Versus no treatment:** We found no RCTs. **Versus desmopressin:** We found one RCT (40 children aged > 5 years with primary nocturnal enuresis) comparing laser acupuncture versus intranasal desmopressin (20–40 μg for 3 months).[16] Laser acupuncture was applied to seven predefined acupuncture areas for 30 seconds per session for 10–15 sessions. Complete response was defined as a reduction in the number of wet nights of at least 90%. At 6 months the RCT found no significant difference between laser acupuncture and intranasal desmopressin in reduction in wet nights (complete responders: 65% with laser acupuncture *v* 75% with desmopressin).

Harms: The RCT did not find any adverse effects with either laser acupuncture or intranasal desmopressin.[16]

Comment: Laser acupuncture treatment may not be widely available.

GLOSSARY

Dry bed training A multicomponent behavioural programme for treatment of nocturnal enuresis in children. Elements of the programme are directed at increasing bladder capacity, strengthening the sphincter, and encouraging rapid movement from bed to toilet.

Substantive changes

Enuresis alarm and dry bed training One RCT added;[13] conclusions unchanged.

TABLE 1 **Treatments for enuresis: advantages and disadvantages (see text, p 473).**

	Short term relief of symptoms (14 consecutive dry nights)	Long term relief of symptoms	Evidence	Advantages	Disadvantages
Desmopressin (intranasal)[8]	RR *v* placebo 1.2, 95% CI 1.1 to 1.3	No better than placebo after completion of treatment	Meta-analysis of 10 RCTs	Effective within days, few adverse effects with appropriate pretreatment advice	Case reports of water intoxication
Tricyclic drugs (imipramine)[9]	RR *v* placebo 5.0, 95% CI 2.4 to 10.4	No better than placebo (RR 1.1)	Meta-analysis of 4 RCTs	Effective within days	Risk of lethal overdose, frequent significant adverse effects
Enuresis alarm[10]	RR *v* no treatment 3.7, 95% CI 2.6 to 5.3	31–61% still dry at 3 months. Nine times less likely relapse than with desmopressin	Meta-analysis of 4 RCTs	Safe	Takes longer to become dry, needs good cooperation from child and family
Standard home alarm clock[11]	77.1% *v* 61.8% with waking after 3 hours' sleep (RR 1.3; P = 0.03)	No better at 3 months than waking after 3 hours' sleep (66% dry *v* 56%; P = 0.19)	1 RCT, 125 people	Safe, does not require bed wetting to initiate alarm	None reported
Dry bed training[12]	RR *v* no treatment 2.5, 95% CI 0.55 to 11.4	No better than no treatment (RR 0.4, 95% CI 0.14 to 1.13)	1 good quality RCT, 45 people	Safe	Requires high degree of motivation
Dry bed training[13]	66% *v* 25% for alarm and *v* 8% for no treatment (P < 0.001)	58% v 17% for alarm remained completely dry 6 months after completion of dry bed training	1 small RCT, 36 children		
Dry bed training plus alarm[12]	RR *v* no treatment 10, 95% CI 2.69 to 37.24	No better than alarm alone (RR 1.0, 95% CI 0.7 to 1.5)	1 RCT, 45 people	Safe	Requires an even greater input from the family than either treatment alone

Nosebleeds in children

Search date June 2003

Gerald McGarry

QUESTIONS

INTERVENTIONS

Key Messages

- **Antiseptic cream** One RCT found that chlorhexidine/neomycin cream reduced nosebleeds compared with no treatment at 8 weeks.
- **Antiseptic cream versus cautery** One small RCT found no significant difference in nosebleeds between chlorhexidine/neomycin cream and silver nitrate cautery at 8 weeks. However, the study may have lacked power to detect clinically important differences between treatments. Some children found the smell and taste of the antiseptic cream unpleasant. All children found cautery painful despite the use of local anaesthesia.
- **Cautery plus antiseptic cream** One small RCT found insufficient evidence about the effects of silver nitrate cautery plus chlorhexidine/neomycin cream compared with chlorhexidine/neomycin cream alone.
- **Cautery versus no treatment** We found no RCTs about the effects of this intervention.

DEFINITION Recurrent idiopathic epistaxis is recurrent, self limiting, nasal bleeding in children for which no specific cause is identified. There is no consensus on the frequency or severity of recurrences.

INCIDENCE/ PREVALENCE A cross-sectional study of 1218 children (aged 11–14 years) found that 9% had frequent episodes of epistaxis.[1] It is likely that only the most severe episodes are considered for treatment.

AETIOLOGY/ RISK FACTORS In children, most epistaxis occurs from the anterior part of the septum in the region of Little's area.[2] Initiating factors include local inflammation, mucosal drying, and local trauma (including nose picking).[2] Epistaxis caused by other specific local (e.g. tumours) or systemic factors (e.g. clotting disorders) is not considered here.

PROGNOSIS Recurrent epistaxis is less common in people over 14 years old, and many children "grow out" of this problem.

AIMS OF INTERVENTION To reduce the number and severity of epistaxis episodes; to minimise adverse effects of treatment.

OUTCOMES Number and severity of epistaxis episodes.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION What are the effects of treatments for recurrent idiopathic epistaxis in children?

OPTION ANTISEPTIC CREAMS

One RCT found that chlorhexidine/neomycin cream reduced nosebleeds compared with no treatment at 8 weeks. One small RCT found no significant difference in nosebleeds between chlorhexidine/neomycin cream and silver nitrate cautery at 8 weeks, although the study may have lacked power to detect a clinically important effect. Some children found the smell and taste of antiseptic cream unpleasant. All children found cautery painful, despite the use of local anaesthesia.

Benefits: We found no systematic review. **Versus no treatment:** We found one RCT (103 children aged 3–13 years with recurrent epistaxis for a mean 20 months, unblinded design) that compared antiseptic cream (chlorhexidine hydrochloride 0.1%, neomycin sulphate 3250 U/g) applied to both nostrils twice daily for 4 weeks versus no treatment.[3] It found that antiseptic cream significantly increased the proportion of children who had complete resolution of bleeding compared with no treatment at 8 weeks (no bleeding in past 4 weeks: 26/47 [55%] with antiseptic cream *v* 12/41 [29%] with no treatment; RR 0.53, 95% CI 0.31 to 0.91; NNT 4, 95% CI 3 to 9). **Versus cautery:** We found one small RCT (48 children aged 3–14 years with at least 1 episode of epistaxis during the previous 4 weeks and a "history of repeated epistaxis"), which compared antiseptic cream (chlorhexidine hydrochloride 0.1%, neomycin sulphate 3250 U/g) applied to both nostrils twice daily for 4 weeks versus silver nitrate cautery.[4] Cautery was undertaken in secondary care using silver nitrate applied on a stick to prominent vessels or bleeding points. The RCT found no significant difference in the proportion of children with complete resolution of bleeding at 8 weeks (no bleeding during the past 4 weeks: 12/24 [50%] with

antiseptic cream *v* 13/24 [54%] with cautery; RR 0.92, 95% CI 0.54 to 1.59). It also found similar rates of partial success with antiseptic cream compared with cautery at 8 weeks (proportion of children with 50% reduction in number of bleeds during the past 4 weeks: 4/24 [16.6%] with antiseptic cream *v* 3/24 [12.5%] with cautery) and failure at 8 weeks (proportion of children with less than 50% reduction in number of bleeds in past 4 weeks: 7/24 [29%] with antiseptic cream *v* 6/24 [25%] with cautery). **Plus cautery:** See benefits of silver nitrate cautery, p 480.

Harms: The RCT comparing antiseptic cream with no treatment gave no information about adverse effects.[3] Some commercial antiseptic creams contain arachis (peanut) oil, and the RCT excluded all children with peanut allergies.[3] The RCT comparing antiseptic cream with cautery found no adverse reactions with antiseptic cream, but some children found the smell and taste unpleasant (no further data reported).[4] Chlorhexidine/neomycin cream may cause occasional skin reactions. All children undergoing cautery experienced pain, even with 5% cocaine as a local anaesthetic.[4]

Comment: See comment under silver nitrate cautery, p 480.

OPTION SILVER NITRATE CAUTERY

We found no RCTs comparing silver nitrate cautery with no treatment. One small RCT found no significant difference in nosebleeds between silver nitrate cautery and antiseptic cream at 8 weeks. One small RCT found insufficient evidence about the effects of silver nitrate cautery plus chlorhexidine/neomycin cream versus chlorhexidine/neomycin cream alone.

Benefits: We found no systematic review. **Versus no treatment:** We found no RCTs. **Versus antiseptic cream:** See benefits of antiseptic creams, p 479. **Plus antiseptic cream:** One RCT (40 adults, 24 children) compared once only silver nitrate cautery plus chlorhexidine hydrochloride 0.1%/neomycin sulphate 3250 U/g cream twice daily for 2 weeks versus antiseptic cream alone.[5] The RCT did not provide discrete results in children and included too few children to draw conclusions.

Harms: The RCT did not report harms.[5] Recognised complications of cautery include pain and septal perforation, although the incidence of septal perforation following unilateral cautery in children is not known (see harms of antiseptic creams, p 480).

Comment: Both RCTs involving silver nitrate cautery were undertaken in the context of secondary care.[4,5] Silver nitrate cautery is also used in primary care. It is unknown whether complication rates differ. Simultaneous bilateral cautery in children is not recommended because of an expected increased risk of perforation.

QUESTIONS

INTERVENTIONS

See glossary, p 495

Key Messages

Reducing pain related distress during heel puncture

- **Holding (skin to skin) versus swaddling in term infants** RCTs found that holding reduced crying during heel puncture compared with swaddling in term infants.
- **Oral glucose** RCTs found that oral glucose reduced pain responses (particularly the duration of crying) in preterm and term infants compared with water or no treatment.

- **Oral sucrose** Systematic reviews and additional RCTs found good evidence in preterm infants and limited evidence in term infants that oral sucrose reduced pain responses (particularly the duration of crying) compared with water or no treatment. One RCT found that sucrose did not appear to increase the benefit of holding. Three RCTs in term infants found that sucrose plus pacifier was more effective than pacifier alone, although one RCT in preterm infants found no significant difference in pain score between a pacifier dipped in sucrose and pacifier alone. One RCT found insufficient evidence about the effects of oral sucrose compared with lidocaine–prilocaine emulsion in term infants undergoing heel puncture.
- **Other sweeteners** RCTs have found that other sweeteners (hydrogenated glucose or an artificial sweetener, 10 parts cyclamate and 1 part saccharin) reduce pain scores and the percentage of time spent crying in term infants compared with water.
- **Pacifiers** RCTs in term and preterm infants have found that pacifiers given before heel puncture reduce pain responses compared with no treatment.
- **Positioning (tucking arms and legs) in preterm infants** One RCT found limited evidence that pain responses were reduced by tucking the arms and legs into a mid-line flexed position during heel puncture.
- **Rocking** We found limited evidence that rocking reduces pain related stress compared with placebo.
- **Multiple doses of sweet solution** One small RCT found no significant difference in pain of heel puncture between multiple and single doses of sucrose.
- **Swaddling** One small RCT found no significant difference in pain responses from swaddling compared with no swaddling.
- **Breast milk or breast feeding** RCTs found no evidence that breast milk or breast feeding during heel puncture reduced pain responses or crying in neonates compared with water.
- **Prone position** One RCT found no significant difference in pain score between prone position and either side or supine position during heel puncture.
- **Topical anaesthetics** Systematic reviews and additional RCTs found no evidence of reduced pain responses, particularly crying, following heel puncture with topical anaesthetic (lidocaine, lidocaine–prilocaine emulsion, or tetracaine [amethocaine]) compared with placebo.
- **Warming** Two RCTs in term infants found no benefit of warming before heel puncture.

Reducing pain related distress during venepuncture

- **Breast feeding** One RCT found that breast feeding during venepuncture reduced pain responses compared with oral water or being held. The RCT found no significant difference in pain response between breast feeding and oral glucose.
- **Oral glucose** RCTs have found that oral glucose reduces pain responses (particularly the duration of crying) in term and preterm infants compared with water or no treatment. One RCT found no significant difference in pain scores between sucrose and glucose.
- **Oral sucrose** RCTs have found that oral sucrose reduces pain responses (particularly the duration of crying) in term and preterm infants compared with water or no treatment. One RCT found no significant difference in pain between sucrose and glucose.

Reducing pain during blood sampling in infants

- **Pacifiers** One RCT found that pacifiers reduced pain responses compared with water or no treatment in term infants undergoing venepuncture.
- **Topical anaesthetics** Four RCTs found limited evidence that lidocaine–prilocaine emulsion reduced pain responses to venepuncture compared with placebo. Two RCTs found that tetracaine (amethocaine) gel reduced pain and crying during venepuncture compared with placebo.
- **Other sweeteners** We found no RCTs of other sweeteners for venepuncture.

DEFINITION Methods of sampling blood in infants include heel puncture, venepuncture, and arterial puncture. Heel puncture involves lancing of the lateral aspect of the infant's heel, squeezing the heel, and collecting the pooled capillary blood. Venepuncture involves aspirating blood through a needle from a peripheral vein. Arterial blood sampling is not discussed in this review. RCTs in this review were performed in a hospital care setting and the evidence relates to preterm and ill infants who have multiple blood tests, rather than infants undergoing heel puncture tests for routine screening. The results therefore cannot be applied to routine screening heel puncture tests in healthy infants.

INCIDENCE/ PREVALENCE Almost every infant in the developed world undergoes heel puncture to screen for metabolic disorders (e.g. phenylketonuria). Many infants have repeated heel punctures or venepunctures to monitor blood glucose or haemoglobin. Preterm or ill neonates may undergo 1–21 heel punctures or venepunctures per day.[1–3] These punctures are likely to be painful. Heel punctures comprise 61–87% and venepunctures comprise 8–13% of the invasive procedures performed on ill infants. Analgesics are rarely given specifically for blood sampling procedures, but 5–19% of infants receive analgesia for other indications.[2,3] In one study, comfort measures were provided during 63% of venepunctures and 75% of heel punctures.[3]

AETIOLOGY/ RISK FACTORS Blood sampling in infants can be difficult to perform, particularly in preterm or ill infants. Young infants may have increased sensitivity and more prolonged responses to pain than older age groups.[4] Factors that may affect the infant's pain responses include postconceptional age, previous pain experience, and procedural technique.

PROGNOSIS Pain caused by blood sampling is associated with acute behavioural and physiological deterioration.[4] Experience of pain during heel puncture seems to heighten pain responses during subsequent blood sampling.[5] Other adverse effects of blood sampling include bleeding, bruising, haematoma, and infection.

AIMS OF INTERVENTION To obtain an adequate blood sample with minimal pain for the infant and minimal adverse effects of treatments.

OUTCOMES We found no easily administered, widely accepted assessment of pain in infants. Where available, we have analysed the proportion of infants crying, or the duration of crying. Other pain related responses measured in the studies included facial expressions (the number of specific expressions, or the duration of those expressions), heart rate, and transcutaneous oxygen saturation levels. Studies used composite scales composed of behavioural and cardiorespiratory signs of pain related distress, or both, only some of which have been validated, such as the Premature Infant Pain

Profile (see glossary, p 495) scale. We have not pooled differences in pain related responses or for different pain scales. The assessment of pain is difficult in pre-verbal children. Pain assessment methods varied in the RCTs, and a validated scale was not always used. Some measurements (e.g. facial expression) are difficult to score objectively. In many RCTs, blinding was not possible (e.g. where pacifiers were used).

METHODS *Clinical Evidence* search and appraisal May 2003, and additional hand searches by contributors.

QUESTION **What are the effects of interventions to reduce pain related distress during heel puncture?**

OPTION ORAL SWEET SOLUTIONS

RCTs have found that oral sucrose, glucose, or other sweeteners reduce pain responses in preterm and term infants (particularly the duration of crying when given 2 minutes before blood sampling) compared with water or no treatment. Evidence for sucrose in term infants was more limited; less than half of the RCTs found an effect. One small RCT found no significant difference between multiple and single doses of sucrose in pain scores for heel puncture. We found no clear evidence that any one sugar is superior to the others. There was weak evidence that solutions of 24% or more were more effective. Three RCTs in term infants found that sucrose plus pacifier was more effective than pacifier alone, but one RCT found no effect in preterm infants.

Benefits:

Sucrose: We found one systematic review (search date 2001,[6] 4 RCTs[7–10]) and three additional RCTs[11–13] comparing oral sucrose (0.05–2.00 mL of 7.5–70%) versus water or no treatment in preterm newborns. All seven RCTs found that sucrose (24–70%) significantly reduced pain responses and pain scores compared with water. Three of these seven RCTs also found that the time spent crying during the procedure and the total duration of crying was significantly reduced with sucrose (25% and 50%).[7,9,13] One RCT found no significant difference between 15% sucrose and water.[13] We found one systematic review (search date 2001,[6] 7 RCTs[9,10,14–18]) and 12 additional RCTs[11–13,19–28] comparing oral sucrose (0.05–2.00 mL of 7.5–70%) versus water or no treatment in term newborns. Eight of the 19 RCTs found that sucrose (12–70%) significantly reduced pain scores compared with water.[10,12,15,17,23–26] Eight of the 19 RCTs found that sucrose decreased the percentage of time spent crying compared with water.[14,15,17,19–21,24,28] Nine of the 19 RCTs found that sucrose significantly reduced crying time (mean or median differences 16–90 seconds).[9,16,18,22–27] Two of the 19 RCTs found a significant difference only for infants given 25–50% sucrose and not for those given lower concentrations.[13,16] One RCT used a low concentration of sucrose (2 mL of 7.5%), and found no significant difference in duration of crying.[29] **Sucrose plus pacifier:** We found three RCTs comparing a pacifier (see glossary, p 495) dipped in 12–24% sucrose or table sugar crystals versus pacifier dipped in water.[27,28,30] One RCT was in preterm infants.[30] It found no significant difference in pain responses (mean Premature Infant Pain

Profile [PIPP] score [see glossary, p 495]) between pacifier dipped in 12–24% sucrose or table sugar crystals and pacifier dipped in water.[30] Two RCTs were in term infants.[27,28] Both RCTs found that pacifier dipped in 12–24% sucrose or table sugar crystals reduced crying time compared with pacifier dipped in water.[27,28] **Sucrose plus holding:** We found one RCT (94 term infants) comparing sucrose, sucrose plus holding, holding with water, and water alone.[15] It found that pain scores and duration of crying decreased in the holding group compared with no holding and in the sucrose groups compared with no sucrose, but the differences were of borderline significance. There was no evidence of an interaction between sucrose and holding ($P = 0.37$). We found no RCTs in preterm infants. **Glucose:** We found four systematic reviews (search dates 1995,[31] 2001,[6] 1998,[32] 2000;[33] 2 RCTs [14,34]), three additional RCTs, and one subsequent RCT.[26,35–37] One of the additional RCTs (crossover, 17 infants) was in preterm infants.[35] It found that 10% glucose significantly reduced mean pain scores compared with no treatment. Two RCTs identified by the systematic reviews, two additional RCTs, and one subsequent RCT were in term infants.[14,26,34,35,37] All five RCTs compared glucose (1–2 mL of 10–33% solution) with water or no treatment before heel puncture.[14,26,34,35] Two RCTs found fewer infants cried with 30% glucose compared with water or no treatment.[34,35] One RCT found that 30% glucose significantly reduced crying time (75% decrease) compared with no treatment, but it found no significant difference in crying time (50% decrease) between 10% glucose and no treatment (50% decrease).[34] One RCT found no significant difference in mean crying time between 12% glucose and water.[14] One RCT found a significant reduction in pain scores with 33% glucose compared with no treatment.[37] One RCT found no significant difference in mean crying time or pain scores between 12.5% glucose and water (pain: mean PIPP score reduced by 2.5; $P < 0.001$).[26] **Glucose plus pacifier:** We found three RCTs comparing a pacifier dipped in 10–33% glucose versus no treatment, water, glucose alone, or pacifier alone.[26,36,37] One crossover RCT was in preterm infants.[36] It found that glucose plus pacifier significantly reduced the mean pain score compared with no treatment (glucose plus pacifier *v* no treatment: reduction in mean PIPP score 3.6 for glucose plus pacifier; $P = 0.001$).[36] Two RCTs were in term infants.[26,37] The RCTs found that glucose (12.5% and 33%, respectively) dipped pacifiers significantly reduced crying time and pain score compared with glucose alone, water, or no treatment.[26,37] **Other sweeteners:** We found three systematic reviews (search dates 1995,[31] 2001,[6] 1998;[32] 1 RCT[17]) and one additional RCT in term infants.[38] The RCT in the review found that hydrogenated glucose (see glossary, p 495) significantly decreased pain scores, duration of first cry, and percentage of time spent crying compared with water, but found no significant difference compared with sucrose.[17] The additional RCT (120 term infants) comparing an artificial sweetener (10 parts cyclamate and 1 part saccharin) with water found small but significant differences in percentage of time crying and pain scores.[38] We found no RCTs in preterm infants. **Concentration of glucose or sucrose:** We found two systematic reviews (search dates 2001[6] and 1998;[32] 1 RCT[34]) and six additional RCTs of the effects of

glucose or sucrose concentration in heel puncture.[14,16,17,22,34,39] We found no RCTs solely in preterm infants. We found one RCT of 60 term and preterm infants.[34] It found no significant difference between 10% and 30% glucose in the duration of crying or in the proportion of babies who cried at all (no crying: 40% with 10% glucose *v* 53% with 30% glucose; $P > 0.05$). Three RCTs were in term infants.[14,16,17] One RCT (75 neonates) found that increasing concentrations of sucrose (2 mL of 12.5%, 25%, and 50%) produced significantly greater reductions in duration of crying.[16] The other two RCTs (56 infants) found no difference in duration of crying with different sucrose concentrations (2 mL of 25–50% or 12–25% sucrose).[14,17] **Multiple doses of sweeteners:** We found one RCT (32 preterm neonates, mean gestation 31 weeks), which compared a single dose (0.5 mL) of 24% sucrose 2 minutes before heel puncture versus three doses given 2 minutes before the procedure, immediately before the procedure, and during the procedure.[11] Pain scores measured at five points during the procedure were significantly different only at the latest time. We found no RCTs in term infants. **Sucrose versus glucose:** We found two RCTs (226 term infants undergoing heel puncture) comparing glucose versus sucrose.[22,26] One RCT found that 30% sucrose reduced crying time by a mean of 30 seconds compared with 30% glucose ($P = 0.006$).[22] The second RCT found no significant difference between 12.5% sucrose and 12.5% glucose.[26] We found no RCTs in preterm infants. **Sucrose versus breast milk:** We found one small RCT (20 term infants).[28] It found that sucrose plus pacifier significantly reduced the percentage of time crying compared with colostrum plus pacifier. We found no RCTs in preterm infants.

Harms: No adverse effects from oral sucrose or glucose administered to full term or preterm infants were reported in any of the RCTs. Transient choking and oxygen desaturation have been associated with the administration of oral sweeteners (directly into the mouth and when administered on a pacifier).[40] The safety of repeated oral administration of sucrose or glucose has not been adequately investigated. There is no evidence that repeated dosing with sweeteners leads to conditioning. Theoretical adverse effects include hyperglycaemia and necrotising enterocolitis.

Comment: There is concern that parents, impressed with the calming effect of sweeteners, may continue to use it at home. This could be harmful in high concentrations or repeated doses. Some studies were crossover RCTs, which may produce biased estimates of the effect of sucrose if neonates become habituated to pain or if the washout period between interventions is too short.[7,9,12] Only some RCTs reported adequate concealment of allocation.[7,8,11,15,23,35,39] In one study, it was uncertain whether infants were randomly allocated.[20] Most had blinded measurement of at least some of the pain responses, particularly crying, on the basis of independent audio or video tape recordings. One RCT had no blinded outcome assessment.[9] We found inadequate evidence about the benefits or harms of repeated administration of sucrose or glucose for repeated blood sampling.

Reducing pain during blood sampling in infants

OPTION BREAST MILK OR BREAST FEEDING

RCTs found no evidence that breast milk or breast feeding reduced pain responses or crying in neonates undergoing heel puncture compared with water. One RCT found no evidence that breast milk plus pacifier was more effective than pacifier alone. One RCT found that breast feeding reduced pain responses compared with swaddling in the cot.

Benefits: **Breast milk:** We found one systematic review (search date 1998,[32] 2 RCTs,[18,34] 126 preterm and term neonates undergoing heel puncture) and two subsequent RCTs (177 term infants)[25,38] comparing breast milk or colostrums (1–2 mL) versus water. None found a significant effect of breast milk on duration of crying[18,25,34,38] or proportion of infants not crying.[34] **Breast milk plus pacifier:** One RCT (20 term infants) found no significant difference between infants given a pacifier (see glossary, p 495) dipped in breast milk versus a pacifier dipped in water.[28] **Breast feeding:** One RCT compared term infants who were held and breast fed with infants given water or breast milk in their cot (62 term infants).[25] No significant effect was found for breast feeding compared with water or breast milk on the duration of crying. Another RCT (30 term infants) compared breast feeding with being swaddled in the cot.[41] Breast feeding decreased the duration of grimacing (mean 17.2 seconds in breastfed *v* 83.3 seconds in swaddled babies) and the duration of crying (mean 8.8 seconds breastfed *v* 72.7 seconds).

Harms: None reported.

Comment: Concealment of allocation was not clearly stated in any RCT. Assessment of pain responses was blind in two RCTs[25,38] and not clearly stated in two other RCTs.[18,34]

OPTION TOPICAL ANAESTHETICS

Systematic reviews and additional RCTs found no evidence of reduced pain responses, particularly crying, following heel puncture with topical anaesthetic (lidocaine, lidocaine–prilocaine emulsion, or tetracaine [amethocaine]) compared with placebo.

Benefits: **Lidocaine or lidocaine–prilocaine emulsion:** We found three systematic reviews (search dates 1996,[42] 1998,[32] and 1998;[43] 5 RCTs[44–48]) and one additional RCT,[1] comparing lidocaine or lidocaine–prilocaine emulsion versus placebo in neonates undergoing heel puncture. Treatments were usually given 30–60 minutes before heel puncture, with the exception of one RCT that randomised infants to eight application times (10–120 minutes before heel puncture).[47] The six RCTs used different assessments of pain responses. Three RCTs included 186 preterm neonates,[1,44,45] and three RCTs included 192 infants who were mainly term neonates.[46–48] None of the RCTs found a significant difference in pain scores between lidocaine or lidocaine–prilocaine emulsion and placebo. One RCT found no significant difference between lidocaine–prilocaine emulsion and placebo in the proportion of infants who cried during the procedure (54/56 [96%] *v* 52/54 [96%]).[47] **Tetracaine (amethocaine) versus placebo:** One RCT

(60 infants, median gestation 36 weeks, undergoing heel puncture using an automated device) found no significant difference between tetracaine and placebo in pain score or the proportion of infants who cried (20/30 [67%] with tetracaine *v* 13/29 [45%]; ARI +22%, 95% CI −4% to +47%).[49] **Topical anaesthetic versus sucrose:** We found no studies of topical anaesthetic versus sweet solutions for heel puncture. **Topical anaesthetic versus pacifiers:** We found no RCTs.

Harms: We found six RCTs (250 infants), which reported absence of adverse reactions to lidocaine–prilocaine emulsion or to placebo, or no difference in minor, transient local reactions.[1,46–48,50,51] One cohort study (500 neonates) found unusual cutaneous effects associated with lidocaine–prilocaine emulsion in four neonates under 32 weeks' gestation.[52] Methaemoglobinaemia can occur with the prilocaine constituent of lidocaine–prilocaine emulsion. Levels of methaemoglobin over 25–30% can cause clinical symptoms of hypoxia.[53] We found one systematic review (search date 1996, 12 RCTs or cohort studies, > 355 neonates)[42] and two subsequent RCTs (167 neonates)[1,53] of lidocaine–prilocaine emulsion for heel puncture, venepuncture, circumcision, or lumbar puncture. All but one of these studies found mean methaemoglobin levels less than 1.5% in neonates given lidocaine–prilocaine emulsion. The other RCT (47 preterm and term infants given lidocaine–prilocaine emulsion) found that the highest mean methaemoglobin levels (2.3%, range 0.6–6.2%) occurred after 15 days of repeated doses of lidocaine–prilocaine emulsion.[52] A systematic review found two case reports of neonates who were treated with oxygen at methaemoglobin levels of 12% and 16%.[42] No local skin reactions were seen after application of tetracaine or placebo in the 140 neonates studied.

Comment: Some of the studies reported adequate concealment of allocation.[51,54–56] Three RCTs used videotaped recordings of pain responses to blind assessors to the intervention.[50,51,54,55] In the other RCTs, although placebo ointment was used, pain responses were assessed by observers at the time of the procedure, rather than by scoring of video film. Deduction of treatment allocation may have been possible in the studies including lidocaine–prilocaine emulsion because of the smell and skin blanching caused by lidocaine–prilocaine emulsion. One study excluded 25% of children who had high behaviour scores before puncture, and presented results only for selected subgroups.[50] The findings of this study may be difficult to generalise.

OPTION PACIFIERS

Eight RCTs have found reduced pain responses in term and preterm infants given pacifiers compared with no treatment before heel puncture. Three RCTs found weak evidence that pacifiers dipped in sucrose reduced pain responses compared with pacifiers alone.

Benefits: **Pacifier alone:** We found one systematic review (search date 2001,[6] 1 RCT[30]) and seven additional RCTs comparing pacifiers (see glossary, p 495) versus no treatment (445 infants, of whom

271 were preterm).[24,30,36,57–60] Four of the RCTs were crossover trials.[30,36,57,58] Pacifiers were given 2–5 minutes before heel puncture. RCTs found that pacifiers significantly reduced pain responses[36,45,59] or the percentage of time spent in a distressed, fussy, or awake state compared with no pacifiers.[58,59] In the three RCTs in term infants, those given a pacifier cried for significantly less time,[24,57,60] spent less time in fussy or awake states,[60] or had reduced pain score.[57] However, reductions were not significant for all measures of pain; in one study grimacing was not significantly reduced by the pacifier[24] and, in another, the pain score was similar during the procedure but fell more quickly in babies given pacifiers.[57] **Pacifier plus multimodal sensory stimulation:** We found two RCTs.[36,37] They found that a pacifier plus multimodal sensory stimulation (pacifer plus glucose, massage, visual, and auditory stimulation) during heel puncture significantly reduced the pain score when compared with no treatment,[36] or pacifier alone, or glucose plus pacifier.[37] One RCT (crossover, 17 preterm infants) found a mean Premature Infant Pain Profile score (see glossary, p 495) reduction when compared with no pacifier (7.15; $P < 0.001$) and when compared with glucose plus pacifer, pacifier alone, or glucose alone (mean Premature Infant Pain Profile score reduction 2.6–4.55; $P < 0.01$ for each of the 3 comparisons).[36] Another RCT found that multimodal sensory stimulation was even more effective than glucose plus pacifier in reducing pain scores in term infants.[37] **Pacifiers plus sucrose:** See benefits of oral sweet solutions, p 485.

Harms: No adverse effects were reported in any of the studies. The use of pacifiers has been associated with transient choking and oxygen desaturation.

Comment: None of the studies explicitly defined the method of allocation to pacifier or no treatment. Three RCTs blinded assessors to the intervention by analysing audio tapes of crying during the procedure.[36,58,60] Measurement of pain responses on the basis of facial expressions were not blinded to the pacifiers or music intervention.

OPTION PHYSICAL CONTACT (HOLDING, ROCKING, POSITIONING, SWADDLING, WARMING, AND PRIOR HANDLING)

We found insufficient evidence from one small RCT about the effects of swaddling. Two RCTs have found that holding reduces crying during heel puncture compared with swaddling. One RCT found that sucrose did not appear to modify the effect of holding. We found limited evidence that rocking reduces pain related stress compared with placebo. One RCT found limited evidence that pain responses were reduced by tucking the arms and legs into a mid-line flexed position during heel puncture, or by avoiding stressful handling before heel puncture. One RCT found no significant difference in pain score between prone position and either side or supine position during heel puncture. Two RCTs found no effect of warming before heel puncture.

Benefits: **Swaddling versus no swaddling:** We found no systematic review but found one small crossover RCT (15 neonates).[61] It found no significant difference in facial expressions of pain or arousal state

between swaddling immediately after heel puncture and no swaddling.[61] **Holding versus swaddling:** We found no systematic review but found two RCTs (124 term infants undergoing heel puncture).[15,62] One RCT (30 infants) compared holding the baby with skin to skin contact versus being swaddled in a crib.[62] It found that holding significantly reduced crying and grimacing compared with swaddling (proportion crying during procedure 8% *v* 45%; ARR 37%, CI not reported; NNT 3, 95% CI 2 to 13). **Rocking:** We found no systematic review but found two RCTs comparing rocking versus no intervention.[8,60] One RCT (44 preterm infants, 25–34 weeks' gestation) compared 0.05 mL water given before heel puncture versus simulated rocking using a respirator attached to an air mattress.[8] The study found no significant differences in facial expressions of pain. The other RCT (40 term neonates) compared no intervention with being held vertically and rocked by the examiner.[60] The study found that rocking reduced the duration of crying ($P = 0.05$) during the procedure and the risk of persistent crying (2/20 [10%] with rocking *v* 9/20 [45%] with no intervention; ARR 35%, CI 10% to 60%; NNT 3, 95% CI 2 to 10). **Positioning:** We found no systematic review but found four RCTs comparing positioning, swaddling, or stressful handling versus no intervention.[30,61,63,64] One crossover RCT (122 preterm infants, 25–34 weeks' gestation, undergoing heel puncture) compared prone position versus side or supine position.[30] The study found no significant difference in the mean pain score. Another RCT (crossover, 30 preterm neonates, 25–35 weeks' gestation) compared facilitative tucking during and after heel puncture (defined as the gentle containment of arms and legs in a flexed, mid-line position) versus no intervention.[63] The RCT found a significant reduction in the total crying time and time to quietening (mean cry duration 2.2 *v* 0.3 minutes; $P < 0.001$). The fourth RCT (48 mainly preterm infants, mean gestation < 35 weeks) compared handling (as if being prepared for a lumbar puncture) with avoidance of handling for 10 minutes prior to heel puncture.[64] The study found that prior handling increased facial expressions of pain, the proportion of time crying, and crying at all during the 2 minutes after heel puncture (21/21 [100%] handled babies cried *v* 21/27 [78%] non-handled babies; ARR +22%; CI −24% to +68%). **Warming:** We found one systematic review (search date 1998,[32] 1 RCT[65]) and one subsequent RCT.[66] The RCT identified by the review compared 57 term infants undergoing heel puncture on 80 occasions with an automated lancet with (41 infants) or without (40 infants) prior warming of the heel. The heel was warmed for 10 minutes with a gel pack at 40 °C. It found no significant difference in the proportion of infants who grimaced and cried between warming and not warming (14/41 [34%] *v* 10/40 [25%]; RR 1.4, 95% CI 0.7 to 2.7). Sampling time was slightly longer in the warmed heels (median time 44 seconds, interquartile range 25–62 seconds *v* 40 seconds, interquartile range 28–72 seconds), but the number of repeat punctures was slightly lower (5/41 [12%] *v* 8/40 [20%]; RR 0.6, 0.2 to 1.7). The subsequent RCT (100 preterm infants) found no significant difference in the crying time or number of repeated punctures after heel warming compared with no warming.[66]

Harms: No adverse events were reported for any of these interventions.

Comment: **Holding:** Assessment of crying was based on analysis of audio or videotape recordings and was blind to the sucrose intervention but not to holding.[15,62] Assessments based on facial expressions were not blind to the intervention. **Rocking:** The method of allocation to rocking or standard care was adequate in one study[8] and unclear in the other.[59] Both studies used blinded assessment of pain responses based on video[8] and audio tape[60] recordings. **Position, swaddling, and prior handling:** None of the studies explicitly reported the method of allocation to the interventions, and only the study comparing handling versus no handling assessed pain responses blind to the intervention.[64] **Warming:** The method of allocation was not reported and assessment of outcomes was not blind to the intervention.

QUESTION What are the effects of interventions to reduce pain related distress during venepuncture?

OPTION ORAL SWEET SOLUTIONS

RCTs have found that oral sucrose or glucose reduce pain responses (particularly the duration of crying) compared with water, topical anaesthetic or no treatment in term and preterm infants undergoing venepuncture. One RCT found that 25% glucose was more effective than 10% glucose. We found no RCTs of other sweetners.

Benefits: **Sucrose:** We found two systematic reviews (search dates 1995,[31] 2001;[6] 2 RCTs[39,67]) and one additional RCT.[68] One RCT (28 infants) in the review was in preterm infants.[67] It found that 24% sucrose reduced crying time compared with water but found no significant difference between 12% sucrose and water (20 infants: mean duration of crying 19 seconds with 24% sucrose *v* 73 seconds with water). One RCT identified by the review and the additional RCT were in term infants.[39,68] Both RCTs (201 infants) found that 24–30% sucrose significantly reduced the duration of crying and pain scores compared with water or no treatment. **Glucose:** We found four RCTs comparing 2 mL of 10–30% glucose versus water in infants undergoing venepuncture.[35,39,69,70] One RCT (60 infants) was in preterm infants.[69] It found that 25% glucose significantly reduced the duration of crying compared with water but found no significant difference between 10% glucose and water (mean duration of crying: 40.5 seconds [SD 38.98] with 25% glucose *v* 68.9 seconds [SD 44.15] with 10% glucose *v* 85.5 seconds [SD 44.1] with water). Three RCTs were in term infants.[35,39,70] The first RCT (60 infants) found that glucose significantly reduced pain scores compared with water but found no difference in the proportion of infants crying (46% with glucose *v* 39% with water).[35] The second RCT (75 infants) found significantly reduced median pain scores with glucose compared with water or no treatment (median pain score difference 2 [glucose 5, water 7], 95% CI 1 to 4; $P = 0.005$).[39] The third RCT (201 infants) compared 30% glucose plus placebo on the skin versus lidocaine–prilocaine topical anaesthetic cream plus oral water.[70] It found that glucose significantly improved Premature Infant Pain Profile (PIPP) score (see glossary, p 495) and duration of pain compared with topical anaesthetic

cream (PIPP scores: 4.6 with glucose *v* 5.7 with anaesthetic cream, P = 0.0314; median duration of crying: 1 second with glucose *v* 18 seconds with topical anaesthetic, P < 0.001). It also found that glucose significantly reduced the proportion of infants thought to have pain (defined as PIPP > 6: 19.3% with glucose *v* 41.7% with anaesthetic cream, P = 0.0007). **Other sweeteners:** We found no RCTs of other sweeteners for venepuncture. **Concentration of glucose or sucrose:** One RCT found that 25% glucose significantly reduced the duration of crying compared with 10% glucose (40.5 seconds *v* 68.9 seconds).[69] **Sucrose versus glucose:** One RCT (150 term infants) found no significant difference between 30% sucrose and 30% glucose in pain scores.[39]

Harms: No adverse effects from oral sucrose or glucose administered to full term or preterm infants were reported in any of the RCTs. Transient choking and oxygen desaturation have been associated with the administration of oral sweeteners (directly into the mouth and when administered on a pacifier).[40] The safety of repeated oral administration of sucrose or glucose has not been adequately investigated. Theoretical adverse effects include hyperglycaemia and necrotising enterocolitis.

Comment: See comment under oral sweet solutions with heel puncture, p 487.

OPTION TOPICAL ANAESTHETICS

Four RCTs found limited evidence that lidocaine–prilocaine emulsion reduced pain responses to venepuncture compared with placebo. Two RCTs found that tetracaine (amethocaine) gel reduced pain and crying during venepuncture compared with placebo.

Benefits: **Lidocaine–prilocaine emulsion:** We found two systematic reviews (search dates 1996[42] and 1998;[32] 2 RCTs[54,71]) and two additional RCTs[50,51], which compared lidocaine–prilocaine emulsion versus placebo in infants undergoing venepuncture. One RCT (120 term infants) found that lidocaine–prilocaine emulsion significantly reduced the duration of crying and pain score at 15 seconds after venepuncture compared with placebo, but found no significant difference in pain score 60 seconds after venepuncture (median duration of crying: 12 seconds *v* 31 seconds; P < 0.05; pain score: Neonatal Facial Coding System score (see glossary, p 495) 287 *v* 374; P = 0.02).[54] The second RCT (60 children) found that 19/28 in the lidocaine–prilocaine emulsion group and 14/28 in the placebo group did not cry at all during the procedure.[71] The study did not measure duration of crying or pain score. The third RCT (41 infants and toddlers) found that lidocaine–prilocaine emulsion significantly reduced behavioural pain score compared with placebo (P < 0.01).[50] The fourth RCT (19 preterm infants) found no significant difference in pain or total duration of crying between lidocaine–prilocaine emulsion and placebo (pain assessed using Neonatal Facial Coding System score, mean difference 0, 95% CI –2.00 to +1.75; median difference in duration of crying: –22 seconds, 95% CI –96 seconds to +24 seconds).[51] **Tetracaine (amethocaine) versus placebo:** Two RCTs (80 preterm and term

neonates undergoing venepuncture) found that tetracaine significantly reduced pain scores and the proportion who cried compared with placebo (4/19 [21%] with tetracaine *v* 15/20 [75%] with placebo; ARR 54%, 95% CI 2% to 80%; NNT 2, 95% CI 1 to 4).[55,56] **Topical anaesthetic versus sucrose:** We found one RCT (55 venepunctures in 51 term neonates), which compared lidocaine–prilocaine emulsion versus 24% sucrose versus lidocaine–prilocaine emulsion plus sucrose versus water.[68] Crying was taped and assessed blind to treatment. Lidocaine–prilocaine emulsion alone was reported to be less effective than sucrose alone or lidocaine–prilocaine emulsion plus sucrose, but analyses were not presented. **Topical anaesthetic versus oral glucose:** See oral sweet solutions, p 492. **Topical anaesthetic versus pacifiers:** We found no RCTs.

Harms: See harms under topical anaesthetics with heel puncture, p 489.

Comment: Some of the studies reported adequate concealment of allocation.[46,47,49] One RCT used videotaped recordings of pain responses to blind assessors to the intervention.[49]

OPTION PACIFIERS

One RCT found that pacifiers reduced pain responses compared with water or no treatment in term infants undergoing venepuncture.

Benefits: We found one RCT (100 term infants undergoing venepuncture) comparing a pacifier (see glossary, p 495) or a pacifier plus sucrose versus no treatment or 2 mL water orally in infants.[67] The study found a significant reduction in the pain score during the procedure (median difference in 10 point pain score 5 for pacifiers alone *v* water and 6 for pacifiers plus sucrose *v* water; $P < 0.0001$).

Harms: The RCT reported no adverse effects.[67] The use of pacifiers has been associated with transient choking and oxygen desaturation.

Comment: The RCT did not explicitly define the method of allocation to pacifier or no treatment.[67]

OPTION BREAST FEEDING

One RCT found that breast feeding during venepuncture reduced pain responses compared with oral water or being held. The RCT found no significant difference in pain response between breast feeding and oral glucose

Benefits: We found no systematic reviews but we found one RCT.[72] The RCT (180 term infants) compared four treatments while the infant was held in its mother's arms during venepuncture: breast feeding, no intervention, sterile water, and 30% glucose plus pacifier. It found that breast feeding significantly reduced pain response compared with holding alone or sterile water (median premature infant pain profile score [see glossary, p 495]: 4.5 with breast feeding *v* 13 with holding *v* 12 with sterile water; $P < 0.0001$ for breast feeding *v* holding; $P < 0.0001$ for breast feeding *v* sterile water). It found no significant difference in pain response between breast feeding and glucose (median premature infant pain profile score 4.5 with breast feeding *v* 4 with glucose, $P = 0.28$).

Harms: The RCT found no adverse effects.[72]

Comment: Blinding was impossible in the RCT because of the nature of the interventions.[72]

GLOSSARY

Hydrogenated glucose syrup An aqueous solution of hydrogenated part hydrolysed starch composed of a mixture of mainly maltitol with sorbitol and hydrogenated oligosaccharides and polysaccharides. Preparations containing a minimum 98% maltitol are known as maltitol syrup.

Neonatal Facial Coding System (NFCS) score Facial coding system used to evaluate pain responses in full term and preterm infants. Presence or absence of six facial actions (e.g. eyes squeezed shut, deepening of the naso-labial furrow) is recorded.

Pacifier A device with a teat that a baby sucks on for comfort. Some pacifiers can deliver a liquid to the baby. Also known as a "dummy", "soother", or "plug" in some countries.

Premature Infant Pain Profile (PIPP) score A seven item composite scale that scores behavioural and cardiorespiratory pain responses coded 0 to 3 (maximum score 21).

Sudden infant death syndrome

Search date March 2003

David Creery and Angelo Mikrogianakis

QUESTIONS

INTERVENTIONS

*Observational evidence only, RCTs unlikely to be conducted

See glossary, p 504

Key Messages

- **Advice to avoid prone sleeping** Several observational studies found that campaigns involving advice to encourage non-prone sleeping positions were followed by a reduced incidence of sudden infant death syndrome. RCTs are unlikely to be conducted.
- **Advice to avoid tobacco smoke exposure** Several observational studies found limited evidence that campaigns to reduce several risk factors for sudden infant death, which included tobacco smoke exposure, were followed by a reduced incidence of sudden infant death syndrome. RCTs are unlikely to be conducted.
- **Advice to avoid bed sharing** One observational study found that a campaign to reduce several risk factors for sudden infant death, which included advice to avoid bed sharing, was followed by a reduced incidence of sudden infant death syndrome. RCTs are unlikely to be conducted.
- **Advice to avoid over heating or over wrapping** Three observational studies found limited evidence that campaigns to reduce several risk factors for sudden infant death, which included over wrapping, were followed by a reduced incidence of sudden infant death syndrome. RCTs are unlikely to be conducted.
- **Advice to avoid soft sleeping surfaces** We found no evidence on the effects of avoiding soft sleeping surfaces in the prevention of sudden infant death syndrome.
- **Advice to breastfeed** One non-systematic review of observational studies and three additional observational studies found that campaigns to reduce several risk factors for sudden infant death, which included advice to breastfeed, were followed by a reduced incidence of sudden infant death syndrome. In some countries, however, incidence had begun to fall before the national advice campaigns. RCTs are unlikely to be conducted.

- **Advice to promote soother use** We found insufficient evidence on soother use in the prevention of sudden infant death syndrome.

DEFINITION Sudden infant death syndrome (SIDS) is the sudden death of an infant aged under 1 year that remains unexplained after review of the clinical history, examination of the scene of death, and postmortem.

INCIDENCE/ PREVALENCE The incidence of SIDS has varied over time and among nations (incidence per 1000 live births of SIDS in 1996: Netherlands 0.3, Japan 0.4, Canada 0.5, England and Wales 0.7, USA 0.8, and Australia 0.9).[1]

AETIOLOGY/ RISK FACTORS By definition, the cause of SIDS is not known. Observational studies have found an association between SIDS and several risk factors including prone sleeping (see glossary, p 504) position,[2,3] prenatal or postnatal exposure to tobacco smoke,[4] soft sleeping surfaces,[5,6] hyperthermia/over wrapping (see tables A, B, and C on web extra),[7,8] bed sharing (particularly with mothers who smoke),[9,10] lack of breastfeeding,[11,12] and soother (see glossary, p 504) use.[7,13]

PROGNOSIS Although by definition prognosis is not applicable for an affected infant, the incidence of SIDS is increased in the siblings of that infant.[14,15]

AIMS OF INTERVENTION To reduce the incidence of SIDS, with minimal adverse effects from interventions.

OUTCOMES Incidence of SIDS; adverse effects of interventions, measured directly or by quality of life questionnaires.

METHODS *Clinical Evidence* search and appraisal March 2003, including a search for observational studies.

QUESTION **What are the effects of interventions to reduce the risk of sudden infant death syndrome?**

OPTION **ADVICE TO AVOID PRONE SLEEPING**

One non-systematic review and 12 observational studies found that campaigns involving advice to encourage non-prone sleeping positions were followed by a reduced incidence of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to avoid prone sleeping (see glossary, p 504) positions versus no such advice (see comment below). **Observational studies after national advice campaigns:** We found one non-systematic review (3 observational studies, 1 of which has also been reported separately[16]),[12] and 12 additional observational studies after national advice campaigns (see comment below).[9,17–28] The review and additional observational studies describe eight campaigns that delivered advice to avoid prone positioning alone (see table 1, p 506),[17–19,21,22,24-26] and seven campaigns that provided advice to avoid a combination of different risk factors including prone positioning (see table 2, p 507).[9,12,16,20,23,27,28] The review and additional observational studies all found that the incidence of

sudden infant death syndrome (SIDS) was reduced after the campaigns (see table 1, p 506 and table 2, p 507). One of the additional observational studies found that the incidence of prone positioning decreased significantly after the campaign (from 54% before campaign to 5% after campaign; $P < 0.001$).[27]

Harms: No increased frequency of adverse effects of non-prone positioning were reported in 13 observational studies of advice to avoid prone sleeping.[9,12,16–28] Two studies found no increase in the risk of inhaling vomitus associated with non-prone positioning.[26,29] Two observational studies have documented a temporal relationship between advice to avoid prone sleeping and an increase in the incidence of occipital plagiocephaly without synostosis (see glossary, p 504), whereas the incidence of other forms of plagiocephaly with synostosis remained constant.[30,31]

Comment: The review of SIDS risk factor reduction campaigns in Norway, Denmark, and Sweden reported that the campaign in Norway provided advice to avoid prone sleeping plus advice to avoid tobacco smoke exposure.[12] However, the original paper describing the Norwegian campaign reported that this campaign only provided advice to avoid prone sleeping.[16] One of the additional observational studies reported that the incidence of SIDS was declining before the campaign started, and hence the reduction attributable to advice provided by the campaign is not clear.[9,20] A second additional observational study did not report how advice was provided or exactly which SIDS risk factors were targeted, and it did not describe details of the advice given to avoid exposure to cigarette smoke (i.e. prenatally, postnatally, or both; maternal smoking alone or smoking by other household members as well).[23] A third additional observational study did not specify whether the advice to stop smoking was given to mothers or other family members and what advice was given regarding avoidance of over heating.[27] Systematic reviews of observational studies have found an association between prone sleeping position and an increased risk of SIDS, leading to the initiation of non-prone sleep campaigns in several countries.[2,3] RCTs investigating the effects of advice to avoid prone positioning may be considered unethical given the existing observational evidence; they would also be difficult to conduct given the extremely large units of randomisation required and the high level of pre-existing public awareness regarding the risks associated with prone positioning in sleep

OPTION ADVICE TO AVOID TOBACCO SMOKE EXPOSURE

One non-systematic review and four observational studies found limited evidence that campaigns to reduce several risk factors for sudden infant death, which included tobacco smoke exposure, were followed by a reduced incidence of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to avoid tobacco smoke exposure versus no such advice (see comment below). **Observational studies after national advice campaigns:** We found one non-systematic review (3 observational studies, 1 of which has also been reported separately[16]),[12] and four

additional observational studies after national advice campaigns (see table 2, p 507).[9,20,23,27,28] The review and additional observational studies found that the campaigns were all followed by a reduced incidence of sudden infant death syndrome (SIDS) during the data collection periods (see table 2, p 507). However, the campaigns included advice in addition to avoiding tobacco smoke exposure, and in some countries the incidence of SIDS had started to fall before the campaign started (see comment under advice to avoid prone sleeping, p 500). The first additional observational study found that the population attributable risk (see glossary, p 504) of SIDS associated with maternal smoking alone was 44% (prevalence 19%; OR 5.17), and for maternal smoking plus bed sharing it was 33% (prevalence 5%; OR 11.1).[9,20] The third additional observational study found that the percentage of mothers not smoking during pregnancy increased significantly after the campaign (from 77% before campaign to 82% after campaign; $P < 0.01$).[27] The fourth additional observational study found that maternal smoking in Kanagawa province in Japan decreased from 9.4% to 0% after the campaign.[28]

Harms: None of the studies we found reported evidence on harms of a reduction in infant tobacco smoke exposure.

Comment: The SIDS reduction attributable to a reduction in maternal smoking is unclear. RCTs investigating the effects of advice to reduce infant tobacco smoke exposure would be difficult to conduct given the extremely large units of randomisation required and the high level of pre-existing public awareness regarding the risks associated with tobacco smoke exposure.

OPTION ADVICE TO AVOID SOFT SLEEPING SURFACES

We found no evidence on the effects of advice to avoid soft sleeping surfaces in the prevention of sudden infant death syndrome.

Benefits: We found no systematic review, RCTs, or observational studies of sufficient quality (see comment below).

Harms: None of the studies we found reported evidence on harms of advice to avoid soft sleeping surfaces.

Comment: RCTs investigating the effects of advice to avoid soft sleeping surfaces would be difficult to conduct given the extremely large units of randomisation required.

OPTION ADVICE TO AVOID OVER HEATING OR OVER WRAPPING

One non-systematic review and one observational study found limited evidence that campaigns to reduce several risk factors for sudden infant death, which included over wrapping, were followed by a reduced incidence of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to avoid overheating or over wrapping (see glossary, p 504) versus no such advice (see comment below). **Observational studies after national advice campaigns:** We found one non-systematic review

(3 observational studies, 1 of which has also been reported separately[16]),[12] and one additional observational study after national advice campaigns (see table 2, p 507).[27] Two of the national advice campaigns reported in the review and the additional observational study provided advice to avoid over heating or over wrapping plus advice to avoid other risk factors for sudden infant death syndrome (see comment under advice to avoid prone sleeping, p 500).[12,27] The third campaign reported by the review did not provide advice on over heating or over wrapping.[12,16] The review and additional observational study found that the campaigns were all followed by a reduction in the incidence of sudden infant death syndrome during the data collection periods (see table 2, p 507).

Harms: None of the studies we found reported evidence on harms of advice to avoid over heating or over wrapping.

Comment: RCTs investigating the effects of advice to avoid over heating or over wrapping would be difficult to conduct given the extremely large units of randomisation required.

OPTION ADVICE TO AVOID BED SHARING

One observational study found that a campaign to reduce several risk factors for sudden infant death, which included advice to avoid bed sharing, was followed by a reduced incidence of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to avoid bed sharing versus no advice (see comment below). **Observational studies after national advice campaigns:** We found one observational study, which reported the results of a national campaign that provided advice to avoid bed sharing, to avoid prone sleeping (see glossary, p 504), to avoid exposing infants to tobacco smoke from any source either during pregnancy or for the first year of life, and to breastfeed if possible (see comment below) (see table 2, p 507).[9,20] The observational study found that the incidence of sudden infant death syndrome reduced after the campaign (see table 2, p 507), and that the population attributable risk (see glossary, p 504) for sudden infant death syndrome associated with maternal smoking plus bed sharing was 33% (prevalence 5%; OR 11.1).

Harms: None of the studies we found reported evidence on harms associated with advice to avoid bed sharing.

Comment: The observational study reported that advice to avoid bed sharing was introduced after the main campaign had started.[9,20] The study also reported that the incidence of sudden infant death syndrome was declining before the campaign started, and hence the reduction attributable to advice provided by the campaign is not clear. RCTs investigating the effects of advice to avoid bed sharing would be difficult to conduct given the extremely large units of randomisation required.

OPTION ADVICE TO BREASTFEED

One non-systematic review and three observational studies found that campaigns to reduce several risk factors for sudden infant death, which included advice to breastfeed, were followed by a reduced incidence of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to encourage breastfeeding versus no such advice in order to reduce the incidence of sudden infant death syndrome (SIDS; see comment below). **Observational studies after national advice campaigns:** We found one non-systematic review (3 observational studies, 1 of which has also been reported separately[16]),[12] and three additional observational studies after national advice campaigns (see table 2, p 507).[9,20,27,28] The review and additional observational studies found that the campaigns were all followed by a reduced incidence of SIDS during the data collection periods (see table 2, p 507). However, the campaigns included advice other than advice to encourage breastfeeding, and in some countries the incidence of SIDS had started to fall before the campaign started (see comment under advice to avoid tobacco smoke exposure, p 501). The second additional observational study found that the incidence of no breastfeeding decreased significantly after the campaign (from 21% before campaign to 7% after campaign; $P < 0.001$).[27] The third additional observational study found that rates of breastfeeding only in Kanagawa province in Japan increased from 53.1% to 67.3% after the campaign.[28]

Harms: None of the studies we found reported evidence on harms of with advice to encourage breastfeeding.

Comment: RCTs investigating the effects of promotion of breastfeeding would be unethical given the evidence of benefits associated with breastfeeding.

OPTION ADVICE TO PROMOTE SOOTHER USE

We found insufficient evidence on soother use in the prevention of sudden infant death syndrome.

Benefits: We found no systematic review and no RCTs comparing advice to encourage use of a soother (see glossary, p 504) with no such advice to reduce the incidence of sudden infant death syndrome. **Observational studies after national advice campaigns:** We found no observational studies after national advice campaigns. **Other observational studies:** We found one systematic review (search date 2000) that identified four case control studies.[32] All four studies included in the review found an association between increased soother use and a reduced risk of sudden infant death syndrome, but none of the studies concluded that the association was causal.

Harms: The studies we found provided no evidence on harms of soother use.

Sudden infant death syndrome

Comment: RCTs investigating the effects of advice to promote soother use would be difficult to conduct given the extremely large units of randomisation required.

GLOSSARY

Occipital plagiocephaly with or without synostosis Flattening of the occipital bone with or without a malformation of the corresponding cranial suture line.
Over wrapping Wrapping/bundling of infants in excessive amounts of clothing or bedding to result in sweating, raised core temperatures, or both.
Population attributable risk A measure of the disease rate in exposed people compared with that in unexposed people, multiplied by the prevalence of exposure to the risk factor in the population.
Prone sleeping Sleeping on one's front.
Soother (dummy, pacifier) An object placed in the infant's mouth for the sole purpose of providing comfort.

Urinary tract infection in children

Search date May 2003

James Larcombe

QUESTIONS

INTERVENTIONS

*Based on consensus. RCTs would be considered unethical.

See glossary, p 521

Key Messages

Treatment of acute infection

- **Antibiotics** There is consensus that antibiotics are likely to be beneficial compared with placebo. Placebo controlled trials of antibiotics for symptomatic acute urinary tract infection in children are considered unethical.

Urinary tract infection in children

- **Oral antibiotics (as effective as initial intravenous antibiotics in children without severe vesicoureteric reflux or renal scarring)** One RCT found no significant difference between oral cephalosporins alone and initial intravenous plus continued oral cephalosporins in duration of fever, reinfection, renal scarring, or extent of scarring in children aged 2 years or younger with first confirmed urinary tract infection. The RCT found weak evidence that, in children with grades III–IV reflux, renal scarring at 6 months may be more common with oral compared with initial intravenous treatment.
- **Immediate empirical antibiotic treatment (unclear benefit compared with treatment based on microscopy and culture)** We found no RCTs comparing early empirical treatment with awaiting the results of microscopy or culture in acute urinary tract infection in children. Retrospective analysis of one RCT found no significant difference in risk of renal scarring between cephalosporin treatment within 24 hours compared with 24 hours after the onset of fever in children under 2 years of age with urinary tract infections.
- **Longer (7–10 days) courses of initial intravenous antibiotics (no more effective than shorter [3 days] courses of intravenous antibiotics in children with acute pyelonephritis)** Two RCTs found no significant difference between long (7–10 days) and short (3 days) courses of initial cephalosporins in renal scarring in children with acute pyelonephritis.
- **Longer (7–14 days) courses of oral antibiotics (no more effective than shorted [2–4 days] courses for non-recurrent lower urinary tract infections in the absence of renal tract abnormality)** One systematic review found no significant difference between longer courses (7–14 days) and shorter courses (2–4 days) of the same antibiotic in cure rate at 7 days after treatment in children with no history of renal tract abnormality and judged not to have acute pyelonephritis. However, longer courses may be associated with more adverse effects.
- **Prolonged delay in treatment (> 7 days)** We found no RCTs. Five retrospective studies found that medium to long term delays (4 days to 7 years) in treatment may be associated with an increased risk of renal scarring.
- **Single dose of oral amoxicillin (less effective than longer course [10 days] or oral amoxicillin)** One systematic review has found that single dose amoxicillin reduces cure rate at 3–30 days compared with a longer (10 days) course of amoxicillin.

Prevention of recurrence

- **Immunotherapy** One systematic review in premature and low birth weight neonates has found that intravenous immunoglobulins reduce serious infections, including urinary tract infections, compared with placebo. One RCT in children with recurrent urinary tract infection found that adding pidotimod (an immunotherapeutic agent) to antibiotic treatment reduced recurrence compared with adding placebo.
- **Prophylactic antibiotics** One systematic review found limited evidence that prophylactic antibiotics (co-trimoxazole, nitrofurantoin) reduced recurrence of urinary tract infection in children compared with placebo or no treatment. One RCT found that nitrofurantoin reduced recurrence of urinary tract infection over 6 months compared with trimethoprim. However, more children discontinued treatment with nitrofurantoin because of adverse effects. We found no RCTs evaluating the optimum duration of prophylactic antibiotics.

- **Surgical correction of moderate to severe bilateral vesicoureteric reflux (grades III–IV) with bilateral nephropathy** One small RCT found a steady, but not statistically significant, decline in glomerular filtration rate over 10 years with medical treatment compared with surgery in children with moderate to severe bilateral vesicoureteric reflux and bilateral nephropathy.
- **Surgical correction of minor functional anomalies** We found no RCTs. One observational study suggested that children with minor anomalies do not develop renal scarring and therefore may not benefit from surgery.
- **Surgical correction of moderate to severe vesicoureteric reflux with adequate glomerular filtration rate (similar benefits to medical management)** One systematic review and subsequent RCTs found that, although surgery abolished reflux, there was no significant difference between surgical and medical management (prophylactic antibiotic treatment) in preventing complications from urinary tract infection after 6 months to 5 years in children with moderate to severe vesicoureteric reflux. There was insufficient evidence of any difference between the two groups in preventing recurrent urinary tract infection.

DEFINITION Urinary tract infection (UTI) is defined by the presence of a pure growth of more than 10^5 colony forming units of bacteria per millilitre of urine. Lower counts of bacteria may be clinically important, especially in boys and in specimens obtained by urinary catheter. Any growth of typical urinary pathogens is considered clinically important if obtained by suprapubic aspiration. In practice, three age ranges are usually considered on the basis of differential risk and different approaches to management: children under 1 year; young children (1–4, 5, or 7 years, depending on the information source); and older children (up to 12–16 years). Recurrent UTI is defined as a further infection by a new organism. Relapsing UTI is defined as a further infection with the same organism.

INCIDENCE/ PREVALENCE Boys are more susceptible before the age of 3 months; thereafter the incidence is substantially higher in girls. Estimates of the true incidence of UTI depend on rates of diagnosis and investigation. At least 8% of girls and 2% of boys will have a UTI in childhood.[1]

AETIOLOGY/ RISK FACTORS The normal urinary tract is sterile. Contamination by bowel flora may result in urinary infection if a virulent organism is involved or if the child is immunosuppressed. In neonates, infection may originate from other sources. *Escherichia coli* accounts for about 75% of all pathogens. *Proteus* is more common in boys (about 30% of infections). Obstructive anomalies are found in 0–4% and vesicoureteric reflux in 8–40% of children being investigated for their first UTI.[2] One meta-analysis of 12 cohort studies (537 children admitted to hospital for UTI, 1062 kidneys) found that 36% of all kidneys had some scarring on DMSA scintigraphy (see glossary, p 521) and that 59% of children with vesicoureteric reflux on micturating cystourethography had at least one scarred kidney (pooled positive likelihood ratio 1.96, 95% CI 1.51 to 2.54; pooled negative likelihood ratio 0.71, 95% CI 0.58 to 0.85). There was evidence of heterogeneity in likelihood ratios among studies. The authors concluded that vesicoureteric reflux is a weak predictor of renal damage in children admitted to hospital.[3] Thus although vesicoureteric reflux is a major risk factor for adverse outcome, other as yet unidentified triggers may also need to be present.

PROGNOSIS After first infection, about 50% of girls have a further infection in the first year and 75% within 2 years.[4] We found no figures for boys, but a review suggests that recurrences are common under 1 year of age, but rare subsequently.[5] Renal scarring occurs in 5–15% of children within 1–2 years of their first UTI, although 32–70% of these scars are noted at the time of initial assessment.[2] The incidence of renal scarring rises with each episode of infection in childhood.[6] Retrospective analysis of an RCT comparing oral versus intravenous antibiotics found that new renal scarring after a first UTI was more common in children with vesicoureteric reflux than in children without reflux (logistic regression model; AR of scarring: 16/107 [15%] with reflux *v* 10/165 [6%] without reflux; RR 2.47, 95% CI 1.17 to 5.24).[7] A study (287 children with severe vesicoureteric reflux treated either medically or surgically for any UTI) evaluated the risk of renal scarring with serial DMSA scintigraphy over 5 years. It found that younger children (aged < 2 years) were at greater risk of renal scarring than older children regardless of treatment for the infection (AR for deterioration in DMSA scan over 5 years: 21/86 [24%] for younger children *v* 27/201 [13%] for older children; RR 1.82, 95% CI 1.09 to 3.03).[8] One prospective study found that children of all ages who presented with symptoms of pyelonephritis (see glossary, p 521), were likely to have renal abnormalities (abnormal initial scans in 34/65 [52%] children).[9] Another prospective study found that the highest rates of renal scarring after pyelonephritis occurred between 1–5 years of age.[10] A further prospective study by the same team found that children aged over 1 year had more abnormalities on DMSA scans at 3 months after an episode of pyelonephritis (54/129 [42%] of older children *v* 22/91 [24%] of younger children; RR 1.73, 95% CI 1.14 to 2.63).[11] They noted conflicting results in previous literature on this subject.[11] They also found that girls were more likely than boys to develop scarring on DMSA scan at 3 months after an episode of pyelonephritis (67/171 [39%] girls *v* 9/49 [18%] boys; RR 2.13, 95% CI 1.15 to 3.96).[11] Renal scarring is associated with future complications: poor renal growth, recurrent adult pyelonephritis, impaired glomerular function, early hypertension, and end stage renal failure.[12–15] A combination of recurrent UTI, severe vesicoureteric reflux, and the presence of renal scarring at first presentation is associated with the worst prognosis. One prospective observational study assessed the persistence of scarring on DMSA scans in children with a first UTI.[16] Grading of scars was as follows: mild (< 25% of kidney affected), moderate (25–50% of kidney), and severe (> 50% of kidney). The study found that vesicoureteric reflux was associated with more persistent scarring at 6 months (in children with severe scarring on initial scan: 7/8 [88%] with reflux had a persisting lesion *v* 1/7 [14%] without reflux; RR 6.13, 95% CI 0.98 to 38.00; in children with mild to moderate scarring on initial scan: 3/8 [38%] with reflux had a persisting lesion *v* 5/31 [16%] without reflux; RR 2.70, 95% CI 0.81 to 9.10).[16] The study also found that vesicoureteric reflux was associated with a higher risk of pyelonephritis on the initial scan (RR for pyelonephritis with reflux *v* without reflux 1.62, 95% CI 1.14 to 2.31).

AIMS OF INTERVENTION To relieve acute symptoms; to eliminate infection; and to prevent recurrence, renal damage, and long term complications.

OUTCOMES **Short term:** clinical symptoms and signs (dysuria, frequency, and fever); urine culture; incidence of new renal scars. **Long term:** incidence of recurrent infection; prevalence of renal scarring; renal size and growth; renal function; prevalence of hypertension and renal failure.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION What are the effects of treatment of acute urinary tract infection in children?

OPTION ANTIBIOTICS VERSUS PLACEBO

There is a consensus that antibiotics are likely to be beneficial compared with placebo. Placebo controlled trials of antibiotics for symptomatic acute urinary tract infections in children are considered unethical.

Benefits: We found no RCTs.

Harms: We found no RCTs.

Comment: Placebo controlled trials would be considered unethical because there is a strong consensus that antibiotics are likely to be beneficial. The improved response seen with longer compared with very short courses of antibiotics is indirect evidence that antibiotics are likely to be more effective than no treatment.

OPTION IMMEDIATE EMPIRICAL VERSUS DELAYED ANTIBIOTIC TREATMENT

We found no RCTs comparing early empirical treatment versus delayed treatment based on the results of microscopy or culture in acute urinary tract infection in children. Retrospective analysis of one RCT found no significant difference in risk of renal scarring between cephalosporin treatment within 24 hours compared with 24 hours after the onset of fever in children under 2 years of age with urinary tract infections. Five retrospective studies found that medium to long term delays (4 days to 7 years) in treatment may be associated with an increased risk of renal scarring.

Benefits: We found no RCTs comparing immediate empirical treatment with treatment delayed while awaiting the results of microscopy or culture. We found one RCT that compared oral cefixime for 14 days (double dose on day 1) with intravenous cefotaxime for 3 days plus oral cefixime for the succeeding 11 days for urinary tract infection in children under 2 years.[7] Retrospective analysis of its results found no evidence that children treated 24 hours after the onset of fever were at greater risk of renal scarring than children presenting within 24 hours (9/99 [9%] of children presenting before 24 hours *v* 19/159 [12%] of children presenting later; RR 1.3, 95% CI 0.6 to 2.7; P = 0.29).

Harms: The RCT did not report on any adverse effects.[7]

Urinary tract infection in children

Comment: Five retrospective observational studies found increased rates of scarring in children in whom diagnosis was delayed between 4 days (in acute urinary tract infection) to 7 years (when a child presented with chronic non-specific symptoms).[2]

OPTION LONGER VERSUS SHORT COURSES OF ORAL ANTIBIOTICS

One systematic review found no significant difference between longer courses (7–14 days) and shorter courses (2–4 days) of the same antibiotic in cure rate at 7 days after treatment in children with no history of renal tract abnormality and judged not to have acute pyelonephritis. However, longer courses may be associated with more adverse effects. One systematic review found that single dose amoxicillin decreased cure rate at 3–30 days after the start of treatment compared with longer course (10 days).

Benefits: We found two systematic reviews that compared longer versus short course of the same antibiotic (search dates 1999[17] and 2002[18]). Both reviews included the following antibiotics: amoxicillin, nitrofurantoin, trimethoprim/sulfadiazine, nalidixic acid, pivmecillinam, nitrofurantoin, amoxicillin/clavulanic acid, and cefuroxime. We found one systematic review (search date 2001, 17 RCTs) that compared longer with shorter courses of any antibiotic.[19] **Versus single dose and short course:** The first review (17 RCTs, children and adolescents aged < 18 years with uncomplicated cystitis) included single dose drug regimens.[17] It found that longer (≥ 5 days) courses of antibiotic increased microbiological cure rate between 3–30 days after start of treatment compared with short (≤ 4 days) course (difference in cure rates 7.9%, 95% CI 2.1% to 13.8%).[17] However, studies were statistically heterogeneous and meta-analysis may not have been appropriate. The review found that longer (10 days) amoxicillin course increased microbiological cure rate between 3–30 days after enrolment compared with single dose amoxicillin (4 RCTs: difference in cure rate for longer *v* short course 13%, 95% CI 4% to 24%; NNT with longer course for cure 8, 95% CI 5 to 25; no statistical heterogeneity among studies in meta-analysis). However, it found no significant difference between longer (7–10 days) and shorter course or single dose (≤ 3 days) co-trimoxazole for microbiological cure (6 RCTs: difference in cure rate for longer *v* short course +6.2%, 95% CI –3.7% to +16.2%). The second systematic review excluded single dose regimens.[18] The third systematic review similarly found that 7–14 day courses of any antibiotic reduced treatment failure compared with single day or single dose regimens (RR 2.73, 95% CI 1.38 to 5.40).[19] Compared with any short course, including single day or single dose regimens, it found that longer courses reduced treatment failure (RR 1.94, 95% CI 1.19 to 3.15).[19] **Versus short course, but not single dose or single day regimens:** The second review (search date 2002, 10 RCTs, 652 children and adolescents aged 3 months to 18 years with urinary tract infections [UTI] and asymptomatic infection) excluded antibiotic courses of less than 2 days' duration.[18] All studies in the review excluded children with known renal tract abnormalities or acute pyelonephritis (see glossary, p 521) and all included children with a history of recurrent UTI. The review

found no significant difference between longer (7–14 days) and short (2–4 days) antibiotic courses for microbiological cure within 7 days of treatment (8 RCTs: RR of positive urine culture ≤ 7 days after treatment for longer *v* short courses 1.06, 95% CI 0.64 to 1.76).[18] It also found no significant difference between longer and shorter courses in UTI recurrence 1–15 months after treatment (10 RCTs: RR 0.95, 95% CI 0.70 to 1.29). The review found no significant difference between longer (7–14 days) and short (2–4 days) course of sulphonamides, such as co-trimoxazole, for persistence of UTI after treatment or recurrence of UTI 10 days to 15 months after treatment (6 RCTs, 233 children: RR of UTI at end of treatment 1.72, 95% CI 0.64 to 3.80; RR of recurrent UTI 1.04, 95% CI 0.71 to 1.52).[18] The third review found no significant difference between 7–14 day courses and 3 day course of any antibiotic for treatment failure (RR 1.36, 95% CI 0.68 to 2.72).[19]

Harms: The first systematic review reported that dose related adverse effects, such as neutropenia with β-lactam antibiotics, seemed to increase in frequency with the length of administration.[17] The second systematic review found no significant difference between short and longer courses for antibiotic resistant UTI (persistent resistant bacteriuria at the end of treatment, 1 RCT: RR 0.57, 95% CI 0.32 to 1.01; resistant recurrent UTI, 3 RCTs: RR 0.39, 95% CI 0.12 to 1.29).[18]

Comment: The studies included in the reviews differed in the lengths of treatment and antibiotics used; the definitions of cure, relapse, and reinfection; and the diagnostic criteria for pyelonephritis or complicated UTI. Comparisons were made both for the whole group and for subgroups. In the first review, treatment groups were compared with fixed or random effects models, based on statistical analysis of the heterogeneity of the groups.[17] The second review included an unspecified number of children with asymptomatic bacteriuria.[18] The clinical importance of treating this group remains unclear. Several factors may reduce the generalisability of results to all children with lower UTI. First, the review excluded children with acute pyelonephritis only, which may not have excluded all cases of upper UTI. Second, all the RCTs in the second review included children with recurrent UTI, who have higher rates of treatment failure than children with no history of UTI.[18] Finally, many studies included in the reviews were in children attending outpatient departments and emergency rooms. Response to treatment may be different in this group compared with unselected populations.[19]

OPTION ORAL VERSUS INITIAL INTRAVENOUS ANTIBIOTICS

One RCT found no significant difference between oral cephalosporins alone and initial intravenous plus continued oral cephalosporins in duration of fever, reinfection rate, renal scarring, or extent of scarring in children aged 2 years or younger with a first confirmed urinary tract infection. The RCT found weak evidence that in children with grades III–IV reflux, renal scarring at 6 months may be more common with oral compared with initial intravenous treatment.

Benefits: We found one RCT (309 children, aged ≤ 2 years, fever > 38.2 °C, with a first urinary tract infection confirmed from catheter specimen) sufficiently powered to produce meaningful results.[7] The RCT compared oral cefixime for 14 days (double dose on day 1) with initial intravenous cefotaxime for 3 days plus 11 days of oral cefixime.[7] It found no significant difference between treatments in mean duration of fever, reinfection rate, incidence of renal scarring, and mean extent of scarring (fever duration: 24.7 hours with oral treatment *v* 23.9 hours with initial iv treatment; P = 0.76; reinfection rate: 132/153 [86%] with oral treatment *v* 134/153 [88%] with initial iv treatment; P = 0.28); incidence of renal scarring: 15/153 [10%] with oral treatment [21 children not scanned and counted as having no scarring] *v* 11/153 [7%] with initial iv treatment [13 children not scanned]; P = 0.21; mean extent of scarring: 8% of renal parenchyma with oral treatment *v* 9% with initial iv treatment). The RCT found weak evidence from a post hoc subgroup analysis in children with grades III–IV (see glossary, p 521) reflux that renal scarring at 6 months may be more common with oral compared with initial intravenous treatment (new renal scarring within 6 months: 8/24 [33%] with oral treatment *v* 1/22 [5%] with initial iv treatment; ARI 29%, 95% CI 8% to 49%; NNH 3, 95% CI 2 to 13).[7]

Harms: The RCT did not report on adverse effects.[7]

Comment: The trial excluded 3/309 [1%] children because investigators considered that the severity of symptoms in these children warranted intravenous treatment.[7]

OPTION LONGER VERSUS SHORT COURSES OF INITIAL INTRAVENOUS ANTIBIOTICS IN CHILDREN WITH PYELONEPHRITIS

Two RCTs in children with acute pyelonephritis found no significant difference between long (7–10 days) and short (3 days) course of initial intravenous cephalosporins in renal scarring in children with acute pyelonephritis.

Benefits: We found two RCTs comparing the effect of long and short course of initial intravenous antibiotics (ceftriaxone) on development of renal scarring in children with acute pyelonephritis (see glossary, p 521). One RCT (220 children aged 3 months to 16 years with positive urine culture and acute renal lesions on initial DMSA scintigraphy [see glossary, p 521]) compared a 10 day with a 3 day course of initial intravenous ceftriaxone 50 mg/kg daily followed by oral cefixime (4 mg/kg twice daily) to complete a 15 day course.[11] Scintigraphy was repeated after 3 months. Renal scars were defined as persistent or partially resolved changes in the same location as the lesions on the original DMSA scan. The RCT found no significant difference between a 10 day and a 3 day course of initial intravenous antibiotic treatment in development of renal scarring at 3 months (AR 36/110 [33%] children with 10 day course *v* 40/110 [36%] children with 3 day course; RR 1.10, 95% CI 0.77 to 1.60). After adjustment for age, sex, duration of fever before treatment, degree of inflammation, presence of vesicoureteric reflux, and recruitment centre there were no differences between the two treatment groups (P = 0.84).[11] The second RCT (92 children aged

6 weeks to 13 years, with a clinical diagnosis of acute pyelonephritis, positive urine culture, and abnormal DMSA scan) compared a 7 day with a 3 day course of initial intravenous ceftizoxime followed by oral cefixime.[20] The DMSA scan was repeated after 6 months for detection of total or partial persistence of renal abnormalities. The RCT found no significant difference between a 3 day and a 7 day course of initial intravenous antibiotic treatment on renal abnormalities at 6 months (11/44 [25%] children with 3 day course *v* 8/43 [19%] children with 7 day course; RR 1.34, 95% CI 0.60 to 3.01).

Harms: The RCTs did not assess harms.[11,20]

Comment: Unlike the studies of long versus short courses of oral treatment and the study comparing oral with intravenous antibiotics, there were few exclusions for severe presentation. In the larger study, 206 children failed to meet the strict entry criteria,[11] but there were then no further exclusions; 11 of 103 [11%] children were excluded in the smaller study.[20]

QUESTION What are the effects of interventions to prevent recurrence?

OPTION PROPHYLACTIC ANTIBIOTICS

One systematic review found limited evidence that prophylactic antibiotics (co-trimoxazole, nitrofurantoin) reduced urinary tract infection recurrence in children compared with placebo or no treatment. One RCT found that nitrofurantoin reduced recurrence of urinary tract infection over 6 months compared with trimethoprim. However, more children discontinued treatment with nitrofurantoin because of adverse effects. We found no RCTs evaluating the optimum duration of prophylactic antibiotics.

Benefits: **Versus no prophylaxis:** We found one systematic review (search date 2001)[21] The systematic review (3 RCTs, 151 children aged < 18 years at risk of urinary tract infection [UTI] but without a renal tract abnormality or major neurological, urological, or muscular disease) compared the effects of antibiotics (nitrofurantoin, co-trimoxazole) with placebo or no treatment on risk of recurrent UTI.[21] There was variation between the RCTs in the duration of antibiotic prophylaxis (10 weeks to 12 months) and method of concealment (see comment below). The review found that antibiotics reduced the risk of recurrent UTI compared with placebo or no treatment (RR 0.36, 95% CI 0.16 to 0.77).[21] **Comparison of antibiotics:** We found one systematic review (search date 2001, 1 RCT) comparing nitrofurantoin with trimethoprim.[21] It found that nitrofurantoin reduced recurrence of UTI over 6 months compared with trimethoprim (RR 0.48, 95% CI 0.25 to 0.92; NNT 5, 95% CI 3 to 33). **Duration of prophylaxis:** We found no RCTs evaluating the optimum length of prophylaxis even in children with vesicoureteric reflux (although 2 studies of prolonged acute treatment were identified).[22]

Harms: **Versus no prophylaxis:** No adverse effects were reported in the RCTs included in the systematic review.[21] **Comparison of antibiotics:** One RCT found that more children discontinued treatment with nitrofurantoin compared with trimethoprim because of adverse effects, including nausea, vomiting, or stomach ache (RR 3.17, 95% CI 1.36 to 7.37; NNH 5, 95% CI 3 to 13).[21] One study found that although gastrointestinal flora were affected by treatment, *E coli* (cultured from rectal swabs from 70% of children) remained sensitive to the prophylactic antibiotic co-trimoxazole).[23] However, another study found that children who had recently received co-trimoxazole for 4 weeks or more were more likely to have resistant *E coli* isolates than those who had received no antibiotics (OR 23.4, 95% CI 12.0 to 47.6).[24]

Comment: The systematic review was thorough but the RCTs it identified had weak methods.[21] None of the RCTs included in the systematic review used intention to treat analyses. Only one had adequate concealment and only one specified the outcome measures. It may not be possible clinically to identify children who are at high risk of recurrent UTIs and long term damage.[25] Routine prophylaxis until the results of investigations are known may, therefore, be warranted, but we found no good evidence about the benefits or harms of antibiotic prophylaxis.

OPTION IMMUNOTHERAPY

One systematic review in premature and in low birth weight neonates has found that intravenous immunoglobulins reduce serious infections, including urinary tract infections, compared with placebo. One RCT in children with recurrent urinary tract infection found that adding pidotimod (an immunotherapeutic agent) to antibiotic treatment reduced recurrence compared with adding placebo.

Benefits: **Intravenous immunoglobulin:** We found one systematic review (search date 1997, 15 RCTs), which compared intravenous immunoglobulin (see glossary, p 521) prophylaxis with placebo or no treatment.[26] It found that intravenous immunoglobulin prophylaxis reduced serious infections, including urinary tract infections [UTIs], in preterm and in low birth weight neonates (RR for all serious infections 0.80, 95% CI 0.68 to 0.94; NNT 24, 95% CI 15 to 83).[26] The dose varied from 120 mg/kg to 1 g/kg. The number of treatments varied from 1–7. The specific effect on UTIs was not reported. **Other immunotherapeutic agents:** We found one RCT (double blind, 60 children aged 2–8 years with recurrent UTI) comparing pidotimod versus placebo when added to standard antibiotic treatment.[27] The study included a further 60 day phase, using half dose pidotimod compared with half dose placebo. The RCT found that adding pidotimod reduced relapse rates compared with adding placebo at 60 days (4/30 [13%] with added pidotimod *v* 13/30 [43%] with added placebo; $P < 0.05$).[27] An open pilot study (40 children) compared nitrofurantoin versus an antigenic extract of *E coli*.[28] No significant difference was found between the two treatments during active treatment or during the subsequent 6 months.

Harms: Parenteral treatment can cause pain, and there is an unmeasured risk from the administration of human blood products.[26] **Intravenous immunoglobulin:** The systematic review found that prophylactic intravenous immunoglobulin was not associated with any short term serious adverse effects.[26] **Other immunotherapeutic agents:** In the RCT of pidotimod, the only adverse effects recorded were thought to be attributable to concomitant antibiotic treatment.[27] The open pilot study found no significant difference in withdrawal rates between the antigenic extract of *E coli* (1/22 [5%] children) and nitrofurantoin (1/18 [6%] children).[28]

Comment: **Intravenous immunoglobulin:** We found no evidence for or against the suggestion that preparations with specific antibodies against common pathogens are more beneficial.[29] The greatest benefits were noted in units with higher nosocomial infection (see glossary, p 521) rates. It remains unclear whether intravenous immunoglobin is only justified where infection control policies have failed to reduce the infection rate.[26] Preterm and low birth weight neonates might have greater immune deficiency than other neonates and might be expected to gain more from treatment with immunoglobulin. **Other immunotherapeutic agents:** We found one non-randomised, age matched study in 10 otherwise healthy girls (aged 5–11 years) with recurrent UTI who were given intramuscular injections of inactivated uropathogenic bacteria. It found that the girls who had received the inactivated uropathogenic bacteria had reduced frequency of subsequent UTI compared with 10 other age matched girls with UTI who had not received the inactivated bacteria preparation.[30] This study is limited by its non-randomised design and small sample size. We found another study (40 children aged 3–12 years with recurrent UTI caused by *E coli* and no anatomical or functional impairments of the urinary tract) comparing prophylactic antibiotics (amoxicillin with clavulanic acid or cephalosporins) versus prophylactic antibiotics plus an immunomodulator with *E coli* antigens for 3 months followed up for 3 months after the end of treatment.[31] The method of randomisation was not stated. The study found that urinary secretory immunoglobulin A levels, initially low in both groups, were raised 3 months after the end of treatment with antibiotics plus immunomodulator group but not with antibiotics alone. It also found that antibiotics plus immunomodulator reduced recurrences over 6 months compared with antibiotics alone (recurrences: 2/25 [8%] with antibiotics plus immunomodulator *v* 8/13 [61%] with antibiotics alone).[31]

OPTION SURGICAL CORRECTION FOR MINOR FUNCTIONAL ANOMALIES

We found no RCTs. One observational study suggested that children with minor anomalies do not develop renal scarring and therefore may not benefit from surgery.

Benefits: We found no systematic review or RCTs.

Harms: Potential harms include the usual risks of surgery.

Comment: One small prospective observational study (271 children) suggested that children with minor anomalies do not develop renal scarring and therefore may not benefit from surgery.[32] Renal scars were present in more children with moderate degrees of vesicoureteric reflux than in children with minor anomalies (8/20 [40%] with moderate degrees of vesicoureteric reflux *v* 0/6 [0%] with minor anomalies). In the presence of major anomalies, the prevention of urinary tract infections is not the prime motive of surgical intervention.

OPTION SURGICAL CORRECTION FOR VESICOURETERIC REFLUX

One systematic review and two subsequent RCTs found that, although surgery abolished reflux, there was no significant difference between surgical and medical management (prophylactic antibiotic treatment) in preventing complications from urinary tract infections after 6 months to 5 years in children with moderate to severe vesicoureteric reflux. There was insufficient evidence of any difference between the two groups in preventing recurrent urinary tract infection. One small RCT found a steady but not statistically significant decline in glomerular filtration rate over 10 years with medical treatment compared with surgery in children with moderate to severe bilateral vesicoureteric reflux and bilateral nephropathy.

Benefits: **Versus medical management:** We found one systematic review[33] and two subsequent RCTs.[34,35] The systematic review (search date 1988, 4 RCTs, 830 children with moderate to severe [grades III–V (see glossary, p 521)] vesicoureteric reflux) compared surgical correction with medical management (continuous prophylactic antibiotics).[33] It found that surgery abolished reflux, but found no significant differences in rates of subsequent urinary tract infection, renal function, incidence of new renal scars, hypertension, or end stage renal failure among groups over 6 months to 5 years. The first subsequent RCT (132 children aged ≤ 10 years with grades III–V vesicoureteric reflux, glomerular filtration rate ≥ 70 mL/minute per 1.73 m^2) compared surgery with medical management (prophylactic antibiotics) over 5 years. The RCT found no significant difference in development of new renal scarring between surgery and medical management but found that surgery reduced the incidence of pyelonephritis (see glossary, p 521) compared with medical treatment (5/64 [8%] with surgery *v* 15/68 [22%] with medical treatment; ARR 14%, 95% CI 2% to 19%; RRR 65%, 95% CI 10% to 87%).[34] The second subsequent RCT (25 boys and 27 girls aged 1–12 years with bilateral vesicoureteric reflux [grades III–V] and bilateral nephropathy, glomerular filtration rate ≥ 20 mL/minute per 1.73 m^2) compared corrective surgery with medical management (prophylactic antibiotics: co-trimoxazole, trimethoprim, or nitrofurantoin) over 4 years.[35] It found no significant difference in development of new scars between medical treatment and corrective surgery after 4 years (AR 7/54 [13%] kidneys with medical treatment *v* 8/50 [16%] kidneys with corrective surgery; RR 0.81, 95% CI 0.32 to 2.07).[35] **Longer term outcome:** We found one RCT (25 boys and 27 girls aged 1–12 years with bilateral vesicoureteric reflux [grades III–V] and bilateral nephropathy) with 10 years of follow up.[35] It found a steady decline in glomerular filtration

rate over 10 years in children on medical treatment compared with surgery (see table 1, p 523). There was no statistically significant difference between medical treatment and surgery, but the study was underpowered to detect a clinically important effect.

Harms:

Versus medical management: The review gave no information on surgical complications, and none of the individual studies were designed to compare rates of adverse effects.[33] In one arm of the subsequent RCT, 7/9 (78%) children who had postoperative obstruction developed evidence of renal scarring on DMSA scintigraphy (see glossary, p 521). This may have negated an otherwise beneficial effect of surgery over medical management.[34]

Comment:

Versus medical management: The best results were obtained by centres handling the greatest number of children.[36] Surgery is usually considered only in children with more severe vesicoureteric reflux (grades III–V), who are less likely to experience spontaneous resolution.[5,37] **Longer term outcome:** The RCT involving children with bilateral moderate to severe vesicoureteric reflux and nephropathy found that, over a period of 4 years, 20/54 (37%) kidneys of children in the medical group had spontaneous resolution to no, or minimal, vesicoureteric reflux (grades 0 or I) and that corrective surgery was possible without complications in 47/50 (94%) kidneys in the surgical group (ARI 57%, 95% CI 47% to 69%).[35] We found one prospective cohort study (226 children aged 5 days to 12 years who presented with urinary tract infection and vesicoureteric reflux [grades III–IV]) with follow up of 10–41 years.[12] It found that surgery was associated with a higher rate of resolution of reflux compared with medical treatment (AR of resolution from age 8–14 years on micturating cystourethrography: 29/33 [88%] with surgery *v* 134/193 [69%] with medical treatment; ARI 19%, 95% CI 6% to 31%). The study did not compare clinical outcomes.[12]

GLOSSARY

DMSA scintigraphy A scan following intravenous injection of a radioisotope solution, which is excreted by the kidneys. The scan yields information about the structure and function of the urinary tract.

Intravenous immunoglobulins Immunoglobulin preparations derived from donated human plasma containing antibodies prevalent in the general population.

Nosocomial infection Definitions vary but typically an infection arising at least 48–72 hours after admission to hospital. The infection may have been acquired from other people, hospital staff, the hospital environment, or from pre-existing subclinical infection.

Pyelonephritis Inflammation of the kidney and its pelvis caused by bacterial infection.

Severity of vesicoureteric reflux:

Grade I Reflux into ureters only.

Grade II Reflux into ureters, pelvis, and calyces.

Grade III Mild to moderate dilatation or tortuosity of ureters and mild to moderate dilatation of pelvis, but little or no forniceal blunting.

Grade IV As grade III, but with complete obliteration of forniceal angles, yet maintenance of papillary impressions in calyces.

Grade V Gross dilatation of ureters, pelvis, and calyces, and papillary impressions in calyces obliterated.

Urinary tract infection in children

TABLE 1 **Average glomerular filtration rates in children with bilateral vesicoureteric reflux and bilateral nephropathy at the commencement of the study, at 4 years, and at 10 years after randomisation to medical or surgical management (see text, p 520).[35]**

Mean GFR (mL/minute)	At entry	At 4 years	At 10 years
Medical management	72.4	70.2	68.3
Surgical management	71.7	73.7	74.1
Difference in change in GFR from entry (95% CI)	–	+7.1% (–6.4% to +20.6%)	+8.9% (–10.3% to +28.2%)

GFR, glomerular filtration rate.

Key Messages

- **Early cholecystectomy** Four RCTs found that operation before the scheduled date because of recurrent or worsening symptoms was necessary in 13–19% of people receiving delayed cholecystectomy (open or laparoscopic cholecystectomy after 6–8 weeks). The RCTs found no significant difference between early (within 72 hours) and delayed cholecystectomy (open or laparoscopic) in intraoperative or postoperative complications, but found that early cholecystectomy reduced hospital stay. Two RCTs found that early laparoscopic cholecystectomy increased duration of operation compared with delayed laparoscopic cholecystectomy but reduced use of analgesics. The RCTs found no significant difference between early and delayed laparoscopic cholecystectomy in the rate of conversion to open cholecystectomy.
- **Laparoscopic cholecystectomy** Two RCTs found that laparoscopic cholecystectomy reduced duration of surgery, use of nasogastric tube, duration of antibiotic treatment, use of analgesia, and hospital stay. One RCT found no significant difference in rates of postoperative complications between laparoscopic and open cholecystectomy. The other RCT found fewer major and minor postoperative complications with laparoscopic cholecystectomy. The rate of conversion from laparoscopic to open cholecystectomy was 16–27%.
- **Minilaparoscopic cholecystectomy** One RCT found that minilaparoscopic and conventional laparoscopic cholecystectomy were associated with similar use of analgesics, hospital stay, and rates of conversion to open cholecystectomy. Minilaparoscopic cholecystectomy marginally increased duration of surgery.

- **Open cholecystectomy** Two RCTs found that open cholecystectomy increased duration of surgery, use of nasogastric tube, duration of antibiotic treatment, use of analgesia, and hospital stay. One RCT found no significant difference in rates of postoperation complications between open and laparoscopic cholecystectomy. The other RCT found more postoperative complications with open cholecystectomy. The rate of conversion from laparoscopic to open cholecystectomy was 16–27%. Conversion from laparascopic to open cholecystectomy is needed if the laparoscopic procedure cannot be completed without risking injury to surrounding structures or when bleeding cannot be stopped. Open cholecystectomy is required in people who have a fistula from the gallbladder into the bile duct or intestine, and in some people who have perforation and abscess in the right upper quadrant.

DEFINITION **Acute cholecystitis** results from obstruction of the cystic duct usually by a gallstone followed by distension and subsequent chemical or bacterial inflammation of the gallbladder. People with acute cholecystitis usually have unremitting right upper quadrant pain, anorexia, nausea, vomiting, and fever. About 95% of people with acute cholecystitis have gallstones (calculous cholecystitis) and 5% lack gallstones (acalculous cholecystitis).[1] **Acute cholangitis** is a severe complication of gallstone disease and is generally a result of bacterial infection. People with acute cholangitis often have jaundice, haemodynamic instability, and mental status changes in addition to right upper quadrant pain and fever. This review does not include people with acute cholangitis.

INCIDENCE/ PREVALENCE The incidence of acute cholecystitis among people with gallstones is unknown. Twenty per cent of people admitted to hospital for biliary tract disease have acute cholecystitis.[1] The number of cholecystectomies carried out for acute cholecystitis has increased from the mid 1980s to the early 1990s, especially in elderly people.[2] Acute calculous cholecystitis is three times more common in women than men up to the age of 50 years, and about 1.5 times more common in women than men thereafter.[1]

AETIOLOGY/ RISK FACTORS Acute calculous cholecystitis seems to be caused by obstruction of the cystic duct by a gallstone or local mucosal erosion and inflammation caused by a stone, but cystic duct ligation alone does not produce acute cholecystitis in animal studies. The role of bacteria in the pathogenesis of acute cholecystitis is not clear; positive cultures of bile or gallbladder wall are found in 50–75% of cases.[3,4] The cause of acute acalculous cholecystitis is uncertain and may be multifactorial, including increased susceptibility to bacterial colonisation of static gallbladder bile.[1]

PROGNOSIS Complications of acute cholecystitis include perforation of the gallbladder, pericholecystic abscess, and fistula caused by gallbladder wall ischaemia and infection. In the USA, the overall mortality from complications is about 20%.[5]

AIMS OF INTERVENTION To reduce mortality and morbidity relating to acute cholecystitis, with minimal adverse effects of treatment.

OUTCOMES Mortality at 30 days, persistent pain, tolerance to food, recurrent attacks of cholecystitis, quality of life, and adverse effects of treatment. Some outcomes relate to surgery: duration of surgery, need for naso-gastric tube, analgesic use, antibiotic use, surgical

complications (bile duct injuries, pancreatitis, other), and duration of hospital stay. Conversion of a planned laparoscopic cholecystectomy to an open cholecystectomy (see glossary, p 532) is a surrogate outcome.

METHODS *Clinical Evidence* search and appraisal June 2003. None of the RCTs stated whether participants had calculous or acalculous cholecystitis. The RCTs excluded people unable to undergo surgery because of co-morbid conditions and contraindications for cholecystectomy.

QUESTION **What are the effects of treatments for acute cholecystitis?** New

OPTION **LAPAROSCOPIC CHOLECYSTECTOMY**

Two RCTs found that laparoscopic cholecystectomy reduced duration of surgery, use of nasogastric tube, use of analgesia, and hospital stay. One RCT found no significant difference in rates of postoperative complications between laparoscopic and open cholecystectomy. The other RCT found fewer major and minor postoperative complications with laparoscopic cholecystectomy. The rate of conversion from laparoscopic to open cholecystectomy was 16–27%. Conversion from laparascopic to open cholecystectomy is needed if the laparoscopic procedure cannot be completed without risking injury to surrounding structures or when bleeding cannot be stopped. Open cholecystectomy is required in people who have a fistula from the gallbladder into the bile duct or intestine, and in some people who have perforation and abscess in the right upper quadrant.

Benefits: **Versus no treatment:** We found no systematic review and no RCTs comparing laparoscopic cholecystectomy (see glossary, p 532) versus no treatment. **Versus open cholecystectomy:** See glossary, p 532. We found no systematic review, but found two RCTs.[6,7] Both RCTs found that laparoscopic cholecystectomy improved intraoperative and postoperative outcomes compared with open cholecystectomy. The first RCT (271 people with acute cholecystitis) compared laparoscopic (146 people) versus open (97 people) cholecystectomy.[6] The rate of conversion from laparoscopic to open cholecystectomy was 27%. The people randomised to receive open cholecystectomy were on average 10 years older than people receiving laparoscopic cholecystectomy ($P < 0.001$), and had a significantly higher incidence of comorbid conditions ($P = 0.002$) and gangrenous cholecystitis ($P = 0.03$). The RCT found no significant difference in duration of surgery between laparoscopic and open cholecystectomy (mean 60 minutes with laparoscopic *v* 90 minutes with open; $P < 0.00001$), use of nasogastric tube (51% with laparoscopic *v* 94% with open; $P < 0.0001$), use of analgesia (75 mg pethidine with laparoscopic *v* 175 mg with open; $P < 0.0001$), and hospital stay (3 days with laparoscopic *v* 7 days with open cholecystectomy; $P < 0.0001$). The second RCT (63 people with acute cholecystitis) comparing laparoscopic versus open cholecystectomy found that there were no deaths or bile duct injuries in either group.[7] The rate of conversion from laparoscopic to open cholecystectomy was 16%. The people randomised to each

group were of similar age (mean 60 years), weight, and clinical status (1 person receiving laparoscopic cholecystectomy and 1 receiving open cholecystectomy had diffuse peritonitis). The RCT found that laparoscopic cholecystectomy significantly reduced hospital stay compared with open cholecystectomy (4 days with laparoscopic *v* 14 days with open cholecystecomy; P = 0.0063). It found no significant difference in duration of surgery between laparoscopic and open cholecystectomy (mean 108 minutes with laparoscopic *v* 99 minutes with open; P = 0.49).

Harms:

Versus open cholecystectomy: The first RCT found no significant difference between laparoscopic cholecystectomy and open cholecystectomy in the proportion of people with postoperative complications (24/146 [16%] with laparoscopic *v* 25/97 [26%] with open; reported as non-significant, CI not reported).[6] Complications were classified as surgical infections (wound infection, subphrenic or subhepatic abscess), non-infectious surgical (bile duct injury, haemorrhage), remote infections (urinary or respiratory), and miscellaneous (atelectasis, deep vein thrombosis). The second RCT found that laparoscopic cholecystectomy significantly reduced postoperative complications compared with open cholecystectomy (major complications 0% with laparoscopic *v* 23% with open; minor complications 3% with laparoscopic *v* 19% with open; P = 0.0048 for all complications with laparoscopic *v* open).[7] Major complications included myocardial infarction, pneumonia and sepsis, femoral artery embolism, serious wound infection, late incisional hernia requiring surgical repair, adhesive intestinal obstruction within 1 month of cholecystectomy, and retained common bile duct stone. Minor complications included diarrhoea, urinary infection, and confusion.

Comment:

Neither of the RCTs differentiated between calculous and acalculous cholecystitis. The first RCT found that laparoscopic surgery was associated with fewer complications if undertaken by more experienced surgeons.[6] Open cholecystectomy is primarily required in people who have a fistula from the gallbladder into the bile duct or intestine and in some people who have perforation and abscess in the right upper quadrant. Conversion from laparoscopic to open cholecystectomy is needed if the laparoscopic procedure cannot be completed without risking injury to surrounding structures or when bleeding cannot be stopped. We found one systematic review and one prospective study in people with symptomatic gallstones that did not differentiate between people with and without acute cholecystitis. The review (search date 1995) indirectly compared outcomes in people who had laparoscopic cholecystectomy (98 case series or RCTs, 78 747 people with symptomatic gallstones) with outcomes in people who had open cholecystectomy (28 case series or RCTs, 12 973 people treated with open cholecystectomy).[8] It found that laparoscopic cholecystectomy was associated with lower mortality (86–91/100 000 with laparoscopic *v* 660–740/100 000 with open cholecystectomy; CI not reported) but a higher rate of bile duct injury (36–47/10 000 with laparoscopic *v* 19–29/10 000 with open cholecystectomy; CI not reported). One prospective non-randomised study (1518 people with symptomatic gallstones) assessed surgical complications associated with laparoscopic

cholecystectomy.[9] Laparoscopic cholecystectomy was associated with surgical complications in 5% of participants and with bile or hepatic duct injuries in 0.5% of participants. The mean hospital stay was 1.2 days. The conversion rate to open cholecystectomy was 4.7%.

OPTION OPEN CHOLECYSTECTOMY

Two RCTs found that open cholecystectomy increased duration of surgery, use of nasogastric tube, duration of antibiotic treatment, use of analgesia, and hospital stay compared with laparoscopic cholecystectomy. One RCT found no significant difference in rates of postoperative complications between open and laparoscopic cholecystectomy. The other RCT found more major and minor postoperative complications with open cholecystectomy. The rate of conversion from laparoscopic to open cholecystectomy was 16–27%. Conversion from laparoscopic to open cholecystectomy is needed if the laparoscopic procedure cannot be completed without risking injury to surrounding structures or when bleeding cannot be stopped. Open cholecystectomy is required in people who have a fistula from the gallbladder into the bile duct or intestine and in some people who have perforation and abscess in the right upper quadrant.

Benefits: **Versus no treatment:** We found no systematic review and no RCTs comparing cholecystectomy versus no treatment. **Versus laparoscopic cholecystectomy:** See benefits of laparoscopic cholecystectomy, p 526.

Harms: **Versus laparoscopic cholecystectomy:** See harms of laparoscopic cholecystectomy, p 527.

Comment: **Versus laparoscopic cholecystectomy:** See comments under laparoscopic cholecystectomy, p 527.

OPTION MINILAPAROSCOPIC CHOLECYSTECTOMY

One RCT found that minilaparoscopic and conventional laparoscopic cholecystectomy were associated with similar use of analgesics, hospital stay, and rates of conversion to open cholecystectomy. Minilaparoscopic cholecystectomy marginally increased duration of surgery.

Benefits: **Versus no treatment:** We found no systematic review and no RCTs comparing minilaparoscopic cholecystectomy (see glossary, p 532) versus no treatment. **Versus conventional laparoscopic cholecystectomy:** See glossary, p 532. We found one RCT (69 people with acute cholecystitis) comparing minilaparoscopic cholecystectomy (2–3 mm diameter instruments) versus conventional laparoscopic cholecystectomy (5 mm diameter instruments).[10] It found no significant difference between minilaparoscopic and conventional laparoscopic cholecystectomy in the rate of conversion to open cholecystectomy (7.9% with minilaproscopic *v* 6.5% with conventional laparosopic cholecystectomy; P = 0.597). It found that a similar proportion of people needed postoperative antiemetics plus analgesics (30/35 [86%] with minilaparoscopic *v* 22/29 [76%] with conventional laparoscopic) and found no significant difference between minilaparoscopic and

conventional laparoscopic cholecystectomy in duration of hospital stay (mean 4.3 days with minilaparoscopic *v* 4.2 days with conventional laparoscopic cholecystectomy; P value reported as non-significant, CI not reported). Minilaroscopic cholecystectomy marginally increased duration of surgery compared with conventional laparoscopic cholecystectomy (mean 113.8 minutes with minilaparoscopic *v* 98.2 minutes with conventional laparoscopic; P = 0.056).

Harms: The RCT found no major complications associated with minilaparoscopic or conventional laparoscopic cholecystectomy, but it may have been underpowered to detect clinically important adverse effects.[10]

Comment: The RCT did not differentiate between calculous and acalculous cholecystitis.

OPTION EARLY VERSUS DELAYED CHOLECYSTECTOMY

Four RCTs found that operation before the scheduled date because of recurrent or worsening symptoms was necessary in 13–19% of people receiving delayed cholecystectomy (open or laparoscopic cholecystectomy after 6–8 weeks). The RCTs found no significant difference between early (within 72 hours) and delayed cholecystectomy (open or laparoscopic) in intraoperative or postoperative complications, but found that early cholecystectomy reduced hospital stay. Two RCTs found that early laparoscopic cholecystectomy increased duration of operation compared with delayed laparoscopic cholecystectomy but reduced use of analgesics. The RCTs found no significant difference between early and delayed laparoscopic cholecystectomy in the rate of conversion to open cholecystectomy.

Benefits: We found no systematic review. **Early versus delayed open cholecystectomy:** We found two RCTs comparing early versus delayed open cholecystectomy (see glossary, p 532).[11,12] The RCTs found that operation was necessary before the scheduled date in 13–14% of people receiving delayed cholecystectomy. The first RCT (165 people with acute cholecystitis) compared early (mean time to operation 1.6 days) versus delayed (mean time to operation 2.6 months) open cholecystectomy.[11] There was no significant difference between people randomised to receive early or delayed open cholecystectomy in terms of age (mean 57.8 years with early surgery *v* 56.7 years with delayed surgery), duration of symptoms (mean 2.2 days with early surgery *v* 2.3 days with delayed surgery), or previous history of biliary disease (55% with early surgery *v* 45% with delayed surgery; P value reported as non-significant for all comparisons). Operation before the scheduled date because of peritonitis, jaundice, cholangitis or empyema was necessary in 10/82 (13%) people receiving delayed open cholecystectomy. There were no deaths in people receiving early cholecystectomy and one death in people receiving delayed. The RCT found similar intraoperative complications between early and delayed cholecystectomy and found no significant difference in duration of surgery (mean 93 minutes with early *v* 85 minutes with delayed; P > 0.10). However, it found that early open cholecystectomy significantly reduced hospital stay compared with

delayed open cholecystectomy (10.7 days with early *v* 18.2 with delayed, mean difference 7.5 days; P < 0.001). The second RCT (192 people) compared early open cholecystectomy (mean time to operation 2.5 days) versus delayed open cholecystectomy (mean time to operation not reported).[12] The RCT gave no information about characteristics and clinical status of people randomised to receive early compared with delayed cholecystectomy. Operation before the scheduled date because of worsening or recurrent symptoms was necessary in 15/91 patients (14%) assigned to delayed cholecystectomy. There were no deaths in people receiving early cholecystectomy and one death in people receiving delayed. The RCT found no significant difference between early and delayed cholecystectomy in intraoperative and postoperative complications (15% in both groups), but found that early cholecystectomy significantly reduced hospital stay (9.1 days with early *v* 15.5 days with delayed; P < 0.05). **Early versus delayed laparoscopic cholecystectomy:** We found two RCTs comparing early versus delayed laparoscopic cholecystectomy.[13,14] The RCTs found that operation was necessary before the scheduled date in 16–19% of people receiving delayed cholecystectomy. The first RCT (104 people) compared early (within 24 hours of admission) versus delayed (after 6–8 weeks) laparoscopic cholecystectomy.[13] There was no significant difference in terms of age between people receiving early and delayed laparoscopic cholecystectomy (55.8 years with early *v* 56.1 years with delayed laparoscopic; P = 0.90). In people receiving delayed laparoscopic cholecystectomy, operation before the scheduled date because of worsening or recurrent symptoms was necessary in 8/51 (16%) people, and 5/51 (10%) people did not have surgery because of successful conservative treatment. The RCT found no significant difference in the rate of conversion to open cholecystectomy between early and delayed laparoscopic cholecystectomy (21% with early *v* 24% with delayed; P = 0.74), or use of postoperative analgesics (2 doses pethidine with early *v* 1 dose pethidine with delayed cholecystectomy; P = 0.14). The second RCT (99 people) compared early laparoscopic cholecystectomy (median time to operation 63 hours) versus delayed laparoscopic cholecystectomy (median time to operation 67 days).[14] There was no significant difference between people receiving early and delayed laparoscopic cholecystectomy in terms of age (59 years with early *v* 61 years with delayed; P = 0.812), duration of symptoms (2 days with early *v* 2 days with delayed surgery; P = 0.164), or previous history of biliary symptoms (33% with early surgery *v* 32% with delayed laparoscopic cholecystectomy; P = 0.872). Operation before the scheduled date was necessary in 8/41 (19.5%) people receiving delayed laparoscopic cholecystectomy, five because of peritonitis and three because of persistent fever. The RCT found no significant difference in the rate of conversion to open cholecystectomy between early and delayed laparoscopic cholecystectomy, although more people receiving delayed laparoscopic cholecystectomy converted to open (5/45 [11%] with early *v* 9/41 [23%] with delayed; P = 0.174). It found

that early laparoscopic cholecystectomy significantly reduced use of analgesics (mean 1 dose with early *v* 2 doses with delayed; $P < 0.004$) and total hospital stay (6 days with early *v* 11 days with delayed; $P < 0.001$) compared with delayed laparoscopic cholecystectomy.

Harms:

Early versus delayed open cholecystectomy: In the first RCT, 11 people (15%) undergoing delayed cholecystectomy had recurrent symptoms during the waiting period (5 with acute cholecystitis, 2 with acute pancreatitis, 4 with biliary colic).[11] The RCT found no significant difference between early and delayed open cholecystectomy in the proportion of people who had postoperative complications (14% with early *v* 17% with delayed; P value reported as non-significant, CI not reported). The second RCT also found no significant difference in the proportion of people who had postoperative complications (14.9% with early *v* 15.4% with delayed; P value reported as non-significant, CI not reported). The complications in both RCTs included pneumonia, wound infection, wound dehiscence, incisional hernia, intra-abdominal abscess, mesenteric thrombosis, pancreatitis, myocardial infarction, and transient psychosis. **Early versus delayed laparoscopic cholecystectomy:** The first RCT found that early laparoscopic cholecystectomy significantly increased duration of operation compared with delayed laparoscopic cholecystectomy (122.8 minutes with early *v* 106.6 minutes with delayed, $P < 0.04$).[13] It found no significant difference in postoperative complications between early and delayed laparoscopic cholecystectomy (5/53 [9%] *v* 3/38 [8%]; $P = 0.80$). Postoperative complications included subphrenic collection, a bile leak from the cystic duct stump, superficial wound infection, and postoperative respiratory failure requiring mechanical ventilation for 3 days. The second RCT also found that early laparoscopic cholecystectomy significantly increased duration of operation compared with delayed (mean 135 minutes with early *v* 105 minutes with delayed; $P = 0.022$), but found no significant difference in the proportion of people who had postoperative complications between early and delayed cholecystectomy (6/45 [13%] with early group *v* 12/41 [29%] with delayed; $P = 0.07$). Postoperative complications included wound infection bile leak, intra-abdominal fluid collection, chest infection, urinary tract infection, bile duct injury, intra-abdominal bleeding, retained ductal stone, ileus, and atrial fibrillation.

Comment:

People with acute cholecystitis who have multiple comorbid conditions and relative contraindications for cholecystectomy may be treated with antibiotics, a low fat diet, and in some instances a cholecystostomy tube. Due to a high rate of recurrent cholecystitis, most patients undergo a delayed cholecystectomy when their comorbid conditions are better controlled. Only one of the RCTs gave information on the number of people who did not undergo surgery because of successful conservative treatment.[13] **Early versus delayed open cholecystectomy:** Surgeons in the RCTs had a variety of experience. In the first RCT, open cholecystectomies were performed by staff surgeons and senior residents only, with 85% of the operations performed by one of the authors of the RCT.[11] In the second RCT, open cholecystectomies were performed

by a large number of surgeons of "varied experience".[12] **Early versus delayed laparoscopic cholecystectomy:** All laparoscopic cholecystectomies were carried out by "experienced surgeons" who had carried out ≥50 previous laparoscopic cholecystectomies in one RCT[13] and ≥300 in the other.[14] None of the RCTs differentiated between calculous and acalculous cholecystitis.

GLOSSARY

Laparoscopic cholecystectomy involves removal of the gallbladder using a projection camera and 5–10 mm trocar ports.
Minilaparoscopic cholecystectomy involves removal of the gallbladder using a projection camera and 2–3 mm trocar ports.
Open cholecystectomy involves removal of the gallbladder via laparotomy.

QUESTIONS

INTERVENTIONS

*Based on consensus opinion

See glossary, p 542

Key Messages

- **Internal anal sphincterotomy** One systematic review found no significant difference between internal anal sphincterotomy and anal stretch in persistence of fissures. Both procedures healed 70–95% of fissures. It found no significant difference between open and closed internal anal sphincterotomy in persistence of fissures. Four RCTs have found that sphincterotomy improved fissure healing compared with topical glyceryl trinitrate after 6 weeks to 2 years.
- **Anal advancement flap (as effective as internal anal sphincterotomy based on 1 small RCT)** One small RCT found no significant difference between lateral internal anal sphincterotomy and anal advancement flap in patient satisfaction or fissure healing.
- **Botulinum A toxin-haemagglutinin complex** RCTs found that botulinum A toxin-haemagglutinin complex increased fissure healing at 2 months compared with placebo or topical glyceryl trinitrate. Two RCTs found no significant difference between high dose and low dose botulinum A toxin-haemagglutinin complex in healing rates after 2–3 months. One RCT found that compared with botulinum A toxin-haemagglutinin complex, sphincterotomy increased fissure healing at 12 months. It also increased time taken to return to daily activities.
- **Topical glyceryl trinitrate** RCTs comparing topical glyceryl trinitrate versus placebo found mixed results for healing and pain, and results were difficult to interpret owing to differing durations and doses of treatments. However, consensus opinion still regards glyceryl trinitrate as an effective first line treatment for chronic anal fissure. One RCT found no significant difference between glyceryl trinitrate ointment and a glyceryl trinitrate patch in fissure

healing at 8 weeks. One RCT found no significant difference between topical glyceryl trinitrate and topical diltiazem in fissure healing at 8 weeks. One RCT, identified by a systematic review, found that botulinum A toxin-haemagglutinin complex increased fissure healing after 2 months compared with glyceryl trinitrate. Four RCTs found that internal anal sphincterotomy improved fissure healing compared with topical glyceryl trinitrate after 6 weeks to 2 years.

- **Anal stretch (as effective as internal anal sphincterotomy but higher rates of flatus incontinence)** One systematic review found no significant difference between internal anal sphincterotomy and anal stretch in persistence of fissures. It found that both procedures healed 70–95% of fissures. Anal stretch increased rates of flatus incontinence compared with internal anal sphincterotomy.
- **Botulinum A toxin-haemagglutinin complex plus nitrates** We found no RCTs comparing botulinum A toxin-haemagglutinin complex plus nitrates versus placebo. One small RCT found that botulinum A toxin-haemagglutinin complex plus topical isosorbide dinitrate three times daily increased fissure healing at 6 weeks compared with botulinum A toxin-haemagglutinin complex alone. It found no significant difference at 8 or 12 weeks.
- **Diltiazem** We found no placebo controlled RCTs. One RCT found no significant difference in healing rates between topical diltiazem and topical glyceryl trinitrate at 8 weeks. One small RCT found no significant difference in fissure healing after 8 weeks between oral diltiazem and topical diltiazem.
- **Indoramin** One RCT found no significant difference between oral indoramin and placebo in fissure healing at 6 weeks.

DEFINITION Anal fissure is a split or tear in the lining of the distal anal canal. It is a painful condition often associated with fresh blood loss from the anus and perianal itching. **Acute anal fissures** have sharply demarcated, fresh mucosal edges, often with granulation tissue at the base. **Chronic anal fissures** margins are indurated, there is less granulation tissue, and muscle fibres of the internal anal sphincter may be seen at the base. Fissures persisting for longer than 6 weeks are generally defined as chronic.

INCIDENCE/ PREVALENCE Anal fissures are common in all age groups, but we found no evidence to measure incidence.

AETIOLOGY/ RISK FACTORS Low intake of dietary fibre may be a risk factor for the development of acute anal fissure.[1] People with anal fissure often have raised resting anal canal pressures with anal spasm.[2,3] Men and women are equally affected by anal fissure, and up to 11% of women develop anal fissure after childbirth.[4]

PROGNOSIS Placebo controlled studies found that 70–90% of untreated "chronic" fissures did not heal during the study.[5,6]

AIMS OF INTERVENTION To relieve symptoms (pain, bleeding, and irritation); to heal the fissure; to minimise adverse effects of treatment.

OUTCOMES Proportion of people with fissure healing (intact anal mucosal lining); symptom score for intensity of symptoms of pain, bleeding, and irritation (typically a linear visual analogue scale that consists of

an unmarked 100 mm horizontal line, the left end of which represents absence of symptoms and the right end represents the worst symptoms imaginable; a vertical mark is made across this line by the person with the fissure); proportion of people reporting adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal May 2003.

QUESTION **What are the effects of treatments for chronic anal fissure?**

OPTION **TOPICAL GLYCERYL TRINITRATE**

RCTs comparing topical glyceryl trinitrate with placebo found mixed results for healing and pain, and results were difficult to interpret owing to differing durations and doses of treatments. Consensus opinion regards glyceryl trinitrate as an effective first line treatment for chronic anal fissure. One RCT found no significant difference between glyceryl trinitrate ointment and a glyceryl trinitrate patch in fissure healing at 8 weeks. One RCT found no significant difference between topical glyceryl trinitrate and topical diltiazem in fissure healing at 8 weeks. One RCT, identified by a systematic review, found that botulinum A toxin-haemagglutinin complex increased fissure healing after 2 months compared with glyceryl trinitrate. Four RCTs found that internal anal sphincterotomy improved fissure healing compared with topical glyceryl trinitrate after 6 weeks to 2 years.

Benefits:

Versus placebo: We found one systematic review (search date not reported, 4 RCTs, 312 people; no statistical pooling of data reported)[7] and two subsequent RCTs (see comment below).[8,9] The first RCT in the review (80 people) found that after 8 weeks of treatment, glyceryl trinitrate (GTN) (see glossary, p 542) (0.2% twice daily) significantly increased healing of anal fissures compared with placebo (analysis not by intention to treat; 3 people excluded; AR for healing: 26/38 [68%] with GTN *v* 3/39 [8%] with placebo; RR 8.90, 95% CI 2.94 to 26.95), and significantly reduced median pain scores (pain scores measured using a visual analogue scale; 0 = no pain and 100 = worst pain imaginable; reduction in median score: 67.0 with GTN *v* 16.0 with placebo; $P < 0.05$).[5] The second RCT (70 people) in the review compared three treatments given for 8 weeks: 0.2% GTN three times daily; escalating dose topical GTN (0.2% increasing to 0.6%); and placebo.[6] It found that GTN significantly increased anal fissure healing compared with placebo 2 weeks after the end of treatment (AR for healing: 15/23 [65%] with 0.2% GTN *v* 16/23 [70%] with escalating dose GTN *v* 7/22 [32%] with placebo; RR for both GTN groups *v* placebo 2.10, 95% CI 1.11 to 4.03). It found no significant difference in pain scores between GTN and placebo (measured using a linear analogue scale from 0 to 10; scores depicted graphically; $P = 0.04$ for both GTN groups *v* placebo).[6] The third RCT (43 people) identified by the review found no significant difference between GTN (0.2% twice daily) and placebo in healing of anal fissures after 4 weeks of treatment (AR for healing: 11/24 [46%] with GTN *v* 3/19 [16%] with placebo; RR 2.00, 95% CI 0.65 to 6.45), and did not provide comparative data between treatments

for pain scores.[10] The fourth RCT (132 people) identified by the review found no significant difference between GTN (0.2% twice daily) and placebo in healing of anal fissures after 4 weeks of treatment (AR for healing: 29/59 [49%] with GTN *v* 31/60 [52%] with placebo; RR 0.95, 95% CI 0.67 to 1.36), and did not provide comparative data between treatments for pain scores.[11] The first subsequent RCT (304 people with fissure symptoms for at least 30 days) compared eight treatments: GTN at doses of 0.1, 0.2, or 0.4% twice or three times daily, or placebo twice or three times daily.[8] It found no significant difference in fissure healing between any of the GTN treatment groups (0.1, 0.2, or 0.4% twice or three times daily) and placebo at 8 weeks (intention to treat analysis: 0.1% GTN *v* placebo $P < 0.63$; 0.2% GTN *v* placebo $P < 0.12$; 0.4% GTN *v* placebo $P < 0.64$; AR values not reported). However, it found that 0.4% GTN significantly reduced pain compared with placebo at 8 weeks (improvement in average pain score on a 100 point visual analogue scale: 72 with 0.4% GTN *v* 51 with placebo; P value not reported). The study had large loss to follow up (21%), which may limit reliability of results. The second subsequent RCT (200 people) found no significant difference in healing or pain between GTN (0.1, 0.2, or 0.4% twice daily) and placebo after 8 weeks of treatment (AR for healing: 62/133 [46.6%] with all GTN treatments *v* 18/48 [37.5%] with placebo, $P = 0.3$; pain scores not reported: 0.1% GTN *v* placebo $P = 0.40$; 0.2% GTN *v* placebo $P = 0.34$; 0.4% GTN *v* placebo $P = 0.64$).[9] **Versus internal anal sphincterotomy:** We found one systematic review (search date not reported, 1 RCT),[7] one additional RCT,[12] and two subsequent RCTs.[13,14] The RCT (82 people with chronic anal fissures receiving stool softeners and fibre supplements) identified by the review found that internal anal sphincterotomy (see glossary, p 542) significantly improved fissure healing at 6 weeks compared with 0.25% GTN ointment three times daily (AR for healing: 34/38 [89%] with internal anal sphincterotomy *v* 13/44 [30%] with GTN; ARI 60%, 95% CI 38% to 81%; RR 3.0, 95% CI 1.9 to 4.8).[15] The additional RCT (49 people with chronic anal fissure of duration 4 months receiving a high fibre diet and a laxative) also found that internal anal sphincterotomy significantly improved fissure healing compared with topical GTN (ointment [0.2%] or patch [10 mg] at 1 year; 11/12 [92%] with internal anal sphincterotomy *v* 24/37 [65%] with GTN; RR 1.40, 95% CI 1.05 to 1.89).[12] The first subsequent RCT (60 people) found that internal anal sphincterotomy significantly increased healing at 8 weeks compared with 0.2% GTN ointment three times daily (AR for healing: 26/27 [96%] with internal anal sphincterotomy *v* 20/33 [61%] with GTN; RR 1.60, 95% CI 1.20 to 2.11).[13] The second subsequent RCT (70 people) found that internal anal sphincterotomy significantly improved fissure healing compared with GTN (0.2% three times daily for 8 weeks) at 2 months (AR for healing: 35/35 [100%] with internal anal sphincterotomy *v* 19/35 [54%]; $P = 0.02$).[14] See also benefits of internal anal sphincterotomy, p 541. **Versus botulinum A toxin-haemagglutinin complex:** See glossary, p 542. See benefits of botulinum A toxin-haemagglutinin complex, p 538. **GTN ointment versus GTN patch:** We found one RCT (42 people), which found no significant difference between GTN ointment (0.2%

twice daily) and a GTN patch (10 mg/day) in fissure healing at 8 weeks (analysis not by intention to treat; 5 people excluded; AR for healing: 12/18 [67%] with GTN ointment *v* 12/19 [60%] with GTN patch; RR 1.10, 95% CI 0.66 to 1.70).[12] **Versus topical diltiazem:** We found one RCT (72 people), which found no significant difference between GTN (0.2% ointment applied twice daily for 6–8 weeks) and topical diltiazem (2% cream applied twice daily for 6–8 weeks) in fissure healing at 8 weeks (AR for healing: 25/29 [86%] with GTN *v* 24/31 [77%] with diltiazem; RR 0.69, 95% CI 0.39 to 1.22).[16]

Harms: **Versus placebo:** Topical GTN caused headaches in 18–72% of people compared with 12–27% with placebo.[5,6,9,10] **Versus internal anal sphincterotomy:** Sphincterotomy caused flatus incontinence in 1/35 (2.9%) people.[14] **Versus diltiazem:** One RCT found that GTN significantly increased adverse effects compared with diltiazem (AR for adverse effects: 21/29 [72%] with GTN *v* 13/31 [42%] with diltiazem; RR 1.84, 95% CI 1.11 to 3.04).[16] Headaches and gastrointestinal adverse effects were more common with GTN than with diltiazem (headaches: 17/29 [59%] with GTN *v* 8/31 [26%] with diltiazem; RR 2.06, 95% CI 1.18 to 3.59; gastrointestinal effects: 9/29 [31%] with GTN *v* 3/31 [10%] with diltiazem; significance not reported).

Comment: **Versus placebo:** Results of the RCTs are difficult to interpret because of differences between trials in entry criteria, in the doses and durations of GTN treatments used, and in the advice and application of topical GTN. We found insufficient evidence about the optimal duration and dose of topical GTN treatment. The first subsequent RCT (304 people) included people with fissure symptoms for at least 30 days, who would not have been classified as having chronic anal fissures according to our criteria. This may have resulted in a lack of power to detect an effect of GTN in people with chronic anal fissures.[8] Entry criteria may have varied among the trial centres in the two subsequent large RCTs. The authors, therefore, believe that some of the single centre RCTs, which have tightly controlled entry criteria and dosage regimens, probably reflect the effectiveness of GTN more accurately than the multicentre RCTs. Consensus opinion regards GTN as being an effective first line treatment for chronic anal fissures.

OPTION DILTIAZEM

We found no placebo controlled RCTs. One RCT found no significant difference in healing rates between topical diltiazem and topical glyceryl trinitrate at 8 weeks. One small RCT found no significant difference in fissure healing after 8 weeks between oral diltiazem and topical diltiazem.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Topical diltiazem versus topical glyceryl trinitrate:** See glossary, p 542. See benefits of topical glyceryl trinitrate, p 535. **Oral versus topical diltiazem:** We found one RCT (50 people with

chronic anal fissures), which found no significant difference in healing between oral diltiazem (60 mg twice daily) and 2% topical diltiazem gel (700 mg twice daily) after 8 weeks of treatment (AR for healing: 9/24 [38%] with oral diltiazem *v* 17/26 [65%] with diltiazem gel; RR 0.57, 95% CI 0.32 to 1.03).[17]

Harms: **Oral versus topical diltiazem:** The RCT reported that oral diltiazem caused adverse effects in 8/24 (33%) people (nausea/vomiting in 3 people, headache in 2 people, rash in 2 people, altered sense of smell and taste in 1 person). No adverse effects were reported with topical diltiazem.[17]

Comment: We found insufficient evidence about the optimal duration of diltiazem treatment. The role of diltiazem in treating fissures previously failing to heal with glyceryl trinitrate is also unclear.

OPTION INDORAMIN

One RCT found no significant difference between oral indoramin and placebo in fissure healing after 6 weeks, but may have been too small to detect a clinically important difference.

Benefits: We found no systematic review. **Versus placebo:** We found one small RCT (23 people with chronic anal fissures). It found no significant difference between oral indoramin (20 mg twice daily) and placebo for fissure healing at 6 weeks (AR for healing: 1/14 [7%] with indoramin *v* 2/9 [22%] with placebo; RR 0.30, 95% CI 0.03 to 3.05; see comment below).[18] The RCT did not provide comparative data between treatments for pain scores.

Harms: The RCT reported that indoramin caused adverse effects in 7/14 (50%) of people.[18]

Comment: The RCT was small and may have lacked adequate power to detect a clinically important difference. It found that the single fissure that healed with indoramin recurred after 3 months.[18]

OPTION BOTULINUM A TOXIN-HAEMAGGLUTININ COMPLEX (BOTULINUM A TOXIN-HC)

RCTs found that botulinum A toxin-haemagglutinin complex increased fissure healing at 2 months compared with placebo or topical glyceryl trinitrate 0.2%. Two RCTs found no significant difference between high dose and low dose botulinum A toxin-haemagglutinin complex in healing rates after 2–3 months. One RCT found that compared with botulinum A toxin-haemagglutinin complex, internal anal sphincterotomy increased fissure healing at 12 months. It also increased time taken to return to daily activities.

Benefits: **Versus placebo:** We found one systematic review (search date not reported, 1 RCT, 30 people with chronic idiopathic anal fissure).[7] The RCT identified by the review compared botulinum A toxin-haemagglutinin complex (see glossary, p 542) (botulinum A toxin-hc) (Botox preparation) versus placebo (saline) injection into the internal anal sphincter.[19] It found that botulinum A toxin-hc significantly increased healing rates (formation of a scar) after 2 months

compared with placebo (AR for healing: 11/15 [73%] with botulinum A toxin-hc *v* 2/15 [13%] with placebo; ARR 60%, 95% CI 25% to 95%; RR 5.5, 95% CI 1.5 to 21.0). **Versus topical glyceryl trinitrate (GTN):** We found one systematic review (search date not reported, 1 RCT, 50 people with chronic anal fissure).[7] The RCT identified by the review found that, after 2 months, botulinum A toxin-hc injection (20 U Botox preparation) significantly increased fissure healing rates compared with 6 weeks of treatment with 0.2% GTN (see glossary, p 542) (96% with botulinum A toxin-hc *v* 60% with GTN; P = 0.005).[20] **Different doses of botulinum A toxin-hc:** We found no systematic review. We found two RCTs.[21,22] The first RCT (50 people) found no significant difference between higher dose (40 U) and lower dose (20 U) botulinum A toxin-hc (Dysport preparation) in healing rates at 3 months (20/25 [80%] with higher dose *v* 19/25 [76%] with lower dose; RR 1.10, 95% CI 0.78 to 1.41).[21] The second RCT (150 people) compared lower dose botulinum A toxin-hc (20 U Botox preparation; re-treatment with 30 U for persistent fissure at 1 month) versus higher dose botulinum A toxin-hc (30 U; re-treatment with 50 U for persistent fissure at 1 month).[22] It found that higher dose botulinum A toxin-hc increased healing rates at 1 month compared with lower dose (65/75 [87%] with higher dose *v* 55/75 [73%] with lower dose; P = 0.04). It found no significant difference in healing rates at 2 months (72/75 [96%] healed with higher dose *v* 67/75 [89%] healed with lower dose; RR and CI values not reported; P reported as non-significant). **Versus internal anal sphincterotomy:** We found one RCT (111 people with symptoms for at least 2 months and internal anal sphincter visible in base of fissure).[23] It found that internal anal sphincterotomy (see glossary, p 542) significantly increased healing compared with botulinum A toxin-hc (about 0.3 U/kg) at 12 months (AR for healing: 47/50 [94%] with internal anal sphincterotomy *v* 46/61 [75%] with botulinum A toxin-hc). **Plus nitrates:** See botulinum A toxin-hc plus nitrates, p 540.

Harms:

Versus placebo or GTN: Two RCTs reported no adverse effects associated with the use of botulinum A toxin-hc.[19,20] Earlier pilot studies have reported complications associated with the use of botulinum A toxin-hc, including pain, bleeding, sepsis associated with injection, and faecal incontinence, in up to 7% of people.[24,25] **Different doses botulinum A toxin-hc:** One RCT comparing different doses of botulinum A toxin-hc found flatus incontinence in 6% of people for less than 2 weeks, and faecal incontinence in 4% of people for 1 week.[21] One RCT found that mild flatus incontinence was more common with higher versus lower dose botulinum A toxin-hc at 2 weeks after injection (5/75 [7%] with higher dose *v* 0/75 [0%] with lower dose; RR and CI values not reported).[22] **Versus internal anal sphincterotomy:** One RCT found that internal anal sphincterotomy significantly delayed return to daily activities compared with botulinum A toxin-hc (14.8 days with sphincterotomy *v* 1.0 day with botulinum A toxin-hc; P < 0.0001).[23] It also found that more people experienced complications after sphincterotomy than botulinum A toxin-hc injection (transient flatus incontinence in 7 cases and serious incontinence in 1 case with sphincterotomy *v* no incontinence with botulinum A toxin-hc).

Comment: Recurrent fissure may occur after treatment is discontinued. We found one non-randomised controlled trial (57 people with idiopathic anal fissure), which found that a higher dosage regimen (20 U Botox preparation) versus a lower dosage regimen (15 U Botox preparation) of botulinum A toxin-hc increased the proportion of people with healed fissures at 2 months (23/34 [68%] with high dose *v* 10/23 [43%] with low dose).[26]

OPTION BOTULINUM A TOXIN-HAEMAGGLUTININ COMPLEX (BOTULINUM A TOXIN-HC) PLUS NITRATES

We found no RCTs comparing botulinum A toxin-haemagglutinin complex plus nitrates versus placebo. One small RCT found that botulinum A toxin-haemagglutinin complex plus topical isosorbide dinitrate three times daily increased fissure healing at 6 weeks compared with botulinum A toxin-haemagglutinin complex alone. It found no significant difference at 8 or 12 weeks.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus botulinum A toxin-haemagglutinin complex (botulinum A toxin-hc) alone:** We found one RCT (30 people with anal fissures that had not healed with topical isosorbide dinitrate alone), which found that botulinum A toxin-hc (see glossary, p 542) injection (20 U) followed by topical isosorbide dinitrate (2.5 mg three times daily) significantly increased the proportion of people with healed anal fissures at 6 weeks compared with botulinum A toxin-hc injection alone (10/15 [67%] with botulinum A toxin-hc plus isosorbide dinitrate *v* 3/15 [20%] with botulinum A toxin-hc alone; ARI 47%, 95% CI 11% to 82%; RR 3.30, 95% CI 1.14 to 9.75; NNT 3, 95% CI 2 to 5).[27] It found no significant difference at 8 and 12 weeks after treatment (healing at 8 weeks: 11/15 [73%] with botulinum A toxin-hc plus isosorbide dinitrate *v* 9/15 [60%] with botulinum A toxin-hc alone; P value reported as non-significant; healing at 12 weeks: 11/15 [73%] with botulinum A toxin-hc plus isosorbide dinitrate *v* 10/15 [66%] with botulinum A toxin-hc alone; P value reported as non-significant).

Harms: The RCT did not report on harms.[27] See harms of botulinum A toxin-haemagglutinin complex, p 539.

Comment: The RCT was small and may have lacked power to detect statistically significant differences at 8 and 12 weeks.[27]

OPTION INTERNAL ANAL SPHINCTEROTOMY

One systematic review found no significant difference between internal anal sphincterotomy and anal stretch in persistence of fissures, and found that both procedures healed 70–95% of fissures. However, it found that anal stretch increased rates of flatus incontinence compared with internal anal sphincterotomy. The review found no significant difference between open and closed internal anal sphincterotomy in persistence of fissures. One RCT found no significant difference between internal anal sphincterotomy and anal advancement flap in patient satisfaction or fissure healing. Four RCTs have found that sphincterotomy improved fissure healing compared with topical glyceryl trinitrate after 6 weeks to 2

years. One RCT found that compared with botulinum A toxin-haemagglutinin complex, sphincterotomy increased fissure healing at 12 months. It also increased time taken to return to daily activities.

Benefits: **Versus anal stretch:** We found one systematic review (search date not reported; data pooled for end points of persistence of fissure and postoperative incontinence of flatus; 6 RCTs, 386 people), which compared internal anal sphincterotomy (see glossary, p 542) versus anal stretch (see glossary, p 542).[28] It found that both internal anal sphincterotomy and anal stretch healed 70–95% of fissures. The review found no significant difference between anal stretch and internal anal sphincterotomy in persistence of fissures (6 RCTs; RR 1.16, 95% CI 0.65 to 2.08; see comment below). **Open versus closed internal anal sphincterotomy:** The systematic review found no significant difference between open and closed internal anal sphincterotomy in persistence of fissures (2 RCTs; RR 1.61, 95% CI 0.28 to 9.28; see comment below).[28] **Versus topical glyceryl trinitrate:** See glossary, p 542. See benefits of topical glyceryl trinitrate, p 535. **Versus botulinum A toxin-hc:** See glossary, p 542. See benefits of botulinum A toxin-haemagglutinin complex, p 538. **Versus anal advancement flap:** We found no systematic review. We found one RCT (40 people), which found no significant difference between internal anal sphincterotomy and anal advancement flap (see glossary, p 542) in patient satisfaction or fissure healing at 3 months (patient satisfaction: 3/20 [15%] "dissatisfied", 11/20 [55%] "satisfied", 6/20 [30%] "excellent" with sphincterotomy *v* 3/20 [15%] "dissatisfied", 6/20 [30%] "satisfied", 11/20 [55%] "excellent" with anal advancement flap; P value not reported; fissures healed: 20/20 [100%] with sphincterotomy *v* 17/20 [85%] with anal advancement flap; P = 0.12).[29]

Harms: **Versus anal stretch:** The systematic review found that anal stretch significantly increased rates of flatus incontinence compared with internal anal sphincterotomy (4 RCTs; RR 6.63, 95% CI 2.06 to 21.3; see comment below).[28] **Open versus closed internal anal sphincterotomy:** The review found no significant difference between open versus closed lateral internal anal sphincterotomy in the risk of postoperative flatus incontinence (2 RCTs; RR 0.79, 95% CI 0.29 to 2.13; see comment below).[28] **Versus anal advancement flap:** In a single RCT (40 people), no person experienced incontinence after either anal sphincterotomy or after anal advancement flap.[27] **Versus topical glyceryl trinitrate:** See harms of topical glyceryl trinitrate, p 537. **Versus botulinum A toxin-hc:** See harms of botulinum A toxin-haemagglutinin complex, p 539.

Comment: Only two outcomes were considered by the systematic review: persistence of the fissure and flatus incontinence.[28] Other outcomes (e.g. complications related to wound healing) may be relevant. The review reported that, in contrast to the evidence from randomised studies, observational studies found that anal stretch

significantly increased rates of persistence of fissures compared with internal anal sphincterotomy in four retrospective studies (RR 1.89, 95% CI 1.28 to 2.81).[28] The possibility of lower rates of fissure healing with anal advancement flap than with anal sphincterotomy requires further investigation.

GLOSSARY

Anal advancement flap Edges of the fissure are excised and healthy anal mucosa is mobilised to cover the defect.

Anal stretch Traditionally index and middle fingers of each hand inserted into the anal canal and pulled in opposite directions, the stretch held for 1 minute.

Botulinum A toxin-haemagglutinin complex (botulinum A toxin-hc) A formulation of botulinum A toxin and haemagglutinin for injection. Different preparations are used at different doses for the same indication and the strength (in units) of one preparation may not be equivalent to that of another preparation labelled as containing the same number of units.

Internal anal sphincterotomy Incision in the internal anal sphincter either posteriorly or laterally, but more commonly laterally, and usually "tailored" to the length of the fissure.

Topical glyceryl trinitrate (GTN) Usually applied as 0.2–0.3% ointment.

Substantive changes

Topical glyceryl trinitrate Three RCTs added;[8,9,14] categorisation unchanged.

Botulinum A toxin-haemagglutinin complex One RCT added;[23] categorisation unchanged.

Key Messages

Treatments

- **Adjuvant antibiotics** One systematic review and one subsequent RCT in children and adults with simple or complicated appendicitis undergoing appendicectomy have found that prophylactic antibiotics reduce wound infections and intra-abdominal abscesses compared with no antibiotics. Subgroup analysis from the systematic review has found that antibiotics reduce the number of wound infections in children with complicated appendicitis compared with no antibiotics. However, subgroup analysis from the systematic review found no significant difference in the number of wound infections between antibiotics and no antibiotics in children with simple appendicitis. One subsequent RCT in children with simple appendicitis found no significant difference with antibiotic prophylaxis compared with no antibiotic prophylaxis in wound infections, but the RCT may have been too small to exclude a clinically important difference.
- **Laparoscopic surgery versus open surgery (in children)** One systematic review has found that, in children, laparoscopic surgery reduced the number of wound infections and the length of hospital stay compared with open surgery, but found no significant difference in postoperative pain, time to mobilisation, or proportion of intra-abdominal abscesses.
- **Antibiotics versus surgery** One small RCT in adults with suspected appendicitis found that conservative treatment with antibiotics reduced pain and morphine consumption for the first 10 days compared with appendicectomy. However, the RCT found that 35% of people treated with antibiotics were readmitted within 1 year with acute appendicitis and subsequently underwent appendicectomy.

- **Laparoscopic surgery versus open surgery (in adults)** One systematic review and one subsequent RCT have found that laparoscopic surgery in adults reduces wound infections, postoperative pain, duration of hospital stay, and time taken to return to work compared with open surgery. However, the systematic review found that laparoscopic surgery increased postoperative intra-abdominal abscesses compared with open surgery.
- **Open surgery versus no treatment** We found no RCTs comparing open surgery versus no surgery.
- **Stump inversion at open appendicectomy** One RCT found no significant difference between stump inversion and simple ligation in wound infection, length of hospital stay, or intra-abdominal abscesses. Another RCT found that stump inversion increased wound infections compared with simple ligation, but found no significant difference between groups for intra-abdominal abscesses or length of hospital stay.

DEFINITION Acute appendicitis is acute inflammation of the vermiform appendix.

INCIDENCE/ PREVALENCE The incidence of acute appendicitis is falling, although the reason for this is unclear. The reported lifetime risk of appendicitis in the USA is 8.7% in men and 6.7% in women,[1] and there are about 60 000 cases reported annually in England and Wales. Appendicitis is the most common surgical emergency requiring operation.

AETIOLOGY/ RISK FACTORS The cause of appendicitis is uncertain, although various theories exist. Most relate to luminal obstruction, which prevents escape of secretions and inevitably leads to a rise in intraluminal pressure within the appendix. This can lead to subsequent mucosal ischaemia, and the stasis provides an ideal environment for bacterial overgrowth. Potential causes of the obstruction are faecoliths, often because of constipation, lymphoid hyperplasia, or caecal carcinoma.[2]

PROGNOSIS The prognosis of untreated appendicitis is unknown, although spontaneous resolution has been reported in at least 1/13 (8%) episodes.[3] The recurrence of appendicitis after conservative management,[3,4] and recurrent abdominal symptoms in certain people,[5] suggests that chronic appendicitis and recurrent acute or subacute appendicitis may also exist.[6] The standard treatment for acute appendicitis is appendicectomy. RCTs comparing treatment with no treatment would be regarded as unethical. The mortality from acute appendicitis is less than 0.3%, rising to 1.7% after perforation.[7] The most common complication of appendicectomy is wound infection, occurring in 5–33% of cases.[8] Intra-abdominal abscess formation occurs less frequently, in 2% of appendicectomies.[9] A perforated appendix in childhood does not appear to have subsequent negative consequences on female fertility.[10]

AIMS OF INTERVENTION To reduce pain; prevent postoperative infection; shorten hospital stay; and hasten return to normal activity.

OUTCOMES Wound infection rates; intra-abdominal infection rates; postoperative pain; return of bowel function; return to normal activity; mortality.

METHODS *Clinical Evidence* search and appraisal October 2003.

QUESTION **What are the effects of medical treatment for acute appendicitis?**

OPTION **ANTIBIOTICS**

We found no RCTs comparing antibiotics versus placebo or no treatment. One small RCT in adults with suspected appendicitis found that conservative treatment with antibiotics reduced pain and morphine consumption for the first 10 days compared with appendicectomy. However, the RCT found that 35% of people treated with antibiotics were readmitted within 1 year with acute appendicitis and subsequently had an appendicectomy.

Benefits: **Versus no treatment:** We found no systematic review and no RCTs comparing antibiotics versus placebo or no treatment. **Versus surgery:** We found one RCT (40 adults with suspected appendicitis), which compared antibiotic treatment (iv cefotaxime 2 g twice daily plus tinidazole 800 mg/day for 2 days followed by oral ofloxacin 200 mg twice daily plus tinidazole 500 mg twice daily for 8 days) versus open appendicectomy.[4] It found that antibiotics significantly reduced pain in the period from 12 hours to 10 days after initiation of treatment compared with appendicectomy ($P < 0.01$; other data presented graphically) and significantly reduced morphine consumption ($P < 0.001$).

Harms: **Versus no treatment:** We found no systematic review and no RCTs. **Versus surgery:** The RCT (40 adults with suspected appendicitis) found that all people treated conservatively with antibiotics were discharged from hospital within 48 hours, except one who had surgery for generalised peritonitis after a perforation of the appendix 12 hours after randomisation to receive antibiotic treatment.[4] The RCT found that 7/20 (35%) people who received conservative management were readmitted with acute appendicitis and had an appendicectomy within 1 year (mean 7 months, range 3–12 months). The RCT found that there was one wound infection in the surgically treated group, and that no deaths occurred with either treatment.

Comment: Inclusion criteria for the RCT included typical symptoms and signs of acute appendicitis, such as positive findings on ultrasound, and raised neutrophil/C reactive protein levels on blood assays.

QUESTION **What are the effects of surgical treatment for acute appendicitis?**

OPTION **OPEN SURGERY**

We found no systematic review or RCTs of open surgery compared with no treatment. One RCT in adults with suspected appendicitis found that conservative treatment with antibiotics reduced pain and morphine consumption compared with appendicectomy for the first 10 days after starting treatment. However, it found that 35% of people treated with antibiotics were readmitted within 1 year with acute appendicitis and subsequently underwent appendicectomy.

Benefits: **Versus no treatment:** We found no systematic review or RCTs of open surgery versus no treatment. **Versus antibiotics:** See benefits of antibiotics, p 546.

Harms: **Versus no treatment:** We found no RCTs. **Versus antibiotics:** See harms of antibiotics, p 546.

Comment: Surgery is now a well established treatment. An RCT that compares open surgery versus no treatment is unlikely to be conducted due to ethical concerns.

OPTION LAPAROSCOPIC SURGERY VERSUS OPEN SURGERY

One systematic review and one subsequent RCT have found that laparoscopic surgery in adults reduces wound infections, postoperative pain, duration of hospital stay, and time taken to return to work compared with open surgery. However, the systematic review found that laparoscopic surgery increased postoperative intra-abdominal abscesses compared with open surgery. The review found that, in children, laparoscopic surgery reduced the number of wound infections and the length of hospital stay compared with open surgery, but found no significant difference in postoperative pain, time to mobilisation, or proportion of intra-abdominal abscesses.

Benefits: We found one systematic review (search date 2002)[11] and one subsequent RCT[12] comparing laparoscopic surgery versus open surgery. **In adults:** The systematic review found that laparoscopic surgery significantly reduced the number of wound infections compared with open surgery, but significantly increased the number of postoperative intra-abdominal abscesses (wound infections: 34 RCTs, 4324 adults; 86/2213 [4%] with laparoscopic surgery *v* 161/2111 [8%] with open surgery; OR 0.47, 95% CI 0.36 to 0.62; abscesses: 34 RCTs, 4373 adults; 41/2239 [2%] with laparoscopic surgery *v* 13/2134 [< 1%] with open surgery; OR 2.77, 95% CI 1.61 to 4.77).[11] The review also found that laparoscopic surgery significantly reduced pain on the first postoperative day, and reduced the length of hospital stay and time taken to return to work (reduction in pain measured using a 100 mm visual analogue scale: 8 mm, 95% CI 3 mm to 13 mm; reduction in length of hospital stay: 0.7 days, 95% CI 0.4 days to 1.0 days; reduction in time to return to work: 3 days, 95% CI 1 day to 5 days). The subsequent RCT (200 adults with suspected appendicitis) found that laparoscopic surgery significantly reduced pain on the second and seventh postoperative days compared with open surgery (pain assessed on a visual analogue scale [1 = no pain; 10 = unbearable pain]; mean pain score on day 2: 2.79 with laparoscopic surgery *v* 4.77 with open surgery, $P < 0.001$; mean pain score on day 7: 1.26 with laparoscopic surgery *v* 1.95 with open surgery, $P < 0.001$).[12] The RCT found that laparoscopic surgery significantly reduced the time to return to full activity compared with open surgery (15.85 days *v* 19.65 days, $P < 0.01$), although it found no significant difference in incidence of postoperative complications or in length of hospital stay between laparoscopic and open surgery (postoperative complications: 9/96 [9.4%] with laparoscopic surgery *v* 7/104 [6.7%] with open surgery, $P > 0.05$; length of hospital stay: 4.7 days with

laparoscopic surgery *v* 5.0 days with open surgery; difference stated as not significant). **In children:** The systematic review (5 RCTs, 436 children aged 1–16 years) found that laparoscopic surgery significantly reduced the number of wound infections and the length of hospital stay compared with open surgery (wound infections: 5 RCTs, 436 children; OR 0.22, 95% CI 0.08 to 0.61; difference in hospital stay: 1 RCT, difference of –0.7 days, 95% CI –1.1 days to –0.3 days).[11] The review found no significant difference between laparoscopic surgery and open surgery for intra-abdominal abscesses, in postoperative pain, and in the time to mobilisation (intra-abdominal abscesses: 5 RCTs, 436 children: 1/220 [0.45%] with laparoscopic appendicectomy *v* 1/216 [0.46%] with conventional appendicectomy; OR 1.00, 95% CI 0.06 to 16.50; postoperative pain: 2 RCTs, 124 children; difference in visual analogue scale –0.068 cm, 95% CI –0.797 cm to +0.660 cm; time to mobilisation: 1 RCT, 58 children; difference of –0.25 days, 95% CI –0.65 days to +0.15 days).

Harms: The review did not report any further data on harms.[11]

Comment: The systematic review included people with a clinical diagnosis of acute appendicitis and provided no information on preoperative imaging or the use of perioperative antibiotics.[11] Analyses were performed on an intention to treat basis. Studies reporting a negative appendicectomy (see glossary, p 551) rate of more than 50% were excluded. The number of trials looking specifically at paediatric practice is small and, as in the adult studies, not all outcomes were assessed in all trials. Most trials were unblinded and, in addition, heterogeneity was present in most analyses, although not for wound infections or intra-abdominal abscesses. The definition and reporting of additional operative or postoperative complications was inconsistent. One RCT included in the review subsequently presented results from a subset of 25 children aged 4–15 years with complicated appendicitis.[13] It found no significant difference between laparoscopic and open surgery in the length of hospital stay or time to return to normal activities. It found two major complications (one pelvic abscess and one entero-cutaneous fistula) in 13 people receiving laparoscopic surgery compared with no major complications in 12 people receiving open surgery. In the subsequent RCT, participants were required to stay in hospital for a minimum of 3 days.[12]

OPTION STUMP INVERSION AT OPEN APPENDICECTOMY

One RCT found no significant difference between stump inversion and simple ligation in wound infection, length of hospital stay, or intra-abdominal abscesses. Another RCT found that stump inversion increased wound infections compared with simple ligation, but found no significant difference between groups for intra-abdominal abscesses or length of hospital stay.

Benefits: We found no systematic review but found two RCTs.[14,15] The first RCT (735 people aged 14–91 years with complicated or simple appendicitis — see glossary, p 551) compared double invagination (purse string with Z stitch, 374 people) versus simple ligation of the

stump (361 people).[14] The RCT found no significance difference in wound infection, length of hospital stay, or intra-abdominal abscesses between double invagination and simple ligation (wound infection: 33/374 [8.8%] with double invagination *v* 30/361 [8.3%] with simple ligation; length of hospital stay: 4.6 days with double invagination *v* 4.9 days with simple ligation; intra-abdominal abscesses: 6/374 [1.6%] with double invagination *v* 2/361 [< 1%] with simple ligation). The second RCT (134 people aged 4–90 years) compared simple ligation versus double invagination.[15] The RCT found a significantly higher incidence of wound infection with double invagination compared with simple ligation but found no significant difference for intra-abdominal abscesses or length of hospital stay (wound infection: 4/55 [7.3%] with double invagination *v* 0/79 [0%] with simple ligation, P = 0.017; abscesses: 1 in each group; length of hospital stay: median 5 days for both groups).

Harms: In the two RCTs, postoperative adhesive ileus was seen more frequently in the double invagination groups (6/374 [1.6%] with double invagination *v* 1/361 [< 1%] with simple ligation, P < 0.05;[14] 1/55 [1.8%] with double invagination *v* 0/79 [0%] with simple ligation[15]). No other specific complications were documented.[14,15]

Comment: Increased complications after invagination are believed to be due to longer operative time. Both trials comment on potential caecal distortion after invagination of the appendix stump, which has mimicked caecal cancer on subsequent contrast imaging — a further potential hazard of stump invagination.[14,15]

QUESTION What are the effects of adjuvant treatments for acute appendicitis?

OPTION ADJUVANT ANTIBIOTICS

One systematic review and one subsequent RCT in children and adults with simple or complicated appendicitis undergoing appendicectomy have found that prophylactic antibiotics reduce wound infections and intra-abdominal abscesses compared with no antibiotics. Subgroup analysis from the systematic review has found that antibiotics reduce the number of wound infections in children with complicated appendicitis compared with no antibiotics. However, subgroup analysis from the systematic review found no significant difference in the number of wound infections between antibiotics and no antibiotics in children with simple appendicitis. One subsequent RCT in children with simple appendicitis found no significant difference with antibiotic prophylaxis compared with no antibiotic prophylaxis in wound infections, but the RCT may have been too small to exclude a clinically important difference.

Benefits: **Versus placebo or no treatment:** We found one systematic review (search date 2000, 44 RCTs or CCTs, 9298 adults and children having an appendicectomy with either simple appendicitis or complicated appendicitis — see glossary, p 551)[9] and one subsequent RCT, which compared antibiotic prophylaxis versus placebo or no prophylaxis.[16] The review found that perioperative systemic antibiotic prophylaxis significantly reduced wound infections and

intra-abdominal abscesses compared with no antibiotic prophylaxis (wound infections, 20 RCTs/CCTs: 287/4326 [7%] with antibiotics *v* 632/4317 [15%] with no antibiotics; OR 0.32, 95% CI 0.24 to 0.42; see comment below; intra-abdominal abscesses, 8 RCTs/CCTs: 16/2211 [< 1%] with antibiotics *v* 39/2257 [2%] with no antibiotics; OR 0.35, 95% CI 0.13 to 0.91).[9] Subgroup analysis found that, in people with simple appendicitis, antibiotic prophylaxis significantly reduced wound infections and intra-abdominal abscesses compared with no antibiotics (wound infections, 26 RCTs/CCTs: 113/2610 [4%] with antibiotics *v* 286/2707 [11%] with no antibiotics; OR 0.37, 95% CI 0.30 to 0.46; intra-abdominal abscesses, 8 RCTs/CCTs: 9/1433 [< 1%] with antibiotics *v* 22/1535 [1%] with no antibiotics; OR 0.46, 95% CI 0.23 to 0.94). A subgroup analysis in people with complicated appendicitis found that antibiotic prophylaxis significantly reduced wound infections but found no significant difference in intra-abdominal abscesses (wound infections, 24 RCTs/CCTs: 121/645 [19%] with antibiotics *v* 175/507 [35%] with no antibiotics; OR 0.28, 95% CI 0.21 to 0.38; intra-abdominal abscesses, 3 RCTs/CCTs: 3/262 [1%] with antibiotics *v* 4/205 [2%] with no antibiotics; OR 0.54, 95% CI 0.12 to 2.43). The review also found no significant difference in wound infections between topical antibiotics and placebo (52/339 [15%] with topical antibiotics *v* 61/340 [18%] with placebo; OR 0.77, 95% CI 0.49 to 1.23). **In children:** The systematic review (7 RCTs, 987 children aged 0–15 years with either simple or complicated appendicitis) found no significant difference between perioperative systemic antibiotic prophylaxis and no antibiotic prophylaxis in wound infections or intra-abdominal abscesses (wound infections: 23/548 [4%] with antibiotics *v* 34/542 [6%] with no antibiotics; OR 0.64, 95% CI 0.37 to 1.10; intra-abdominal abscesses: 1/142 [< 1%] with antibiotics *v* 5/141 [4%] with no antibiotics; OR 0.25, 95% CI 0.05 to 1.26; see comment below).[9] Subgroup analysis in children with simple appendicitis found no significant difference between treatments in wound infections, although in children with complicated appendicitis, antibiotic prophylaxis significantly reduced wound infections (simple appendicitis, 3 RCTs/CCTs: 7/347 [2%] with antibiotics *v* 8/357 [2%] with no antibiotics; OR 0.92, 95% CI 0.33 to 2.57; complicated appendicitis, 3 RCTs/CCTs: 5/134 [4%] with antibiotics *v* 15/119 [13%] with no antibiotics; OR 0.31, 95% CI 0.12 to 0.77). The subsequent RCT (108 children with simple appendicitis) compared three treatments: no antibiotic, one antibiotic dose (1 g ceftriaxone), and 5 days of regular antibiotics (1 g/day ceftriaxone).[16] The RCT reported that only one wound infection occurred, and this was in a child who received no antibiotics (other numerical data not provided).

Harms: Several harms have been considered in the benefits section. The review and RCT did not report any further data on harms.[9,16]

Comment: The systematic review did not distinguish between antibiotic regimens or between different antibiotic drugs.[9] These issues are being addressed in a systematic review to be published in the future. There were limited numbers of children in the systematic review and RCT; therefore, the results may lack statistical power.[9,16] The review

found insufficient data to provide subgroup analysis for numbers of intra-abdominal abscesses in children with either simple or complicated appendicitis.[9] The benefit of antibiotics for simple appendicitis in children is unclear. The review did not report on preoperative imaging studies.[9]

GLOSSARY

Complicated appendicitis Perforated or gangrenous appendicitis or the presence of a periappendicular abscess.

Simple appendicitis Clinically normal or inflamed appendix, in the absence of gangrene, perforation, or abscess around the appendix.

Negative appendicectomy Term used for an operation performed for suspected appendicitis, in which the appendix is found to be normal on histological evaluation.

Colonic diverticular disease

Search date June 2003

John Simpson and Robin Spiller

QUESTIONS

INTERVENTIONS

See glossary, p 560

Key Messages

Treatment for uncomplicated diverticular disease

- **Rifaximin (plus dietary fibre supplementation *v* dietary fibre supplementation alone)** One RCT in people with uncomplicated diverticular disease has found that rifaximin plus dietary fibre supplementation improved symptoms compared with dietary fibre supplementation alone after 12 months of treatment.
- **Bran and ispaghula husk** Two small RCTs found no consistent effect of bran or ispaghula husk compared with placebo on symptom relief after 12–16 weeks.
- **Elective surgery** We found no RCTs of elective open or laparoscopic colonic resection.
- **Lactulose** One small RCT found no significant difference between lactulose and a high fibre diet in self rated improvement after 12 weeks.
- **Methylcellulose** One small RCT found no significant difference between methylcellulose and placebo in mean symptom score after 3 months.

Treatment to prevent complications

- **Increased fibre intake** We found no RCTs of advice to consume a high fibre diet or of dietary fibre supplementation.
- **Mesalazine (after an attack of acute diverticulitis)** One methodologically flawed RCT provided insufficient evidence about effects of mesalazine compared with no treatment in people previously treated for an episode of acute diverticulitis.

Treatment for acute diverticulitis

- **Medical treatment** We found no RCTs comparing medical treatment versus placebo. One small RCT found no significant difference between intravenous cefoxitin and intravenous gentamicin plus intravenous clindamycin in rates of clinical cure. Observational studies in people with acute diverticulitis have found low mortality with medical treatment, but found that recurrence rates may be high.
- **Surgery (for diverticulitis complicated by generalised peritonitis)** We found no RCTs comparing surgery versus no surgery or versus medical treatment. One RCT found no significant difference in mortality between acute resection and transverse colostomy of the sigmoid colon. A second RCT found no significant difference in mortality between primary and secondary sigmoid colonic resection, but found that primary resection reduced rates of postoperative peritonitis and emergency reoperation. We found no RCTs comparing open versus laparoscopic surgery.

DEFINITION Colonic diverticula are mucosal out pouchings through the large bowel wall. They are often accompanied by structural changes (elastosis of the taenia coli, muscular thickening, and mucosal folding). They are usually multiple and occur most frequently in the sigmoid colon. If diverticula are associated with symptoms, then this is termed diverticular disease (see glossary, p 560).

INCIDENCE/ PREVALENCE In the UK, the incidence of diverticulosis (see glossary, p 560) increases with age; about 5% of people are affected in their fifth decade of life and about 50% by their ninth decade.[1] Diverticulosis is common in developed countries, although there is a lower prevalence of diverticulosis in Western vegetarians consuming a diet high in roughage.[2] Diverticulosis is almost unknown in rural Africa and Asia.[3]

AETIOLOGY/ RISK FACTORS There is an association between low fibre diets and diverticulosis of the colon.[3] Prospective observational studies have found that both physical activity and a high fibre diet are associated with a lower risk of developing diverticular disease.[4,5] One case control study found an association between the ingestion of non-steroidal anti-inflammatory drugs and the development of severe diverticular complications, including pericolic abscess, generalised peritonitis, bleeding, and fistula formation.[6] People in Japan, Singapore, and Thailand develop diverticula that affect mainly the right side of the colon.[7]

PROGNOSIS Symptoms will develop in 10–25% of people with diverticula at some point in their lives.[1] It is unclear why some people develop symptoms and some do not. Even after successful medical treatment of acute diverticulitis (see glossary, p 560) almost two thirds of people suffer recurrent pain in the lower abdomen.[8] Recurrent

diverticulitis is observed in 7–42% of people with diverticular disease, and after recovery from the initial attack, the calculated yearly risk of suffering a further episode is 3%.[9] About half of recurrences occur within 1 year of the initial episode and 90% occur within 5 years.[10] Complications of diverticular disease (perforation, obstruction, haemorrhage, and fistula formation) are each seen in about 5% of people with colonic diverticula when followed up for 10–30 years.[11] Intra-abdominal abscess formation may also occur.

AIMS OF INTERVENTION To reduce mortality, symptoms, and complications, with minimal adverse effects.

OUTCOMES Subjective gastrointestinal symptoms assessed by the use of validated questionnaires. Admission and readmission rates as a result of diverticular disease and its complications. Incidence of diverticulitis, haemorrhage, perforation, abscess, fistula formation, and mortality. Stool weight and transit time are surrogate outcomes.

METHODS *Clinical Evidence* search and appraisal June 2003.

QUESTION **What are the effects of treatments for uncomplicated diverticular disease?**

OPTION **BRAN AND ISPAGHULA HUSK**

Two RCTs in people with uncomplicated diverticular disease found no consistent effect of bran or ispaghula husk compared with placebo on symptom relief after 12–16 weeks.

Benefits: **Versus placebo:** We found no systematic review, but found two RCTs comparing fibre supplements versus placebo.[12,13] The first RCT (76 people with uncomplicated diverticular disease [see glossary, p 560], no other gastrointestinal disorders, and no prior abdominal operations) compared three treatments: bran crispbread (6.99 g/day fibre); ispaghula husk drink (a bulk forming laxative; 9.04 g/day fibre); and placebo (2.34 g/day fibre).[12] It found no significant differences among treatments for pain score, lower bowel symptom score (combination of the pain score and sensation of incomplete emptying, straining, stool consistency, flatus, and aperients taken), or total symptom score (including nausea, vomiting, dyspepsia, belching, and abdominal distension; see comment below) after 16 weeks. The RCT also found that both active treatments significantly reduced straining at stool, increased wet stool weight and stool frequency, and significantly softened the stools after 16 weeks compared with placebo (straining: bran *v* placebo, $P < 0.01$; ispaghula husk *v* placebo, $P < 0.001$; wet stool weight: both active treatments *v* placebo, $P < 0.001$; stool frequency: both active treatments *v* placebo, $P < 0.001$; stool softening: both active treatments *v* placebo, $P < 0.001$; CI not reported for any comparisons). The second RCT (18 people with symptoms of diverticular disease and radiologically confirmed diverticula and no other colonic disorder) compared bran crispbread (6.7 g/day fibre) versus placebo crispbread (0.6 g/day fibre).[13] It found that bran crispbread significantly improved total symptom score (RR and CI not provided; $P < 0.002$) and pain score (RR and CI not reported; $P < 0.02$), but found no significant difference in the scores for

bowel dysfunction (passage of excessive flatus, need to strain, frequency of evacuation, consistency of motion, presence of anal pain on defecation, feeling of incomplete evacuation, presence of blood or mucus, use of laxatives) or dyspeptic symptoms (nausea, vomiting, heartburn, belching, and abdominal distension) after 3 months.

Harms: No significant adverse effects were reported in the RCTs.[12,13]

Comment: In the first RCT, 18/76 (24%) people withdrew from the trial and analysis of data was not by intention to treat.[12] The RCT did not specify the exact number of people receiving each treatment, precluding calculations of relative risk and confidence interval. People in both RCTs had been investigated to exclude coexisting abdominal pathology but the extent of the investigations was not stated.[12,13] Both studies were small in size, of short duration, and the difference in fibre content between control and treatment interventions was also small. Both treatment and control groups improved during the RCTs. One further RCT has been identified and is awaiting translation.[14]

OPTION METHYLCELLULOSE

One small RCT in people with uncomplicated diverticular disease found no significant difference between methylcellulose and placebo in symptom scores at 3 months.

Benefits: We found no systematic review but found one RCT (30 people with symptomatic diverticular disease [see glossary, p 560] and no other gastrointestinal disease) that compared methylcellulose (500 mg twice daily) versus placebo.[15] It found no significant difference between treatments on mean symptom score after 3 months (see comment below; mean symptom score 13.0 with methylcellulose *v* 16.7 with placebo; difference in means –3.7, 95% CI –8.9 to +1.5).

Harms: None reported.

Comment: The RCT used a categorical scale for several different symptoms where 1 = mild and 6 = severe.[15] The score used to assess symptoms and signs was not described clearly, but included barium enema results. The RCT was small, of short duration, and both the methylcellulose and placebo treatments were associated with an improvement in symptom scores. Diverticular disease was confirmed by barium enema but the extent of other investigations to exclude comorbidity was not stated.

OPTION LACTULOSE

One small RCT in people with uncomplicated diverticular disease found no significant difference between lactulose and a high fibre diet in self rated improvement after 12 weeks.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus high fibre diet:** We found one RCT (43 people with diverticular disease [see glossary, p 560] and no other abdominal pathology) comparing lactulose (15 mL twice daily) versus a high fibre diet

(30–40 g/day fibre).[16] It found no significant difference in the proportion of people who reported their symptoms to be much improved after 12 weeks (see comment below; 7/20 [35%] with lactulose *v* 9/21 [43%] with high fibre diet; RR 0.80, 95% CI 0.34 to 1.77).

Harms: The RCT found a non-significant increase in the risk of new symptoms with high fibre diet compared with lactulose (12/21 [57%] with high fibre diet *v* 9/20 [45%] with lactulose; RR 1.30, 95% CI 0.70 to 2.34).[16] The symptoms were described as minor but no further details were provided. The RCT found that 2/20 (10%) people taking lactulose withdrew from the trial because of symptoms: one with abdominal pain and one with nausea.

Comment: Although "much improved" was used as an outcome by the RCT, this term was not defined clearly.[16] People were investigated to exclude coexisting abdominal pathology but the extent of the investigations was not stated.

OPTION ANTIBIOTICS (RIFAXIMIN)

One RCT in people with uncomplicated diverticular disease has found that rifaximin plus dietary fibre supplementation improved symptoms compared with dietary fibre supplementation alone after 12 months of treatment.

Benefits: We found no systematic review but found one RCT.[17] The RCT (168 people with uncomplicated diverticular disease [see glossary, p 560]) compared dietary fibre supplementation (glucomannan 2 g/day) plus oral rifaximin (see glossary, p 560) (400 mg twice daily) versus dietary fibre supplementation (glucomannan 2 g/day) plus placebo. Both treatments were given for 7 days each month for 1 year (see comment below). The RCT found that dietary fibre supplementation plus rifaximin significantly increased the proportion of people with no symptoms or only mild symptoms after 12 months of treatment (69% with rifaximin *v* 39% with placebo; P = 0.001; results presented graphically; absolute numbers not provided). The RCT found no significant difference between treatments in the severity of diarrhoea, tenesmus, or upper abdominal pain (absolute data and significance testing not reported).

Harms: The RCT did not report on harms.[17]

Comment: The RCT reported that 17/168 (10%) people did not complete the trial, although analysis was not by intention to treat.[17] For each treatment group, 2/84 (2%) people were withdrawn because of acute diverticulitis (see glossary, p 560).

OPTION ELECTIVE SURGERY

We found no RCTs of elective open or laparoscopic colonic resection in people with uncomplicated diverticular disease.

Benefits: We found no systematic review or RCTs.

Harms: We found no data on harms of elective surgery in people with diverticular disease (see glossary, p 560).

Comment: None.

QUESTION **What are the effects of treatments to prevent complications of diverticular disease?**

OPTION ADVICE TO INCREASE FIBRE INTAKE

We found no RCTs examining complication rates after advice to consume a high fibre diet or dietary fibre supplementation.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: Fibre is often used with the aim of preventing complications in people with diverticular disease (see glossary, p 560) because observational studies have found that the disease is less frequent in populations with high fibre intake (see incidence/prevalence, p 553).

OPTION MESALAZINE

One methodologically flawed RCT provided insufficient evidence about effects of mesalazine compared with no treatment in people previously treated for an episode of acute diverticulitis.

Benefits: We found no systematic review. One RCT (166 people previously treated for an episode of mild/moderate diverticulitis) compared 8 weeks of treatment with oral mesalazine (400 mg twice daily) versus no treatment.[18] People in both groups had received intramuscular sulbactam–ampicillin (1.5 g twice daily) and oral rifaximin (see glossary, p 560) (400 mg twice daily) for 7 days before randomisation. The RCT found that mesalazine reduced symptomatic recurrence at 4 years compared with no treatment (12/81 [15%] with mesalazine *v* 39/85 [46%] with no treatment; RR 0.32, 95% CI 0.18 to 0.57; NNT 4, 95% CI 3 to 6).[18] See comment below.

Harms: The RCT found that abdominal pain was more common with mesalazine than no treatment (13/81 [16%] with mesalazine *v* 4/85 [5%] with no treatment; RR 3.40, 95% CI 1.16 to 10.00; NNH 8, 95% CI 4 to 70).[18]

Comment: The RCT provided insufficient information on several factors.[18] The recurrence of inflammation was diagnosed according to unspecified clinical and laboratory criteria. Methods for determining symptom scores, including the assessment and diagnosis of pain were not reported. Forty four people did not complete the study, but there was no difference in withdrawal rate between groups (3 people died; 9 people had a severe complication of diverticular disease [see glossary, p 560], and 33 were withdrawn because of "poor" adherence to treatment [poor adherence was not defined]).[18] One non-randomised controlled trial (218 people with at least 2 episodes of acute diverticulitis [see glossary, p 560] in the previous year, 193 analysed) compared treatment with rifaximin (400 mg twice daily for 7 days followed by 400 mg twice daily for 7 days/month) plus mesalazine (800 mg three times daily for 7 days followed by 800 mg twice daily for 7 days/month) versus rifaximin

alone (400 mg twice daily for 7 days followed by 400 mg twice daily for 7 days/month).[19] It found that rifaximin plus mesalazine significantly increased the proportion of people who were symptom free at 12 months compared with rifaximin alone (89/104 [86%] with rifaximin plus mesalazine *v* 44/89 [49%] with rifaximin alone, $P < 0.0005$).

QUESTION **What are the effects of treatments for acute diverticulitis?**

OPTION **MEDICAL TREATMENT**

We found no RCTs comparing medical treatment versus placebo in people with acute diverticulitis. One small RCT found no significant difference between intravenous cefoxitin and intravenous gentamicin plus intravenous clindamycin in rates of clinical cure. Observational studies in people with acute diverticulitis have found low mortality with medical treatment, but found that recurrence rates may be high.

Benefits: We found no systematic review. **Versus placebo:** We found no RCTs. **Versus other medical treatments:** We found one RCT (51 people with a clinical diagnosis of acute diverticulitis (see glossary, p 560) who did not need immediate surgery) that compared intravenous cefoxitin (1–2 g every 6 hours) with intravenous gentamicin (1.7 mg/kg loading dose followed by 1.0–1.4 mg/kg every 8 hours) plus intravenous clindamycin (total dose of 2400–2700 mg/day in 3 or 4 equal doses).[20] It found no significant difference in clinical cure rate (see comment below; 27/30 [90%] with cefoxitin *v* 18/21 [86%] with gentamicin plus clindamycin; RR 1.10, 95% CI 0.85 to 1.30).

Harms: In the RCT, toxicity (possibly antibiotic related) occurred with both treatments, although the proportion of people affected was not significantly different between treatments (2/30 [7%] with cefoxitin *v* 3/21 [14%] with gentamicin plus clindamycin; RR 0.47, 95% CI 0.09 to 2.56).[20]

Comment: Clinical cure was defined as complete resolution of symptoms and signs associated with diverticulitis plus discharge from hospital without recurrence for at least 6 weeks or plus having had an elective surgical procedure with primary anastomosis in the absence of colostomy without septic complications.[20] We found many observational studies of medical treatment for acute diverticulitis, with variable follow up periods (1–12 years), which consistently report low mortality (0–5%).[9,21–23] These observational trials also reported that 7–42% of people treated medically suffer recurrent episodes of acute diverticulitis.

OPTION **SURGERY**

We found no RCTs comparing surgery with no surgery or with medical treatment. One RCT found no significant difference in mortality between acute resection and transverse colostomy of the sigmoid colon. A second RCT found no significant difference in mortality between primary and

secondary sigmoid colonic resection, but found that primary resection reduced rates of postoperative peritonitis and emergency reoperation. We found no RCTs comparing open versus laparoscopic surgery.

Benefits: We found no systematic review. **Surgery versus placebo or medical treatment:** We found no RCTs. **Comparison of types of open surgery:** We found two RCTs.[24,25] Both were small and may have lacked power to detect clinically important effects. The first RCT (62 people with diffuse peritonitis complicating perforated acute diverticulitis [see glossary, p 560] of the left colon; median age 72 years) compared acute sigmoid colonic resection (see glossary, p 560) versus no acute resection (acute transverse colostomy, suture, and omental covering of a visible perforation).[24] The RCT found no significant difference between acute sigmoid colonic resection and no acute resection in mortality within 30 days (mortality: 8/31 [26%] with acute resection *v* 6/31 [19%] with no acute resection; RR 1.30, 95% CI 0.52 to 3.39). However, subgroup analysis of people with purulent peritonitis (46 people) found that acute sigmoid colonic resection significantly increased postoperative mortality compared with no acute resection (6/25 [24%] with acute resection *v* 0/21 [0%] with no acute resection; ARI 24.0%, 95% CI 4.5% to 44.0%). Subgroup analysis of people with faecal peritonitis (16 people) found no significant difference between acute sigmoid colonic resection and no acute resection in postoperative mortality (2/6 [33%] with acute resection *v* 6/10 [60%] with no acute resection; RR 0.60, 95% CI 0.16 to 1.92; see comment below). This subgroup analysis probably lacked power to detect a clinically important difference. The second RCT (105 people with generalised peritonitis complicating sigmoid diverticulitis; mean age 66 years) compared primary versus secondary sigmoid colonic resection.[25] Primary resection involved surgical removal of the affected sigmoid colon plus either formation of an end colostomy, or formation of a primary colorectal anastomosis with or without a proximal defunctioning colostomy (see glossary, p 560). Secondary resection involved initial closing of any visible bowel perforations plus the formation of a defunctioning colostomy. A second (definitive) procedure was then undertaken at a later date to perform a sigmoid colon resection plus a colorectal anastomosis with or without a defunctioning colostomy. The RCT found that primary sigmoid colonic resection significantly reduced rates of postoperative peritonitis after the initial procedure and significantly reduced rates of emergency reoperation compared with secondary sigmoid colonic resection (postoperative peritonitis: 1/55 [2%] with primary resection *v* 10/44 [23%] with secondary resection; RR 0.09, 95% CI 0.01 to 0.70; NNT 5, 95% CI 3 to 12; emergency reoperation: 2/55 [4%] with primary resection *v* 9/48 [19%] with secondary resection; RR 0.19, 95% CI 0.04 to 0.90; NNT 7, 95% CI 4 to 35). The RCT found no significant difference between treatments in mortality (13/55 [24%] with primary resection *v* 9/48 [19%] with secondary resection; RR 1.30, 95% CI 0.60 to 2.70; see comment below). **Open surgery versus laparoscopic surgery:** We found no RCTs.

Harms: The first RCT found no significant difference between acute resection and no acute resection in rates of cardiopulmonary complications, thromboembolism, mental confusion, or other complications

including wound dehiscence, wound infection but no dehiscence, intraperitoneal abscess formation, ileus, colo-cutaneous fistula, and revision of colostomy (cardiopulmonary complications: 13/31 [42%] with acute resection *v* 14/31 [45%] with no acute resection; RR 0.90, 95% CI 0.53 to 1.63; thromboembolism: 3/31 [9.7%] with acute resection *v* 5/31 [16%] with no acute resection; RR 0.60, 95% CI 0.16 to 2.30; mental confusion: 4/31 [13%] with acute resection *v* 4/31 [13%] with no acute resection; RR 1.00, 95% CI 0.27 to 3.65).[24] The second RCT found no significant difference between treatments in rates of wound complications, extra-abdominal septic complications, or extra-abdominal non-septic complications (wound complications: 20/55 [36%] with primary resection *v* 23/48 [48%] with secondary resection; RR 0.80, 95% CI 0.48 to 1.20; extra-abdominal septic complications: 11/55 [20%] with primary resection *v* 12/48 [25%] with secondary resection; RR 0.80, 95% CI 0.39 to 1.65; extra-abdominal non-septic complications: 26/55 [47%] with primary resection *v* 21/48 [44%] with secondary resection; RR 1.08, 95% CI 0.71 to 1.65).[25]

Comment: The first RCT was conducted in a single centre and took 14 years to recruit 62 people.[24] The second RCT was conducted in 17 centres and took 7 years to recruit 105 people.[25] Both studies were small and may have lacked power to detect a significant difference between treatments. The high complication rates reported are not surprising in predominantly elderly people after a perforation of the large bowel. The wide spectrum of presentation and operative treatment options for acute complicated diverticulitis makes RCTs difficult to perform.

GLOSSARY

Acute diverticulitis This condition occurs when a diverticulum becomes acutely inflamed. There may be general symptoms and signs of infection (including fever and rapid heart rate) with or without local symptoms and signs (pain and localised tenderness, usually in the lower left abdomen, sometimes with a mass that can be felt on abdominal or rectal examination).

Acute sigmoid colonic resection Immediate resection of the sigmoid colon, involving end colostomy of the proximal bowel and creating a mucus fistula with the distal bowel or oversewing the rectal stump.

Defunctioning colostomy Stoma created to divert fecal flow, such that feces no longer flows through the anus.

Diverticular disease This term is used to describe diverticula associated with any symptoms.[26] Symptoms commonly include abdominal pain and alteration in bowel habit. Diverticular disease may be complicated by abscess formation, fistulae, perforation, obstruction, or haemorrhage.

Diverticulosis The presence of diverticula that are asymptomatic. Most people with sigmoid colonic diverticula have no symptoms.

Rifaximin A rifamycin antibacterial drug with antimicrobial actions similar to those of rifampicin. It is marketed predominantly in Italy.

Substantive changes

Mesalazine (after an attack of acute diverticulitis) Categorisation changed from Trade off between benefits and harms to Unknown effectiveness after re-evaluating the evidence.

QUESTIONS

INTERVENTIONS

See glossary, p 568

Key Messages

- **Adjuvant chemotherapy** Three systematic reviews and one subsequent RCT have found that adjuvant chemotherapy reduces mortality compared with surgery alone in people with Dukes' A, B, and C colorectal cancer. One RCT found that adding levamisole to adjuvant fluorouracil did not significantly reduce mortality or recurrence compared with adjuvant fluorouracil alone in people with Dukes' A, B, and C colorectal cancer. One RCT found that mortality and recurrence rates were similar with adjuvant fluorouracil plus high or low dose folinic acid in people with Dukes' A, B, and C colorectal cancer.
- **Routine intensive follow up** One systematic review and one subsequent RCT have found that intensive follow up increases survival compared with less intensive follow up in people treated surgically with curative intent.
- **Preoperative radiotherapy** Two systematic reviews and two subsequent RCTs found that adding preoperative radiotherapy to surgery is at least as effective as surgery alone for mortality and recurrence in people with rectal cancer. One RCT found no significant difference in mortality between preoperative and postoperative radiotherapy but preoperative radiotherapy reduced local tumour recurrence. One systematic review has found that preoperative radiotherapy increases early postoperative morbidity.
- **Total mesorectal excision** We found no RCTs of total mesorectal excision in people with rectal cancer. Observational studies suggest that total mesorectal excision may reduce the rate of local recurrence compared with conventional surgery.

DEFINITION Colorectal cancer is a malignant neoplasm arising from the lining (mucosa) of the large intestine (colon and rectum). Nearly two thirds of colorectal cancers occur in the rectum or sigmoid colon. Colorectal cancer may be categorised as A, B, or C Dukes' (see glossary, p 568).

INCIDENCE/ PREVALENCE Colorectal cancer is the third most common malignancy in the developed world. It accounts for about 20 000 deaths each year in the UK and 60 000 deaths each year in the USA. Although the incidence of, and mortality from, colorectal cancer has changed little over the past 40 years, the incidence of the disease has fallen recently in both the UK and the USA.[1,2] In the UK, about a quarter of people with colorectal cancer present with either intestinal obstruction or perforation.[3,4]

AETIOLOGY/ RISK FACTORS Colon cancer affects almost equal proportions of men and women, most commonly between the ages of 60 and 80 years. Rectal cancer is more common in men.[1] The pathogenesis of colorectal cancer involves genetic and environmental factors. The most important environmental factor is probably diet.[5]

PROGNOSIS Overall 5 year survival is about 50% and has not changed over the past 40 years. Disease specific mortality in both USA and UK cancer registries is decreasing but the reasons for this are unclear.[1,2] Surgery is undertaken with curative intent in over 80% of people, but about half experience cancer recurrence.

AIMS OF INTERVENTION To reduce morbidity (e.g. bowel obstruction or perforation) and mortality associated with the tumour; to minimise adverse effects of treatment (e.g. avoiding permanent stoma by restoring intestinal continuity); to maximise quality of life.

OUTCOMES Survival; proportion of people with permanent stoma; incidence of local recurrence; rates of metastasis; adverse effects of treatment; quality of life.

METHODS *Clinical Evidence* search and appraisal December 2002.

QUESTION What are the effects of treatments?

OPTION ADJUVANT CHEMOTHERAPY

Three systematic reviews and one subsequent RCT have found that adjuvant chemotherapy reduces mortality compared with surgery alone in people with Dukes' A, B, and C colorectal cancer. One RCT found that adding levamisole to adjuvant fluorouracil did not significantly reduce mortality or recurrence rate compared with adjuvant fluorouracil alone in people with Dukes' A, B, and C colorectal cancer. One RCT found mortality and recurrence rates were similar with adjuvant fluorouracil plus high or low dose folinic acid in people with Dukes' A, B, and C colorectal cancer.

Benefits: **Versus placebo or no treatment:** We found three systematic reviews[6–8] and one subsequent RCT.[9] The first systematic review (search date 1993, 39 RCTs, 1673 people with Dukes' C colon cancer and 695 with Dukes' B or C rectal cancer [see glossary, p 568]) has found that adjuvant chemotherapy significantly reduces mortality after 5 years compared with surgery alone (OR 0.91, 95%

CI 0.83 to 0.99).[6] The second systematic review (search date not stated, 10 RCTs, 3088 people with Dukes' A, B, or C colorectal cancer) compared 1 week of portal vein infusion of fluorouracil with or without mitomycin–C within 5–7 days of surgery versus no further treatment after surgery.[7] It found that portal vein infusion of fluorouracil significantly reduces mortality compared with surgery alone (absolute reduction in 5 year mortality 6%; P = 0.01). The third systematic review (search date not stated, 7 RCTs, 3437 people with Dukes' B or C colorectal cancer) compared adjuvant treatment with intravenous fluorouracil (plus leucovorin or levamisole) versus surgery alone.[8] It found that adjuvant fluorouracil based treatment significantly reduces mortality and significantly increases the number of people without recurrence at 5 years: 71% with fluorouracil based treatment *v* 64% with surgery alone; HR 0.76, 95% CI 0.68 to 0.85; recurrence free rate: 69% with fluorouracil based treatment *v* 58% with surgery alone; HR 0.68, 95% CI 0.60 to 0.76). The subsequent RCT (1029 people with Dukes' B or C colorectal cancer) compared adjuvant fluorouracil plus levamisole for 1 year versus surgery alone.[9] It found that adding fluorouracil and levamisole reduces mortality compared with surgery alone at 5 years (AR of survival 68% with fluorouracil based treatment *v* 58% with surgery alone; P = 0.007). **Fluorouracil plus levamisole versus fluorouracil alone:** We found one RCT (4927 people with Dukes' A, B, or C colorectal cancer and no residual disease after surgery), which compared chemotherapy with levamisole plus intravenous fluorouracil and folinic acid versus intravenous fluorouracil and folinic acid alone.[10] It found no significant difference in mortality or recurrence rate after 3 years (mortality: OR 1.10, 95% CI 1.00 to 1.22; recurrence: OR 1.00, 95% CI 0.97 to 1.13). **Low versus high dose folinic acid:** We found one RCT (4927 people with Dukes' A, B, or C colorectal cancer and no residual disease after surgery), which compared high dose folinic acid with low dose folinic acid in people given intravenous fluorouracil.[10] It found no significant difference in mortality or recurrence rate after 3 years (mortality: OR 1.04, 95% CI 0.94 to 1.15; recurrence: OR 1.00, 95% CI 0.91 to 1.09).

Harms: We found little good evidence on the harms of adjuvant chemotherapy in the treatment of colorectal cancer. In the first systematic review, the incidence of severe adverse effects (stomatitis, diarrhoea, nausea, and leukopenia) with fluorouracil and levamisole ranged from 10–30%, with life threatening toxicity occurring in about 5% of people.[6] For every 10 people treated, about three will experience an additional, severe adverse effect.[10,11]

Comment: In the UK, people aged over 75 years are not routinely considered for chemotherapy because of its potential toxicity, although we found no evidence to support or refute this policy.

OPTION PREOPERATIVE RADIOTHERAPY IN PEOPLE WITH RECTAL CANCER

Two systematic reviews and two subsequent RCTs found that adding preoperative radiotherapy to surgery is at least as effective as surgery alone for mortality and recurrence in people with rectal cancer. One RCT

found no significant difference in mortality between preoperative and postoperative radiotherapy. However, it found that preoperative radiotherapy reduces local tumour recurrence. One systematic review has found that preoperative radiotherapy increases early postoperative morbidity.

Benefits:

Versus surgery alone: We found two systematic reviews[12,13] and two subsequent RCTs.[14,15] The first systematic review (search date 1999, 14 RCTs, 5974 people with rectal cancer) has found that preoperative radiotherapy significantly reduces mortality and local recurrence at 5 years compared with no preoperative radiotherapy (mortality: OR 0.84, 95% CI 0.72 to 0.98, NNT 25; local recurrence: 11 RCTs, 4494 people, OR 0.49, 95% CI 0.38 to 0.62, NNT 10).[12] It found no significant difference in risk of distant metastases at 5 years (OR 0.93, 95% CI 0.73 to 1.18). The second systematic review (search date not stated, 19 RCTs, 6623 people with rectal cancer) found no significant difference in annual death rates between preoperative radiotherapy and no preoperative radiotherapy (RR 0.94; P = 0.09; CI not reported).[13] The first subsequent RCT (1861 people) compared preoperative radiotherapy plus total mesorectal excision versus total mesorectal excision alone.[14] It found that radiotherapy did not reduce mortality or overall recurrence rate at 2 years (mortality: HR 1.02, 95% CI 0.83 to 1.25; recurrence: 16% with radiotherapy *v* 21% with surgery alone; HR 1.21, 95% CI 0.97 to 1.52). The second subsequent RCT (557 people) found no significant difference between radiotherapy and surgery in mortality or distant metastasis. However, the RCT found that radiotherapy significantly reduced local recurrence after 10 years compared with surgery (mortality: HR 0.87, 95% CI 0.71 to 1.08; distant metastasis: HR 0.97, 95% CI 0.73 to 1.28; local recurrence: 0.46, 95% CI 0.31 to 0.69).[15] **Versus postoperative radiotherapy:** We found one RCT (415 people with Dukes' [see glossary, p 568] B or C rectal carcinoma), which compared preoperative radiotherapy (25.5 Gy in 1 week) with postoperative radiotherapy (60.0 Gy over 7–8 weeks).[16] It found no significant difference in 5 year survival. However, it found that preoperative radiotherapy significantly reduces local tumour recurrence after 5 years (survival: P = 0.5; results presented graphically; absolute numbers not provided; local recurrence: 13% with preoperative *v* 22% with postoperative radiotherapy; RR 0.59, 95% CI 0.37 to 0.91; NNT 11, 95% CI 7 to 49).

Harms:

Versus surgery alone: We found one systematic review (search date 1998, 19 RCTs, 5110 people) of harms associated with preoperative adjuvant radiotherapy.[17] It found that preoperative radiotherapy increased early postoperative morbidity and mortality. Early harms included diarrhoea, wound infections (20% with preoperative radiotherapy *v* 10% with surgery alone), bowel obstruction, cardiovascular problems, and pain. In people with low rectal tumours who underwent abdominoperineal excision, preoperative radiotherapy versus surgery alone increased the rate of perineal wound breakdown (20% *v* 10%). Two RCTs (1027 people) identified by the review found that preoperative radiotherapy compared with surgery alone significantly increased the risk of venous thromboembolism, fracture of the hip, intestinal obstruction, postoperative

fistulae, cardiovascular events, and thrombotic events.[18] One observational study (171 people) found that preoperative radiotherapy increased bowel frequency and urgency, impairing social life in about 30% of people compared with surgery.[19] One RCT (1531 people) found that preoperative radiotherapy increased perioperative blood loss and perineal complications compared with surgery alone, but it found no significant difference in perioperative mortality (mean perioperative blood loss 100 mL greater with radiotherapy; perineal complication rate 29% *v* 18%; P = 0.008).[20]
Versus postoperative radiotherapy: We found one systematic review (search date 1998, 9 RCTs) of harms associated with preoperative versus postoperative radiotherapy.[17] It found that postoperative radiotherapy increased anastomotic complications (breakdown and stricture formation) compared with preoperative radiotherapy.

Comment: There is limited evidence of modest improvement in survival following preoperative radiotherapy compared with surgery alone for rectal cancer. There is some evidence of an improvement in local recurrence but the risk of local recurrence for Dukes' A tumours is so low that preoperative radiotherapy is unlikely to provide much absolute benefit. There are unresolved issues about preoperative staging of rectal cancers and case selection for preoperative radiotherapy.

OPTION ROUTINE INTENSIVE FOLLOW UP

One systematic review and one subsequent RCT has found that intensive follow up increases survival compared with less intensive follow up in people treated surgically with curative intent.

Benefits: We found one systematic review and one subsequent RCT.[21,22] The systematic review (search date 2001, 5 RCTs, 1342 people with colorectal cancer treated surgically with curative intent) found that intensive follow up significantly reduced all cause mortality and time to detection of recurrence, and increased detection rates for isolated local recurrence compared with control follow up (5 year mortality: 197/666 [30%] with intensive follow up *v* 247/676 [37%] with control follow up; RR 0.81, 95% CI 0.70 to 0.94; difference in mean time until detection of any recurrence with intensive *v* control follow up 8.5 months, 95% CI 7.6 months to 9.4 months, P < 0.001; RR for local recurrence, 3 RCTs: 1.61, 95% CI 1.12 to 2.32).[21] The subsequent RCT (358 people with no distant metastases treated surgically with curative intent alone) compared minimal surveillance versus a follow up programme guided by formal assessment of risk of recurrence (risk adapted follow up; see comment).[22] The RCT found that risk adapted follow up significantly improved overall survival at 5 years compared with minimal follow up (actuarial survival at 5 years in people at high risk: 50% with risk adapted follow up *v* 32% with minimal follow up, P < 0.05; in people at low risk: 80% with risk adapted follow up *v* 60% with minimal follow up, P < 0.01).[22]

Harms: We found no evidence about harms.

Comment: One RCT (212 people being followed up after treatment for colorectal cancer) included in the review found that follow up increased feelings of reassurance but not quality of life.[23] Most people in the trial said that they would still prefer follow up even if it did not lead to earlier detection of recurrence. Current follow up regimens are variable in frequency and intensity. We found no evidence on whether follow up should be stopped in elderly people (aged > 75 years), although many people with colorectal cancer are in this age group. The role of carcino-embryonic antigen monitoring is also uncertain. In the RCT assessing risk adapted follow up, rules for follow up in the risk adapted group depended on baseline risk factors.[22] People who had signs of recurrence underwent more sophisticated tests (flexible colonoscopy, barium enema, urography, computed tomography, and nuclear magnetic resonance). Within this group, people at high risk of recurrence underwent intensive follow up with clinical visits and carcino-embryonic antigen tests every 3 months for the first 24 months; every 4 months in year 3, and every 6 months in years 4 and 5. People at high risk also received abdominal and pelvic ultrasound every 6 months for the first 36 months and annually in years 4 and 5, and received chest x ray annually for 5 years. People at high risk and with rectal cancer also received rigid rectosigmoidoscopy. People at low risk of recurrence had low intensity follow up with clinical visits and carcino-embryonic antigen tests every 6 months for the first 24 months then annually in years 3 to 5; abdominal and pelvic ultrasound every 6 months for the first 24 months and annually thereafter, annual chest x ray and, in people with rectal cancer, rigid rectosigmoidoscopy annually for 2 years then every 2 years thereafter and annual chest x ray.

OPTION TOTAL MESORECTAL EXCISION IN PEOPLE WITH RECTAL CANCER

We found no RCTs of total mesorectal excision in people with rectal cancer. Observational studies suggest that total mesorectal excision may reduce the rate of local recurrence compared with conventional surgery.

Benefits: We found no systematic review or RCTs.

Harms: After total mesorectal excision (see glossary, p 568) more people experienced increased stool frequency compared with techniques leaving a rectal stump (median 4–5 daily *v* 1–2 daily). Observational studies have found that there is a higher incidence of anastomotic leakage with total mesorectal excision (11–15% *v* 8–10%).[24]

Comment: One observational study (441 people) compared local recurrence rates before and after the introduction of total mesorectal excision (see table 1, p 570).[25] It found that local recurrence rates 1 year after surgery fell after the introduction of total mesorectal excision (4% before total mesorectal excision *v* 9% after). Several other observational studies have found similar results (see table 1, p 570).[24,26,27] Total mesorectal excision requires coloanal anastomosis, which may be important in the surgical treatment of rectal cancer.[25,26,28] Many surgeons routinely use a temporary defunctioning stoma after total mesorectal excision in an attempt to reduce the clinical consequences of anastomotic leakage.[25]

GLOSSARY

Dukes' classification Dukes' original classification of the pathological stages of carcinoma of the colon and rectum includes three stages: A, limited to mucosa and submucosa; B, penetration of the entire bowel wall and serosa or pericolic fat; C, stages A and B, and invasion into the regional draining lymph node system.[29] More recently, stage D has been proposed to classify patients with advanced and widespread regional involvement (metastasis).

Total mesorectal excision Removal of the entire rectal mesentery along with the rectum by sharp dissection.

QUESTIONS

INTERVENTIONS

Key Messages

- **Macrogols** Three RCTs identified by a systematic review found that macrogols (polyethylene glycols) improved symptoms after 2–20 weeks compared with placebo. One RCT provided insufficient evidence to compare macrogol 3350 versus ispaghula husk. One systematic review found that macrogol 3350 improved global satisfaction and the frequency of bowel movements at 4 weeks compared with lactulose.
- **Ispaghula husk (psyllium)** One RCT identified by a systematic review found that ispaghula husk increased the frequency of bowel movements and improved overall symptoms compared with placebo after 2 weeks. We found limited evidence from two RCTs that ispaghula husk improved symptoms compared with lactulose at 4 weeks. One RCT provided insufficient evidence to compare ispaghula husk versus macrogol 3350. One RCT found no clinically important difference between ispaghula husk and docusate in frequency of bowel movements, stool consistency, straining, or pain after 2 weeks.

Constipation in adults

- **Lactulose** We found limited evidence from two RCTs that lactulose improved symptoms compared with placebo. We found limited evidence from two RCTs that lactulose was less effective in improving symptoms at 4 weeks than ispaghula husk. Three RCTs identified by systematic reviews compared lactulose versus lactitol and found different results. Two RCTs found no significant difference in effectiveness at 2–4 weeks and one RCT found that lactulose was less effective than lactitol in increasing bowel movement frequency at 2 weeks. One RCT identified by a systematic review found that lactulose was less effective than macrogol 3350 in improving global satisfaction and the frequency of bowel movements at 4 weeks.
- **Bran** We found no RCTs of sufficient quality comparing bran versus placebo in adults with idiopathic chronic constipation.
- **Docusate** One systematic review identified no RCTs of sufficient quality comparing docusate versus placebo. One RCT identified by a systematic review found that docusate was less effective than ispaghula husk in increasing the frequency of bowel movements after 2 weeks. It found no significant difference between treatments in stool consistency, straining, or pain.
- **Lactitol** One small crossover RCT identified by a systematic review found that lactitol increased the frequency of bowel movements compared with placebo after 4 weeks. Three RCTs identified by systematic reviews compared lactitol versus lactulose and found different results. Two RCTs found no significant difference in frequency of bowel movements at 2–4 weeks and one RCT found that lactitol increased frequency of bowel movements at 2 weeks compared with lactulose.
- **Bisacodyl; dantron; glycerol/glycerin suppositories; lifestyle advice; magnesium salts; paraffin; phosphate enemas; picosulphate/picosulfate; seed oils/arachis oil; senna; sodium citrate enemas** We found no RCTs in adults with idiopathic chronic constipation.

DEFINITION Bowel habits and perception of bowel habit vary widely within and among populations, making constipation difficult to define strictly. The Rome II criteria (see glossary, p 581) is a standardised tool which diagnoses chronic constipation on the basis of two or more of the following symptoms for at least 12 weeks in the preceding year: straining at defecation on at least a quarter of occasions; stools that are lumpy/hard on at least a quarter of occasions; sensation of incomplete evacuation on at least a quarter of occasions; and three or fewer bowel movements a week.[1] In practice, however, diagnostic criteria are less rigid and are in part dependent on perception of normal bowel habit. Typically, chronic constipation might be diagnosed when a person has bowel actions twice a week or less, for two consecutive weeks, especially in the presence of features such as straining at stool, abdominal discomfort, and sensation of incomplete evacuation. In this chapter, we have included all RCTs that stated that all participants had chronic constipation. Where the definitions of constipation in the RCTs differ markedly from those presented here, we have made this difference explicit. In this chapter, we deal with chronic constipation that is not caused by a specific underlying disease (sometimes known as idiopathic constipation) in adults aged over 18 years. We have excluded studies in pregnant women and in people with constipation associated with underlying specific organic diseases such as autonomic neuropathy, spinal cord injury, bowel obstruction, and paralytic ileus.

INCIDENCE/ PREVALENCE Twelve million general practitioner prescriptions were written for laxatives in England in 2001.[2] Prevalence data are limited by small samples and problems with definition. One UK survey of 731 women found that 8.2% had constipation meeting Rome II criteria, and 8.5% defined themselves as being constipated.[3] A larger survey (1892 adults) found that 39% of men and 52% of women reported straining at stool on more than a quarter of occasions.[4] Prevalence rises in the elderly. Several surveys from around the world suggest that in a community setting, prevalence among the elderly is about 20%.[4–7]

AETIOLOGY/ RISK FACTORS One systematic review found that factors associated with increased risk of constipation included low fibre diet, low fluid intake, reduced mobility, and consumption of drugs such as opioids and anticholinergic antidepressants.[8]

PROGNOSIS Untreated constipation may lead to faecal impaction, particularly in elderly and confused people.[9] Constipation has been suggested as a risk factor for haemorrhoids and colorectal cancer, but evidence of causality is lacking.[9]

AIMS OF INTERVENTION To relieve symptoms of constipation, to restore normal bowel habit, and to improve quality of life, with minimal adverse effects.

OUTCOMES Symptoms (frequency of bowel movements, straining at defecation, hard/lumpy stools, sensation of incomplete evacuation/tenesmus); use of laxatives; cure of constipation (based on Rome II criteria or self or practitioner's report).

METHODS *Clinical Evidence* search and appraisal April 2003.

QUESTION What are the effects of lifestyle advice in adults with idiopathic chronic constipation? New

OPTION LIFESTYLE ADVICE

We found no RCTs of lifestyle advice in adults with idiopathic chronic constipation.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION What are the effects of bulking agents in adults with idiopathic chronic constipation? New

OPTION BRAN

We found no RCTs of sufficient quality comparing bran versus placebo in adults with idiopathic chronic constipation.

Benefits: **Versus placebo:** We found one systematic review (search date 1995), which identified no RCTs of sufficient quality.[10] We found no subsequent RCTs.

Harms: The systematic review gave no information on adverse effects.[10]

Comment: None.

OPTION ISPAGHULA HUSK (PSYLLIUM)

One RCT identified by a systematic review found that ispaghula husk increased the frequency of bowel movements and improved overall symptoms compared with placebo after 2 weeks. We found limited evidence from two RCTs that ispaghula husk improved symptoms compared with lactulose at 4 weeks. One RCT provided insufficient evidence to compare ispaghula husk versus macrogol 3350. One RCT found no clinically important difference between ispaghula husk and docusate in frequency of bowel movements, stool consistency, straining, or pain after 2 weeks.

Benefits: We found two systematic reviews (search dates 1995[10] and 2001[8]). **Versus placebo:** The second review[8] found one RCT (201 people, mean 2.3 bowel movements/week, mean age 49 years, 183 completed the trial). The RCT found that 3.6 g ispaghula husk three times daily significantly increased the frequency of bowel movements after 2 weeks compared with placebo (median bowel movements/week: 7.0 with ispaghula *v* 4.5 with placebo, $P < 0.05$; abdominal pain/discomfort better: 21/35 [60%] with ispaghula *v* 12/26 [46%] with placebo, $P = 0.035$).[11] It also assessed symptoms of straining and constipation as "better", "the same", or "worse" than baseline. It found that, compared with placebo, ispaghula husk significantly increased the proportion of people whose symptoms were "better" (straining "better": 59/70 [84%] with ispaghula *v* 36/63 [57%] with placebo, $P = 0.003$; self assessment that constipation was "better": 90/101 [89%] with ispaghula *v* 46/95 [48%] with placebo; $P < 0.001$). **Versus lactulose:** The earlier systematic review[10] identified one RCT.[12] The RCT (112 outpatients, mean age 50 years) found that 3.5 g ispaghula twice daily significantly increased the frequency of bowel movements after 4 weeks compared with 15 mL lactulose twice daily (7.8 with ispaghula *v* 6.6 with lactulose; $P < 0.05$).[12] It found that a similar proportion of people had straining at stool (no straining: 21/45 [47%] with ispaghula *v* 15/48 [31%] with lactulose; P value not reported) and clinical improvement (defined by practioner's report of overall clinical impression of symptom severity; much improved on Clinical Global Improvement score: 29/45 [64%] with ispaghula *v* 33/48 [69%] with lactulose; P value not reported).[12] The second review[8] identified one RCT.[13] The RCT (394 people presenting to their general practitioner with constipation; 90% had constipation > 7 days) compared 3.5 g ispaghula husk twice daily (224 people) versus other laxatives chosen at the discretion of the general practitioner (170 people, of whom 91 received lactulose).[13] Constipation was defined on the basis of self report of perceived reduction in bowel frequency or difficulty in passing stool over the previous week. Subgroup analysis found that the proportion of movements with hard stools was lower with ispaghula husk than with lactulose at 4 weeks (18% with ispaghula *v* 27% with lactulose; P value not reported). **Versus macrogols:** The second systematic review[8] identified one RCT published only as an abstract (120

people in hospital, mean age 50 years). It found that 13.7 g macrogol 3350 plus electrolytes twice daily significantly increased "overall effectiveness" compared with 3.5 g ispaghula twice daily at 2 weeks (92% with macrogol 3350 *v* 73% with ispaghula; P = 0.005). "Overall effectiveness" was not defined in the review and no further details were available.[8] **Versus docusate:** The second review[8] identified one RCT (170 people, mean age 37 years). It found that 5.1 g ispaghula husk twice daily significantly increased the frequency of bowel movements per week compared with 100 mg sodium docusate twice daily after 2 weeks' treatment (bowel movements: 3.50/week with ispaghula *v* 2.87/week with docusate; P = 0.02). It found no significant difference in frequency of bowel movements, stool consistency, straining, or pain (stool consistency: P = 0.29; straining: P = 0.15; pain: P = 0.12).[8] The difference in frequency of bowel movements was small and is likely to be of little clinical importance.

Harms: **Versus placebo:** The review gave no information on adverse effects.[10] **Versus lactulose:** One RCT identified by the earlier review[10] found that fewer people had soiling at the time of the first bowel motion with ispaghula husk than with lactulose (soiling: 2.1% with ispaghula *v* 8.3% with lactulose; P value not reported).[13] It found that fewer people had abdominal pain over 4 weeks with ispaghula than with lactulose (weeks 1–2: 32% with ispaghula *v* 41% with lactulose; weeks 3–4: 15% with ispaghula *v* 22% with lactulose; P value not reported). **Versus macrogols:** The review gave no information on adverse effects.[8] **Versus docusate:** The review gave no information on adverse effects.[8]

Comment: Reported adverse effects of ispaghula include flatulence, abdominal distension, and a feeling of bloating. However, we were unable to estimate reliably the frequency of these effects.

QUESTION What are the effects of stool softeners in adults with idiopathic chronic constipation? New

OPTION PARAFFIN

We found no RCTs of paraffin in adults with idiopathic chronic constipation.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: Paraffin reduces absorption of fat soluble vitamins (vitamins A, D, E, and K). However, we found no reliable evidence to measure the risk of vitamin deficiency with paraffin in people with chronic constipation.

OPTION SEED OILS/ARACHIS OIL

We found no RCTs of seed oils or arachis oil in adults with idiopathic chronic constipation.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: Arachis oil is derived from peanuts, and is therefore contraindicated in people with peanut allergy.

QUESTION What are the effects of osmotic laxatives in adults with idiopathic chronic constipation? New

OPTION LACTITOL

One small crossover RCT identified by a systematic review found that lactitol increased the frequency of bowel movements compared with placebo after 4 weeks. Three RCTs identified by systematic reviews compared lactitol versus lactulose and found different results. Two RCTs found no significant difference in frequency of bowel movements at 2–4 weeks and one RCT found that lactitol increased frequency of bowel movements at 2 weeks.

Benefits: **Versus placebo:** We found one systematic review (search date 1996,[9] 1 crossover RCT,[14] 43 people recruited in nursing homes passing ≤ 3 bowel movements/week, mean age 84 years). The RCT found that 20 g lactitol four times daily significantly increased the number of bowel movements compared with placebo in the third and fourth week of treatment before crossover (absolute numbers presented graphically; $P < 0.001$).[14] **Versus lactulose:** We found two systematic reviews (search date 1996,[9] search date 2001[8]), which between them identified three RCTs (see comment below). The first RCT (60 people in nursing homes, mean age 79 years) found that 15 g lactitol daily significantly increased the number of bowel movements at 2 weeks compared with 15 mL lactulose daily (5.5/week with lactitol *v* 4.9/week with lactulose; $P = 0.0001$).[9] The second RCT (61 people, mean age 54 years) found no significant difference between lactitol (20 g/day for 3 days then 10 g/day) and lactulose (30 mL syrup [20.1 g]/day for 3 days then 20 mL syrup [13.4 g]/day) in frequency of bowel movements over 4 weeks (6.7/week with lactitol *v* 7.4/week with lactulose; P value reported as non-significant).[8] The third RCT (60 people taking laxatives, mean age 60 years) found no significant difference between lactitol (mean dose 20 g/day) and lactulose 20 mL syrup daily in frequency of bowel movement at 2 weeks (6.09/week with lactitol *v* 5.53/week with lactulose; $P > 0.05$).[8]

Harms: **Versus placebo:** The review gave no information on adverse effects.[9] **Versus lactulose:** The second RCT found that lactitol significantly reduced the proportion of people with adverse effects compared with lactulose (10/32 [31%] with lactitol *v* 16/26 [62%] with lactulose; $P = 0.02$).[8] The third RCT found no significant difference between lactitol and lactulose in adverse events or other symptoms (bloating, flatulence, nausea, cramping, or diarrhoea).[8]

Comment: **Versus lactulose:** Further details may be available in *Clinical Evidence* when we have translated the second and third RCTs into English.[15,16]

OPTION LACTULOSE

We found limited evidence from two RCTs that lactulose improved symptoms compared with placebo. We found limited evidence from two RCTs that lactulose was less effective in improving symptoms at 4 weeks than ispaghula husk. Three RCTs identified by systematic reviews compared lactulose versus lactitol and found different results. Two RCTs found no significant difference in effectiveness at 2–4 weeks and one RCT found that lactulose was less effective than lactitol in increasing bowel movement frequency at 2 weeks. One RCT identified by a systematic review found that lactulose was less effective than macrogol 3350 in improving global satisfaction and the frequency of bowel movements at 4 weeks.

Benefits: We found three systemaic reviews that included trials of lactulose (search dates 1995,[10] 1996,[9] and 2001[8]). **Versus placebo:** Between them the reviews identified four RCTs. The first RCT (24 recruited outpatients, mean age 28 years) found that high dose lactulose (60 mL four times/day) significantly increased the frequency of bowel movements compared with placebo after 1 week (4.5/week with lactulose *v* 2.8/week with placebo; $P < 0.05$).[10] The second RCT (47 people in a nursing home, mean age 85 years, 42 analysed) found that lactulose (30 mL four times/day) significantly reduced five symptoms (cramping, griping, flatulence, tenesmus, and bloating) compared with placebo at 12 weeks ($P = 0.04$). It found no significant difference in the number of bowel movements (4.9/week with lactulose *v* 3.6/week with placebo; $P = 0.10$).[9] The third RCT (103 people, mean age > 60 years) did not report on our outcomes of interest.[9] For a description of the fourth RCT, see comment below. **Versus ispaghula husk:** See benefits of ispaghula husk, p 574. **Versus lactitol:** See benefits of lactitol, p 576. **Versus macrogols:** The most recent review[8] identified one RCT[17] (115 people passing < 3 stools/week, straining at stool, or both). The RCT found that lactulose 20 g daily was significantly less effective than macrogol 3350 26 g daily in increasing the number of weekly bowel movements (0.9 with lactulose *v* 1.3 with macrogol 3350; $P = 0.005$), easing stool evacuation (scored as 0 for easy to 4 for very difficult: absolute mean score: 1.0 with lactulose *v* 0.5 with macrogol 3350; $P < 0.001$), and improving global satisfaction at 1 month (satisfaction scored as 0 for terrible–10 for excellent: 5.2 with lactulose *v* 7.4 with macrogol 3500; $P < 0.001$).[17]

Harms: **Versus placebo:** The reviews gave no information on adverse effects.[9,10] **Versus ispaghula husk:** See harms of ispaghula husk, p 575. **Versus lactitol:** See harms of lactitol, p 576. **Versus macrogols:** The RCT found one adverse event (depression) leading to withdrawal with lactulose compared with two adverse events (acute diarrhoea) with macrogol 3350.[17] It found that macrogol 3350 increased the frequency of liquid stools compared with lactulose over 4 weeks (mean number of loose stools over 4 weeks: 2.4 with macrogol 3350 *v* 0.6 with lactulose; $P = 0.001$).

Comment: **Versus placebo:** The most recent review[8] also identified one crossover RCT,[18] but it was not clear whether results were reported before the crossover. The RCT (55 people) compared lactulose

versus placebo in a crossover design with 4 week treatment periods and a 2 week washout. It found that 30 mL lactulose significantly improved complete or partial treatment success compared with placebo (23/29 [79%] with lactulose *v* 17/26 [65%] with placebo; $P < 0.01$). More detailed results may be available when this RCT is translated.[18]

OPTION MACROGOLS (POLYETHYLENE GLYCOLS)

Three RCTs identified by a systematic review found that macrogols (polyethylene glycols) improved symptoms after 2–20 weeks compared with placebo. One RCT provided insufficient evidence to compare macrogol 3350 versus ispaghula husk. One systematic review found that macrogol 3350 improved global satisfaction and the frequency of bowel movements at 4 weeks compared with lactulose.

Benefits:

Versus placebo: We found one systematic review (search date 2001,[8] 3 RCTs[19–21]). The first RCT identified by the review (70 adults aged 18–73 years meeting Rome diagnostic criteria for chronic constipation [see glossary, p 581] who had previously received a 4 week course of macrogol 4000 14.6 g twice daily) found that continued macrogol 4000 (14.6 g twice daily) significantly increased the proportion of people who were "asymptomatic" at 20 weeks compared with placebo (70% with macrogol 4000 *v* 20% with placebo; $P < 0.001$).[19] "Asymptomatic" was defined as three bowel movement or more a week, no use of laxatives, no straining at defecation, feeling of complete evacuation, and no hard/pellet-like stools. Analysis did not seem to be by intention to treat; significantly more people taking macrogol 4000 completed the trial (70% with macrogol 4000 *v* 30% with placebo; $P < 0.01$).[19] The second RCT identified by the review (151 chronically constipated people with ≤ 2 bowel movements during the 7 day run in period, mean age 47 years, 144 analysed) found that 17 g of macrogols significantly increased the frequency of bowel movements and increased the number of satisfactory bowel movements (defined by self report) compared with dextrose placebo after 14 days (number of bowel movements in week 2: 4.5 with macrogols *v* 2.7 with placebo, $P < 0.001$; satisfactory bowel movements: 68% with macrogols *v* 46% with placebo, $P < 0.001$).[20] The third RCT identified by the review (55 people with < 2 bowel movements a week for > 12 months, mean age 42 years, 48 people analysed) compared twice daily macrogols versus placebo.[21] It found that macrogols significantly increased the number of bowel movements per week, and decreased straining at defecation compared with placebo at 8 weeks (bowel movements/week: 4.8 with macrogols *v* 2.8 with placebo, $P < 0.002$; marked straining: 8% with macrogols *v* 41% with placebo; $P < 0.03$).[21] **Versus ispaghula husk:** See benefits of ispaghula husk, p 574. **Versus lactulose:** See benefits of lactulose, p 576.

Harms:

Versus placebo: The first RCT identified by the review found no significant difference between macrogol 4000 and placebo in adverse events (number of events; nausea 22 with macrogol *v* 17 with placebo; vomiting: 1 event in each group; anal pain: 5 with macrogol *v* 0 with placebo; presence of fresh blood in stool [indicating damage to anorectal mucosa]: 7 with macrogol *v* 2 with placebo; epigastric pain/discomfort: 13 with macrogol *v* 16 with

placebo).[19] The second RCT identified by the review found no significant difference between macrogols and placebo in adverse events.[20] The third RCT in the review found no significant difference in abdominal symptoms at 8 weeks between macrogols and placebo (abdominal pain: 24% with macrogols *v* 35% with placebo; abdominal bloating: 48% with macrogols *v* 70% with placebo; flatulence: 20% with macrogols *v* 39% with placebo; borborygmi: 32% with macrogols *v* 13% with placebo; P values not reported).[21]
Versus ispaghula husk: See harms of ispaghula husk, p 575.
Versus lactulose: See harms of lactulose, p 576.

Comment: None.

OPTION MAGNESIUM SALTS

We found no RCTs of magnesium salts in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PHOSPHATE ENEMAS (RECTAL PHOSPHATES)

We found no RCTs of phosphate enemas in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION SODIUM CITRATE ENEMAS (RECTAL SODIUM CITRATE)

We found no RCTs of sodium citrate enemas in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

QUESTION What are the effects of stimulant laxatives in adults with idiopathic chronic constipation? New

OPTION BISACODYL

We found no RCTs of bisacodyl in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION DANTRON

We found no RCTs of dantron in adults with idiopathic chronic constipation. Animal studies have suggested that dantron may be carcinogenic. Its use is, therefore, recommended only in people who are terminally ill.

Benefits: We found no systematic review and no RCTs (see comment below).

Harms: We found no RCTs.

Comment: Animal studies have suggested that dantron may be carcinogenic. Its use is, therefore, recommended only in people who are terminally ill.

OPTION DOCUSATE

One systematic review identified no RCTs of sufficient quality comparing docusate versus placebo. One RCT identified by a systematic review found that docusate was less effective than ispaghula husk in increasing the frequency of bowel movements after 2 weeks. It found no significant difference between treatments in stool consistency, straining, or pain.

Benefits: **Versus placebo:** We found one systematic review (search date 1995) that identified no RCTs of sufficient quality.[10] **Versus ispaghula husk:** See benefits of ispaghula husk, p 574.

Harms: **Versus placebo:** The review gave no information on adverse effects.[10] **Versus ispaghula husk:** See harms of ispaghula husk, p 575.

Comment: None.

OPTION GLYCEROL/GLYCERIN SUPPOSITORIES

We found no RCTs of glycerol/glycerin suppositories in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION SENNA

We found no RCTs of the effects of senna in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION PICOSULPHATE (PICOSULFATE)

We found no RCTs of picosulphate in adults with idiopathic chronic constipation.

Benefits: We found no systematic review and no RCTs (see comment below).

Harms: We found no RCTs.

Comment: Picosulphate is a powerful stimulant laxative. Use is usually restricted to people with severe constipation or to clear the bowel of stool before surgery or radiological or endoscopic investigation.

GLOSSARY

Rome II criteria (updated 1999) Rome criteria for constipation require two or more of the following symptoms to be present for at least 12 weeks out of the preceding 12 months: straining at defecation on at least a quarter of occasions; stools are lumpy/hard on at least a quarter of occasions; sensation of incomplete evacuation on at least a quarter of occasions; and three or fewer bowel movements a week.[1]

Gastro-oesophageal reflux disease

Search date July 2003

Paul Moayyedi, Brendan Delaney, and David Forman

QUESTIONS

INTERVENTIONS

Key Messages

Initial treatment

- **H_2 receptor antagonists** One systematic review has found that H_2 receptor antagonists reduce the risk of persisting oesophagitis compared with placebo, but are not as effective as proton pump inhibitors.
- **Proton pump inhibitors** One systematic review, one additional RCT, and one subsequent RCT found that proton pump inhibitors increase healing compared with placebo or H_2 receptor antagonists. One systematic review found that esomeprazole 40 mg daily increased healing at 4 weeks compared with omeprazole 20 mg daily. RCTs have found no significant differences in clinical benefit among other proton pump inhibitors.
- **Antacids/alginates** Two RCTs provided limited evidence that antacids reduced symptom scores at 4–8 weeks compared with placebo, but neither found a significant difference in endoscopic healing. We found limited evidence on the effects of antacids compared with H_2 receptor antagonists. The first RCT found no significant difference between antacids compared with cimetidine in endoscopic healing at 8 weeks. The second RCT found that antacids were less effective for heartburn symptoms compared with ranitidine at 12 weeks.

Gastro-oesophageal reflux disease

- **Lifestyle advice** Small RCTs provided insufficient evidence on the effects of raising the head of the bed or weight loss for the treatment of reflux oesophagitis. We found no RCTs on the effects of reducing coffee intake, stopping smoking, reducing alcohol intake, or reducing fatty food intake.
- **Motility stimulants** One RCT found that cisapride increased endoscopic healing compared with placebo at 12 weeks. The use of cisapride has been restricted in some countries because of concerns about heart rhythm abnormalities. We found no RCTs of domperidone or metoclopramide.

Maintenance treatment

- **Proton pump inhibitors** RCTs have found that proton pump inhibitors reduce relapse in people with healed reflux oesophagitis compared with placebo or H_2 receptor antagonist at 6–18 months. One systematic review has found that standard dose lansoprazole (30 mg/day) was as effective as omeprazole (20 mg/day) for maintaining healing at 12 months. However, the systematic review and one subsequent RCT provided evidence that lower dose lansoprazole (15 mg/day) was less effective than higher dose lansoprazole (30 mg/day), omeprazole, or esomeprazole for maintaining healing for up to 12 months.
- **Laparoscopic surgery** One systematic review found no fully published RCTs comparing laparoscopic surgery versus medical treatment for maintenance of remission. Two RCTs found no significant difference between open and laparoscopic fundoplication for remission at 3 months to 2 years. One RCT found that laparoscopic treatment was associated with surgical complications, although the rate was lower than with open surgery.
- **Open surgery** RCTs have found that open Nissen fundoplication compared with medical treatment improved the endoscopic grade of oesophagitis in people with chronic gastro-oesophageal reflux disease and oesophagitis at between 3 and 38 months. However, longer term follow up from one of these RCTs found no significant difference in endoscopic appearance between surgery and medical treatment at 10 years. Two RCTs found no significant difference between open and laparoscopic fundoplication for remission at 3 months to 2 years. One RCT found that mortality was higher with open surgery than with medical treatment. One RCT found that complication rates were higher with open than with laparoscopic surgery.
- **Antacids/alginates** We found no RCTs on the effects of antacids/alginates on the long term management of reflux oesophagitis.
- **H_2 receptor antagonists** One RCT found no significant difference between ranitidine and placebo for relapse of oesophagitis at 6 months in people with previously healed reflux oesophagitis. RCTs have found that H_2 receptor antagonists are less effective than proton pump inhibitors for maintaining remission up to 12 months.
- **Lifestyle advice** We found no RCTs on the effects of lifestyle advice on the long term management of reflux oesophagitis.
- **Motility stimulants** Three RCTs have found that cisapride compared with placebo improved maintenance of healing at 6–12 months. Two further RCTs found no evidence of a difference, but they might have lacked power to detect a clinically significant effect. The use of cisapride has been restricted in some countries because of concerns about effects on heart rhythms. We found no RCTs comparing other prokinetic drugs with placebo or each other in people with gastro-oesophageal reflux disease and oesophagitis.

DEFINITION Gastro-oesophageal reflux disease (GORD) is defined as reflux of gastroduodenal contents into the oesophagus, causing symptoms that are sufficient to interfere with quality of life.[1] People with GORD

often have symptoms of heartburn and acid regurgitation.[2] GORD can be classified according to the results of upper gastrointestinal endoscopy. Currently the most validated method is the Los Angeles classification, where an endoscopy showing mucosal breaks in the distal oesophagus indicate the presence of oesophagitis, which is graded in severity from grade A (mucosal breaks of < 5 mm in the oesophagus) to grade D (circumferential breaks in the oesophageal mucosa).[1,3] Alternatively, severity may be graded according to the Savary–Miller classification (grade I: linear, non-confluent erosions, to grade IV: severe ulceration or stricture).

INCIDENCE/ PREVALENCE Surveys from Europe and the USA suggest that 20–25% of the population have symptoms of GORD, and 7% have heartburn daily.[4,5] In primary care settings, about 25–40% of people with GORD have oesophagitis on endoscopy, but most have endoscopy negative reflux disease.[3]

AETIOLOGY/ RISK FACTORS We found no evidence of clear predictive factors for GORD. Obesity is reported to be a risk factor for GORD but epidemiological data are conflicting.[6,7] Smoking and alcohol are also thought to predispose to GORD, but observational data are limited.[7,8] It has been suggested that some foods, such as coffee, mints, dietary fat, onions, citrus fruits, or tomatoes, may predispose to GORD.[9] However, we found insufficient data on the role of these factors. We found limited evidence that drugs that relax the lower oesophageal sphincter, such as calcium channel blockers, may promote GORD.[10] Twin studies suggest that there may be a genetic predisposition to GORD.[8]

PROGNOSIS GORD is a chronic condition, with about 80% of people relapsing once medication is discontinued.[11] Many people therefore require long term medical treatment or surgery. Endoscopy negative reflux disease remains stable, with a minority of people developing oesophagitis over time.[12] However, people with severe oesophagitis may develop complications such as oesophageal stricture or Barrett's oesophagus.[1]

AIMS OF INTERVENTION To relieve reflux symptoms, increase healing rates, and reduce the complications of GORD, such as stricture formation; to improve quality of life; to minimise adverse effects of treatment.

OUTCOMES Frequency and severity of symptoms; quality of life. Healing rates (assessed endoscopically in people with oesophagitis), which have been shown to be closely associated with clinical outcomes.[13,14] pH measurement of reflux is an intermediate outcome that is often used in RCTs, but it is difficult to interpret clinically. We excluded RCTs based solely on this outcome.

METHODS *Clinical Evidence* search and appraisal July 2003.

QUESTION **What are the effects of initial treatment of gastro-oesophageal reflux disease associated with oesophagitis?**

OPTION LIFESTYLE ADVICE

Small RCTs provided insufficient evidence on the effects of raising the head of the bed or weight loss for the treatment of reflux oesophagitis. We found no RCTs on the effects of reducing coffee intake, stopping smoking, reducing alcohol intake, or reducing fatty food intake.

Benefits: We found no systematic review. **Raising the head of the bed:** One RCT (71 people aged 22–77 years with endoscopically diagnosed gastro-oesophageal reflux [grade C]) compared raising the head of the bed (to produce a 10° slope) versus not raising the head of the bed in people additionally randomised to ranitidine (150 mg twice daily) versus placebo for 6 weeks.[15] It found that, in people taking placebo, raising the head of the bed increased participant reported improvement compared with not raising the head of the bed at 6 weeks (grading of improvement not specified; 10/17 [59%] with bed raised *v* 4/14 [29%] without; significance of individual comparisons not reported). The benefit of raising the head of the bed was increased in people taking ranitidine (13/15 [87%] with ranitidine + raised head of bed *v* 10/17 [59%] with placebo + raised head of bed; significance not stated). Endoscopic appearances were not significantly different among any of the four groups. **Weight loss:** One RCT (20 people with gastro-oesophageal reflux confirmed by 24 hour pH measurement, mean body mass index 31.4 kg/m^2) compared a low calorie diet (430 kcal/day for the first 6 weeks) plus advice and support for 6 months versus standard instructions about reflux disease and general advice to lose weight.[16] It found no significant difference between groups in symptoms or the number of episodes of reflux (analysis not by intention to treat; 19 people in analysis; no further data reported), but the study may have lacked power to detect a clinically significant difference. **Reducing coffee intake; stopping smoking; reducing alcohol intake; reducing fatty food intake:** We found no RCTs on these lifestyle measures.

Harms: We found no RCTs.

Comment: None.

OPTION ANTACIDS/ALGINATES

Two RCTs provided limited evidence that antacids reduced symptom scores at 4–8 weeks compared with placebo, but neither found a significant difference in endoscopic healing. We found limited evidence on the effects of antacids compared with H_2 receptor antagonists. The first RCT found no significant difference between antacids compared with cimetidine in endoscopic healing at 8 weeks. The second RCT found that antacids were less effective for heartburn symptoms compared with ranitidine at 12 weeks.

Benefits: We found no systematic review. **Versus placebo:** We found two RCTs.[17,18] The first RCT (91 people with gastro-oesophageal reflux disease and endoscopically confirmed oesophagitis grade A–C)

compared antacids (1 tablet aluminium hydroxide/magnesium carbonate 1 hour after meals and at bedtime) versus cimetidine (400 mg twice daily) versus placebo for 8 weeks.[17] It found that antacids significantly reduced the number of days with reflux symptoms compared with placebo and reduced the median symptom score (days with reflux: 5 days *v* 13 days, $P < 0.05$; symptom score: measured on a 100 mm visual analogue scale [100 mm = worst score]: 8 with antacids *v* 33 with placebo). However, it found no significant difference in endoscopic healing at 8 weeks (8/27 [30%] with antacids *v* 6/29 [21%] with placebo). The second, smaller RCT (32 people with gastro-oesophageal reflux disease and oesophagitis confirmed by pH monitoring and an acid perfusion test) compared antacids (15 mL doses of aluminium and magnesium hydroxide 7 times daily) versus placebo for 4 weeks.[18] The results of this RCT may be biased in favour of antacids because 11 people who had no heartburn symptoms after taking placebo for 1 week were eliminated from the analysis. It found no significant difference between antacids and placebo in the frequency or severity of reflux or in endoscopic healing at 4 weeks, although it may have lacked power to exclude a clinically significant effect. **Versus H_2 receptor antagonists:** We found two RCTs.[17,18] The first RCT (91 people, described above) found no significant difference between antacids and cimetidine in endoscopic healing at 8 weeks (8/27 [30%] people taking antacids *v* 11/29 [38%] people taking cimetidine).[17] The second RCT (155 people with oesophagitis up to grade D) found that calcium carbonate (750 mg as needed) was significantly less effective than ranitidine for reducing the frequency and severity of heartburn after 1 week (150 mg twice daily) (results presented graphically; $P < 0.05$).[19] Subgroup analysis in people with erosive oesophagitis of grade A or greater (73 people) found that calcium carbonate significantly reduced the proportion of people with endoscopic healing at 12 weeks compared with ranitidine (10/35 [29%] with calcium carbonate *v* 21/38 [55%] with ranitidine; RR 0.52, 95% CI 0.28 to 0.94).

Harms: One of the RCTs (91 people) found that six people in the antacid group reported transient constipation after 4 weeks of treatment.[17] One RCT (32 people) found that antacids caused increased gastrointestinal adverse effects, including diarrhoea, nausea, vomiting, occult blood in the stool, gas, constipation, and duodenal ulcer, compared with controls (12% with antacids *v* 3% with ranitidine; $P = 0.056$).[18] One person taking antacids developed a duodenal ulcer. The RCT also found that a smaller proportion of people had headache, dizziness, insomnia, malaise, fatigue, weakness, chills, and nervousness with antacids versus placebo (1% with antacids *v* 4% with ranitidine), but the difference was not significant ($P = 0.37$).

Comment: None.

OPTION MOTILITY STIMULANTS

One RCT found that cisapride increased endoscopic healing compared with placebo at 12 weeks. The use of cisapride has been restricted in some countries because of concerns about heart rhythm abnormalities. We found no RCTs of domperidone or metoclopramide.

Gastro-oesophageal reflux disease

Benefits: We found no systematic review but found one RCT (177 people with uncomplicated gastro-oesophageal reflux disease and oesophagitis) comparing cisapride (10 or 20 mg 4 times daily) versus placebo for 12 weeks.[20] It found that cisapride 20 mg significantly increased endoscopic healing of oesophagitis compared with placebo at 12 weeks (analysis not by intention to treat; 20 people excluded from analysis: 26/51 [51%] healed with cisapride 20 mg *v* 21/51 [41%] with 10 mg *v* 20/55 [36%] with placebo; $P < 0.05$; no further data reported.) We found no RCTs comparing metoclopramide or domperidone with placebo or other prokinetic drugs.

Harms: In some countries, use of cisapride has been restricted because of concerns about heart rhythm abnormalities that are associated with sudden death.[21] The RCT found no significant difference between cisapride and placebo in any adverse effects.[20] Common adverse events included diarrhoea (16.4% cisapride 20 mg *v* 12.5% cisapride 10 mg *v* 8.3% placebo), headache (11.5% *v* 16.1% *v* 26.7%), and constipation (6.6% *v* 10.7% *v* 6.7%).

Comment: None.

OPTION H_2 RECEPTOR ANTAGONISTS

One systematic review has found that H_2 receptor antagonists reduce the risk of persisting oesophagitis compared with placebo, but are not as effective as proton pump inhibitors.

Benefits: **Versus placebo:** We found one systematic review (search date not reported; 10 RCTs, 2171 people) comparing H_2 receptor antagonists versus placebo in people with oesophagitis.[22] It found that H_2 receptor antagonists significantly decreased the risk of persistent oesophagitis compared with placebo (time to outcome not stated: RR of oesophagitis persisting with H_2 receptor antagonists *v* placebo 0.79, 95% CI 0.72 to 0.87; NNT 6, 95% CI 5 to 10). **Versus proton pump inhibitors:** See benefits of proton pump inhibitors for initial treatment of gastro-oesophageal reflux disease, p 588.

Harms: The systematic review did not report on harms.[22]

Comment: A systematic review evaluating drug treatment in the short term management of oesophagitis is currently being conducted.[23]

OPTION PROTON PUMP INHIBITORS

One systematic review, one additional RCT, and one subsequent RCT found that proton pump inhibitors increase healing compared with placebo or H_2 receptor antagonists. One systematic review found that esomeprazole 40 mg daily increased healing at 4 weeks compared with omeprazole 20 mg daily. RCTs have found no significant differences in clinical benefit among other proton pump inhibitors.

Benefits: **Versus placebo:** We found one systematic review (search date not reported; 4 RCTs, 380 people with gastro-oesophageal reflux disease and oesophagitis) comparing proton pump inhibitors versus placebo.[22] It found that proton pump inhibitors were more effective than placebo for preventing persistence of oesophagitis (RR for persistence 0.31, 95% CI 0.13 to 0.75; time to outcome not

specified; NNT 2, 95% CI 1 to 5). **Versus H_2 receptor antagonists:** The same systematic review (search date not reported, 16 RCTs, 2321 people), one additional RCT, and one subsequent RCT compared proton pump inhibitors with H_2 receptor antagonists.[22,24,25] The systematic review found that proton pump inhibitors significantly decreased persistent oesophagitis compared with H_2 receptor antagonists (RR 0.5, 95% CI 0.43 to 0.58; NNT 4, 95% CI 3 to 4; time to outcome not stated).[22] Both the additional and the subsequent RCT found similar results.[24,25] The additional RCT (177 people with Savary–Miller stages 2–4 oesophagitis) found that lansoprazole (15 mg/day and 30 mg/day) significantly increased endoscopically confirmed healing compared with ranitidine (150 mg daily) at 28 days (33/60 [55%] with lansoprazole 15 mg *v* 44/55 [80%] with lansoprazole 30 mg *v* 20/50 [40%] with ranitidine, $P < 0.01$ for lansoprazole 15 mg *v* ranitidine; $P < 0.001$ for lansoprazole 30 mg *v* ranitidine).[24] The subsequent RCT (221 people with equivalent to > Savary–Miller stage 2 oesophagitis) found that pantoprazole (20 mg and 40 mg daily) significantly increased endoscopically confirmed healing compared with nizatidine (150 mg daily) at 4 and 8 weeks (4 weeks: 48/75 [64%] with pantoprazole 40 mg *v* 43/70 [61%] with pantoprazole 20 mg *v* 16/72 [22%] with ranitidine; $P < 0.001$ for both doses of pantoprazole *v* nizatidine; 8 weeks: 58/70 [83%] with pantoprazole 40 mg *v* 57/72 [79%] with pantoprazole 20 mg *v* 29/70 [41%] with nizatidine; $P < 0.001$ for both doses of pantoprazole *v* nizatidine).[25]

Versus each other: We found two systematic reviews (search dates 2000)[26,27] and three subsequent RCTs[28–30] comparing different proton pump inhibitors in people with reflux oesophagitis. The reviews found similar results, although results in the second review were reported more clearly and covered additional comparisons.[27] The second review found that esomeprazole (40 mg/day) significantly increased healing at 4 weeks compared with omeprazole (20 mg once daily) (3 RCTs; healing rate 1814/2446 [74%] with esomeprazole *v* 1583/2431 [65%] with omeprazole; RR 1.14, 95% CI 1.10 to 1.18; NNT 13, 95% CI 9 to 17). The review found no significant difference between lansoprazole (30 mg) and omeprazole (20 mg) at 4 weeks (5 RCTs; healing rate 704/972 [72%] with lansoprazole v 692/979 [71%] with omeprazole; RR 1.02, 95% CI 0.97 to 1.08). The review found no significant difference between pantoprazole (40 mg) and omeprazole (20 mg) or between rabeprazole (20 mg) and omeprazole (20 mg) at 4 weeks (pantoprazole *v* omeprazole, 3 RCTs, healing rate: 388/574 [68%] with pantoprazole *v* 325/474 [69%] with omeprazole; RR 0.99, 95% CI 0.91 to 1.07; rabeprazole *v* omeprazole, healing rate: 81/100 [81%] with rabeprazole *v* 83/102 [81%] with omeprazole; RR 1.00, 95% CI 0.87 to 1.14).[27] The first subsequent RCT (328 people with grade I oesophagitis) comparing pantoprazole (20 mg once daily) versus omeprazole (20 mg once daily) found no significant difference between treatments in healing rate at 8 weeks or symptom relief at 4 weeks (symptom relief: 77% with pantoprazole *v* 84% with omeprazole; no further data reported; healing rates: 90% with pantoprazole *v* 95% with omeprazole; OR 0.62, 95% CI 0.34 to

1.13).[28] The second subsequent RCT (461 people with symptomatic grade I–IV oesophagitis) compared three interventions: omeprazole (20 mg/day modified release tablets); lansoprazole (30 mg/day); and pantoprazole (40 mg/day).[29] It found no significant difference between omeprazole and lansoprazole or pantoprazole in complete resolution of heartburn symptoms at 8 weeks (89% heartburn free with pantoprazole *v* 87% with omeprazole *v* 81% with lansoprazole; ARR for omeprazole *v* pantoprazole +2%, 90% CI –4.6% to +7.6%; ARI for omeprazole *v* lansoprazole +6%, 90% CI –0.8% to +12.8%). The third subsequent RCT (251 people with symptomatic grade II–III oesophagitis) found no significant difference between rabeprazole (20 mg/day) and omeprazole (40 mg/day) in complete relief of heartburn, regurgitation, or epigastric pain after 3 days (analysis not by intention to treat; relief of heartburn 99/118 [84%] with rabeprazole *v* 96/116 [83%] with omeprazole; ARI +1.1%, 95% CI –8.4% to +10.7%; no regurgitation 101/112 [90%] with rabeprazole *v* 102/115 [89%] with omeprazole; ARI +1.5%, 95% CI –6.5% to +9.5%; no epigastric pain 89/112 [80%] with rabeprazole *v* 99/115 [86%] with omeprazole; ARR +6.6%, 95% CI –3.2% to +16.4%).[30]

Harms: The systematic review gave no information on harms.[22] **Versus H_2 receptor antagonists:** The additional RCT found no significant difference in adverse effects between lansoprazole and ranitidine (AR for any adverse effect: 21% with lansoprazole 15 mg *v* 12% with lansoprazole 30 mg *v* 20% with ranitidine, P not reported).[24] The subsequent RCT found no significant difference in adverse effects between pantoprazole and nizatidine (AR for any adverse effect: 49% with pantoprazole 20 mg *v* 54% with pantoprazole 40 mg *v* 59% with nizatidine).[25] The most common adverse effects were headache and diarrhoea (headache: 10/80 [13%] with pantoprazole 20 mg *v* 15/81 [19%] with pantoprazole 40 mg *v* 19/82 [23%] with nizatidine; diarrhoea: 8/80 [10%] with pantoprazole 20 mg *v* 6/81 [7%] with pantoprazole 40 mg *v* 9/82 [11%] with nizatidine).[25] **Versus each other:** The subsequent RCT found similar rates of adverse events with pantoprazole and omeprazole (any adverse event: 57% with pantoprazole *v* 50% with omeprazole; severe adverse events: 10% *v* 13%; nausea 8% *v* 7%; diarrhoea 5% *v* 6%; headache 6% *v* 3%).[28]

Comment: A systematic review evaluating drug treatment in the short term management of oesophagitis is currently being conducted.[23]

QUESTION **What are the effects of maintenance treatment of gastro-oesophageal reflux disease associated with oesophagitis?**

OPTION **LIFESTYLE ADVICE**

We found no RCTs on the effects of lifestyle advice on the long term management of reflux oesophagitis.

Benefits: We found no systematic review or RCTs.

Harms: We found no RCTs.

Comment: None.

OPTION ANTACIDS/ALGINATES

We found no RCTs on the effects of antacids/alginates on the long term management of reflux oesophagitis.

Benefits: We found no systematic review or RCTs.

Harms: See benefits of antacids/alginates for the initial treatment of gastro-oesophageal reflux disease, p 586.

Comment: None.

OPTION MOTILITY STIMULANTS

Three RCTs have found that cisapride compared with placebo improved maintenance of healing at 6–12 months. Two further RCTs found no evidence of a difference, but they might have lacked power to detect a clinically significant effect. The use of cisapride has been restricted in some countries because of concerns about heart rhythm abnormalities. We found no RCTs comparing other prokinetic drugs with placebo or each other in people with gastro-oesophageal reflux disease and oesophagitis.

Benefits: We found no systematic review. We found five RCTs (1398 people) comparing cisapride (up to 40 mg/day) versus placebo for 6–12 months.[31–35] Two RCTs found no significant difference between treatments in the maintenance of endoscopic healing,[33,35] and three RCTs found that cisapride significantly increased maintenance of healing (see table 1, p 598).[31,32,34] We found no RCTs comparing other prokinetic drugs with placebo for maintanence treatment in people with gastro-oesophageal reflux disease and healed oesophagitis.

Harms: See motility stimulants for initial treatment of gastro-oesophageal reflux disease, p 588.

Comment: None.

OPTION H_2 RECEPTOR ANTAGONISTS

One RCT found no significant difference between ranitidine and placebo for relapse of oesophagitis at 6 months in people with previously healed reflux oesophagitis. RCTs have found that H_2 antagonists are less effective than proton pump inhibitors for maintaining remission at up to 12 months.

Benefits: **Versus placebo:** We found no systematic review. We found one RCT (69 people with endoscopically healed oesophagitis) comparing ranitidine (150 mg at bedtime) versus placebo for 6 months.[36] It found no significant difference between ranitidine and placebo in relapse rates at 6 months (8 people excluded from analysis: 14/33 [42%] with ranitidine *v* 10/28 [36%] with placebo; CI and P value not reported). **Versus proton pump inhibitors:** See benefits of proton pump inhibitors for maintenance treatment in gastro-oesophageal reflux disease, p 592.

Gastro-oesophageal reflux disease

Harms: The RCT found that four people, all taking placebo, reported adverse effects (rashes, transient headache, transient parasthaesia).[36] RCTs have shown similar rates of adverse events between H_2 receptor antagonists and placebo.[37]

Comment: None.

OPTION PROTON PUMP INHIBITORS

RCTs have found that proton pump inhibitors reduce relapse in people with healed reflux oesophagitis compared with placebo or H_2 receptor antagonist at 6–18 months. One systematic review has found that standard dose lansoprazole (30 mg/day) was as effective as omeprazole (20 mg/day) for maintaining healing at 12 months. However, the systematic review and one subsequent RCT provided evidence that lower dose lansoprazole (15 mg/day) was less effective than higher dose lansoprazole (30 mg/day), omeprazole, or esomeprazole for maintaining healing for up to 12 months.

Benefits: **Versus placebo:** We found one systematic review (search date 2000, 7 RCTs, 1320 people with healed oesophagitis),[26] four subsequent RCTs,[38–41] and one additional RCT.[42] The systematic review did not pool results.[26] All seven RCTs included in the review found that proton pump inhibitors (rabeprazole 10 or 20 mg/day; omeprazole 10 or 20 mg/day; lansoprazole 15 or 30 mg/day) reduced relapse rate at 6 months compared with placebo (results reported graphically; RR about 0.1 to about 0.8). The subsequent and additional RCTs found similar results (see table 2, p 599). **Versus H_2 receptor antagonists:** We found one systematic review that compared proton pump inhibitors versus ranitidine (search date 2000, 5 RCTs, 638 people with healed oesophagitis)[26] and one additional RCT.[43] The systematic review did not pool results.[26] All five RCTs included in the review found that proton pump inhibitors (omeprazole 10 or 20 mg/day; lansoprazole 15 or 30 mg/day) reduced relapse rate compared with ranitidine at 6 months (results reported graphically: RR about 0.1 to about 0.6). The additional RCT (264 people with healed oesophagitis and no symptoms of gastro-oesophageal reflux) found that omeprazole (10 mg/day) increased remission rate compared with ranitidine (150 mg twice daily) at 12 months (AR 68% with omeprazole *v* 39% with ranitidine; RR 1.43, 95% CI 1.26 to 1.57).[43] **Versus each other:** We found one systematic review (search date 2001, 12 RCTs),[44] one additional RCT,[45] and two subsequent RCTs.[46,47] The review found that lansoprazole (15 mg/day) was less effective for maintaining healing than esomeprazole (20 mg/day), higher dose lansoprazole (30 mg/day), or omeprazole (20 mg/day) (esomeprazole 20 mg *v* lansoprazole 15 mg: 1 RCT, 1224 people; RR for maintaining healing at 6 months 1.09, 95% CI 1.02 to 1.17; lansoprazole 30 mg *v* lansoprazole 15 mg: 7 RCTs, 1505 people; RR at 12 months 1.12, 95% CI 1.05 to 1.18; omeprazole 20 mg *v* lansoprazole 15 mg: 1 RCT, 597 people; RR at 12 months 1.19, 95% CI 1.10 to 1.30).[44] However, the review found no significant difference between higher dose lansoprazole (30 mg/day) and omeprazole (20 mg/day) for maintenance of healing at 12 months (2 RCTs, 859 people; RR 1.01, 95% CI 0.96 to 1.06). The additional RCT (243 people

with healed oesophagitis) found no significant difference between rabeprazole (10 or 20 mg/day) and omeprazole (20 mg/day) for relapse rates at 12 months (12 months: AR 5% with 10 mg rabeprazole, 4% with 20 mg rabeprazole, 5% with 20 mg omeprazole).[45] The first subsequent RCT (137 people with healed grade I–III oesophagitis) found no significant difference between daily low dose lansoprazole (15 mg) and alternate day full dose lansoprazole (30 mg) for oesophagitis recurrence at 6 months (AR 12.1% with daily low dose lansoprazole *v* 19.0% with alternate day full dose lansoprazole; OR 1.31; 95% CI 0.57 to 3.02).[46] The second subsequent RCT (1236 people with healed Los Angeles classification grade A–D oesophagitis) found that esomeprazole (20 mg/day) significantly increased remission rates compared with lansoprazole (15 mg daily) over 6 months (83% with esomeprazole *v* 74% with lansoprazole, $P < 0.0001$).[47]

Harms: See benefits of proton pump inhibitors for initial treatment in gastro-oesophageal reflux disease, p 588. **Versus each other:** One subsequent RCT found that rates of withdrawal due to adverse events were similar with esomeprazole and lansoprazole (4.7% with esomeprazole *v* 5.2% with lansoprazole, P not reported).[47] It found that the most common adverse event was diarrhoea (5.7% with esomeprazole *v* 6.8% with lansoprazole, P not reported).

Comment: Limited evidence from cohort studies and small RCTs has suggested that long term proton pump inhibitor treatment may be associated with atrophic gastritis in people with *Helicobacter pylori*.[48–50] Gastric atrophy is a risk factor for gastric cancer.[51] However, we found no reliable evidence of long term clinical effects of proton pump inhibitors on gastric cancer rates in people with gastro-oesophageal reflux disease and oesophagitis. One crossover RCT (233 people with upper gastrointestinal disorders; 214 with gastro-oesophageal reflux disease, whose symptoms were controlled with proton pump inhibitors) compared 4 weeks' treatment with omeprazole versus rabeprazole. Post-crossover analysis found that a similar proportion of people preferred each of the treatments over the other (data and P value for overall comparison not reported).[52]

OPTION OPEN SURGERY

RCTs have found that open Nissen fundoplication improves the endoscopic grade of oesophagitis compared with medical treatment in people with chronic gastro-oesophageal reflux disease and oesophagitis at between 3 and 38 months. However, longer term follow up from one RCT found no significant difference in endoscopic appearance between surgery and medical treatment at 10 years. Two RCTs found no significant difference between open and laparoscopic fundoplication for remission at 3 months to 2 years. One RCT found that complication rtes with higher with open than with laparoscopic surgery. The benefit of antireflux surgery in controlling symptoms must be balanced against the small risk of operative mortality (< 1%) associated with this procedure.

Benefits: **Versus medical treatment:** We found one systematic review (search date 1999, 4 RCTs, 518 people with chronic gastro-oesophageal reflux disease [GORD] and oesophagitis).[53] Three

included RCTs compared open antireflux surgery versus antacids and H_2 receptor antagonists in people with severe or complicated GORD. All reported that surgery significantly reduced reflux and improved the endoscopic grade of oesophagitis compared with medical treatment (see table 3, p 600). Ten years' follow up of one of the RCTs included in the review (239/247 people originally enrolled) found no significant difference in endoscopic appearance between open surgery and medical treatment (mean endoscopic grade 1.80 with surgery *v* 1.89 with medical treatment; $P = 0.76$).[54] The fourth RCT in the review (298 people randomised, 255 analysed) compared open antireflux surgery versus omeprazole (20 mg/day) over 5 years.[55] It defined treatment failure as one or more of: moderate or severe heartburn or acid regurgitation; oesophagitis > grade 2; moderate or severe dysphagia; and required or preferred alternative treatment (omeprazole or surgery). It found that surgery significantly reduced treatment failure compared with omeprazole at 5 years (20/103 [19%] with surgery *v* 49/114 [43%] with omeprazole, $P < 0.001$). **Open surgery versus laparoscopic surgery:** We found two RCTs.[56,57] The first RCT (148 people with persistent GORD and oesophagitis following medical treatment) found no significant difference between open and laparoscopic Nissen fundoplication in symptomatic remission at 3 months (35 people excluded from end point analysis: 98% remission with open surgery *v* 97% with laparoscopic surgery; reported as non-significant; no further data reported).[56] The second RCT (42 people with GORD) also found no clear difference in symptoms or endoscopically defined remission at 2 years with open compared with laparoscopic Nissen fundoplication (analysis not by intention to treat; endoscopic remission: all people receiving laparoscopic surgery were in remission *v* all but 2 people with open surgery, number of people in analysis not reported; symptoms [4 people excluded from analysis]: 79% free of heartburn with laparoscopic surgery *v* 58% with open surgery; 95% free of regurgitation in both groups; significance not assessed).[57]

Harms:

Versus medical treatment: One RCT included in the review reported significantly higher mortality with surgery compared with medical treatment, mainly because of cardiovascular disease during long term follow up (RR 1.57, 95% CI 1.01 to 2.46).[54] The systematic review reported that one included RCT found that open Nissen fundoplication significantly increased early satiety, inability to belch, and inability to vomit compared with medical treatment.[53] **Versus laparoscopic surgery:** The first RCT found that overall complication rate (including splenectomy, pneumothorax, subphrenic abscess, wound infection, cicatricial hernia) was higher with open compared with laparoscopic Nissen fundoplication (6/57 [11%] people with laparoscopy *v* 10/46 [22%] with open Nissen fundoplication).[56] The second RCT did not report on operative complications.[57]

Comment:

The benefit of antireflux surgery in controlling symptoms must be balanced against the very small operative mortality (< 1%) associated with this procedure.[58]

OPTION LAPAROSCOPIC SURGERY

One systematic review identified no fully published RCTs comparing laparoscopic surgery versus medical treatment for maintenance of remission. Two RCTs found no significant difference in remission between open and laparoscopic fundoplication at 3 months to 2 years. One RCT found that laparoscopic treatment was associated with surgical complications, although the rate was lower than with open surgery.

Benefits: **Laparoscopic surgery versus medical treatment:** We found one systematic review (search date 1999).[53] It identified no fully published RCTs that examined effects on symptoms or endoscopically defined healing (see comment below). **Laparoscopic surgery versus open surgery:** See benefits of open surgery, p 593.

Harms: **Versus medical treatment:** We found insufficient evidence to compare harms of laparoscopic surgery versus medical treatment. **Versus open surgery:** See harms of open surgery, p 594.

Comment: The review identified one RCT (90 people with severe gastro-oesophageal reflux disease for at least 6 months) that was published as an abstract only.[53] It found similar results for laparoscopic surgery compared with proton pump inhibitors for quality of life at 3 months (scale not reported).

Substantive changes

Proton pump inhibitors (initial treatment) Two RCTs added.[24,25] Categorisation unchanged.

Proton pump inhibitors (maintenance) One RCT added.[47] Categorisation unchanged.

Open surgery More details of one RCT already included in systematic review.[55] Categorisation unchanged.

TABLE 1 **Summary of RCTs comparing cisapride versus placebo for maintenance treatment in people with reflux oesophagitis (see text, p 591).**

Ref	Intervention	Number of people	Duration (months)	Remission with cisapride	Remission with placebo	RR for remaining in remission with cisapride *v* placebo (95 % CI)
30	Cisapride 10 mg twice daily	80 people with healed oesophagitis after cisapride 40 mg/day given for at least 8 wks	6	28/37 (76%)	25/43 (58%)	1.30 (0.95 to 1.79)
31	Cisapride 10 mg twice daily*	443 people with complete endoscopic resolution of active reflux oesophagitis after treatment with an acid antisecretory agent	12	98/149 (66%)	70/143 (49%)	1.35 (1.10 to 1.64)
32	Cisapride 20 mg/day	42 people with healed oesophagitis after omeprazole 20 mg twice daily for 8–14 wks	6	0/21 (0%)	4/21 (19%)	0.81 (0.66 to 1.00)
33	Cisapride 20 mg twice daily†	535 people without reflux or with mild reflux oesophagitis after 4–8 weeks treatment with either H^2 receptor antagonists or proton pump inhibitors	6	74/176 (42%)	65/184 (35%)	1.19 (0.92 to 1.54)
34	Cisapride 20 mg twice daily	298 people with oesophagitis	6	Absolute numbers not reported (55 %)	Absolute numbers not reported (79 %)	CI and P value not reported

*This trial also evaluated cisapride 20 mg at night with similar results to those with cisapride 10 mg twice daily.
†This trial also evaluated cisapride 20 mg daily with similar results to those with cisapride 20 mg twice daily.
Ref, reference. References 30 and 31 used oesophagitis recurrence as the main end point; references 32–34 used reflux symptom recurrence as the main end-point; data from reference 34 was estimated from life tables presented in the results section and is not actual data given in the papers.

TABLE 2 **Further RCTs comparing proton pump inhibitors with placebo for maintenance treatment in people with reflux oesophagitis (see text, p 592).**

Ref	Drug evaluated	Duration (months)	Remission in PPI arm	Remission in placebo arm	RR of remission with PPI *v* placebo (95% CI)
37	Rabeprazole 20 mg/day	12	80/93 (86%)	29/99 (29%)	2.94 (2.13 to 4.00)
38	Rabeprazole 20 mg/day	12	62/69 (90%)	20/70 (29%)	3.13 (2.17 to 4.55)
39	Esomeprazole 40 mg/day	6	77/82 (94%)	22/77 (29%)	3.33 (2.33 to 4.76)
40	Esomeprazole 40 mg/day	6	81/92 (88%)	27/94 (29%)	3.00 (2.22 to 4.17)
41	Omeprazole 10 mg/day*	18	66/130 (51%)	14/133 (11%)	5.00 (2.86 to 8.33)
37	Rabeprazole 10 mg/day*	12	72/93 (77%)	29/99 (29%)	2.63 (1.92 to 3.70)
38	Rabeprazole 10 mg/day*	12	51/70 (73%)	20/70 (29%)	2.56 (1.72 to 3.85)
39	Esomeprazole 20 mg/day*	6	76/82 (93%)	22/77 (29%)	3.23 (2.27 to 4.55)
40	Esomeprazole 20 mg/day*	6	77/98 (78%)	27/94 (29%)	2.70 (1.96 to 3.85)

*Maintenance dose.
PPI, proton pump inhibitor; Ref, reference.

TABLE 3 **Summary of RCTs comparing open antireflux surgery versus medical treatment for maintenance of remission in people with gastro-oesophageal reflux disease and oesophagitis (see text, p 593).**

Ref	Patient population	Intervention	Follow up (months)	Outcome assessed	Result
51	Adults with complicated GORD	88 antacids + ranitidine 77 continuous antacids + ranitidine 82 open Nissen fundoplication	12	Reduction in grade of oesophagitis at 12 months	Surgery significantly more effective than medical treatment (P 0.003; no further data reported)
51	Adults with severe GORD	16 antacids 10 Belsey–Mark IV repair 5 anterior fundoplication + Hills posterior gastropexy	38	Absence of reflux at 1 year using the acid perfusion test	11/15 (73%) with surgery *v* 3/16 (19%) with antacids (OR 11.9, 95% CI 2.1 to 65.2)
51	Adults with GORD and asthma	30 placebo 30 cimetidine 30 posterior gastropexy	3	pH testing for absence of reflux	Not intention to treat: 25/26 (96%) with surgery *v* 3/27 (11%) with control (OR 200, 95% CI 19.4 to 2059)
52	Adults with healed reflux oesophagitis	155 omeprazole 20 mg/day 155 open antireflux surgery	36	Endoscopic remission	Not intention to treat; 103/119 (87%) with surgery *v* 111/113 (83%) with omeprazole (OR not stated)

QUESTIONS

INTERVENTIONS

See glossary, p 613

Key Messages

- ***H pylori* eradication for healing and preventing recurrence of duodenal ulcer** Systematic reviews and one subsequent RCT have found that *H pylori* eradication increases ulcer healing at 6 weeks and reduces 1 year recurrence compared with acid suppression or antisecretory treatment. One systematic review found that *H pylori* eradication compared with ulcer healing alone, or compared with ulcer treatment plus subsequent acid suppression maintenance treatment, reduced the risk of rebleeding.

Helicobacter pylori infection

- ***H pylori* eradication for healing and preventing recurrence of gastric ulcer** One systematic review found no good evidence on endoscopic healing of gastric ulcers. One systematic review has found that *H pylori* eradication treatment, compared with antisecretory treatment, reduces recurrent ulcers at 1 year. Observational evidence identified by the review found that eradication treatment heals 83% of gastric ulcers within 6 weeks of starting treatment. We found no RCTs of *H pylori* eradication treatment on preventing complications of gastric ulcers.
- ***H pylori* eradication for non-ulcer dyspepsia** One systematic review in people with non-ulcer dyspepsia has found that *H pylori* eradication reduces dyspeptic symptoms compared with placebo at 3–12 months.
- ***H pylori* eradication rather than empirical acid suppression for uninvestiaged dyspepsia** One RCT found that *H pylori* eradication increased relief from dyspeptic symptoms compared with placebo after 1 year.
- ***H pylori* eradication rather than endoscopy in people with uninvestigated dyspepsia not at high risk of malignancy** One RCT has found that *H pylori* eradication increased relief from dyspeptic symptoms after 1 year compared with placebo. One systematic review and one subsequent RCT have found no significant difference between *H pylori* testing plus eradication compared with management based on initial endoscopy in dyspepsia after 1 year. The review found that *H pylori* testing plus eradication reduced the need for endoscopy compared with endoscopy based management.
- **Three day quadruple regimen (*v* 1 week triple regimen)** One RCT comparing a 3 day quadruple regimen compared with a 1 week triple regimen found no significant difference in *H pylori* eradication at 6 weeks, but found that people taking the 3 day quadruple regimen experienced fewer days of adverse effects.
- **Triple regimen (*v* dual regimen)** We found no systematic review or RCTs of the effects of dual regimen compared with triple regimens on dyspeptic symptom scores, proportion of individuals with symptoms, quality of life, or mortality. One systematic review has found that dual compared with triple regimens eradicate *H pylori* from fewer people.
- **Two week triple regimen (*v* 1 week triple regimen)** One systematic review found that 14 days treat ment with proton pump inhibitor based treatment increased *H pylori* cure rates compared with 7 days treatment.
- ***H pylori* eradication for gastric B cell lymphoma** We found no RCTs of *H pylori* eradication treatment in people with B cell gastric lymphoma. Observational studies found limited evidence that 60–93% of people with localised, low grade B cell lymphoma respond to *H pylori* eradication treatment possibly avoiding, or delaying, the need for radical surgery, radiotherapy, or chemotherapy.
- ***H pylori* eradication for prevention of gastric cancer (adenocarcinoma)** We found no RCTs of *H pylori* eradication in people at risk of gastric cancer. One RCT in people with gastric atrophy or intestinal metaplasia found that *H pylori* eradication increased the regression of high risk lesions compared with no eradication. We found consistent evidence from observational studies of an association between *H pylori* infection and increased risk of distal gastric adenocarcinoma.

- **One triple regimen versus another** We found no systematic review or RCTs of the effects of different triple regimens on symptoms, quality of life, or mortality. One systematic review has found that clarithromycin 500 mg twice daily compared with clarithromycin 250 mg twice daily plus a proton pump inhibitor plus amoxicillin increases *H pylori* eradication, but found no significant difference between clarithromycin 500 mg twice daily and clarithromycin 250 mg twice daily plus a proton pump inhibitor plus metronidazole in *H pylori* eradication rates. Another systematic review has found that a triple regimen containing ranitidine bismuth plus clarithromycin plus metronidazole compared with a triple regimen containing ranitidine bismuth plus clarithromycin plus amoxicillin increases eradication at 5–7 days.
- ***H pylori* eradication in people with gastro-oesophageal reflux disease** One RCT in people with gastro-oesophageal reflux disease found no significant difference between *H pylori* eradication treatment and placebo in symptomatic relapse.

DEFINITION *Helicobacter pylori* is a Gram negative flagellated spiral bacterium found in the stomach. Infection with *H pylori* is predominantly acquired in childhood. The organism is associated with lifelong chronic gastritis and may cause other gastroduodenal disorders.[1]

INCIDENCE/ PREVALENCE *H pylori* prevalence rates vary with year of birth and social class in the developed world. Prevalence rates in many developed countries tend to be much higher (50–80%) in individuals born before 1950 compared with rates (< 20%) in individuals born more recently.[2] In many developing countries, the infection has a high prevalence (80–95%) irrespective of the period of birth.[3] Adult prevalence is believed to represent the persistence of a historically higher rate of infection acquired in childhood, rather than increasing acquisition of infection during life.

AETIOLOGY/ RISK FACTORS Overcrowded conditions associated with childhood poverty lead to increased transmission and higher prevalence rates. Adult reinfection rates are low — less than 1% a year.[3]

PROGNOSIS *H pylori* infection is believed to be causally related to the development of duodenal and gastric ulceration, gastric B cell lymphoma, and distal gastric cancer. About 15% of people infected with *H pylori* will develop a peptic ulcer, and 1% of people will develop gastric cancer during their lifetime.[4] *H pylori* infection is not associated with a specific type of dyspeptic symptom.

AIMS OF INTERVENTION Improvement in dyspeptic symptoms; reduction in peptic ulcer complications; reduced mortality from peptic ulcer complications of gastric cancer; improved quality of life.

OUTCOMES Dyspeptic symptom scores and proportion of people with symptoms; quality of life; mortality.

METHODS *Clinical Evidence* search and appraisal December 2002.

QUESTION **What are the effects of *H pylori* eradication treatment in people with a proven duodenal ulcer?**

OPTION **ERADICATION TREATMENT IN PEOPLE WITH A PROVEN DUODENAL ULCER**

Systematic reviews and one subsequent RCT have found that *H pylori* eradication compared with acid suppression or antisecretory treatment increases the proportion of ulcers healed at 6 weeks and reduces 1 year recurrence. One systematic review found that *H pylori* eradication compared with ulcer healing alone, or compared with ulcer treatment plus subsequent acid suppression maintenance treatment, reduced the risk of rebleeding.

Benefits:

Endoscopic healing: We found two systematic reviews,[5,6] and one subsequent RCT,[7] of *H pylori* eradication treatment in people with proven duodenal ulcers. The first systematic review (search date 1995, 15 RCTs that directly compared treatments) found that triple regimens compared with antisecretory treatment (see glossary, p 613) increased duodenal ulcer healing rates.[5] Out of 16 trials (15 of them RCTs), 14 found higher healing rates with triple therapy compared with antisecretory drugs alone (the time to outcome varied, the review did not report how many RCTs found significant results, no meta-analysis was conducted, and results were presented graphically). The second systematic review (search date 1996, 7 RCTs conducted in the USA, 989 *H pylori* positive people with duodenal ulcer given dual regimen) assessed ulcer healing in people receiving *H pylori* eradication treatment.[6] It only included RCTs with endoscopic follow up for 6 months after treatment. It found that most duodenal ulcers were endoscopically healed 6 weeks after the start of eradication treatment (68%, 95% CI 65% to 71% with eradication treatment). The review provided no comparative information on the ulcer healing rate in people given control treatment. The subsequent RCT (277 people with active duodenal ulcer) compared eradication treatment (metronidazole plus amoxicillin [amoxycillin] plus omeprazole) for 2 weeks followed by omeprazole 20 mg until the ulcer had healed compared with omeprazole 20 mg twice daily until the ulcer had healed.[7] It found no significant difference between eradication treatment compared with omeprazole alone in healing of duodenal ulcer at 4 weeks (84% *v* 92%; P = 0.07). The RCT assessed the two groups for a further 2 years (see prevention of recurrence below).[7] **Prevention of recurrence:** We found one systematic review[5] and one subsequent RCT,[7] which compared the effects of eradication treatment with antisecretory drugs alone on ulcer recurrence 1 year after treatment. The systematic review (search date 1995, 20 RCTs) directly compared any type of eradication treatment with antisecretory treatment.[5] The review (20 RCTs) found that any type of eradication treatment compared with antisecretory treatment reduced ulcer recurrence at 1 year (128/1059 [12%] with eradication *v* 575/988 [58%] with control). In the subsequent RCT above, the 250 people whose ulcers had healed by 16 weeks entered the next phase of the study, which lasted 2 years.[7] In the first year, people in the omeprazole alone group were given

omeprazole 20 mg and people receiving eradication treatment were given placebo. In the second year, both groups received no treatment and were observed. The RCT found no significant difference on intention to treat analysis in ulcer recurrence between eradication and omeprazole after 1 year (10/139 [7%] with eradication *v* 15/137 [11%] with omeprazole; RR 0.66, 95% CI 0.30 to 1.38). A completer analysis of the second year of observation alone (173 people) found that initial eradication treatment compared with initial omeprazole alone significantly reduced ulcer recurrence (5/86 [6%] with eradication *v* 39/87 [45%] with omeprazole; RR of recurrence 0.13, 95% CI 0.05 to 0.31; NNT 3, 95% CI 2 to 4) after 2 years. **Prevention of bleeding:** We found one systematic review (search date 2000, 4 RCTs, 262 people),[8] which compared *H pylori* eradication versus ulcer treatment alone or versus ulcer treatment plus subsequent acid suppression maintenance treatment. The review found that *H pylori* eradication compared with ulcer treatment alone significantly reduced the risk of rebleeding (6/133 [4.5%] with eradication *v* 28/129 [22%] with ulcer treatment alone; RR 0.24, 95% CI 0.11 to 0.53; NNT 6, 95% CI 4 to 11), and *H pylori* eradication compared with ulcer treatment plus acid suppression also significantly reduced the risk of rebleeding (4/257 [1.6%] with eradication *v* 12/213 [5.6%] with ulcer treatment plus acid suppression; RR 0.3, 95% CI 0.09 to 0.77; NNT 25, 95% CI 13 to 167). **Prevention of perforation or obstruction:** We found no systematic review and no RCTs.

Harms: One systematic review (search date 1995) found that minor adverse effects are common with bismuth (see glossary, p 613) (40% of people), metronidazole (39%), clarithromycin (22%), and tinidazole (7%).[9] Discontinuation of treatment because of severe adverse effects is rare (bismuth 4%, metronidazole 2%, clarithromycin 1%, and tinidazole < 1%).

Comment: We excluded analyses that grouped people by *H pylori* status at the end of the trial. Observational evidence from RCTs suggests that duodenal ulcer recurrence rates 1 year after treatment are lower in people with successful *H pylori* eradication treatment (in the review of US RCTs: 20%, 95% CI 14% to 26%, in people cured of *H pylori* *v* 56%, 95% CI 50% to 61%, for people remaining infected).[6] The recurrence rate in non-US trials was lower than the recurrence rate found in the US trials (6% for people cured of *H pylori*). The difference in recurrence rates between US and non-US studies may be explained partially by the marked loss to follow up in the US trials (9–41%). However, countries with low prevalence of *H pylori* infection also have a low prevalence of duodenal ulcers, but a greater proportion of those ulcers arise from causes other than *H pylori*; therefore, eradication may be less effective where *H pylori* prevalence is low. Poor adherence to *H pylori* eradication treatment and the use of less effective regimens may lead to increased antibiotic resistance in *H pylori*, but we found no direct evidence to support this. The harms of *H pylori* eradication treatment are mainly the minor short term effects of the antibiotics, particularly nausea from metronidazole or clarithromycin, and diarrhoea. Bismuth may turn the stools black.

QUESTION **What are the effects of *H pylori* eradication treatment for people with a proven gastric ulcer?**

OPTION **ERADICATION TREATMENT IN PEOPLE WITH A PROVEN GASTRIC ULCER**

One systematic review found no good evidence on endoscopic healing of gastric ulcers. One systematic review has found that *H pylori* eradication treatment compared with antisecretory treatment reduces recurrent ulcers at 1 year. The review found that, within 6 weeks of starting eradication treatment, 83% of gastric ulcers healed. We found no RCTs of *H pylori* eradication treatment on preventing complications of gastric ulcers.

Benefits: **Endoscopic healing:** We found one systematic review (search date 1995, 6 RCTs), which compared eradication treatment versus no eradication treatment but did not analyse endoscopic healing of gastric ulcers.[5] **Prevention of recurrence:** The systematic review found that *H pylori* eradication treatment compared with 4–6 weeks antisecretory treatment (see glossary, p 613) significantly reduced recurrent ulcers at 1 year (6 RCTs; RR 0.18, 95% CI 0.1 to 0.3; NNT 3, 95% CI 2 to 4).[5] **Prevention of complications:** We found no systematic review or RCTs.

Harms: See harms under effects of eradication treatment for *H pylori* in people with a proven duodenal ulcer, p 606.

Comment: We found one systematic review (search date 1995, 14 cohort studies of people with uncomplicated gastric ulcer), which analysed the *H pylori* eradication arm.[5] It found that, 6 weeks after the start of *H pylori* eradication treatment, 83% (95% CI 78% to 88%) of gastric ulcers were healed.

QUESTION **What are the effects of *H pylori* eradication treatment in people with proven gastro-oesophageal reflux disease?**

OPTION **ERADICATION TREATMENT IN PEOPLE WITH GASTRO-OESOPHAGEAL REFLUX DISEASE**

One RCT in people with gastro-oesophageal reflux disease found no significant difference between *H pylori* eradication treatment and placebo in symptomatic relapse.

Benefits: We found no systematic review but found one RCT (190 *H pylori* positive people with gastro-oesophageal reflux disease but no duodenal ulcer), which compared *H pylori* eradication treatment versus placebo. It found no significant difference in symptomatic relapse (83% in both groups; difference 0%, 95% CI −11% to +11%).[10]

Harms: We found insufficient evidence about the harms of *H pylori* eradication treatment in people with gastro-oesophageal reflux disease. Case control studies have found an increased risk of reflux symptoms after *H pylori* eradication.[11] However, discontinuation of acid suppression treatment after *H pylori* eradication might have

unmasked symptoms of co-existing gastro-oesophageal reflux disease. Two RCTs in people with duodenal ulcer compared the effects of *H pylori* eradication treatment versus placebo on heartburn symptoms, but no analysis by intention to treat was reported.[12,13]

Comment: One RCT (2324 people from the general population who tested positive for *H pylori*) found no significant difference *between H pylori* eradication and placebo in reflux symptoms at 2 years.[14]

QUESTION **What are the effects of *H pylori* eradication treatment in people with B cell lymphoma of the stomach?**

OPTION **ERADICATION TREATMENT IN PEOPLE WITH B CELL LYMPHOMA OF THE STOMACH**

We found no RCTs of *H pylori* eradication treatment in people with B cell gastric lymphoma. Observational studies found limited evidence that 60–93% of people with localised, low grade B cell lymphoma may respond to *H pylori* eradication treatment, possibly avoiding, or delaying the need for radical surgery, radiotherapy, or chemotherapy.

Benefits: We found no systematic review and no RCTs.

Harms: We found no RCTs.

Comment: Treatment options for primary gastric lymphoma include surgery, radiotherapy, chemotherapy, and *H pylori* eradication. We found no direct comparative studies. We found six prospective cohort studies of *H pylori* eradication in people with localised, low grade lymphomas.[15] Tumour regression occurred in 60–93% of people, but responses were sometimes delayed and some people relapsed within 1 year of treatment. A further uncontrolled study (28/34 people with gastric B cell lymphoma (see glossary, p 613) who were found to be *H pylori* positive and were given eradication treatment) found that 14/28 people (50%, 95% CI 31 to 69%) achieved complete remission at 18 months' follow up.[16]

QUESTION **What are the effects of *H pylori* eradication treatment on the risk of developing gastric cancer?**

OPTION **ERADICATION TREATMENT FOR PREVENTION OF GASTRIC CANCER**

We found no RCTs of *H pylori* eradication in people at risk of gastric cancer. One RCT in people with gastric atrophy or intestinal metaplasia found that *H pylori* eradication compared with no eradication increased the regression of high risk lesions. We found consistent evidence from case control studies of an association between *H pylori* infection and increased risk of distal gastric adenocarcinoma.

Benefits: **General population:** We found no systematic review and no RCTs of *H pylori* eradication treatment to prevent gastric cancer (adenocarcinoma). **In people at high risk of gastric cancer:** We found no systematic review and no RCTs of the effects of *H pylori* eradication on the development of gastric cancer in people at high

risk. One RCT (852 people with gastric atrophy or intestinal metaplasia found at screening endoscopy) compared four treatments: *H pylori* eradication treatment; β carotene; ascorbic acid; and placebo.[17] It found that *H pylori* eradication treatment compared with no eradication treatment significantly increased lesion regression (calculated by multivariate modelling) for both atrophy (RR 4.8, 95% CI 1.6 to 14.2) and intestinal metaplasia (RR 3.1, 95% CI 1.0 to 9.3; no absolute numbers provided).

Harms: We found no RCTs in people at risk of gastric cancer.

Comment: We found one systematic review of nested case control studies (search date 1999, 12 studies, 1228 cases, 3406 controls).[18] In the absence of trial data, this is the best evidence of an association between *H pylori* infection and gastric cancer. The review found that, overall, there was a significant association between *H pylori* infection and the subsequent development of gastric cancer (OR 2.36, 95% CI 1.98 to 2.81). The review found no significant association between *H pylori* and cardia cancer (OR 0.99, 95% CI 0.72 to 1.35), but did find a significant association for non-cardia cancer (OR 2.97, 95% CI 2.34 to 3.77). Second, the review found a strong interaction with age and time from sample collection. *H pylori* does not colonise areas of cancer, intestinal metaplasia, or atrophy, and antibodies may be lost with increasing age. Prospective studies with a short time period between the collection of the serum sample and the development of the cancer, or retrospective studies, may underestimate the association. The review found a significant association between *H pylori* and non-cardia (distal) cancer where the time from sampling to cancer was more than 10 years (OR 5.93, 95% CI 3.41 to 10.3).

QUESTION What are the effects of *H pylori* eradication treatment in people with proven non-ulcer dyspepsia?

OPTION ERADICATION TREATMENT IN PEOPLE WITH PROVEN NON-ULCER DYSPEPSIA

One systematic review in people with non-ulcer dyspepsia has found that *H pylori* eradication compared with placebo reduces dyspeptic symptoms at 3–12 months.

Benefits: We found one systematic review (search date 2000, 9 RCTs, 2541 people with non-ulcer dyspepsia), which found that *H pylori* eradication compared with placebo significantly improved recurrent dyspeptic symptoms at 3–12 months (AR of recurrent symptoms 896/1401 [64%] with eradication treatment *v* 820/1140 [72%] with placebo; RR 0.91, 95% CI 0.86 to 0.96; NNT 15, 95% CI 10 to 31).[19] Three RCTs (839 people) in the systematic review found no significant difference between *H pylori* eradication treatment compared with placebo on quality of life at 12 months (WMD −0.25, 95% CI −3.49 to +2.99).[19]

Harms: See harms under effects of eradication treatment for *H pylori* in people with a proven duodenal ulcer, p 606. We found two RCTs that assessed whether *H pylori* eradication treatment increases the prevalence of oesophagitis in people with non-ulcer dyspepsia.[20,21]

They found no significant difference between *H pylori* eradication treatment and placebo in endoscopically assessed oesophagitis (5.7% with eradication treatment *v* 2.9% with placebo; ARI +2.8%, 95% CI –0.5% to +6.0%; RR 2.1, 95% CI 0.9 to 4.6). No trial evaluated individual dyspeptic symptoms, so the effect on reflux symptoms cannot be estimated separately from epigastric pain.

Comment: None.

QUESTION **What are the effects of *H pylori* eradication treatment in people with uninvestigated dyspepsia?**

OPTION **ERADICATION TREATMENT IN PEOPLE WITH UNINVESTIGATED NON-ULCER DYSPEPSIA**

One RCT has found that *H pylori* eradication compared with placebo increased relief from dyspeptic symptoms after 1 year. One systematic review in people not at high risk of gastro-intestinal malignancy and one subsequent RCT in people with uninvestigated dyspepsia have found no significant difference between *H pylori* testing plus eradication and management based on initial endoscopy in dyspepsia after 1 year. The review found that *H pylori* testing plus eradication compared with endoscopy based management reduced the proportion of people requiring endoscopy.

Benefits:

H pylori eradication versus placebo: We found one RCT (294 people with dyspeptic symptoms and confirmed *H pylori* infection), which found that *H pylori* eradication compared with placebo significantly increased relief from dyspeptic symptoms at 1 year (61/145 [42%] *v* 80/149 [54%]; RR 0.78, 95% CI 0.61 to 0.99; NNT 9, 95% CI 5 to 554).[22] **Initial *H pylori* testing plus eradication versus management based on initial endoscopy:** We found one systematic review (search date 1999, 3 RCTs, 1366 people not considered to be at high risk of gastro-intestinal malignancy; see comment below), which compared *H pylori* testing plus eradication versus management based on initial endoscopy.[23] It found no significant difference between *H pylori* testing plus eradication and endoscopy based management in dyspepsia at 1 year (140/414 [34%] *v* 137/414 [33%]; RR 1.02, 95% CI 0.85 to 1.23). It found that *H pylori* testing plus eradication compared with endoscopy based management significantly reduced the proportion of people requiring endoscopy (169/500 [34%] at 2–6 weeks after eradication treatment *v* 486/489 [99%] with prompt endoscopy; RR 0.34, 95% CI 0.30 to 0.39). One subsequent RCT (708 people aged < 55 years referred for endoscopic investigation of dyspepsia by their primary care physician) found no significant difference between *H pylori* eradication and endoscopy in dyspeptic symptoms at 1 year (260/293 [89%] with *H pylori* eradication *v* 249/291 [86%] with endoscopy; RR 1.03, 95% CI 0.97 to 1.1).[24] Only 8.2% of people initially randomised to *H pylori* eradication had an endoscopy in the following year.

Harms: The systematic review gave no information on adverse effects.[23] Two of the RCTs in the review found that a small number of people given *H pylori* eradication treatment discontinued treatment because of short term adverse effects, which were not specified (14/104 [13%] people in the first RCT in the review[25] and 4/80 [5%] in the second RCT[26]).

Comment: The results of the systematic review may not be applicable to all people with dyspepsia. People with "alarm" symptoms (dysphagia, weight loss, jaundice, epigastric mass, or anaemia), or over the age of 55 years, with either continuous epigastric pain or first onset of symptoms in the previous year, may have a significant risk of upper gastrointestinal malignancy and may benefit from prompt endoscopy. Two of the RCTs in the review were conducted in a hospital setting and the third, conducted in primary care, is not yet published in full.[27] One of the RCTs in the review, conducted in a hospital setting, stipulated that all eligible people with dyspepsia who were consulting with a general medical practitioner should be included, but the other entered only routine referrals. The results of the review might not apply directly to primary care, where people with less severe dyspepsia might be treated and *H pylori* eradication rates might be lower, and the reassuring or anxiety provoking effect of specialist consultation might not be replicated.[23]

QUESTION Do eradication treatments differ in their effects?

OPTION DUAL VERSUS TRIPLE REGIMENS

We found no systematic review or RCTs of the effects of dual compared with triple regimens on dyspeptic symptom scores, proportion of individuals with symptoms, quality of life, or mortality. One systematic review has found that dual compared with triple regimens eradicate *H pylori* from fewer people.

Benefits: **Duodenal ulcer complication rates:** We found no systematic review and no RCTs. **Eradication rates:** We found one systematic review (search date 1995; 19 RCTs of omeprazole plus amoxicillin [amoxycillin] versus containing bismuth; 17 RCTs of dual regimens containing a proton pump inhibitor versus triple regimens [see glossary, p 613]).[9] No formal meta-analysis was performed, but dual regimens compared with triple regimens (two antibiotics plus either a proton pump inhibitor or bismuth) eradicated *H pylori* from fewer people (results presented graphically).

Harms: See harms under effects of eradication treatment for *H pylori* in people with a proven duodenal ulcer, p 604.

Comment: Many RCTs of *H pylori* eradication treatment have methodological problems, such as lack of a gold standard for defining cure, and many are published only as an abstract. A systematic review comparing eradication treatments for *H pylori* eradication is in progress.[27] Factors that might influence the choice of eradication treatment for an individual also include ease of adherence, potential harms, allergy or sensitivity, drug resistance, and cost.

OPTION DIFFERENT TRIPLE REGIMENS

We found no systematic review or RCTs of the effects of different triple regimens on dyspeptic symptom scores, proportion of individuals with symptoms, quality of life, or mortality. One systematic review has found that clarithromycin 500 mg twice daily compared with clarithromycin 250 mg twice daily plus a proton pump inhibitor plus amoxicillin increases *H pylori* eradication, but found no significant difference between clarithromycin 500 mg twice daily and clarithromycin 250 mg twice daily plus a proton pump inhibitor plus metronidazole in *H pylori* eradication rates. Another systematic review has found that a triple regimen containing ranitidine bismuth plus clarithromycin plus metronidazole compared with a triple regimen containing ranitidine bismuth plus clarithromycin plus amoxicillin increases eradication at 5–7 days.

Benefits:

Duodenal ulcer complication rates: We found no systematic review and no direct comparison of the effect of different triple regimens (see glossary, p 613) on complication rates. **Eradication rates:** We found four systematic reviews comparing different triple regimens, two of which included indirect comparisons (see glossary, p 613) between RCTs.[9,28–30] The first systematic review (search date 1998, 4 RCTs with direct, head-to-head comparisons of eradication regimens) found that clarithromycin 500 mg twice daily compared with clarithromycin 250 mg twice daily in combination with a proton pump inhibitor (see glossary, p 613) and amoxicillin (amoxycillin) significantly increased *H pylori* eradication (90% with clarithromycin 500 mg *v* 80% with 250 mg; RR 0.89, 95% CI 0.81 to 0.97; NNT 11, 95% CI 6 to 38).[28] The review found no significant difference between clarithromycin 500 mg twice daily and clarithromycin 250 mg twice daily in combination with a proton pump inhibitor and metronidazole in eradication rates (89% with clarithromycin 500 mg twice daily *v* 87% with 250 mg twice daily; RR 0.98, 95% CI 0.93 to 1.04). The second systematic review (search date 2000, 8 RCTs, 1139 people with direct comparisons of eradication regimens) found that ranitidine bismuth (see glossary, p 613) 400 mg daily plus clarithromycin 250 mg plus metronidazole 400 mg twice daily compared with ranitidine 400 mg daily plus clarithromycin 500 mg twice daily plus amoxicillin 1000 mg twice daily significantly increased eradication at 5–7 days (499/565 [88%] *v* 467/574 [81%]; RR 1.09, 95% CI 1.03 to 1.14).[29] The limited evidence from two systematic reviews with indirect comparisons found the highest eradication rates (85–90%) with omeprazole (20 mg daily, or equivalent) plus a combination of two of the following: amoxicillin (1–1.5 g daily), metronidazole (1.2 g daily), or clarithromycin (500 mg daily) with metronidazole or 1 g daily with amoxicillin (see comment below).[9,28] **Antibiotic resistance:** We found one systematic review (search date 1995, 19 RCTs, 1006 people with metronidazole sensitive *H pylori*, 452 with metronidazole resistant *H pylori*)[9] and one subsequent RCT,[31] which assessed the efficacy of metronidazole (or other nitroimidazole) based triple and quadruple regimens with strains of *H pylori* that were resistant in the laboratory. The review found that nitroimidazole based regimens achieved *H pylori* eradication in significantly fewer people with strains showing nitroimidazole resistance in the laboratory than in

people with sensitive strains (99%, 95% CI 97% to 100% eradication in people with sensitive strains *v* 69%, 95% CI 60% to 77% in people with resistant strains).[9] The subsequent RCT (33 people with a proven duodenal ulcer and *H pylori* infection, and primary metronidazole resistance, and 81 without resistance) found that metronidazole resistance decreased the *H pylori* eradication rate with omeprazole, metronidazole and clarithromycin from 77/81 (95.1%) without resistance to 25/33 (75.8%) with metronidazole resistance; RR 0.79, 95% CI 0.62 to 0.93).[31]

Harms: See harms under effects of eradication treatment for *H pylori* in people with a proven duodenal ulcer, p 606.

Comment: Indirect comparison is a weak form of evidence.[9,28] The characteristics of the people, settings, and procedures in the different RCTs may not be comparable. The systematic review assessing nitroimidazole resistance concluded that clinically important reduction of eradication rates is unlikely with a proportion of resistant strains below 15–25%.[9] Systematic reviews of *H pylori* eradication treatments are difficult to interpret (see dual versus triple regimens, p 610).

OPTION DURATION OF *H PYLORI* ERADICATION TREATMENT

One systematic review found that 14 days compared with 7 days treatment with proton pump inhibitor based triple regimens increased *H pylori* cure rates. One subsequent RCT comparing a 3 day quadruple regimen versus a 1 week triple regimen found no significant difference in *H pylori* eradication at 6 weeks, but found that people taking the 3 day quadruple regimen experienced fewer days of adverse effects.

Benefits: **Duodenal ulcer complication rates:** We found no systematic review and no RCTs. **Eradication rates:** We found one systematic review[32] and one subsequent RCT.[33] The review (search date 1999, 7 RCTs, 906 people) compared 14 days treatment with proton pump inhibitor based triple regimens (see glossary, p 613) versus 7 days treatment with proton pump inhibitor based triple regimens.[32] It found that 14 day treatment compared with 7 day treatment significantly increased *H pylori* cure rates (339/470 [72.1%] *v* 353/436 [81.0%]; RR 0.89, 95% CI 0.83 to 0.96; NNT 11, 95% CI 7 to 33). One subsequent RCT (118 people with active duodenal ulcer at endoscopy) compared a 3 day quadruple regimen (lansoprazole plus clarithromycin plus metronidazole plus bismuth subcitrate) versus a 7 day triple regimen (lansoprazole plus clarithromycin plus metronidazole).[33] It found no significant difference in *H pylori* eradication at 6 weeks (50/58 [86.2%] with 3 day quadruple regimen *v* 52/60 [86.7%] with 7 day triple regimen; RR 0.99, 95% CI 0.79 to 1.09).

Harms: See harms under effects of eradication treatment for *H pylori* in people with a proven duodenal ulcer, p 606. The RCT, comparing a 3 day quadruple regimen versus a 1 week triple regimen, found that people taking the 3 day regimen experienced significantly fewer days of bitter taste, bowel disturbance, malaise, and dark stools (mean 2.54 days with 3 day quadruple regimen *v* mean 4.58 days with 7 day triple regimen; $P < 0.001$).[33] The systematic review found insufficient data to report harms.[32]

Comment: The systematic review only considered regimens containing clarithromycin plus either metronidazole or amoxicillin.[32] The risk of failure of a 7 day regimen as opposed to a 14 day regimen in any particular individual will relate to the local prevalence of antibiotic resistance, as 14 day regimens may overcome resistance to one of the antibiotics used. As longer regimens cost more and have a longer duration of minor adverse effects, the balance between local failure rate and cost must be decided on the basis of locally validated data.

GLOSSARY

Antisecretory treatment A treatment that reduces the production of acid by the stomach. These may either be H_2 receptor antagonists or proton pump inhibitors.
Bismuth A compound containing bismuth, such as bismuth subsalicilate or ranitidine bismuth citrate.
Dual regimen *H pylori* eradication regimen consisting of two components.
Indirect comparisons Indirect comparisons combine the results for the same intervention across different RCTs and compare against the results for another intervention combined across different RCTs. This method loses the benefits of randomisation and increases the risk of confounding as the characteristics of the people, settings, and procedures in the different RCTs may not be comparable.
MALT "Mucosa-associated lymphoid tissue" is constitutionally found in the intestine but not in the stomach. MALT lymphoma is also known as B cell gastric lymphoma.
Proton pump inhibitor A drug that directly inhibits the mechanism within the stomach that secretes acid, such as esomeprazole, lansoprazole, omeprazole, or rabeprazole.
Triple regimen *H pylori* eradication regimen consisting of three components. The original "triple regimen" was bismuth subsalicilate, metronidazole, and either amoxicillin (amoxycillin) or tetracycline. Now the term usually applies to a proton pump inhibitor plus two antibiotics.

QUESTIONS

INTERVENTIONS

Key Messages

- **Antidepressants (amitriptyline, clomipramine, desipramine, doxepin, mianserin, trimipramine)** One systematic review found limited evidence from low to moderate quality RCTs that antidepressants (amitriptyline, clomipramine, desipramine, doxepin, mianserin, trimipramine) reduced symptoms of irritable bowel syndrome compared with placebo in the short term. It was not clear whether effects on irritable bowel syndrome were independent of effects on psychological symptoms.
- **Smooth muscle relaxants (cimetropium bromide, hyoscine butyl bromide, mebeverine hydrochloride, otilonium bromide, pinaverium bromide, trimebutine)** One systematic review found limited evidence that smooth muscle relaxants (cimetropium bromide, hyoscine butyl bromide, mebeverine hydrochloride, otilonium bromide, pinaverium bromide, trimebutine) improved symptoms compared with placebo. One subsequent RCT found no significant difference between alverine and placebo in improvement in abdominal pain, although the study may have lacked power to exclude a clinically important effect.
- **Alosetron** RCTs have found that alosetron (a $5HT_3$ receptor antagonist) improves symptoms in women with diarrhoea predominant or alternating irritable bowel syndrome compared with placebo. However, it is associated with adverse effects, particularly constipation, and has been restricted in some countries because of concerns that it may be associated with ischaemic colitis.

Irritable bowel syndrome

- **5HT$_4$ receptor agonists (tegaserod)** One large RCT in people with constipation predominant irritable bowel syndrome found that tegaserod improved overall symptoms. It was more likely to cause diarrhoea compared with placebo.
- **5HT$_3$ receptor antagonists other than alosetron** We found no RCTs examining 5HT$_3$ receptor antagonists other than alosetron.
- **Fibre supplementation** Limited evidence from small RCTs suggests that fibre supplementation does not improve symptoms compared with placebo.

DEFINITION

Irritable bowel syndrome (IBS) is a chronic non-inflammatory condition characterised by abdominal pain, altered bowel habit (diarrhoea or constipation), and abdominal bloating, but with no identifiable structural or biochemical disorder. Symptom based criteria, such as the Manning criteria (see table 1, p 624),[1] the Rome I criteria (see table 2, p 624),[2] and the Rome II criteria (see table 3, p 625),[3] aid diagnosis but their main use is in defining populations in clinical trials. IBS is often categorised according to predominant symptoms (diarrhoea, constipation, or alternating between diarrhoea and constipation).

INCIDENCE/ PREVALENCE

Estimates of incidence and prevalence vary depending on the diagnostic criteria used to define IBS. One cross-sectional postal survey (4476 people aged 20–69 years) in Teeside, UK, defined IBS as recurrent abdominal pain on more than six occasions during the previous year plus two or more of the Manning criteria (see table 1, p 624).[4] It estimated prevalence in the UK to be 16.7% (95% CI 15.4% to 18.0%) overall, with a prevalence of 22.8% (95% CI 20.8% to 24.8%) among women, and 10.5% (95% CI 8.9% to 12.1%) among men.[4] A cross-sectional postal survey (4500 people aged > 17 years) in Australia found prevalences of IBS of 13.6% (95% CI 12.3% to 14.8%) using the Manning criteria (see table 1, p 624), 6.9% (95% CI 6.0% to 7.8%) using the Rome I criteria (see table 2, p 624), and 4.4% (95% CI 3.5% to 5.1%) using the Rome II criteria (see table 3, p 625).[5]

AETIOLOGY/ RISK FACTORS

The pathophysiology of IBS is not certain. Studies on the aetiology of IBS have been descriptive or retrospective, and are of limited reliability. Suggested aetiological factors include: abnormal gastrointestinal motor function;[6–8] enhanced visceral perception;[9–11] psychosocial factors such as a history of childhood abuse;[12] genetic predisposition,[13–15] and a history of enteric mucosal inflammation.[16,17] We found no reliable prospective data to measure these associations.

PROGNOSIS

A retrospective study reviewed the medical records of people with IBS (112 people aged 20–64 years when diagnosed with IBS at the Mayo Clinic, USA, in 1961–1963). IBS was defined as the presence of abdominal pain associated with either disturbed defecation or abdominal distension and the absence of organic bowel disease.[18] Over a 32 year period, death rates were similar among people with IBS compared with age and gender matched controls. One postal survey (4432 adults aged 20–69 years) found that people with IBS are significantly more likely to have had a cholecystectomy than controls (OR 1.9, 95% CI 1.2 to 3.2).[4] A paper reporting on the same survey population (2238 women aged 20–69 years) found that women with IBS were significantly more likely to have had a hysterectomy than controls (OR 1.6, 95% CI 1.1 to 2.2).[19]

AIMS OF INTERVENTION To improve symptoms and reduce disability with minimal adverse effects.

OUTCOMES Severity of IBS symptoms (in particular abdominal pain, constipation, diarrhoea, bloating, and urgency of defecation) using validated self report instruments including: Adequate Relief;[20] the Irritable Bowel Severity Scoring System;[21] the Gastrointestinal Symptom Rating Scale;[22,23] the Functional Bowel Disorder Severity Index;[24] the IBS Symptom Questionnaire;[24] Quality of life and global impact of IBS; the Irritable Bowel Syndrome Quality of Life Measurement;[25,26] the Irritable Bowel Syndrome Quality of Life Questionnaire;[27] the Digestive Health Status Instrument;[28] the Functional Digestive Disorder Quality of Life Questionnaire;[29] the Irritable Bowel Syndrome Health Related Quality of Life questionnaire.[30] Adverse effects of treatment.

METHODS *Clinical Evidence* search and appraisal October 2002.

QUESTION What are the effects of treatments in people with irritable bowel syndrome? New

OPTION ANTIDEPRESSANT MEDICATION

One systematic review found limited evidence from low to moderate quality RCTs that antidepressants (amitriptyline, clomipramine, desipramine, doxepin, mianserin, trimipramine) reduced symptoms of irritable bowel syndrome compared with placebo. It was not clear whether effects on irritable bowel syndrome were independent of effects on psychological symptoms.

Benefits: We found one systematic review (search date 1998; 8 RCTs solely in people with irritable bowel syndrome [IBS]; 575 people).[31] It found that antidepressants (amitriptyline, clomipramine, desipramine, doxepin, mianserin, trimipramine) significantly improved symptoms compared with placebo (262 people in 7 RCTs with dichotomous outcomes defined as "improvement in abdominal pain" or "response to treatment": OR 4.2, 95% CI 2.3 to 7.9; ARR 32%, 95% CI 15% to 48%; NNT 3, 95% CI 2 to 7; 575 people in 8 RCTs with continuous outcome measures for abdominal pain: SMD 0.9, 95% CI 0.6 to 1.2). We found no subsequent RCTs.

Harms: The systematic review did not analyse combined data on adverse effects, but did report on one RCT (25 people), in which mianserin significantly increased fatigue compared with placebo (80% with mianserin *v* 14% with placebo; P value not reported).[31] Of the other studies in the review, six RCTs did not assess adverse effects and one RCT did not describe adequately how adverse effects were recorded.[31]

Comment: The review reported that the studies were short term and of low to moderate quality. In addition, the studies did not adjust for the effects of antidepressants on underlying depression, which could account for some of the benefits of antidepressants in people with IBS.

OPTION SMOOTH MUSCLE RELAXANTS

One systematic review found limited evidence that smooth muscle relaxants (cimetropium bromide, hyoscine butyl bromide, mebeverine hydrochloride, otilonium bromide, pinaverium bromide, trimebutine) improved symptoms compared with placebo. One subsequent RCT found no significant difference between alverine and placebo in improvement in abdominal pain, although the RCT may have lacked power to exclude a clinically important effect.

Benefits: We found one systematic review (search date 1999, 23 RCTs in which at least 51% of people had irritable bowel syndrome [IBS]; 1888 people)[32] and one subsequent RCT.[33] The review found that smooth muscle relaxants (cimetropium bromide, hyoscine butyl bromide, mebeverine hydrochloride, otilonium bromide, pinaverium bromide, trimebutine) significantly increased global improvement, reduced pain, and improved abdominal distension compared with placebo (global improvement: 21 RCTs, 1852 people; OR 2.13, 95% CI 1.77 to 2.58; improvement in pain: 11 RCTs, 1135 people; OR 1.65, 95% CI 1.30 to 2.10; improvement in abdominal distension: 6 RCTs, 885 people; OR 1.46, 95% CI 1.10 to 1.94).[32] However, the review found no significant difference between smooth muscle relaxants and placebo for constipation (4 RCTs, 230 people; OR 0.89, 95% CI 0.60 to 1.31). The subsequent RCT (107 people with Rome II IBS [see table 3, p 625]) compared 12 weeks of treatment with alverine citrate 120 mg three times daily versus placebo.[33] The main efficacy outcomes were abdominal pain scores recorded at each clinical visit (at recruitment, after a 2 week run in period, and after 4, 6, 10, and 12 weeks of treatment) and on self reported diary cards completed during the run in period, between visits at weeks 4 and 6, and between visits at weeks 10 and 12. The RCT found no significant difference in symptoms between alverine citrate and placebo over 12 weeks of treatment (AR for symptom improvement: 66% with alverine citrate *v* 58% with placebo; $P = 0.5$; no further data reported; percentage reduction in mean daily diary scores for abdominal pain from diary card 1 to diary card 3: 43.7% with alverine citrate *v* 33.3% with placebo; $P > 0.5$, but it may have lacked power to exclude a clinically important effect).

Harms: The systematic review found no significant difference in adverse events between smooth muscle relaxants and placebo (18 RCTs, 1384 people; mean percentage of people with adverse events: 14% with smooth muscle relaxants *v* 10% with placebo; $P = 0.08$).[32] The subsequent RCT reported no serious adverse effects with alverine.[33]

Comment: Heterogeneity in inclusion criteria among identified trials in the review may limit the reliability of the meta-analysis.[32] Some of the included trials did not use standard diagnostic criteria and many used poorly validated outcome measures. The review excluded studies on dicyclomine and peppermint oil, citing a high risk of adverse effects. It also excluded trials of propantheline, so the results might not apply to all smooth muscle relaxants.

OPTION 5HT$_4$ RECEPTOR AGONISTS

One large RCT in people with constipation predominant irritable bowel syndrome found that tegaserod improved overall symptoms compared with placebo. It was more likely to cause diarrhoea compared with placebo.
